The learning rate (lr) was set as $2e-5$ and optimized with the "Adam" optimizer, and cross-entropy was adopted as the loss function, with batch size 64. To optimize our training progress for video features, we utilize a pre-trained video understanding model by [3] as the starting point. Table I summarizes the hyperparameters of CapFormer .

B. Evaluation Metrics

We use Recall-Oriented Understudy for Gisting Evaluation (ROUGE) as the evaluation metrics. In particular, we use Rouge-L: Longest Common Subsequence (LCS) measure. Rouge-L has two types of evaluation: sentence-level LCS and summary-level LCS. We adopt sentence-level LCS using LCS-based F-measure, calculated between the original video description S of length m and the generated description D of length n. Specifically,

$$R_{lcs} = \frac{LCS(S,D)}{m}, \tag{13}$$

$$P_{lcs} = \frac{LCS(S,D)}{n}, \tag{14}$$

$$F_{lcs} = \frac{\left(1+\beta^2\right)R_{lcs}P_{lcs}}{R_{lcs}+\beta^2 P_{lcs}}, \tag{15}$$

where $LCS(S,D)$ is the length of a longest common subsequence of S and D, and $\beta = P_{lcs}/R_{lcs}$ when $F_{lcs}/R_{lcs} = F_{lcs}/P_{lcs}$. The R, P, and F refer to the Recall, Precision, and F-measure, respectively. Using these metrics, we report the outcome of Eq. (15) as the result of our model, referred to as ROUGE-L.

V. Results

Table II records the ROUGE-L score for CapFormer compared with other models tested on the MSR-VTT dataset. Results show that the CapFormer model outperforms other methods considered for comparison. Specifically, we achieved 66.4% for ROUGE-L, the highest among all considered methods at the time of the experiment.

A representative description output by CapFormer is shown in Fig. 4. Here, the predicted sentence and its reference are shown for comparison purposes. The samples show various outputs that can be observed in three groups: 1) relevant description (a,b,h), 2) relevant but not complete (e,f), and 3)

irrelevant descriptions (g,d), which overall attributed to the accuracy of the model.

The improvement over other methods is potentially attributed to using divided space-time attention and description attention by jointly learning the context of words and their associated visual features using attention only, implying that the CapFormer approach may produce the same or better results than other methods that complex in design and may combine multiple methods apart from attention. Furthermore, the design of CapFormer suggests that such a simple design could also solve similar problems, such as video question-answering and video retrieval, due to the power of the attention method and similarities in the process. From the preliminary experiments, we also discovered that the performance of CapFormer can be further improved with more hyperparameter tuning, computational power, and data. We believe this because we managed to improve the result from the initial experiment (61.2%) to (66.4%) with parameters tuning, implying that more experiments could potentially enhance the model even better. Table I reported the set of hyperparameters we used to achieve our best result (66.4%).

VI. CONCLUSION

The main goal of this paper is to propose a simplified video description model based on the joint-attention mechanism. Principally, we argued that transformers in the video domain are emerging, and the need for efficient design to perform video descriptions is paramount. There are various designs and suggestions in the literature; however, processing the spatial and temporal along with their description requires complex design. The proposed joint-attention mechanism is a powerful yet simple technique in this regard. Our CapFormer architecture consists of an encoder to learn the visual features of the video and a decoder to jointly learn how to decode a relevant sentence to describe these features. When evaluated and validated on a large video dataset (MSR-VTT), the design has shown promising results. We learned from the experiments that CapFormer could generate relevant video descriptions with a better result than the other models when tested on the MSR-VTT dataset evaluated on the ROUGE-L metric. The results also suggest that more experiments could lead to even better results, which we shall explore in our future work.

***Abstract*—Multiscale processing is fundamental for image processing. Most multiscale processing splits signals into base and detail signals and then manipulates the detail signal. Local Laplacian filtering (LLF), multiscale processing, has an unusual form: manipulation and then separation. This structure brings out the high performance of the filter. However, LLFs are limited to the form of Laplacian pyramids, which requires downsampling to create image pyramids; it causes misalignments around edges. In this study, we break away from the pyramid and extend the interpretation to multiscale filters that locally enhance the contrast. We propose a local difference of Gaussian (DoG) filter (LDF) for the solution. DoG filtering can remove the downsampling in the filter. Moreover, we further improve the computational speed using the precomputing technique introduced in LLF. Furthermore, to accelerate it, we utilize $O(1)$ Gaussian filtering for large-scale filtering. Experimental results show that the proposed method suppresses overshoot and undershoot around sharp edges caused by the misalignment. Furthermore, the proposed method can keep computational speed even when the convolutional radius is large by $O(1)$ Gaussian filtering.**

I. Introduction

When capturing images, the contrast of the subject cannot be perfectly transferred due to diffraction of light, aberrations, surface reflections, and other physical characteristics of light and lenses. In particular, contrast is low in regions of high spatial frequency. The modulation transfer function expresses this relationship. Therefore, the image is multiscaled, and a nonlinear contrast transformation function enhances the contrast. In this study, the value referenced by the contrast transformation function is changed for each pixel to improve the local contrast. By improving the contrast at a specific spatial frequency, a locally good-looking image is generated, and by multiscaling the image and retaining only the coefficients of the relevant pixel among the coefficients after processing, more precise edge information can be obtained than by performing contrast transformation after multiscaling. In this way, an image with improved contrast at all positions in the image is obtained by processing each pixel so that the modulation transfer function is changed for each pixel.

Manipulation of images with multiscale analysis is a challenging task. For multiscale processing, an input image is decomposed into multiple layers by various methods: Gaussian and Laplacian pyramids [1], wavelet transform [2], and difference of Gaussians (DoG) form the scale-space analysis [3]. Multiscale processing manipulates coefficients of pyramid, wavelet, or scale-space representations. Then, the layered signals are collapsed to obtain an output image.

Unsharp masking is a straightforward multiscale process. The method has two layers: a base layer and a detail layer. The base layer is a Gaussian/box-filtered image, and the detail layer is the subtraction of the base layer from the input image. The detail layer is linearly multiplied to control the enhancement level. However, this approach produces large halos.

The Laplacian pyramid is utilized to extend two layers to multiple layers. Pyramid-based processing directly enhances the pyramid coefficient [4]–[6]. Instead of linear enhancement of coefficients, S-tone or Gaussian weighting is used to suppress large amplitude. In the Gaussian pyramid-based approach, gradients in pyramid images are optimized to scale factors to avoid halos [7].

The signal decomposition is extended to have an edge-preserving property. Seminal work uses bilateral filtering [8] to generate base signals in two-layer decomposition [9] instead of linear filtering. The cost-consuming part of bilateral filtering is accelerated by Fast Fourier transform (FFT) [9], and further accelerated by following accelerated methods [10], [11]. The two-layer decomposition based on bilateral filtering is extended to multiple layers using iterative bilateral filtering. Multiscale bilateral decomposition is accelerated by skipped filtering [12]. Skipping is further accelerated by hardware [13]. This approach has difficulty in determining parameters to suppress halo and other edge-reversal artifacts. The following work computes a multiscale edge-preserving decomposition with a least-square scheme instead of bilateral filtering [14]. The other extension uses iterative local linear regression filtering [15], similar to guide image filtering [16], [17].

The edge-avoiding wavelet [18], [19] is an edge-preserving extension of the wavelet transform. The method constructs a basis based on the edge content of the images. The wavelet becomes non-linear filtering. Also, iterative bilateral filtering-based decomposition [12] is one of À-Trous wavelet methods [20]. The method is extended to multilateral filtering for the computer graphics context [21].

The previous edge-preserving scale-space methods have difficulty handling each iterative and enhancement processing

parameter. Local Laplacian filtering (LLF) [22] solves the difficulty. LLF is an extension of the Laplacian pyramid [23] to have an edge-aware pyramid. This approach locally enhances the contrast quickly and generates Laplacian pyramids for each pixel for image detail control. LLF has better visual quality than other multiscale processing; however, LLF has a high processing cost. The following works accelerate the construction per pixel of the Laplacian pyramid: fast LLF [24] and Gaussian Fourier pyramid [25]. Also, LLF is accelerated by FPGA [26]. Edge-aware upsampling can also accelerate filtering, e.g., joint bilateral upsampling [27], guided image upsampling [28], bilateral guided upsampling [29], and local-LUT upsampling [30].

The processing flow is the most significant difference between the previous methods and LLF. Conventional methods, such as linear filter, edge-preserving smoothing, and wavelet methods, all perform the following steps: 1) separation, 2) enhancement, and 3) integration. However, the structure has difficulty controlling the smoothing level of scale-space and amplifying each level. Also, it has drawbacks of edge ambiguity in downsampling, and downsampling-based approaches do not preserve the translation invariance property.

In contrast, LLF is different: 1) local enhancement, 2) separation, and 3) integration, where the order of enhancement and separation is reversed. This processing flow more easily controls the parameters. In this paper, we break away from the concept of pyramids and consider a new edge-preserving scale-space analysis based on the concept of the different processing orders. Moreover, the new scale-space method solves the inevitable aliasing problem of pyramid processing, like the concept of stationary wavelet transforms [31].

The contributions of this paper are as follows:

- We replace the Laplacian pyramid with the multiscale filtering of DoG in LLF to increase the controllability and generality of scale-space named local DoG filter (LDF).
- We accelerate the DoG computation by recent $O(1)$ Gaussian filtering (GF) with a fast LLF formulation to accelerate LDF.

II. Preliminary

A. Gaussian Pyramid and Laplacian Pyramid

In this section, we review the Laplacian pyramid. Laplacian pyramid is used for various applications, such as compression [23], texture synthesis [32], and harmonization [33].

Here, we introduce the Gaussian pyramid. Let I be an input image, and let the Gaussian pyramid be defined as the set of $G_\ell[I]$, where $\ell \in \mathcal{L} = \{0, 1, 2, \ldots, \ell_{\max}\} \subset \mathbb{N}$. The lowest level of the Gaussian pyramid is $G_0[I] = I$, and the other level of pyramids $G_{\ell+1}[I]$ are equal to the downsampled blurred image of $G_\ell[I]$:

$$G_\ell[I] = \mathrm{downsampling}(\mathcal{G}_\sigma * G_{\ell-1}[I]), \tag{1}$$

where $\mathcal{G}_\sigma *$ means Gaussian convolution with standard deviation σ. The image of $G_{\ell+1}[I]$ has half the width and height of $G_\ell[I]$. Usually, the Gaussian convolution for pyramid building is implemented using the binomial distribution with five taps for integer operations, and the regarded standard deviation is about $\sigma = 1$.

The difference between the current-level pyramid and the upsampled next-level pyramid defines the Laplacian pyramid:

$$L_\ell[I] = G_\ell[I] - \mathrm{upsampling}(G_{\ell+1}[I]), \tag{2}$$

where $\mathrm{upsampling}(\cdot)$ is an operator that doubles the width and height of the image size by using a smoothing kernel. Usually, the smoothing kernel is the same kernel as $\mathcal{G}_\sigma$. Note that the highest level of the Laplacian pyramid is $L_{\ell_{\max}}[I] = G_{\ell_{\max}}[I]$.

In the Gaussian pyramid, the filtering parameter of each level, σ, is fixed. Iterative processing and downsampling change each level's actual parameter, i.e., equivalent to the full resolution parameter. The relationship between each scale and actual σ_ℓ at each level is essential for scale-space analysis.

Here, we show the relationships. Iterative Gaussian convolutions can be merged and represented by one large standard deviation value by the semi-group property of Gaussian:

$$\mathcal{G}_{\sigma 1} * \mathcal{G}_{\sigma 2} = \mathcal{G}_\sigma, \quad \sigma = \sqrt{\sigma_1^2 + \sigma_2^2}. \tag{3}$$

The Gaussian convolution is applied for each level. The σ for each level becomes the sum of each variance until the level. Note that the image is downsampled for each level; thus, the supporting distribution is doubled by the level. The actual standard deviation for each level σ_ℓ is defined as follows:

$$\sigma_\ell = \sigma \sqrt{\sum_{l=1}^{\ell} 2^l} \quad (\ell > 0), \quad \sigma_0 = 0, \tag{4}$$

where σ is the base value of a standard deviation for constructing Gaussian and Laplacian pyramids.

B. Manipulating Laplacian Pyramid

We show the example of manipulating the Laplacian pyramid for detail enhancement.

We boost the pyramid coefficients for multiscale detail enhancement except for the coarsest layer of $\sup \mathcal{L}$. We usually use an S-tone-like function to suppress overshoot for boosting, while the most straightforward function is $r(x, 0) = kx$, where $k > 1$ is a constant value. If $k = 1$, there is no boosting, and the resulting image is the input image. Note that the representation of the argument 0 in $r(x, 0)$ is unnecessary for this case; however, it is used to match the form of the latter remapping function for the local Laplacian filtering. The later section refers to the remapping function. Finally, remapped signals are collapsed to obtain the output image:

$$O = L_{\ell_{\max}}[I] + \sum_{\ell \in \mathcal{L} \setminus \{\ell_{\max}\}} r(L_\ell[I], 0). \tag{5}$$

C. Local Laplacian Filtering

We review the basic structure of local Laplacian filtering (LLF). In LLF, an output pixel value O_p at pixel $p = (x, y)$ is defined by constructing a pixel-dependent Laplacian pyramid of the output image, $L[O]_p$, called the local Laplacian pyramid.

Each level ℓ of pyramid $L_\ell[O]_p$ is constructed per pixel. Finally, the output pixel O_p is the summation of the value on p for each level, i.e., collapsing pyramid:

$$O_p = \sum_{\ell \in \mathcal{L}} L_\ell[O]_{p_\ell}, \tag{6}$$

where p_ℓ is the relative position of p for each level ℓ, and becomes sub-pixel. The size of the next level image in the pyramid is half, so the accessing position of pixel p also becomes half. For assessing sub-pixel, we interpolate intensity.

There are three steps to compute the coefficient itself $L_\ell[O]_{p_\ell}$. First, a remapping function $r(\cdot)$ is applied for the input image I and then creates the intermediate image $\tilde{I} = r(I, G_\ell[I]_p)$, where $r(\cdot)$ depends on the coefficient of the Gaussian pyramid at level ℓ at p. We will discuss the details of the remapping function later.

Next, we construct a Laplacian pyramid of the remapped image $L_\ell[\tilde{I}]$, and then we select a pyramid coefficient at p that is $L_\ell[\tilde{I}]_p$ as an output coefficient of $L_\ell[O]_p$. By repeating this process in all positions p and levels ℓ, we can get the Laplacian pyramid of the output pyramid $L[O]$.

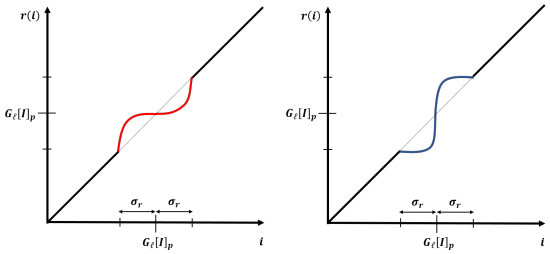
Finally, we get the output image by collapsing the pyramid $L[O]$. The computational cost of this process is $O(\sigma|\mathcal{L}|N \log N)$ per pixel, where N is the number of image pixels. The separable Gaussian filtering requires $O(\sigma)$ for each level $|\mathcal{L}|$, and a pyramid requires contains $N \log N$ pixels.

Careful implementation can reduce the processing pyramid size. Let $R \in \mathbb{N}$ be the convolution radius: $R = \lceil n\sigma \rceil, n \in \mathbb{R}$, usually $n = 3.0$. The deep pyramid layer hierarchy requires outside pixels of the shallower layers. The required outside radius at level ℓ is defined as follows:

$$R_l = R \sum_{\ell=0}^{l} 2^\ell, \tag{7}$$

Therefore, we require $2 * R_l + 1$ pixels to build a pyramid. For example, $R_l \in \{1, 3, 7, 15, 31, 63, 127, \ldots\}$. R_l is exponentially increasing; thus, the trimmed pyramid size can rapidly reach the maximum size of N.

The approximated acceleration of LLF, called fast LLF [24], can reduce the order $O(\sigma|\mathcal{L}||\mathcal{I}|)$ per pixel, where $|\mathcal{I}| \in \mathbb{N}$ is the number of approximation samples. The method builds a limited number of pyramids and then blends the pyramid to approximate the result.



D. Remapping Function

The remapping function is defined as:

$$r(x, g) = x - (x - g)f(x - g), \tag{8}$$

where, x is input signal intensity, and g is the controlling center value. This function enhances/smooths signals. In LLF, $g = G_\ell[I]_p$, where $G_\ell[I]_p$ is a coefficient of a Gaussian pyramid, while f is specifically defined for each application. This paper used the Gaussian function with multiplying factor m as f.

$$f(x - g) = m \exp\left(\frac{(x - g)^2}{-2\sigma_r^2}\right) \tag{9}$$

(a) detail smoothing (b) detail enhancement

Fig. 1: . Remapping functions ($m = 1$).

The sign of m switches enhancing or smoothing signals, and the magnitude control strength of signal control. Figure 1 shows an example of remapping functions.

III. Proposed Method

We extend the concept of LLF to a multiscale filter that manipulates the contrast in advance, named Local DoG Filter (LDF). Furthermore, the LDF is accelerated using the fast LLF form. Moreover, we use $O(1)$ Gaussian filtering (GF) for further acceleration.

A. Definition

Under the concept of LDF, The difference between LDF and LLF is the scale-space structure: pyramid or DoG. In conventional LLF, the image at level $\ell+1$ is a quarter-size image at ℓ due to downsampling. In contrast, the LDF's image size of each level ℓ is equal due to no downsampling.

First, we build the scale-space blurring representation instead of the Gaussian pyramid. The definition of scale-space $G_\ell[I]$ is as follows:

$$G_\ell[I] = \begin{cases} I & (\ell = 0) \\ \mathcal{G}_{\sigma_\ell} * I & (\text{otherwise}). \end{cases} \tag{10}$$

Here, we redefine $L_\ell[O]$ at a pixel p by using DoG. DoG filtering means the difference between two GFs that have different σ values; thus, $L_\ell[O]_p$ is defined as follows:

$$L_\ell[O]_p = \begin{cases} (\mathcal{G}_{\sigma_\ell} * r(I, G_\ell[I]_p) - \mathcal{G}_{\sigma_{\ell+1}} * r(I, G_\ell[I]_p))_p \\ \qquad\qquad (0 \le \ell \le \ell_{\max} - 1) \\ (\mathcal{G}_{\sigma_\ell} * I)_p \qquad (\ell = \ell_{\max}), \end{cases} \tag{11}$$

where σ_ℓ is the Gaussian scale parameter for each level ℓ. Steps between each level σ_ℓ depend on the applications and have more flexibility than the Laplacian pyramid. For example, we can set a small step when fine scaling is required. In this paper, however, we apply (4) for comparison with conventional LLF.

Finally, an output value O_p is obtained by collapsing the DoG stack:

$$O_p = \sum_{\ell \in \mathcal{L}} L_\ell[O]_p. \tag{12}$$

We do not need upsampling and downsampling, unlike the pyramid-based LLF.

The required number of pixels for a DoG kernel is σ^2, and each level does not have dependency. Moreover, we can compute a pixel using a convolution. In this case, separable filtering is ineffective since separable filtering is used to convolute whole pixels. Therefore, the order is $O(|\mathcal{L}|\sigma^2)$ per pixel. LLF requires $O(\sigma|\mathcal{L}|N\log N)$, larger than our representation.

B. Acceleration

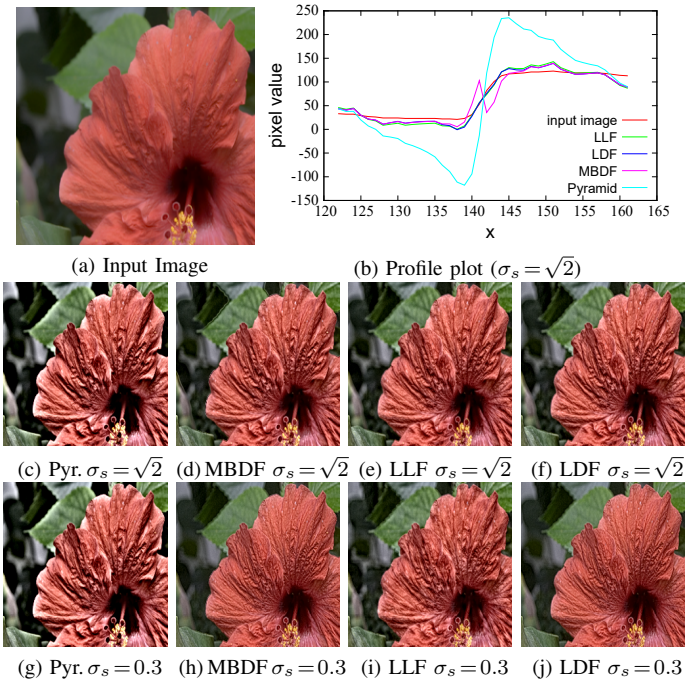
Here, we rewrite the LDF representation for acceleration. We call the accelerated method *fast LDF*. The concept is that $r(I, G_\ell[I]_p)$ in (11) has a limited number of variations. Let a sample i be an integer value, $i \in \mathcal{I} \subset \mathbb{Z}$. First, remapping images $\mathcal{R}_i$ are prepared for each intensity i:

$$\mathcal{R}^i = r(I, i) \quad \forall i \in \mathcal{I}. \tag{13}$$

Second, the DoGs for each remapping image are built:

$$L_\ell[\mathcal{R}_i] = \mathcal{G}_{\sigma_\ell} * \mathcal{R}^i - \mathcal{G}_{\sigma_{\ell+1}} * \mathcal{R}^i \quad \forall i \in \mathcal{I}. \tag{14}$$

Eqs. (13) and (14) do not exist pixel accessing operator p since processing for each pixel is the same. Thus, the GF in (14) can be regarded as the usual GF for entire images. GF can be accelerated using the usual approaches, such as FFT, discussed in the following.



Next, DoGs of the remapped images are combined with the local Laplacian DoG by referring to the Gaussian stacks of (10):

$$L_\ell[O]_p = \sum_{i\in\mathcal{I}} w(G_\ell[I]_p, \mathcal{R}^i_p) L_\ell[\mathcal{R}^i]_p, \tag{15}$$

where w is the weight function for the linear interpolation. Equation (14) sums up each DoG of the remapped image weighted by w. Finally, we can obtain an output value O_p by collapsing the DoG based on (12).

Here, we discuss Gaussian convolution in (14). The order of fast LDF with the naïve implementation of GF is $O(|\mathcal{I}|\sigma^2)$. We perform $|\mathcal{I}|$ times GFs for each pixel, and the order of GF is $O(\sigma^2)$ per pixel. A separable representation can reduce the GF order to $O(\sigma)$. In this case, the LLF order is $O(N|\mathcal{I}|\sigma)$, which is the same as the conventional method of "fast" LLF. The GF is further accelerated by constant-time algorithms, which have two representations: infinite impulse response (IIR) and finite impulse response (FIR).

Typical examples of the IIR filter are the addition model [34] and the multiplication model [35]. The order of these methods is $O(K)$ per pixel, where K is the approximate order. However, the implementation of IIR is not faster than the implementation of recursive FIR [36]. In terms of FIR approximation methods, sliding DCT-based GF has been proposed [37]–[43]. The computational order of this method is also $O(K)$. Currently, sliding DCT-based GF has the best performance in terms of accuracy and processing speed [42]. Therefore, we use the sliding DCT-based GF for the implementation of LDF. The parameter of K is independent of the filtering parameter of σ, so the approximation has a constant-time property for σ. Using constant-time GF, the order of LDF is $O(|\mathcal{I}|K)$, *named fast $O(1)$ LDF* because the algorithm is constant for σ.

IV. Experimental Results

We demonstrate the performance of the LDF, fast LDF, and fast $O(1)$ LDF on accuracy and speed. The code is written in C++ with OpenMP parallelization and AVX vectorization. The CPU tested is the Intel Core i9–9980XE (3.0 GHz, 18-cores/36-threads). We remove subnormal numbers in Gaussian distributions for acceleration based on [44].

First, we compare the output images of various methods: pyramid-enhancement of Eq. (5), multiscale bilateral decomposition filter (MBDF) [12], LLF [22] and the proposed LDF. Pyramid and MBDF are preenhancement methods. Figure 2 shows the output of these images and the profile plots of each signal. These images have two σ_s settings: $\sigma_s \in \{0.3, \sqrt{2}\}$. The pyramid has halos, while the other methods solve the problem. MBDF has edge reversals (e.g., the leaf contour in the image's upper left corner), while LLF and LDF solve the problem. LLF and LDF in $\sigma = \sqrt{2}$ have almost the same response, whereas, in the smaller case of $\sigma = 0.3$, the results are different.

Figure 3(a) shows the profile plots then $\sigma = 0.3$. The

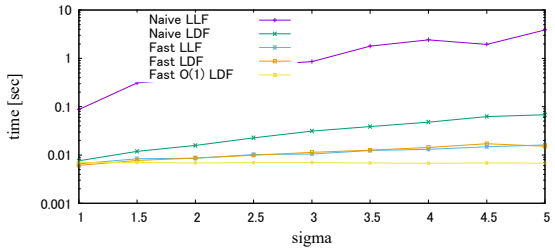

Fig. 4: Processing time ($\ell_{\max} = 2$, $K = 3$). σ_s is the standard deviation of $\ell = 1$, and the radius of the kernel is truncated by $3\sigma_\ell$ for each level in LDF. For conventional LLF, we used a fixed kernel radius, $3\sigma_s$, for each downsampled image. Test images are Kodak 24 images (768×512).

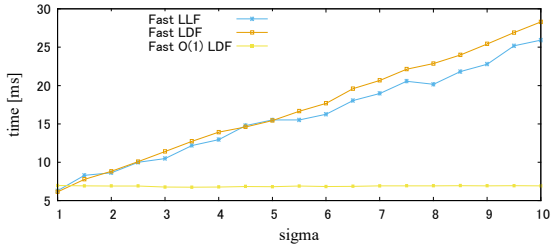

Fig. 5: Processing time of selected methods in Fig. 4. The Y scale is *not the log scale*, and the unit is *ms*.

responses differ, while the case $\sigma = \sqrt{2}$ is almost the same. The difference between high-level signals and low-level signals generates a Laplacian pyramid. The low-level signals are an approximation of Gaussian filtering using the semigroup property and downsampling. Figure 3(b) shows the approximation accuracy of Gaussian filtering. Due to downsampling, aliasing is produced in a small σ_s case; therefore, the accuracy of the approximation is low. The low approximation accuracy produces the difference between LLF and LDF.

Figure 4 shows the computational time (log scale in Y) of each method: naïve LLF [22], fast LLF [24], naïve LDF, fast LDF, fast O(1) LDF. Naïve LLF requires many processing areas, while naïve LDF needs less area; thus, the processing time of LDF is faster than the naïve LLF. For the other case, Fig. 5 shows faster plots with the removal of the logarithmic scale. The computational time of fast LDF and fast LLF is proportional to σ, while fast $O(1)$ LDF exhibits a constant time property. Except for the tiny sigma case (around $\sigma = 1$), the proposed method is faster than the other. Note that due to cache efficiency, when σ is small, the naïve GF implementation is faster than the $O(1)$ GF-based one.

V. Conclusion

This study proposed a local DoG filter (LDF) that creates image pyramids without downsampling. The pure definition of the proposed method generates DoG per pixel; however, it is more efficient than naïve LLF. Furthermore, we accelerate it by changing the form to share the convolution between pixels. Moreover, we use constant-time Gaussian filtering to accelerate large-scale filtering. In our future work, we extend the method to have color space [45] and to perceptually enhance images [46].

***Abstract*—This paper introduces a new benchmarking dataset for marine snow removal of underwater images. Marine snow is one of the main degradation sources of underwater images that are caused by small particles, e.g., organic matter and sand, between the underwater scene and photosensors. We mathematically model two typical types of marine snow from the observations of real underwater images. The modeled artifacts are synthesized with underwater images to construct large-scale pairs of ground truth and degraded images to calculate objective qualities for marine snow removal and to train a deep neural network. We propose two marine snow removal tasks using the dataset and show the first benchmarking results of marine snow removal. The *Marine Snow Removal Benchmarking Dataset* is publicly available online.**

I. Introduction

Image restoration has been one of the main topics of computer vision for decades [10], [11], [28], [35]–[38]. In the current era of deep learning, the quality of image restoration for various tasks has been significantly improved under a sufficient number of pairs of ground truth and degraded images. Accordingly, the current focus on image restoration will be for images taken under extreme situations such as underwater, satellite, and medical images [1], [3], [6], [12], [14], [20], [23], [24], [26], [27], [31]–[34], [39], [41]. This problem is called *extreme image restoration* herein. Extreme images often have an untypical degradation beyond that of a Gaussian model, and the numbers of available images for training and modifying restoration algorithms are also limited. As a result, extreme image restoration is a challenging problem.

In this paper, we focus on underwater image enhancement. Its main challenge is mostly due to the fact that we generally have no ground truth images. This makes it difficult to evaluate the objective qualities of the restored images and measure the restoration performance. Moreover, the lack of pairs of ground truth and degraded image causes a difficulty in training a neural network (if we consider using a deep neural network for restoration) because the loss functions of the image restoration typically evaluate some objective image quality metrics such as mean squared error (MSE) and structured similarity index (SSIM) [40]. Hence, unsupervised restoration methods, including linear and nonlinear filtering, are still popular in underwater image enhancement [2], [6], [24].

This work is supported in part by Japan Science and Technology Agency (JST) Advanced International Collaborative Research Program (AdCORP) under Grant JPMJKB2307 and JSPS KAKENHI under Grant 23K17461.

Several studies for underwater image enhancement with deep neural networks have been proposed [14], [18], [20], [22], [23], [32], [33], [42]. Most focus on removing the color shift from underwater images. That is, the blueish underwater images are restored by enhancing the red and green channels. Conventional underwater image enhancement methods using deep neural networks tackle the problem on the lack of large-scale underwater image datasets in various ways. For example, the studies in [4], [14], [32], [33] synthetically generate degraded images from clean images taken on the ground by simulating the degradation processes of absorption and scattering. Moreover, [15], [20], [25] use generative adversarial networks. And a number of challenges to improving the restoration performance still exist, some promising results have been presented. However, such studies ignore another main source of degradation for underwater images: *Marine snow*.

In this paper, we consider a marine snow removal (MSR) problem for underwater images by constructing a large-scale dataset containing underwater image pairs. Marine snow is a typical underwater image degradation, examples of which are shown in Fig. 1. Marine snow artifacts are visible in digital images when we take an underwater image using a flashlight. Small particles in the scene, e.g., organic matter and sand, cause marine snow. The particles reflect the light from the flashlight, and the reflected light will be captured by the photosensors. Marine snow is often annoying in underwater photography because it affects the overall image quality. However, the particles are unevenly distributed in the scene, and the degradation process is difficult to model completely. Therefore, standard methods for marine snow removal are still limited to simple median-filter-based approaches [5], [13], [18], [21]. Moreover, as with standard underwater image enhancement, we do not have a pair of ground truth and degraded images to calculate the objective image qualities and tune the parameters of the restoration algorithms.

We propose marine snow synthesis methods for solving the above-mentioned problems of MSR. In other words, we *intentionally* append the marine snow artifacts to real underwater images without marine snow and generate pairs of ground truth images and degraded images (i.e., clean underwater images and their corresponding images with marine snow artifacts). The key for synthesizing artifacts is to mathematically model marine snow in digital images as accurately as possible. From actual marine snow images, we discover that many marine snow artifacts can be modeled through two typical pixel value

distributions. By utilizing this finding, we can synthetically generate many pairs of underwater images with/without marine snow artifacts.

We also propose two marine snow removal tasks and develop datasets corresponding to these tasks. This *Marine Snow Removal Benchmarking Dataset* (MSRB Dataset) is the first attempt in this field and is publicly available online[1]. We also present the first MSR benchmarking results using the MSRB Dataset: We compare the objective performance of marine snow removal among median filters and a deep neural network. Real MSR results as well as the limitations are also described.

The remainder of this paper is organized as follows: Section II reviews several related studies for underwater image enhancement. Two representative marine snow models that we discovered are presented in Section III along with their synthesizing method. The MSRB Dataset specifications are introduced in Section IV and include the description of the two tasks. The first MSR benchmarking results with objective image quality metrics are shown in Section V. Real MSR results and limitations are described in Section VI. Finally, we provide some concluding remarks in Section VII.

II. Related Studies

There have been few studies on modeling marine snow in digital images. Its seminal study is described in [7], [8]. A marine snow artifact is modeled using a Gaussian function in which the artifact is less transparent in its center than in its surrounding area. This method is better than the traditional salt and pepper noise; however, it does not simulate the actual shapes of marine snow artifacts. As a result, the center part of marine snow becomes excessively thick and the generated images are far from the real ones.

MSR is also an underrepresented problem in underwater image enhancement. Here, we briefly review some existing approaches.

A widely used method for MSR is a median filter (MF) [9], [19]. If marine snow artifacts can be assumed sufficiently small (typically 1–3 pixels in diameter), MF is expected to work because small marine snow artifacts can be considered to have a salt-and-pepper effect. However, it significantly blurs the entire image, particularly when we use a large filter kernel size.

Specific to MSR, a modified version of a MF is proposed in [5], [17]. This method applies the MF selectively if the target pixel has a higher intensity than the surrounding pixels. However, it is still difficult to remove large marine snow artifacts.

A few MSR methods for video sequences have also been proposed. They utilize the fact that marine snow artifacts continuously move in consecutive video frames. In [16], background modeling is used to remove marine snow artifacts from a static scene. Marine snow artifacts are tracked and a customized MF is applied to the detected artifacts in [13]. However, they are not applicable to a single underwater image. Importantly, all methods above are based on a model-based approach. This is mainly due to a lack of high-quality datasets, as mentioned in Section I.

A deep learning-based MSR method is proposed in [18]. Its training dataset consists of synthesized marine snow images, corresponding ground truth images, marine snow masks. This dataset also contains real underwater images with marine snow (without ground truth). Marine snow particles are manually made with Adobe Photoshop: That results in a lack of randomness and scalability.

In the following, we address the contributions of this study; marine snow models and the dataset specifications.

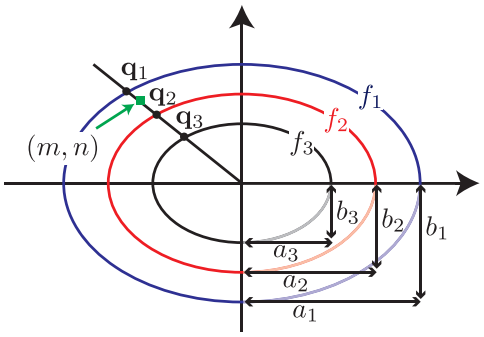

Fig. 3: Ellipses used for marine snow synthesis.

III. Marine Snow Models

There are various sources of marine snow and it is impractical to estimate the sources of all particles from a single underwater image. Instead of the estimation of the sources, we model the pixel value distributions of marine snow artifacts from observations of underwater images.

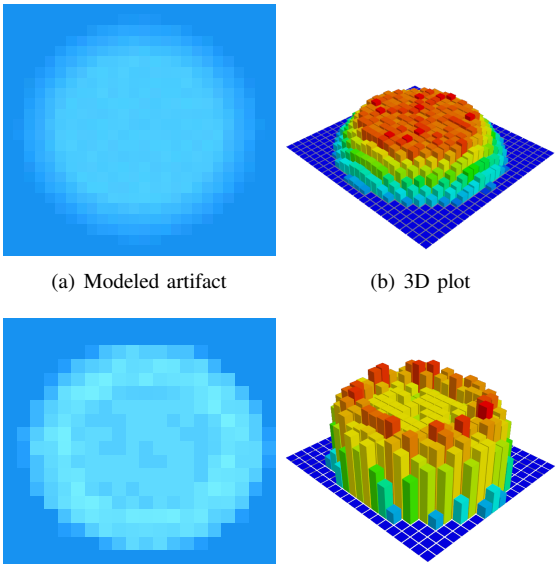
A. Real Marine Snow Examples

First, we start by showing marine snow examples in real underwater images. Figs. 2(a) and (c) show enlarged portions of representative marine snow artifacts cropped from real underwater images. Although they look similar, their pixel value distributions are slightly different.

Taking a closer look, the 3D plots of Figs. 2(a) and (c) are shown in Figs. 2(b) and (d), respectively. As clearly observed, they do *not* have a shape like a Gaussian function in contrast to the conventional assumption in [7], [8]. Rather than a Gaussian function, these 3D plots are similar to *elliptic conical frusta*, i.e., sliced elliptic cones. Furthermore, the top surfaces of the frusta have different characteristics between Figs. 2(b) and (d). In our preliminary observation, most marine snow artifacts can be classified into these two representative shapes. In the following, we present the mathematical models of marine snow artifacts that reflect the above-mentioned observations.

B. Marine Snow Model 1: Highland Type

The first marine snow model is the *Highland Type* (type H). The type H marine snow corresponds to Fig. 2(a) and can be modeled as an elliptic conical frustum with a rough surface.



For modeling type H marine snow, we first suppose to have two ellipses f_1 and f_2, both centered at the coordinates (k, l). As shown in Fig. 3, we assume the focal points of f_1 and f_2 are located on the horizontal axis, i.e., the ellipses are wider, for simplicity. Let a_i and b_i be the semi-major and semi-minor axes of f_i where $i \in \{1, 2\}$, respectively. Suppose that f_1 is larger than f_2, i.e., $a_1 > a_2$ and $b_1 > b_2$ and the eccentricities of f_1 and f_2 are identical, i.e., $\frac{a_1}{b_1} = \frac{a_2}{b_2}$.

For notational simplicity, (k, l) is set to $(0, 0)$ hereafter. The (m, n)th pixel value of the type H marine snow $h(m, n)$ is formulated as follows:

$$h(m,n) = \begin{cases} c + \epsilon & \frac{m^2}{a_2^2} + \frac{n^2}{b_2^2} \le 1 \\ c\frac{d(\mathbf{p},\mathbf{q}_1)}{d(\mathbf{q}_1,\mathbf{q}_2)} + \epsilon & 1 < \frac{m^2}{a_2^2} + \frac{n^2}{b_2^2} \wedge \frac{m^2}{a_1^2} + \frac{n^2}{b_1^2} \le 1 \\ 0 & \text{otherwise,} \end{cases} \tag{1}$$

where c is a constant that determines the transparency of the marine snow, $d(\cdot, \cdot)$ calculates the Euclidean distance between two points, and ϵ is a small perturbation that mimics a rough surface. Furthermore, $\mathbf{p} := [m, n]^\top$ and $\mathbf{q}_i$ is the intersection of the ellipse f_i and the straight line crossing (m, n), as illustrated in Fig. 3.

An example of the synthesized type H marine snow artifacts is shown in Fig. 4(a) along with its 3D plot in Fig. 4(b). See the similarity in Figs. 2(a) and (b). For creating a dataset, the major axis of $h(m, n)$ is randomly rotated and the transparency c is also randomly chosen. These specifications are shown later in Section IV.

(a) Modeled artifact (b) 3D plot

(c) Modeled artifact (d) 3D plot

Fig. 4: Proposed marine snow models. Top: Type H marine snow. Bottom: Type V marine snow.

C. Marine Snow Model 2: Volcanic Crater Type

The second marine snow model is the volcanic crater type (type V). An example of type V marine snow is shown in Figs. 2(c) and (d). This can be modeled by a modified version of the type H with an overshoot top edge of the frustum.

For the type V marine snow, we consider another ellipse f_3, where a_3 and b_3 are its semi-major and semi-minor axes, respectively. It is located inside f_2, as illustrated in Fig. 3. As for the type H, focal points of all ellipses are assumed to be located along the horizontal axis and their eccentricities are identical, i.e., $\frac{a_1}{b_1} = \frac{a_2}{b_2} = \frac{a_3}{b_3}$.

Based on the type H function $h(m, n)$, the (m, n)th pixel value of the type V marine snow $v(m, n)$ is formulated as

TABLE I: Parameter settings for marine snow synthesis where $\mathcal{U}(v_{\min}, v_{\max})$ is a continuous uniform distribution between $v_{\min}$ and $v_{\max}$.

Parameter	Setting
c in (1)	$\mathcal{U}\{10, 80\}^*$
c_r in (2)	$\mathcal{U}\{1, 40\}^*$
Gaussian filter size in (3)	$(2r+1) \times (2r+1)$ where $r \sim \mathcal{U}(1, 6)$
a_2	$\begin{cases}\mathcal{U}(1,3) & \text{for small marine snow artifacts}\\ \mathcal{U}(3,16) & \text{for large marine snow artifacts}\end{cases}$
b_2	$\begin{cases}\mathcal{U}(0.3a_2, a_2) & \text{for small marine snow artifacts}\\ \mathcal{U}(0.8a_2, a_2) & \text{for large marine snow artifacts}\end{cases}$
a_1	$\mathcal{U}(a_2, 2a_2)^\dagger$
a_3	$\mathcal{U}(0.5a_2, a_2)^\ddagger$

† b_1 is obtained from the eccentricity of $f_2(m, n)$
‡ b_3 is obtained from the eccentricity of $f_2(m, n)$

$v(m,n) = h(m,n) + g(m,n)$, where $g(m,n)$ is the *rim* term defined as

$$g(m,n) = \begin{cases} c_r\left(1 - \frac{d(\mathbf{p}, \frac{1}{2}(\mathbf{q}_2+\mathbf{q}_3))}{\frac{1}{2}d(\mathbf{q}_2,\mathbf{q}_3)}\right) & 1 < \frac{m^2}{a_3^2} + \frac{n^2}{b_3^2} \wedge \frac{m^2}{a_2^2} + \frac{n^2}{b_2^2} \leq 1 \\ 0 & \text{otherwise,} \end{cases} \tag{2}$$

where c_r is the constant for the maximum rim height and $\mathbf{q}_3$ indicates the coordinates of the intersection of the ellipse f_3 and the straight line crossing (m, n).

The synthesized type V marine snow artifact is shown in Figs. 4(c) and (d), which are similar to the real versions in Figs. 2(c) and (d).

D. Synthesizing Images with Marine Snow

By using the marine snow models introduced in the previous subsections, we synthesize the marine snow with underwater images.

Let $U \in \mathbb{R}^{H \times W \times 3}$ be an original underwater image. First, we randomly select a target pixel coordinate (k, l) to append the marine snow. Second, we randomly select the major and minor axes of the ellipses a_i and b_i. In addition, the direction of the major axis is randomly set. Third, for each channel, type H or V marine snow is independently generated, where the parameters c and c_r are independently set. We denote an image with one marine snow artifact as M, where pixel values in M are all-zero except the marine snow artifact. Finally, U and M are combined as follows to yield the synthesized image I:

$$I_{k,l,t} = \begin{cases} M_{k,l,t} + G_{k,l,t} & M_{k,l,t} \geq 0 \\ U_{k,l,t} & \text{otherwise} \end{cases} \tag{3}$$

where $G \in \mathbb{R}^{H \times W \times 3}$ is the Gaussian filtered version of U that reflects blur owing to marine snow.

We iterate the process until a predetermined number of marine snow artifacts are appended.

IV. Dataset Specifications

In this section, we present the specifications of synthesized marine snow artifacts in the MSRB Dataset. It is designed for two tasks:

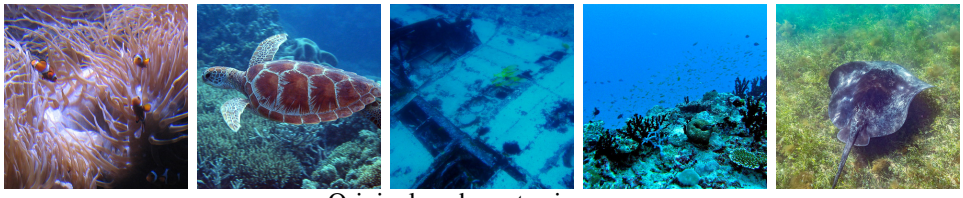
Task 1: Removal of small-sized marine snow artifacts.
Task 2: Removal of various-sized marine snow artifacts.

Clearly, Task 2 is more difficult than Task 1.

First, detailed parameters and setups shared in both tasks are presented. Second, we introduce MSR Tasks with corresponding synthesized images.

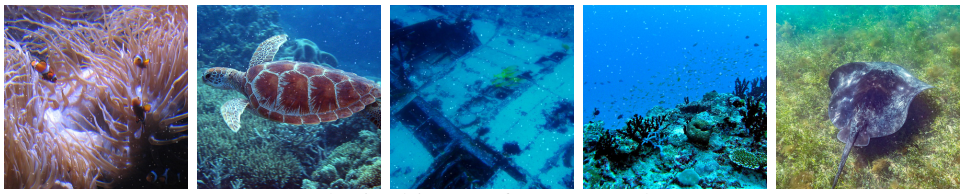
A. General Setup

Each sub-dataset corresponding to an MSR Task contains $2,300$ training image pairs and 400 test image pairs, all having a pixel resolution of 384×384. An image pair contains one original underwater image and one image containing synthesized marine snow artifacts. All original images are collected from flickr[2] under a Creative Commons Attribution-NonCommercial-ShareAlike 2.0 Generic (CC BY-NC-SA 2.0) License.



Each synthesized image contains N marine snow particles where N is chosen from $\mathcal{U}\{100, 600\}$, in which $\mathcal{U}\{v_{\min}, v_{\max}\}$ is a discrete uniform distribution between $v_{\min}$ and $v_{\max}$. In each synthesized image, type H and V marine snow particles are randomly generated with a probability of 0.7 for type H and 0.3 for type V, according to our preliminary observations. The other representative parameters introduced in the previous section are listed in Table I. Most of the parameters are determined according to our preliminary observations of real underwater images with marine snow artifacts.

B. MSR Task 1: Removing Small-Sized Marine Snow Artifacts



We introduce the first MSR Task: Removal of small-sized marine snow artifacts. In Task 1, the maximum width/height of the artifacts is restricted to 6 pixels, which corresponds to roughly 1.6% of the image width/height. Task 1 is designed for underwater scenes where particles are relatively far from the photosensors. Because the task is relatively simple, the conventional MF approach is expected to be successfully applied (at least partially).

Examples of test image pairs in MSR Task 1 are shown in Fig. 5. As clearly visualized, the synthesized images have various sized (but small) marine snow artifacts.

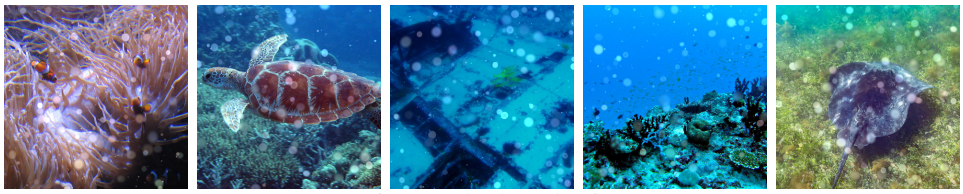
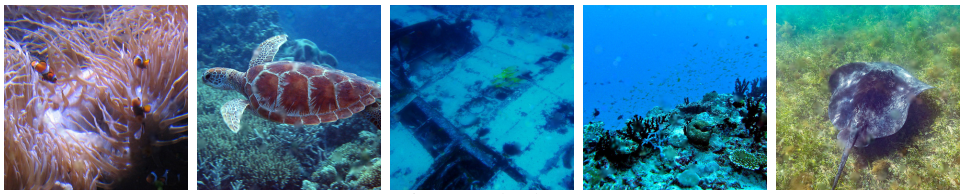
Restoration results by U-Net.

Fig. 6: MSR Task 1 results.



C. MSR Task 2: Removing Various-Sized Marine Snow Artifacts

The second MSR task is designed for underwater scenes containing particles in various distances. As a result, the synthesized images for Task 2 have small- and large-sized marine snow artifacts. For large-sized artifacts, we set the largest width/height of marine snow to 32 pixels, which corresponds to 8.3% compared to the image width. Furthermore, the probabilities of small- and large-sized artifacts are set to 0.7 and 0.3, respectively.



Training image examples for Task 2 are also shown in Fig. 5. The images have various-sized artifacts and the degraded areas

Fig. 7: MSR Task 2 results.

are larger than the images in Task 1.

In the following, we show the benchmarking results of MSR as well as the real MSR.

V. MSR Benchmarking Results

In this section, we present the first benchmarking performance for MSR Tasks 1 and 2. The methods used for the benchmarking are 1) MF [19], 2) adaptive MF [5], and 3) U-Net [29]. The kernel size of MFs is set to 3×3 or 5×5 pixels. Thanks to the MSRB Dataset, we can train a deep neural network for removing (synthesized) marine snow. For a benchmarking purpose, we train U-Net [29] using the dataset. The parameter settings are slightly different from the original.

The MSR results for Tasks 1 and 2 are shown in Figs. 6 and 7, respectively. As clearly observed, MF oversmoothes the images, which results in blur even for regions without marine snow artifacts. The adaptive MF suppresses blur; however, many artifacts are not removed mainly owing to the threshold-based algorithm. Furthermore, both MFs do not operate successfully for large marine snow artifacts in Task 2. By contrast, U-Net successfully removes marine snow for both tasks. Even for Task 2, it is able to suppress the large marine snow artifacts because of its multiresolution structure and the large number of trainable parameters.

For an objective comparison, we compute the average PSNRs and SSIMs over the test datasets. We summarize the results in Table II. The objective measure indicates that U-Net is superior to the MFs for both MSR tasks. Note that all MFs present smaller PSNRs/SSIMs than those of the synthesized images because they filtered areas without marine snow. By contrast, U-Net achieves a better objective quality than the synthesized images, which implies the effect of a deep neural network for MSR.

TABLE II: Average PSNRs and SSIMs over the test dataset.

	Task 1		Task 2	
Method	PSNR	SSIM	PSNR	SSIM
MF (3×3)	28.55	0.846	22.81	0.770
MF (5×5)	25.98	0.711	21.93	0.645
Adaptive MF (3×3)	29.88	0.910	23.35	0.842
Adaptive MF (5×5)	28.08	0.861	22.83	0.794
U-Net	**36.82**	**0.978**	**30.95**	**0.932**
Synthesized image	32.20	0.945	23.83	0.876

VI. Real Marine Snow Removal Examples

We construct the MSRB Dataset to mimic real marine snow artifacts. In this section, we show the real MSR results and present limitations of the dataset.

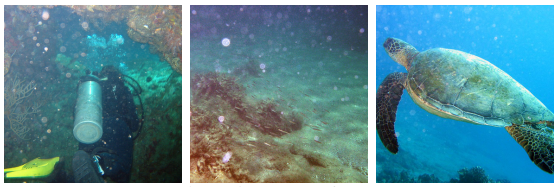
A. Real Marine Snow Removal

Fig. 8 shows MSR results for some real images. We use MF, adaptive MF, and U-Net as in the previous section. In addition, Deep WaveNet [30] is applied to validate the regular underwater enhancement model works for marine snow removal. U-Net is trained using MSRB Task 2 Dataset. The trained model of Deep WaveNet is taken from the original authors' GitHub repository.

As clearly observed, MFs cannot suppress marine snow artifacts because of their various sizes and different transparencies. Deep WaveNet also fails to remove marine snow artifacts. That means marine snow cannot be suppressed by underwater image enhancement techniques alone. U-Net presents a better

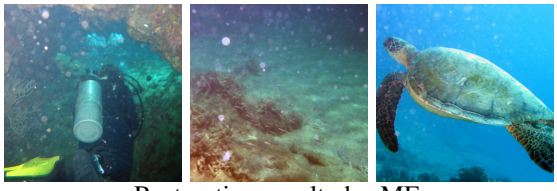
restoration image quality than MFs: It (partly) suppresses artifacts having both small and large sizes. This implies the effectiveness of deep-learning-based methods trained using the MSRB Dataset for real MSR.

Note that thick marine snow artifacts remain in the restored images. The reason for this could be two-fold: First, U-Net is not specifically designed for MSR although we slightly customized its structure. A neural network designed specifically for MSR would improve the performance. Second, our proposed model classifies marine snow artifacts into two representative types. Marine snow artifacts not fitted to these types are not well removed. This limitation is described in the next section.



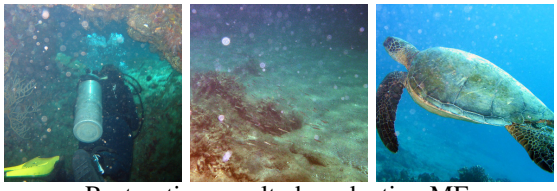
B. Limitations

Because our MSR benchmarking dataset is based on synthesizing marine snow artificially into real underwater images, some limitations exist. First, the dataset is designed for removing marine snow artifacts and does not aim at achieving other underwater image enhancements such as color correction. The design of a simultaneous restoration of MSR and color correction is an interesting area of future study.



Although U-Net trained using the MSRB Dataset presents promising results, the dataset itself is imperfect. Specifically, real MSR performances are occasionally limited if MSR artifacts are not fitted to our marine snow models. Examples are shown in Fig. 9, which compares real underwater images and their restoration results using U-Net. Typically, U-Net fails to suppress artifacts when marine snow artifacts are larger and denser than our MSR benchmarking dataset. Moreover, if the lighting conditions differ from the dataset, the current version of U-Net will fail. Through a future study, this can be improved by carefully updating the MSRB Dataset to reflect various underwater scenes.

VII. Conclusions



In this paper, the *Marine Snow Removal Benchmarking Dataset* was proposed. We mathematically modeled two representative marine snow artifacts and synthesized them in real underwater images. Two MSR tasks, the removal of small-sized and various-sized marine snow artifacts were also proposed. The first benchmarking results were also shown, which revealed the effectiveness of a deep neural network for MSR compared to median filter-based methods. MSR for real underwater images indicates that our MSRB Dataset contributes to real MSR problems. Our future studies will include improving the marine snow models as well as designing deep neural networks specifically designed for MSR.

Cross-Frame Foreground Structural Similarity Modeling by Convolutional Sparse Representation

***Abstract*—In this paper, we propose a foreground-background separation (FBS) method using a novel foreground model based on convolutional sparse representation (CSR). Existing FBS methods are based on the assumption that the foreground component is sparse or continuous in time, resulting in poor separation performance for videos containing sparse noise/fast moving objects or for low frame rate ones. Therefore, we propose to use CSR to characterize the similar structure of the foreground component scattered in each frame. This CSR-based model can adaptively capture the "shape" of the foreground component and thus can accurately separate it even under the above difficulties. We formulate FBS as an optimization problem incorporating the CSR-based model and develope an algorithm to solve it based on alternating minimization. Experiments using an infrared video and an electron microscope video show that the proposed foreground model is superior to existing models.**

I. Introduction

Foreground-background separation (FBS) is a preprocessing technique for decomposing video data into dynamic foreground and static background components [1]. These components contain helpful information for subsequent processing, such as motion detection [2], moving object detection [3], and background subtraction [4]. However, since video data (especially those obtained from specialized measurements such as infrared videos and microscope videos) often contains various types of noise, it is very important to establish noise-robust FBS techniques.

To cope with the presence of noise and the lack of ground-truth data, many FBS methods take the approach of solving optimization problems that incorporate functions to characterize each component. There are two main categories of existing foreground models: the sparsity-based model [5], [6] and the total variation model [7]–[11]. The first model captures the sparsity of the foreground component but does not distinguish it from sparse noise. The second model characterizes smoothly moving objects based on their spatial correlation and temporal continuity. However, this model is unable to separate the foreground component from low frame-rate videos containing fast-moving objects.

Most types of foreground objects have similar spatial structure across frames (we call it *cross-frame similar structure*). As a typical example, Figure 1 shows that the shape of the airplane in the foreground component does not change over time. By capturing the cross-frame similar structure, the foreground component can be separated from noisy video data where the positions of foreground objects change significantly.

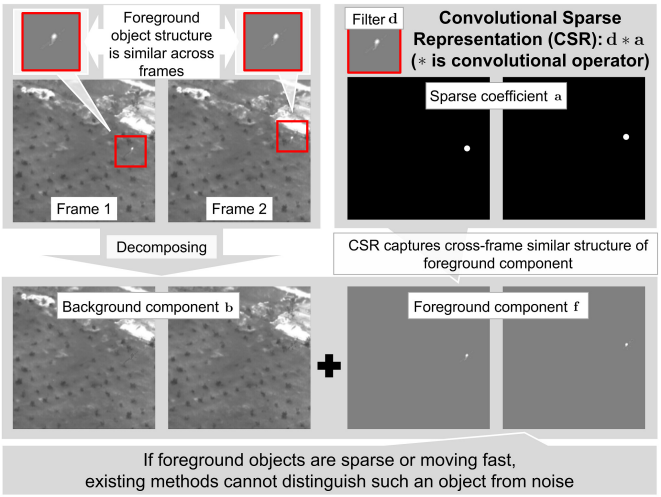

Fig. 1. Cross-frame similar structure in video data. The video data includes the complex ground scenes in the background component and an airplane in the foreground component.

In this paper, we propose a FBS method using a foreground model based on convolutional sparse representation (CSR) [12]–[15]. CSR can capture the specific spatial structure scattered throughout data [16]–[18]. The main contributions are as follows.

- We propose to use CSR to characterize the cross-frame similar structure of the foreground component scattered in each frame. This CSR-based model can adaptively capture the "shape" of the foreground component and thus can accurately separate it even under the aforementioned difficulties.
- We formulate FBS as an optimization problem incorporating CSR. The formulation is designed to separate the foreground and background components while removing sparse and Gaussian-like random noise.
- We develop an algorithm for solving optimization problems based on alternating optimization (ALM). ALM requires solving subproblems with certain variables fixed, and in our case, solvers for these subproblems are established based on the preconditioned primal-dual splitting algorithm (P-PDS) [19]–[21] and the fast iterative shrinkage-thresholding algorithm (FISTA) [22]. P-PDS can automatically adjust the appropriate stepsizes based on the problem structure, while FISTA converges at a

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

very fast rate, allowing each subproblem to be solved efficiently.

Experiments using an infrared (IR) video and an electron microscope (EM) video show that the proposed foreground model is superior to existing models.

II. Preliminaries

A. Notation

The ℓ_1, ℓ_2, and operator norms are defined as $\|\mathbf{x}\|_1 := \sum_i |\mathbf{x}_i|$, $\|\mathbf{x}\|_2 := \sqrt{\sum_i \mathbf{x}_i^2}$, and $\|\mathfrak{L}\|_{\mathrm{op}} := \sup_{\mathbf{x}\neq\mathbf{0}} \|\mathfrak{L}(\mathbf{x})\|_2/\|\mathbf{x}\|_2$, respectively. We denote the ℓ_p ball centered by $\mathbf{c}$ with a radius α as $B^{\mathbf{c}}_{p,\alpha} := \{\mathbf{y} \,|\, \|\mathbf{y}-\mathbf{c}\|_p \leq \alpha\}$. The adjoint operator of a linear operator $\mathfrak{L}$ is denoted as $\mathfrak{L}^*$.

B. Convolutional Sparse Representation (CSR) [14]

CSR [14] models data $\mathbf{x}$ as the sum of convolutions between dictionary filters $\mathbf{d} := \{\mathbf{d}_d \,|\, d = 1,\dots,D\}$ and sparse coefficient $\mathbf{a} := \{\mathbf{a}_d \,|\, d = 1,\dots,D\}$:

$$\begin{aligned}\min_{\mathbf{d},\mathbf{a}} \frac{1}{2}\|\mathbf{x} - \sum_{d=1}^{D} \mathbf{d}_d * \mathbf{a}_d\|_2^2 + \lambda \sum_{d=1}^{D} \|\mathbf{a}_d\|_1 \\ \text{s.t. } \mathbf{d}_d \in S_{2,1} := \{\mathbf{y} \,|\, \|\mathbf{y}\|_2 = 1\}\,(d = 1,\dots,D),\end{aligned} \quad (1)$$

where $*$ denotes the convolution operator. The first term guarantees the fidelity between the data $\mathbf{x}$ and the sum of convolutions. The second term promotes the sparsity of the coefficient $\mathbf{a}$. By combining these terms using the appropriate balancing parameter $\lambda > 0$, CSR can capture specific spatial structure scattered throughout the data $\mathbf{x}$. The unit ℓ_2 sphere constraints on filters $\mathbf{d}_d$ allows us to avoid ambiguity between filters and coefficients. The standard approach to solve Prob. (1) is ALM with respect to filters and coefficients.

III. Proposed Method

A. Problem Formulation

Consider that an observed video (of size $n_1 \times n_2 \times n_3$) $\mathbf{v} \in \mathbb{R}^{n_1 n_2 n_3}$ is modeled by

$$\mathbf{v} = \bar{\mathbf{f}} + \bar{\mathbf{b}} + \bar{\mathbf{s}} + \mathbf{n}, \quad (2)$$

where $\bar{\mathbf{f}}$, $\bar{\mathbf{b}}$, $\bar{\mathbf{s}}$, and $\mathbf{n}$ are the true foreground component, the true background component, sparsely distributed noise such as outliers, and random noise, respectively.

Based on the model in (2), we newly formulate FBS as the following optimization problem:

$$\begin{aligned}\min_{\mathbf{f},\mathbf{b},\mathbf{s},\mathbf{d},\mathbf{a}} \frac{1}{2}\|\mathbf{f} - \sum_{d=1}^{D} \mathbf{d}_d * \mathbf{a}_d\|_2^2 + \lambda \sum_{d=1}^{D} \|\mathbf{a}_d\|_1 + \sum_{i=1}^{K} R_i(\mathbf{L}_i\mathbf{b}) \\ \text{s.t. } P_M(\mathbf{f}+\mathbf{b}+\mathbf{s}) \in B^{\mathbf{v}_M}_{2,\varepsilon},\ \mathbf{s} \in B^{\mathbf{0}}_{1,\eta_{\mathbf{s}}},\ \mathbf{f} \in B^{\mathbf{0}}_{1,\eta_{\mathbf{f}}}, \\ \mathbf{d}_d \in S_{2,1}\,(d = 1,\dots,D).\end{aligned} \quad (3)$$

For handling dynamic background scenes arising from a moving camera, Prob. (3) contains the orthogonal projection P_M. This projection maps panoramic video data onto a subspace M that represents dynamic scenes [8]. The first and second terms and the fourth constraint build CSR that captures the cross-frame similar structure of foreground objects. The third term is a general form of background modeling including linear operators $\mathbf{L}_i$ and functions R_i.[1] The first constraint guarantees the data-fidelity to projected observed data $\mathbf{v}_M = P_M(\mathbf{v})$. The second and third constraints guarantee the sparsity of noise and the foreground component. Using these constraints instead of an data-fidelity and a sparse terms allow us to easily adjust hyperparameters since parameters ε, $\eta_{\mathbf{s}}$, and $\eta_{\mathbf{f}}$ can be determined based only on noise and foreground component intensities. Indeed, this kind of constrained formulation has played an important role in facilitating the parameter setting of signal recovery problems [23]–[29].

Algorithm 1 Solver for the main FBS problem (3)

Input: $\mathbf{f}^{(0)}, \mathbf{b}^{(0)}, \mathbf{s}^{(0)}, \mathbf{a}^{(0)}, \mathbf{d}^{(0)}$
Output: $\mathbf{f}^{(t)}, \mathbf{b}^{(t)}, \mathbf{a}^{(t)}$

1: Initialize $t = 0, \mathbf{f}^{(0)}, \mathbf{b}^{(0)}, \mathbf{s}^{(0)}, \mathbf{d}^{(0)}, \mathbf{a}^{(0)}$;
2: **while** A stopping criterion are not satisfied **do**
3: Updating $\mathbf{f}$, $\mathbf{b}$, $\mathbf{s}$, $\mathbf{a}$ with fixed $\mathbf{d}^{(t)}$ by solving Prob. (4) via Algorithm 2;
4: Updating $\mathbf{d}$ with fixed $\mathbf{f}^{(t+1)}$, $\mathbf{b}^{(t+1)}$, $\mathbf{s}^{(t+1)}$, $\mathbf{a}^{(t+1)}$ by solving Prob. (10) via Algorithm 3;
5: $t \leftarrow t+1$;

B. Optimization

To solve Prob. (1), we alternately update the variables $\mathbf{f}$, $\mathbf{s}$, $\mathbf{b}$, $\mathbf{a}$ and the variable $\mathbf{d}$ as shown in Algorithm 1. The details of algorithms solving each subproblem are as follows.

1) Updating $\mathbf{f}$, $\mathbf{s}$, $\mathbf{b}$, *and* $\mathbf{a}$*:* With $\mathbf{d}$ fixed, the subproblem with respect to $\mathbf{f}$, $\mathbf{s}$, $\mathbf{b}$, and $\mathbf{a}$ in Prob. (3) can be written as the following optimization problem:

$$\begin{aligned}\min_{\mathbf{f},\mathbf{b},\mathbf{s},\mathbf{a}} \frac{1}{2}\|\mathbf{f} - \sum_{d=1}^{D} \mathbf{d}_d * \mathbf{a}_d\|_2^2 + \lambda \sum_{d=1}^{D} \|\mathbf{a}_d\|_1 + \sum_{i=1}^{K} R_i(\mathbf{L}_i\mathbf{b}) \\ \text{s.t. } P_M(\mathbf{f}+\mathbf{b}+\mathbf{s}) \in B^{\mathbf{v}_M}_{2,\varepsilon}, \mathbf{s} \in B^{\mathbf{0}}_{1,\eta_{\mathbf{s}}}, \mathbf{f} \in B^{\mathbf{0}}_{1,\eta_{\mathbf{f}}}.\end{aligned} \quad (4)$$

Using indicator functions[2] $\iota_{B^{\mathbf{v}_M}_{2,\varepsilon}}$, $\iota_{B^{\mathbf{0}}_{1,\eta_{\mathbf{f}}}}$, and $\iota_{B^{\mathbf{0}}_{1,\eta_{\mathbf{s}}}}$ of norm balls $B^{\mathbf{v}_M}_{2,\varepsilon}$, $B^{\mathbf{0}}_{1,\eta_{\mathbf{s}}}$, and $B^{\mathbf{0}}_{1,\eta_{\mathbf{f}}}$, we translate Prob. (4) into the following equivalent optimization problem:

$$\begin{aligned}\min_{\mathbf{f},\mathbf{b},\mathbf{s},\mathbf{a}} \iota_{B^{\mathbf{0}}_{1,\eta_{\mathbf{f}}}}(\mathbf{f}) + \iota_{B^{\mathbf{0}}_{1,\eta_{\mathbf{s}}}}(\mathbf{s}) + \lambda \sum_{d=1}^{D} \|\mathbf{a}_d\|_1 + \sum_{i=1}^{K} R_i(\mathbf{L}_i\mathbf{b}) \\ + \frac{1}{2}\|\mathbf{f} - \sum_{d=1}^{D} \mathbf{d}_d * \mathbf{a}_d\|_2^2 + \iota_{B^{\mathbf{v}_M}_{2,\varepsilon}}(P_M(\mathbf{f}+\mathbf{b}+\mathbf{s})).\end{aligned} \quad (5)$$

Prob. (5) can be solved by P-PDS [19], [20].

[1] For example, if we respectively set $\mathbf{L}$ and R to the identity operator and the nuclear norm, the third term in (3) characterizes the foreground component as low-rank, as seen in [5].

[2] For a given nonempty closed set C, the indicator function of C is defined as $\iota_C(\mathcal{X}) := 0$, if $\mathcal{X} \in C$; ∞, otherwise.

Algorithm 2 P-PDS solver for the subproblem (4)

Input: $\mathbf{f}^{(0)}, \mathbf{b}^{(0)}, \mathbf{s}^{(0)}, \mathbf{a}^{(0)}, \mathbf{d}^{(t)}$
Output: $\mathbf{f}^{(l)}, \mathbf{b}^{(l)}, \mathbf{a}^{(l)}$

1: Initialize $l = 0, \mathbf{z}_{1,1}, \ldots, \mathbf{z}_{1,K}, \mathbf{z}_2, \mathbf{z}_3$;
2: Setting stepsizes $\gamma_{\mathbf{f}}, \gamma_{\mathbf{b}}, \gamma_{\mathbf{s}}, \gamma_{\mathbf{a}}, \gamma_{\mathbf{z}}$ as (6);
3: **while** A stopping criterion is not satisfied **do**
4: $\quad \mathbf{f}' \leftarrow \mathbf{f}^{(l)} - \gamma_{\mathbf{f}}(\mathbf{z}_2^{(l)} + P_M(\mathbf{z}_3^{(l)}))$;
5: $\quad \mathbf{f}^{(l+1)} \leftarrow \mathrm{prox}_{\gamma_{\mathbf{f}} \iota_{B^{\mathbf{0}}_{1,\eta_{\mathbf{f}}}}}(\mathbf{f}')$ by the algorithm in [30];
6: $\quad \mathbf{b}^{(l+1)} \leftarrow \mathbf{b}^{(l)} - \gamma_{\mathbf{b}}(\sum_{i=1}^{K} \mathbf{L}_K^{\top} \mathbf{z}_{1,K}^{(l)} + P_M(\mathbf{z}_3^{(l)}))$;
7: $\quad \mathbf{s}' \leftarrow \mathbf{s}^{(l)} - \gamma_{\mathbf{s}} P_M(\mathbf{z}_3)$;
8: $\quad \mathbf{s}^{(l+1)} \leftarrow \mathrm{prox}_{\gamma_{\mathbf{s}} \iota_{B^{\mathbf{0}}_{1,\eta_{\mathbf{s}}}}}(\mathbf{s}')$ by the algorithm in [30];
9: $\quad$ **for** $d = 1, \cdots, D$ **do**
10: $\quad\quad \mathbf{a}_d' \leftarrow \mathbf{a}_d^{(l)} - \gamma_{\mathbf{a}_d}(\mathfrak{C}^*_{\mathbf{d}_d^{(t)}}(-\mathbf{z}_2^{(l)}))$;
11: $\quad\quad \mathbf{a}_d^{(l+1)} \leftarrow \mathrm{prox}_{\gamma_{\mathbf{a}_d} \lambda \|\cdot\|_1}(\mathbf{a}_d')$;
12: $\quad$ **for** $i = 1, \ldots, K$ **do**
13: $\quad\quad \mathbf{z}_{1,i}' \leftarrow \mathbf{z}_{1,i}^{(l)} + \gamma_{\mathbf{z}} \mathbf{L}_i (2\mathbf{b}^{(l+1)} - \mathbf{b}^{(l)})$;
14: $\quad\quad \mathbf{z}_{1,i}^{(l+1)} \leftarrow \mathbf{z}_{1,i}' - \gamma_{\mathbf{z}} \mathrm{prox}_{\frac{1}{\gamma_{\mathbf{z}}} R_i}(\frac{1}{\gamma_{\mathbf{z}}} \mathbf{z}_{1,i}')$;
15: $\quad \mathbf{z}_2' \leftarrow (2\mathbf{f}^{(l+1)} - \mathbf{f}^{(l)}) - \sum_{d=1}^{D} \mathfrak{C}_{\mathbf{d}_d^{(t)}}(2\mathbf{a}_d^{(l+1)} - \mathbf{a}_d^{(l)})$;
16: $\quad \mathbf{z}_2^{(l+1)} \leftarrow (\mathbf{z}_2^{(l)} - \gamma_{\mathbf{z}} \mathbf{z}_2') - \gamma_{\mathbf{z}} \mathrm{prox}_{\frac{1}{2\gamma_{\mathbf{z}}} \|\cdot\|_2^2}(\frac{1}{\gamma_{\mathbf{z}}}(\mathbf{z}_2^{(l)} - \gamma_{\mathbf{z}} \mathbf{z}_2'))$;
17: $\quad \mathbf{z}_3' \leftarrow \mathbf{z}_3^{(l)} + \gamma_{\mathbf{z}} P_M(2(\mathbf{f}^{(l+1)} + \mathbf{b}^{(l+1)} + \mathbf{s}^{(l+1)}) - (\mathbf{f}^{(l)} + \mathbf{b}^{(l)} + \mathbf{s}^{(l)}))$;
18: $\quad \mathbf{z}_3^{(l+1)} \leftarrow \mathbf{z}_3' - \gamma_{\mathbf{z}} \mathrm{prox}_{\frac{1}{\gamma_{\mathbf{z}}} \iota_{B^{\mathbf{v}_M}_{2,\varepsilon}}}(\frac{1}{\gamma_{\mathbf{z}}} \mathbf{z}_3')$;
19: $\quad l \leftarrow l + 1$;

We show the detailed algorithm in Algorithm 2. Following a method [20], [21] that selects reasonable stepsize, the parameters $\gamma_{\mathbf{f}}, \gamma_{\mathbf{b}}, \gamma_{\mathbf{s}}, \gamma_{\mathbf{a}}, \gamma_{\mathbf{z}}$ are determined as follows:

$$\begin{aligned} &\gamma_{\mathbf{f}} = \tfrac{1}{2}, \gamma_{\mathbf{b}} = \tfrac{1}{1+\sum_{i=1}^{K} \|\mathbf{L}_i\|_{\mathrm{op}}^2}, \gamma_{\mathbf{s}} = 1, \\ &\gamma_{\mathbf{a}} = \tfrac{1}{\sum_{d=1}^{D} \|\mathfrak{C}_{\mathbf{d}_d}\|_{\mathrm{op}}^2}, \gamma_{\mathbf{z}} = \tfrac{1}{3+D}, \end{aligned} \tag{6}$$

where $\mathfrak{C}_{\mathbf{d}_d}(\mathbf{a}) = \mathbf{d}_d * \mathbf{a}$. The proximity operators[3] of $\|\cdot\|_1$, $\frac{1}{2}\|\cdot\|_2^2$, and $\iota_{B^{\mathbf{v}_M}_{2,\varepsilon}}$ (in lines 11, 16, and 18 of Algorithm 2) are respectively calculated as

$$[\mathrm{prox}_{\alpha\|\cdot\|_1}(\mathbf{x})]_i = \mathrm{sgn}(x_i) \max\{|x_i| - \alpha, 0\}, \tag{7}$$

$$\mathrm{prox}_{\frac{\alpha}{2}\|\cdot\|_2^2}(\mathbf{x}) = \frac{\mathbf{x}}{1+\alpha}, \tag{8}$$

$$\mathrm{prox}_{\alpha \iota_{B^{\mathbf{v}_M}_{2,\varepsilon}}}(\mathbf{x}) = \begin{cases} \mathbf{x}, & \text{if } \mathbf{x} \in B^{\mathbf{v}_M}_{2,\varepsilon}; \\ \mathbf{v}_M + \frac{\varepsilon(\mathbf{x}-\mathbf{v}_M)}{\|\mathbf{x}-\mathbf{v}_M\|_2}, & \text{otherwise.} \end{cases} \tag{9}$$

2) Updating $\mathbf{d}$*:* With $\mathbf{f}$, $\mathbf{s}$, $\mathbf{b}$, and $\mathbf{a}$ fixed, the subproblem with respect to $\mathbf{d}$ in Prob. (3) can be written as the following optimization problem:

$$\min_{\mathbf{d}} \frac{1}{2}\|\mathbf{f} - \sum_{d=1}^{D} \mathbf{d}_d * \mathbf{a}_d\|_2^2 \,\mathrm{s.t.}\, \mathbf{d}_d \in S_{2,1}\ (d = 1, \ldots, D). \tag{10}$$

[3]The proximity operator of a proper lower semicontinuous convex function f with a parameter $\alpha > 0$ is defined as $\mathrm{prox}_{\alpha f}(\mathbf{x}) := \mathrm{argmin}_{\mathbf{y}} f(\mathbf{y}) + \frac{1}{2\alpha}\|\mathbf{x} - \mathbf{y}\|_2^2$.

Algorithm 3 FISTA solver for the subproblem (10)

Input: $\mathbf{d}^{(0)}, \mathbf{f}^{(t)}, \mathbf{a}^{(t)}, \gamma$
Output: $\mathbf{d}^{(l)}$

1: Initialize $l = 0, \tau^{(0)} = 1, \mathbf{z}_1, \ldots, \mathbf{z}_D$;
2: **while** A stopping criterion is not satisfied **do**
3: $\quad \tau^{(l+1)} \leftarrow \frac{1+\sqrt{1+4\tau^{(l)}\tau^{(l)}}}{2}$;
4: $\quad$ **for** $d = 1, \ldots, D$ **do**
5: $\quad\quad \mathbf{d}_d' \leftarrow \mathbf{z}_d^{(l)} - \gamma \mathfrak{A}^*_{\mathbf{a}_d^{(t)}}(\sum_{d=1}^{D} \mathfrak{A}_{\mathbf{a}_d^{(t)}}(\mathbf{d}_d^{(l)}) - \mathbf{f}^{(t)})$;
6: $\quad\quad \mathbf{d}_d^{(l)} \leftarrow \mathrm{prox}_{\gamma \iota_{S_{2,1}}}(\mathbf{d}_d')$;
7: $\quad\quad \mathbf{z}_d^{(l+1)} \leftarrow \mathbf{d}_d^{(l+1)} + \left(\frac{\tau^{(l)}-1}{\tau^{(l+1)}}\right)(\mathbf{d}_d^{(l+1)} - \mathbf{d}_d^{(l)})$;
8: $\quad l \leftarrow l + 1$;

Using indicator function of $S_{2,1}$, we translate Prob. (10) into the following equivalent optimization problem:

$$\min_{\mathbf{d}} \frac{1}{2}\|\mathbf{f} - \sum_{d=1}^{D} \mathbf{d}_d * \mathfrak{A}_d\|_2^2 + \sum_{d=1}^{D} \iota_{S_{2,1}}(\mathbf{d}_d). \tag{11}$$

Prob. (11) is non-convex, but it can be approximately solved by FISTA [22].

We show the detailed algorithm in Algorithm 3. The stepsize parameter γ is set as $\gamma = \frac{1}{\sum_{d=1}^{D} \|\mathfrak{A}_{\mathbf{a}_d}\|_{\mathrm{op}}^2}$, where $\mathfrak{A}_{\mathbf{a}_d}(\mathbf{d}) = \mathbf{d} * \mathbf{a}_d$. The proximity operator of $\iota_{S_{2,1}}$ can be calculated as $\mathrm{prox}_{\gamma \iota_{S_{2,1}}}(\mathbf{x}) = \frac{\mathbf{x}}{\|\mathbf{x}\|_2}$ if $\mathbf{x} \neq \mathbf{0}$; $\frac{1}{n_d}\mathbf{1}$, otherwise [14], where n_d is the size of filters $\mathbf{d}_d$ and $\mathbf{1}$ is the all-one vector.

IV. Experiments and Discussion

A. Experimental Settings

To demonstrate the effectiveness of our CSR-based model, we compare it with existing foreground models: the sparsity-based model (SP) [5] and the total variation model (TV) [8]. To fairly compare the effectiveness of the foreground models, the same background model was used for all methods. Specifically, the static-scene constraint was used because it can exactly capture the static component [31]. We adjusted the parameters of the existing methods to achieve the best performances. All experiments were performed using MATLAB (R2022b) on a Windows 10 computer with an Intel core i9-10900K 3.7GHz processor, 32GB of RAM, and NVIDIA GeForce RTX 3090 GPU.

As the ground-truth IR and EM videos, we used Airplane video data (cropped into a size of $256 \times 256 \times 30$) from Science Data Bank [32] and T cell video data (cropped into a size of $100 \times 100 \times 30$) [33], respectively. The pixel values were normalized into $[0, 1]$. Contaminating these ground-truth videos by white Gaussian noise with 0.05 and 0.1 of the standard deviation σ and Salt & Pepper noise with 0 and 0.05 of the rate $p_{\mathbf{s}}$, we generated observed videos.

For Algorithm 1, we set the max iteration number to 300 and the stopping criterion to $\|\mathbf{b}^{(n+1)} - \mathbf{b}^{(n)}\|_2 / \|\mathbf{b}^{(n)}\|_2 \leq 10^{-5}$ and $\|\mathbf{f}^{(n+1)} - \mathbf{f}^{(n)}\|_2 / \|\mathbf{f}^{(n)}\|_2 \leq 10^{-5}$. Moreover, we set the maximum iterations of Algorithms 2 and 3 to 1000 and 10, respectively. The parameters $\eta_{\mathbf{s}}$ and ε in (3) were

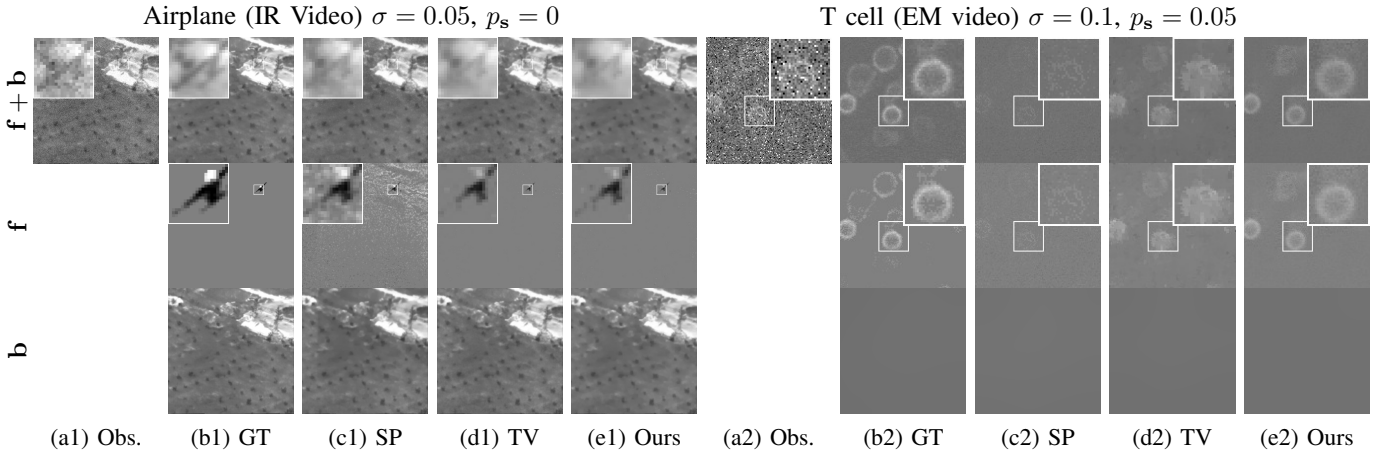

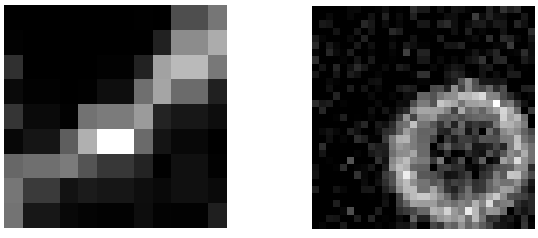

Fig. 2. FBS results. Left five columns are Airplane results ($\sigma = 0.05$ and $p_{\mathbf{s}} = 0$). Right five columns are T cell results ($\sigma = 0.1$ and $p_{\mathbf{s}} = 0.05$).

(a) Airplane (IR Video) (b) T cell (EM video)

Fig. 3. Some filters $\mathbf{d}$ obtained in the FBS process with our model. (a) shows airplane wing. (b) shows T cell.

set as $\eta_{\mathbf{s}} = 0.5 p_{\mathbf{s}} n_1 n_2 n_3$ and $\varepsilon = 0.9\sigma\sqrt{(1-p_{\mathbf{s}})n_1 n_2 n_3}$. The balancing parameter λ was manually adjusted to achieve the best performance. Specifically, we adopted $\lambda = 0.005$, $\lambda = 0.1$, $\lambda = 0.05$, and $\lambda = 0.1$ for Airplane ($p_{\mathbf{s}} = 0$), Airplane ($p_{\mathbf{s}} = 0.05$), T cell ($p_{\mathbf{s}} = 0$), and T cell ($p_{\mathbf{s}} = 0.05$), respectively. As the size of filters $\mathbf{d}_d$, 9×9 and 31×31 were used for Airplane and T cell, respectively. The parameter $\eta_{\mathbf{f}}$ determined from the size and intensity of foreground objects as $\eta_{\mathbf{f}} = 1080$ and $\eta_{\mathbf{f}} = 6615$ for Airplane and T cell, respectively. For the quality measures, we used the mean of the peak-signal-to-noise ratio (PSNR) [dB]: $\mathrm{PSNR}(\mathbf{q}, \bar{\mathbf{q}}) := 1/n_3 \sum_{k=1}^{n_3} 10\log_{10}(n_1 n_2 / \|\mathbf{q}_{n_3} - \bar{\mathbf{q}}_{n_3}\|_2^2)$, and the mean of structural similarity (SSIM) [34] for $\mathbf{f}+\mathbf{b}$, $\mathbf{f}$, and $\mathbf{b}$, where $\mathbf{q}_k$ is a kth frame of a video to be evaluated and $\bar{\mathbf{q}}_k$ is a reference frame to $\mathbf{q}_k$.

B. Experimental Results and Discussion

Table I shows PSNRs and SSIMs of FBS results, where the best values are highlighted in bold. Figure 2 depicts the FBS results of Airplane ($\sigma = 0.05$ and $p_{\mathbf{s}} = 0$) and T cell ($\sigma = 0.1$ and $p_{\mathbf{s}} = 0.05$). SP did not separate noise and foreground objects (see the middle row of Figs. 2 (c1) and (c2)), resulting in low PSNRs and SSIMs. TV resulted in higher PSNRs in some cases, but our method was better in

SSIMs for almost all cases. In particular, TV did not restore the spatial structure of airplane wing tips and cells (see Figs. 2 (d1) and (d2)). This is because the airplane and cells are not temporally continuous due to fast movement. In contrast, with our model, the foreground component was accurately separated (see Figs. 2 (e1) and (e2)). This is because our model characterizes the foreground component as the sum of convolutions between filters (Fig. 3) and sparse coefficients, and captures the cross-frame similarity structure.

V. Conclusion

We have proposed a novel FBS method incorporating CSR, which captures the cross-frame similar structure of the foreground component. By obtaining filters representing the shape of foreground objects, our method separates the foreground and background components from noisy video. Moreover, we have formulated the FBS as an optimization problem, and have developed an ALM algorithm for solving the problem. The experimental results have illustrated the superiority of our model to existing foreground models.

***Abstract*—A hyperspectral image (HSI) contains vast data, storing hundreds of spectral information with higher resolution than an RGB image. Therefore, considering practical aspects such as data transmission and storage, it is essential to explore the application of standard JPEG compression to an HSI. Conventional JPEG artifact removal methods, such as block and mosquito noise, recover a JPEG image by improving spatial smoothness under the quantization constraint of the DCT coefficients. However, these methods do not consider the application of JPEG compression to HSIs and the low rank of the spectral characteristics of HSIs. This paper proposes a novel optimization method for removing JPEG artifacts from an HSI. Specifically, we formulate a convex optimization problem by introducing a regularization term based on the nuclear norm to the conventional optimization problems. This regularization promotes low rankness in the spectral domain. To solve the proposed problem, we utilize the alternating direction method of multipliers (ADMM). Experiments demonstrate the effectiveness of the proposed method compared to several existing methods applied to both remote and non-remote sensing HSIs.**

***Index Terms*—Hyperspectral image, JPEG compression, total variation, low rank.**

I. Introduction

A hyperspectral image (HSI) is three-dimensional data from tens to hundreds of two-dimensional band images, each taken from visible to near-infrared light using a narrow-band spectral filter, and has much higher wavelength resolution than that of an RGB image [1]. Since different materials generally have different reflectance spectra. The analysis and classification of HSI pixels have applications in earth observation, environmental protection, and disaster monitoring. However, because an HSI often contains a large amount of data, it is expensive to store and transmit, and its applications are limited.

JPEG2000 has been widely adopted to achieve high compression efficiency and quality preservation of HSIs [2]–[7]. JPEG2000 uses pre-processing methods such as spectral direction and spatial direction filtering, which are suited to the characteristics of HSIs, to extract and encode information effectively during compression. However, JPEG2000 may have limited hardware and software compatibility. On the other hand, JPEG, the standard image compression technique, is widely used for its convenience and ability to compress images while maintaining visual quality through simple algorithms efficiently. Applying JPEG to HSIs needs to be considered to extend the range of applications in remote sensing and industrial fields such as visual inspection. However, at higher compression ratios on JPEG, artifacts such as block and mosquito noise may occur, leading to a degradation in image quality.

JPEG artifact removal methods based on optimization have been proposed in [8]–[12]. Bredies and Holler introduced a JPEG decompression model based on a convex optimization problem [8]. The optimization problem consists of the total variation (TV) regularization, which promotes image smoothness, and the block-wise DCT quantization constraint. They solved the problem using a primal-dual algorithm. However, the resulting images often have an undesirable staircasing effect, a well-known TV regularization problem. Ono and Yamada have used the total generalized variation (TGV) regularization instead of the TV regularization [9] to reduce these artifacts and considered the JPEG decompression model with super-resolution interpolation. TGV considers higher-order derivatives and can reduce the staircasing effect while preserving image gradation. However, when these methods are applied directly to each band of the HSI, they cannot sufficiently recover the JPEG artifact-free HSI. This limitation arises because they focus only on promoting smoothness in the spatial domain and do not consider the low rankness of the HSI in the spectral domain.

There have been several attempts to handle the JPEG artifact removal problem by deep convolutional neural networks (CNN) [13]–[15]. Learning-based approaches are fragile to degradation not found in a training data set. When recovering HSIs using CNN-based methods, it is difficult and impractical to construct training data sets and networks. For example, since exposure time, capturing spectral bands, and object details vary greatly depending on the scenes, it is necessary to construct a plurality of networks suitable for each scene and appropriately replace them according to an input scene.

In this paper, we propose a JPEG artifact removal method for HSIs based on spatial-spectral regularization. By incorporating a regularization term with the nuclear norm, which promotes the low rankness of HSIs in the spectral domain, we extend the conventional optimization problem consisting of the TV-based spatial regularization and block-wise DCT quantization constraint to HSIs. The proposed problem is solved using the alternating direction method of multipliers (ADMM). In the experiments, we show the effectiveness of the proposed method compared with several existing methods.

The paper is organized as follows. In Section II, we present

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

several mathematical preliminaries to introduce the proposed method. Section III introduces a proposed JPEG artifact removal method for HSIs. In Section IV, several examples are shown to verify the validity of the proposed method. Finally, we conclude this paper in Section V.

II. Preliminaries

A. Total Variation

TV is defined as the sum of gradient intensities of an image, which represents the characteristic of the local smoothness of natural images. The TV regularization can promote image smoothness while preserving edges and is often used for image recovery problems such as noise/blur removal and missing pixel recovery.

By letting $\mathbf{D}_v$ and $\mathbf{D}_h \in \mathbb{R}^{N\times N}$ be the vertical and horizontal first-order differential operators, respectively, with Neumann boundaries, the differential operator is expressed by $\mathbf{D} := [\mathbf{D}_v^\top \ \mathbf{D}_h^\top]^\top \ \left(\in \mathbb{R}^{2N\times N}\right)$ for a vectorized gray image with N pixels, and then TV [16], [17] is defined as

$$\begin{aligned}\|\mathbf{x}\|_{\mathrm{TV}} := \|\mathbf{D}\mathbf{x}\|_{1,2}^{(2N)} &= \sum_{i=1}^{N}\sqrt{\sum_{k=0}^{1}(\mathbf{D}\mathbf{x})_{i+kN}^2},\\ &= \sum_{i=1}^{N}\sqrt{(\mathbf{D}_v\mathbf{x})_i^2+(\mathbf{D}_h\mathbf{x})_i^2},\end{aligned} \tag{1}$$

where $\|\mathbf{x}\|_{1,2}^{(KN)} := \sum_{i=1}^{N}\sqrt{\sum_{i=1}^{K-1}x_{i+kN}^2}$ is the $\ell_{1,2}$-norm, and $(\mathbf{D}_v\mathbf{x})_i$, $(\mathbf{D}_h\mathbf{x})_i$ are the i-th element of $\mathbf{D}_v\mathbf{x}$, $\mathbf{D}_h\mathbf{x}$, respectively.

B. Total Generalized Variation

TGV is an extension of TV that considers higher-order derivatives. It is a regularization technique widely used in image processing and computer vision.

TGV [18] in the case of second-order is given by

$$\|\mathbf{x}\|_{\mathrm{TGV}}^{(\alpha)} := \min_{\mathbf{D}\mathbf{x}=\mathbf{p}+\mathbf{q}}\left\{\alpha\|\mathbf{p}\|_{1,2}^{(2N)}+(1-\alpha)\|\mathbf{G}\mathbf{q}\|_{1,2}^{(3N)}\right\}, \tag{2}$$

where $\alpha > 0$ is the weight that controls the balance between the first-order and second-order derivative the total variation costs, and

$$\mathbf{G} := \begin{bmatrix}-\mathbf{D}_v^\top & \mathbf{O}\\ -\mathbf{D}_h^\top & -\mathbf{D}_v^\top\\ \mathbf{O} & -\mathbf{D}_h^\top\end{bmatrix} \in \mathbb{R}^{3N\times 2N}.$$

Minimizing TGV regularization with image fidelity can promote local flatness while preserving gradation, resulting in staircasing effect-free smoothing.

C. Alternating direction method of multipliers

ADMM [19] is an algorithm for solving convex optimization problems expressed as follows

$$\min_{\mathbf{x},\mathbf{z}} f(\mathbf{x})+g(\mathbf{z}) \quad \text{s.t. } \mathbf{z}=\mathbf{L}\mathbf{x} \tag{3}$$

where f is a differentiable convex function, g is a non-differentiable convex function, and $\mathbf{L}$ is a linear operator. To find the solution of the unknown $\mathbf{x}$ and the auxiliary variables $\mathbf{z}$, the ADMM algorithm is given for any $\mathbf{x}^{(0)}$, $\mathbf{z}^{(0)}$ and $\rho > 0$ by

$$\begin{aligned}\mathbf{x}^{(k+1)} &= \arg\min_{\mathbf{x}}\left\{f\left(\mathbf{x}^{(k)}\right)+\tfrac{\rho}{2}\left\|\mathbf{z}^{(k)}-\mathbf{L}\mathbf{x}^{(k)}-\mathbf{d}^{(k)}\right\|_2^2\right\}\\ \mathbf{z}^{(k+1)} &= \arg\min_{\mathbf{z}}\left\{g\left(\mathbf{z}^{(k)}\right)+\tfrac{\rho}{2}\left\|\mathbf{z}^{(k)}-\mathbf{L}\mathbf{x}^{(k+1)}-\mathbf{d}^{(k)}\right\|_2^2\right\}\\ \mathbf{d}^{(k+1)} &= \mathbf{d}^{(k)}+\mathbf{L}\mathbf{x}^{(k+1)}-\mathbf{z}^{(k+1)}\end{aligned} \tag{4}$$

where ρ is a parameter to adjust the weight of the penalty term, k is the number of iterations of the algorithm, and $\mathbf{d}$ is a dual variable. The algorithm is guaranteed to converge to a globally optimal solution after a sufficient number of iterations, regardless of the initial values of the objective function.

III. Proposed Method

A. Problem formulation

Let $\mathbf{u}_m \in \mathbb{R}^N (m = 1,\ldots,B)$ be a vectorized m-th band of an unknown HSI before JPEG compression, where B is the number of the spectral bands. Also let $\mathbf{\Phi}$ and $\mathbf{\Psi} \in \mathbb{R}^{N\times N}$ be the forward and inverse blockwise discrete cosine transform (DCT), respectively. We assume that JPEG compression is applied to each band independently for $m = 1,\ldots,B$ as

$$\mathbf{v}_m = \mathbf{\Psi}\mathcal{Q}(\mathbf{\Phi}\mathbf{u}_m), \tag{5}$$

where $\mathbf{v}_m \in \mathbb{R}^N$ is the m-th band of a given HSI, and $\mathcal{Q}(\cdot)$ is a procedure that performs quantization and dequantization[1].

B. Arranged spectral nuclear norm

To promote the low rankness of an HSI in the spectral domain, we define the arranged spectral nuclear norm (ASNN) for the vectorized HSI $\mathbf{u} := [\mathbf{u}_1^\top,\ldots,\mathbf{u}_B^\top]^\top \in \mathbb{R}^{NB}$ by

$$\|\mathbf{u}\|_{\mathrm{ASNN}} := \|T(\mathbf{u})\|_* = \|[\mathbf{u}_1,\ldots,\mathbf{u}_B]\|_*, \tag{6}$$

where $T(\cdot)$ is the operator for converting a vector into a matrix form, and $\|\cdot\|_*$ is the nuclear norm defined by the sum of all the singular values of $(\cdot)$. ASNN computes the nuclear norm of the horizontally concatenated matrix of vectors for each band of the HSI. Minimizing ASNN regularization can promote the low rankness of the HSI.

C. Optimization problem

Our goal is to recover a JPEG artifact-free HSI from a given JPEG compressed HSI. Conventional optimization problems do not consider applying to multi-/hyper-spectral images. Therefore, we focus on the low-rank spectral features of HSIs and add ASNN regularization into the existing optimization problem to remove JPEG artifacts in the HSI.

The proposed optimization problem is defined by

$$\begin{aligned}&\min_{\mathbf{u}}\|\mathbf{u}\|_{\mathrm{ASNN}}+\lambda\sum_{m=1}^{B}\mathcal{S}(\mathbf{u}_m)\\ &\text{s.t. } \mathbf{u}_m \in C_{[0,r_{\max}]}, \mathbf{u}_m \in C_{\mathbf{v}_m}^{\mathbf{Q}} \ \ (m=1,2,\ldots,B),\end{aligned} \tag{7}$$

[1]We consider a similar JPEG acquisition model formulated in [9], but we do not consider a downsampling operator and a linear blur operator that must be considered in super-resolution interpolation.

TABLE I: Details of the input HSIs.

	Size	Band	Bit
Pavia	256 × 256	102	13
PaviaU	256 × 256	103	13
Salinas	512 × 216	224	14
Indian pines	144 × 144	220	14
Books	536 × 640	65	16

Red objects	536 × 640	65	16
Snacks	536 × 640	65	16

where $\mathcal{S}(\mathbf{u}_m)$ is a regularization function for the spatial smoothness of each band, and $\lambda > 0$ is a balancing weight that controls the smoothness and low rankness of the HSI. Our experiments considered TV and TGV for $\mathcal{S}$. The convex sets $C_{[0,r_{\max}]}$ and $C^{\mathbf{Q}}_{\mathbf{v}_m}$ are defined as

$$C_{[0,r_{\max}]} := \left\{\mathbf{x} \in \mathbb{R}^N \mid 0 \le x_n \le r_{\max}\ (n = 1, \ldots, N)\right\}, \tag{8}$$

$$C^{\mathbf{Q}}_{\mathbf{v}_m} := \left\{\mathbf{x} \in \mathbb{R}^M \mid \mathcal{R}\left(\boldsymbol{\Theta}^{(p)}_{\mathbf{x}}./\mathbf{Q}\right) = \mathcal{R}\left(\boldsymbol{\Theta}^{(p)}_{\mathbf{v}_m}./\mathbf{Q}\right) \left(p = 1, \ldots, M/8^2\right)\right\}. \tag{9}$$

The first constraint limits the pixel range of $\mathbf{u}_m$ in the $[0, r_{\max}]$, where $r_{\max}$ is set to $2^q - 1$ in the case of a q-bit HSI. The second constraint is the quantization constraint on block-wise DCT coefficients used in [8], [9][2]. This constraint makes the quantized DCT coefficients of the unknown image equal to those of the input JPEG image.

By solving (7), we obtain the JPEG artifact-free HSI. The proposed convex Optimization problem can be solved using the ADMM algorithm discussed in Section II-C.

IV. Experiments

To demonstrate the effectiveness of the proposed method, we applied it to remote and non-remote sensing HSIs. Table I shows the size, number of bands, and bits of HSIs. The first to fourth rows correspond to remote sensing examples, while the fifth to eighth rows correspond to non-remote sensing examples[3]. Quantitative evaluation was performed using PSNR and SSIM calculated from the original and recovered HSIs.

The results of our method were compared with those of conventional optimization methods, i.e., the TV- and TGV-based JPEG decompression methods[4]. We set TV and TGV to $\mathcal{S}(\mathbf{x})$ in the proposed optimization problem (7). We call the two approaches "Ours-TV" and "Ours-TGV". For the parameters of our methods, we found the visually best results by adjusting λ. Furthermore, the results of our method were presented in the case of $\lambda = 0$. We call this case "ASNN". That is, this method considers only the spectral low-rankness of the HSIs.

[2] $\Theta^{(p)}_{\mathbf{x}}, \Theta^{(p)}_{\mathbf{v}_m}$ denote the DCT coefficients of the p-th 8×8 block of unknown image $\mathbf{x}$ and input image $\mathbf{v}_m$, respectively. $\mathbf{Q}$ denotes the 8×8 quantization matrix used for quantization of DCT coefficients. $\mathcal{R}(\cdot)$ denotes the rounding process to integer values [9].

[3] We used the remote sensing images provided by https://www.ehu.eus/ccwintco. The non-remote sensing images were taken in our laboratory with HS cameras.

[4] These conventional methods are equivalent to removing ASNN and setting TV and TGV to $\mathcal{S}$, respectively, as $\mathcal{S}(\mathbf{x}) = \|\mathbf{x}\|_{\mathrm{TV}}$ or $\|\mathbf{x}\|_{\mathrm{TGV}}$.

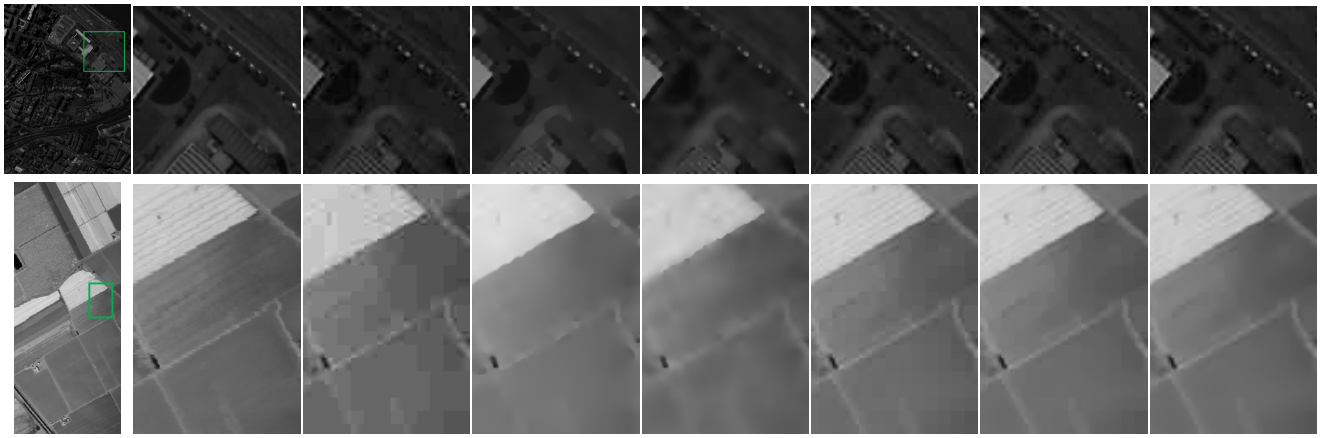
Snacks	0.9737	0.9768	0.9759	0.9810	**0.9824**	0.9821

Tables II and III show the average of PSNR and SSIM of all bands of the recovered HSIs obtained by the proposed and the conventional methods, respectively. One can observe from both tables that Ours-TV has the highest values compared with the conventional methods.

Figures 1 and 2 show the original and input HSIs, and the results of JPEG artifact removal. One can see from Figures 1 and 2 that the proposed methods outperform the conventional methods. The results of the TV- and the TGV-based methods can be removed the block noise. However, details of the HSIs are over smoothed; complex textures are lost, especially in Figures 1(d) and (e). Although ASNN can reduce JPEG artifacts without spatial regularization from Figures 1 and 2(f), adding TV and TGV as regularization in addition to ASNN can reduce block noise more effectively (see Figures 1 and 2(g) and (h)).

V. Conclusion

We proposed the JPEG artifact removal method for HSIs. The proposed optimization problem was defined by spatial-spectral regularization with pixel range constraint and block-wise DCT quantization constraints. The proposed problem can be solved by the ADMM. Experiments confirmed that the proposed methods with TV and TGV outperformed existing TV- and TGV-based JPEG artifact removal methods for several remote and non-remote sensing HSIs.



In future work, we will extend the proposed method to recover the artifacts of JPEG2000 compression, commonly used for HSI compression.

***Abstract*—In this paper, we propose a data-driven multiband image fusion approach called FusionUNet aimed at preserving image features that are specific to the wavelengths of the source images. Specifically, we extract low-level wavelength-specific image features from the source images and use them to guide the training process of the U-Net structure designed to combine source images of various wavelengths. We conducted extensive experiments on public datasets, and the results demonstrate that our algorithm outperforms the state-of-the-art approaches in both qualitative and quantitative aspects.**

***Index Terms*—Image fusion, convolution neural network, infrared image, visible image.**

I. Introduction

Image fusion refers to the task of combining images captured by multiple sensors, which typically measure different wavelength ranges. Compared to an image obtained by a single sensor, a sensor-fused image can reveal more salient details about objects represented in the scene using different wavelengths. For example, longwave infrared (LWIR) sensors capture the thermal radiation emitted from objects directly, which is useful for detecting humans and animals. However, LWIR sensors, such as microbolometers, often have low resolution, and LWIR images lack textural details.

In contrast, semiconductor-based detectors like CCD and CMOS imagers sense reflected visible wavelength (VIS) light from objects. These imagers are a mature technology that allows for densely packed pixels, resulting in high-resolution images with well-controlled pixel uniformity. However, visible wavelength imagery is susceptible to environmental factors such as sunlight, illumination intensity, and smoke/haze, which can negatively impact target detection and tracking by both human observers and computer vision algorithms.

An effective image fusion technique combines the complementary advantages of the source images collected at different wavelengths. For instance, LWIR-VIS image fusion should be robust to environmental factors, enhance the visibility of humans and animals, and preserve high-resolution details. In this paper, we propose a novel framework for a data-driven image fusion neural network called FusionUNet aimed at maintaining the visual cues of wavelength-specific features of VIS and LWIR images. Leveraging a neural network pretrained for general-purpose object recognition classifier (such as VGG16 [1]) as a proxy to a human observer, we posit that a *fusion of the low-level feature maps* extracted from source LWIR and VIS images represent the salient spatial or geometric structures that we want the fused LWIR-VIS image to represent. Under this conjecture, low-level feature maps extracted from a successfully fused LWIR-VIS image will match the low-level wavelength-specific features extracted from source LWIR and VIS images.

II. Background and Related Work

A. Image Fusion Metrics

Denote by $\{I_1, \ldots, I_K\}$ the K source images (possibly from different sensors and wavelength ranges), and $I_F = \mathrm{ImageFusion}\{I_1, \ldots, I_K\}$ represent the output from the image fusion tasks. The loss function is the key part of deep learning-based and non-learning-based image fusion algorithms alike, determining how to retain the source image information in the output fused image.

Two categories of loss/metrics have been used today. First, *statistical attributes* are used to measure the amount of information/context present in the fused images. For instance, entropy is employed to quantify the level of randomness [2], while standard deviation measures the degree of spread in the fused image [3], [4].

The second type of image fusion metric is designed to compare the fused image with each of the source images. For instance, metrics such as mean squared error (MSE), structural similarity index measure (SSIM) [5], and mutual information (MI) [3] are computed between the source image I_k and the fused image I_F to assess the similarity of pixel intensity patterns. Consider the sum of loss metrics (such as mean squared error, mutual information, structural similarity index) comparing the fused image to each of the source images:

$$L = Loss(I_F, I_1) + Loss(I_F, I_2) + \cdots + Loss(I_F, I_K). \tag{1}$$

The sum of losses is sensitive to the degradation of source image details present in the fused image. Considering the fact that sensitivity to target objects varies with the measured wavelengths, it is important to note that the behavior becomes unpredictable when the source images are dissimilar to each other. In other words, there is no fused image I_F that can simultaneously optimize the losses

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

$Loss(I_F, I_1), \ldots, Loss(I_F, I_K)$ in order to optimize the overall loss score L.

B. Image Fusion Approaches

Traditional methods for fusing multiple source images include multiscale transforms [6], [7], sparse dictionaries [8], saliency map-based techniques [9], and others [10].

Multiscale approaches involve decomposing source images into base and detail components, fusing each component separately using rule-based heuristics, and then combining these representations to produce a fused image [11]. Sparse representation methods employ a sliding window strategy to decompose an input image into overlapping patches, using an over-complete dictionary to achieve sparse representation coefficients. These coefficients are fused to reconstruct the final image. Some representations leverage overcompleteness and sparsity to enhance robustness against misregistration and noise [12]. In saliency map-based methods, rule-based heuristics for combining representations are manually crafted, often relying on the principles of saliency maps to highlight important objects for the human visual system or on the sparsity of real-world scene representations [9]. One challenge in designing rule-based fusion methods is addressing the imbalance between source images. For instance, the lack of detail in the visible source image can diminish the distinctive features of warm-body objects present in the LWIR source image [13].

Drawing on the recent advancements in machine learning, image fusion techniques in recent years have benefited from data-driven deep learning-based approaches [14], [15]. GAN-based approaches utilize an adversarial game between the fused image and the source images to retain the characteristic features of different sensors/wavelength modalities [16]–[18]. Autoencoder-based and regression-based methods, on the other hand, learn a mapping to extract salient features and then reconstruct the fused image by minimizing loss functions [19]–[22].

The lack of a "ground truth" fused image makes it challenging to learn the weights and biases of neural networks in a supervised manner. As an alternative, the method proposed in [20] adopts a semi/unsupervised approach by utilizing a pre-trained VGG19 model to extract deep features, which are then used to determine the fusion weights. Similarly, in the field of remote sensing, the method described in [23] employs a U-Net to extract and combine the spectral features from hyperspectral images and spatial representation from multispectral images to yield a sharp/high-resolution hyperspectral images.

III. Proposed Method

A. New Loss Function

The loss function plays a critical role in deep learning-based image fusion algorithms as it determines the information preserved in the fused image. Because there exists no notion of ground truth in image fusion, we characterize some desirable attributes of the fused images below.

We would like objects-of-interests detected from various wavelength source images to also be present in the combined fusion image $I_F = \mathrm{ImageFusion}(I_1, \ldots, I_K)$. However, we do not want to rely on the state-of-the-art data-driven object detection algorithms, such as the *supervised* machine learning methods that rely on a very large dataset with substantial "labeling costs." These labels are object-specific, and they do not generalize across applications.

In this paper, we develop a novel loss function aimed at preserving wavelength-specific features. Let $F_k = \mathrm{Feature}(I_k)$ denote shallow level VGG16 features extracted from kth source image I_k. We introduce a notion of "feature fusion" as follows:

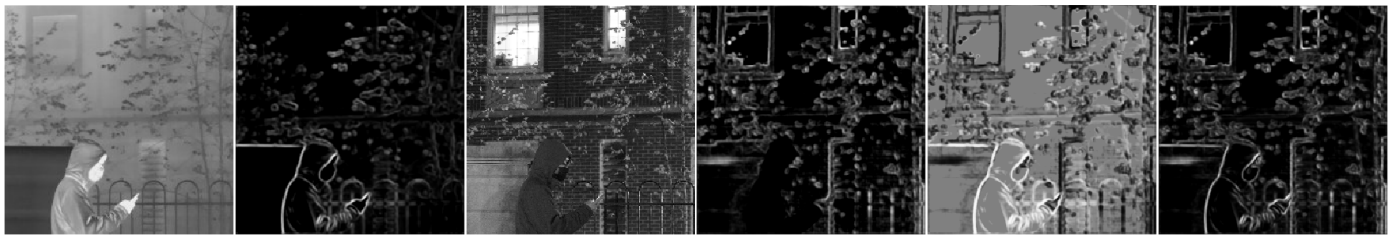
$$\begin{aligned}\mathrm{FeatureFusion}\{I_1, \ldots, I_K\} &= \mathrm{softmax}\{F_1, \ldots, F_k\} \\ &= \frac{\sum_{k=1}^{K} F_k e^{\frac{F_k}{\alpha}}}{\sum_{k=1}^{K} e^{\frac{F_k}{\alpha}}},\end{aligned} \tag{2}$$

where the *softness parameter* α controls the degree to which the small positive-valued feature is preserved. The idea behind $\mathrm{FeatureFusion}\{\cdot\}$ is that if F_k represents features extracted immediately after ReLU layer, then the feature magnitude represents the significance of those feature map coefficients (since small values would have had a high risk of being thresholded by ReLU operator). Since typical feature maps are sparse, the softmax is approximately the union of the wavelength-specific features of the source images. In the case that the supports of feature maps overlap, (2) prioritizes the larger feature values likely indicating visually significant intensity patterns present in each of the images $\{I_1, \ldots, I_K\}$.

An example of the feature fusion is shown in Fig. 1. As evidenced in Fig. 1(e), the merged feature $\mathrm{FeatureFusion}(F_1, F_2)$ successfully represents salient details represented in both LWIR (I_1) and VIS (I_2) source images. For implementation, we used VGG16 in its $M = 5$th layer, which has the size $224 \times 224 \times 64$ and follows the convolutional layer, ReLU layer, convolutional layer, and ReLU layer.

Thus $\mathrm{FeatureFusion}\{I_1, \ldots, I_K\}$ represents the wavelength-specific attributes of the image we would like the fused image $I_F = \mathrm{ImageFusion}\{I_1, \ldots, I_K\}$ to inherit. For this reason, we define the "feature loss" function of fused image I_F as follows:

$$Loss(I_F)\{I_1, \ldots, I_K\} = \|F_F - \mathrm{FeatureFusion}\{I_1, \ldots, I_K\}\|^2, \tag{3}$$



where F_F are the feature map vectors extracted from fused image I_F. For instance, if image fusion is a parametric function:

$$I_F = \mathrm{ImageFusion}_\theta(I_1, \ldots, I_K), \tag{4}$$

then we perform the following optimization task

$$\begin{aligned}\min_\theta \| &\,\mathrm{Feature}(\mathrm{ImageFusion}_\theta(I_1, \ldots, I_K)) \\ &- \mathrm{FeatureFusion}\{I_1, \ldots, I_K\}\|^2.\end{aligned} \tag{5}$$

When this loss function is minimized successfully, we assume that the fused image (4) preserved the wavelength-specific

(a) LWIR Image (b) LWIR Feature (c) VIS Image (d) VIS Feature (e) Softmax Weight (f) Fused Feature

Fig. 1: Infrared- and visible-specific feature maps merged by softmax function. (b)×(e) + (d)×(1-(e)) = (f).

attributes of the source images $\{I_1, \ldots, I_K\}$. It is important to emphasize that the feature extraction layers used in $\mathrm{Feature}(\cdot)$ and fusion feature map $\mathrm{FeatureFusion}(\cdot)$ is fixed feature extraction layers, and only parameter θ of the image fusion technique $\mathrm{ImageFusion}_\theta(\cdot)$ is optimized.

B. Network Architecture and Training Details

For the implementation of $\mathrm{ImageFusion}_\theta(\cdot)$ in (5), we leverage a regression architecture called U-Net, which is a variation on an auto-encoder network where the skip connections retain fine-level localized details while the deeper layers with contracting paths process coarse-level details [24]. U-Net can be trained with limited data and achieve excellent performance, and it has been proven useful in image segmentation[25], denoising [26] as well as in image fusion [14].

The exact configuration of the proposed FusionUNet is shown in Fig. 3, designed to combine two source images in LWIR and VIS. The input is LWIR and VIS source images that are first standardized and then concatenated. The network consists of an encoder (left side) responsible for feature extraction and a decoder (right side) that performs reconstruction. The encoder uses the classic architecture of a convolutional network—repeated two 3×3 convolutions (padding option = same, padding value =0) followed by ReLU. Each downsampling layer is a convolutional layer (Stride = 2×2) rather than the max pooling. We performed five levels of downsampling steps to ensure that the network extracts deep features, and the number of feature channels at each average pool operation was doubled. In the decoder, use the same repeated two 3×3 convolutions followed by ReLU, and the transposed convolutions for upsampling step and reduce half feature channels. The skip connection feature channels were concatenated from the corresponding U-Net encoder level. The final layer is 1×1 convolution, which outputs the final fused image whose size is the same as the input image. The output of FusionUNet is the fused image I_F.

The training process consists of two stages. In the first stage, we pre-train the U-Net to generate the average of the LWIR and VIS source images. This pre-training stage follows a standard U-Net-based regression approach (learning rate=10-5, epoch=30). In the second training stage, we refine the FusionUNet by treating the fused image I_F as the input of pre-trained VGG16 (i.e. fixed) as shown by Fig. 2. We extract the fifth layer of the pre-trained VGG16 network to compute feature loss in (5), which is backpropagated through the U-Net to update the network coefficients (learning rate=10-6 and epoch=15). We empirically found that the pre-training makes the overall process more stable and converges faster. The second training stage improves the image fusion quality by highlighting salient thermal targets and enhancing fine textures.

IV. Experimental Results

A. Experiment Configuration

We evaluated the efficacy of the proposed FusionUNet using the standard metrics described in Section II-A, including entropy, standard deviation, structural similarity index, and mutual information [27]. In addition, we report the feature fusion loss metric in (3) at the fifth layer of VGG16, as proposed in Section III-A. Even though it was designed for training FusionUNet, it is an excellent metric for assessing the low-level edges, shapes, and textures at test time. We standardize the input to VGG16 by subtracting out the ensemble pixel mean of the image.

For benchmarking purposes, the proposed FusionUNet was compared to seven state-of-the-art image fusion methods: IFE-VIP [10], MST_SR [28], TIF [29], VSMWLS [30], LatLRR [20], MDLatLRR [13], and FusionGAN [18]. All the experiments are conducted on a Windows computer with Intel(R) Core(TM) i7-10700 CPU at 2.9 GHz, 64 GB memory, and NVIDIA GeForce GTX 1660Ti.

B. Quantitative Evaluation

The performance metrics of the proposed FusionUNet are reported in Table I. Although no one state-of-the-art image fusion algorithm dominates over the rest, the proposed FusionUNet is the only method to consistently rank within the top three in all metrics (feature loss, entropy, standard deviation, SSIM, and mutual information). We attribute this gain to the fact that the feature loss promotes high fidelity by ensuring consistency between the fused image and the source images, which in turn encourages better SSIM and mutual information scores. Furthermore, the softmax operation in feature fusion leads to a higher degree of information and context in the fused images, as it discards smaller feature map coefficients, resulting in improved entropy and standard deviation scores. Unsurprisingly, FusionUNet yielded the best score for VGG16 feature loss, as it is optimized for this metric.

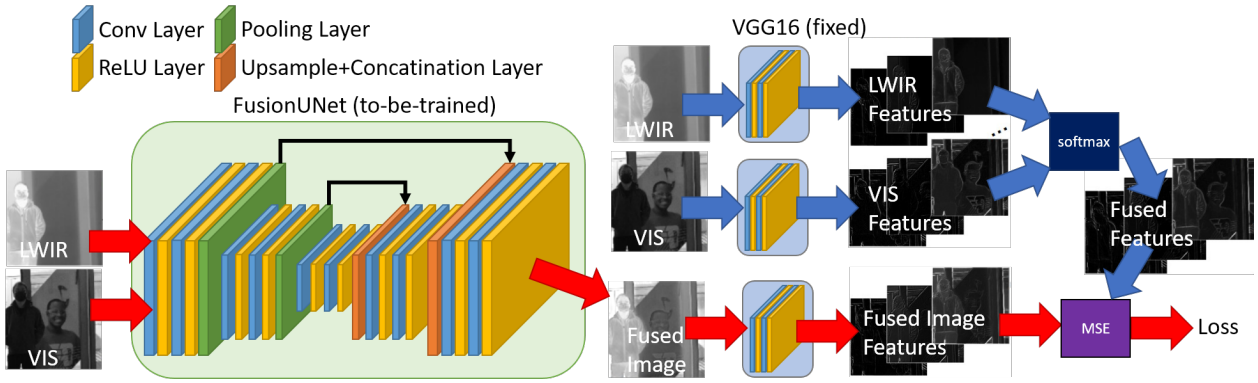


Fig. 2: The architecture of training of proposed method

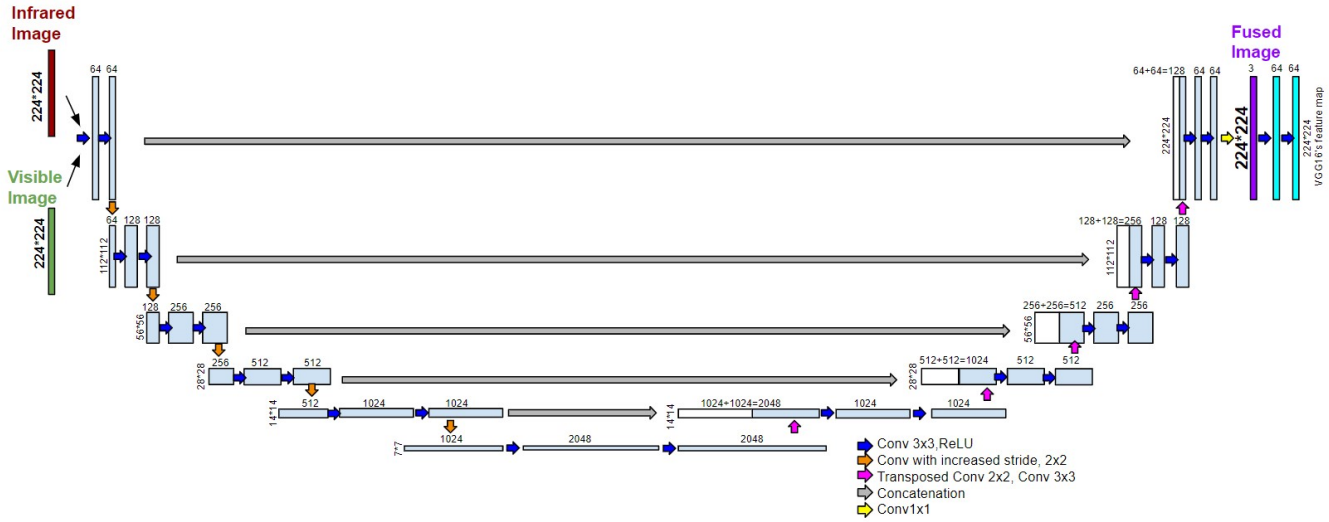

Fig. 3: The architecture of FusionUNet

C. Qualitative Evaluation

Fig. 4 provides visual comparisons of FusionUNet with various state-of-the-art LWIR-VIS fusion methods. For this qualitative evaluation, we selected four scenes from TNO dataset. In the first column of Fig. 4, it can be observed that MST_SR and MDLatLRR methods weaken the thermal salient target. Additionally, FusionGAN's result makes it difficult to identify the VIS environmental details. However, VSMWLS and FusionUNet effectively preserve both LWIR and VIS important objects in this scene. Moving to the second column, it can be seen that IFEVIP and LatLRR methods change the brightness during the fusion process. In contrast, FusionUNet maintains the source information properly and produces a fused image with sharp thermal targets and richer background information. In the third column, MST_SR, VSMWLS, and the proposed FusionUNet interestingly superimpose facial details captured in the VIS source image onto the thermally enhanced LWIR face. Lastly, in the final column examples, FusionUNet outperforms all other state-of-the-art methods in preserving environmental details such as branches and buildings, while still clearly displaying the thermal targets. Additionally, FusionUNet exhibits the least amount of ghosting/halo effect near high contrast LWIR-VIS edges overall.

In terms of appearance, the proposed FusionUNet was most similar to IFEVIP [10]. IFEVIP extracts infrared features through a process involving background subtraction via quadtree decomposition and interpolation, which is then combined with visible information. However, IFEVIP is tailored to low-light conditions, leading to extracting excessive infrared background, degrading the contour information in the fused image. This is evidenced in the second column of Fig. 4, where details of a street lamp are compromised, for example. By contrast, the proposed FusionUNet retains high fidelity on critical spatial/shape details present in both LWIR and VIS images.

V. Conclusion

In this paper, we propose a powerful image fusion algorithm designed to preserve the wavelength-specific features of the source images. Specifically, we apply softmax to approximate the combination of shallow-layer pre-trained VGG16 feature

Fig. 4: Qualitative results of the image fusion on TNO dataset

TABLE I
AVERAGE QUANTITATIVE EVALUATION ON 13 IMAGE PAIRS FROM TNO DATASET

Method	Feature Loss(10^4)	Entropy	Standard Deviation	Structural Similarity Index	Mutual Information
IFEVIP [10]	3.13	6.62	38.78	0.4966	2.20
MST_SR [28]	3.90	6.63	30.20	0.4840	1.07
TIF [29]	4.05	6.73	29.52	0.4804	1.06
VSMWLS [30]	3.45	6.85	34.32	0.5100	1.27
LatLRR [20]	4.30	6.71	42.19	0.4215	1.14
MDLatLRR [13]	4.53	6.29	24.22	0.5120	1.25
FusionGAN [18]	4.99	6.43	26.85	0.3262	1.46
FusionUNet (Ours)	2.92	6.91	41.39	0.5174	1.59

maps extracted from the source images. We then learn the mapping from the source images to a fused image that preserves the fused features using U-Net. Our experimental results demonstrate that our algorithm successfully fuses visible wavelength and longwave infrared images, resulting in a fused image that is sensitive to humans/animals, robust to environmental factors, and preserves high-resolution image features. In comparison to other state-of-the-art algorithms, our fusion results yield higher contrast images with finer spatial details.

The proposed FusionUNet is able to preserve wavelength-specific image features of the source images by extracting and combining feature maps extracted from general-purpose object recognition classifiers. Because of this, FusionUNet has the potential to improve the object detection performance in computer vision applications by ensuring that the targets visible in LWIR and VIS images are detected in the fused image also. The reference code is available for download at `issl.udayton.edu`.

Shot-Noise-Aware Image Signal Restoration for Photoelectronic Charge-Based Sensors

Seishi Takamura
Hosei University, Japan
E-mail: s.takamura@hosei.ac.jp Tel: +81-42-387-4534

***Abstract* — It is widely presumed that digital image sensors can't obtain the brightness of too-bright image information that yields a saturated digital value, e.g., 1023 for 10-bit sensors and 4095 for 12-bit sensors, without the help of brightness reduction such as shortening the shutter duration, applying the optical filter. However, suppose it is allowed to capture the still object multiple times. In that case, we have previously shown that the inevitable existence of optical shot noise enables us to estimate a brightness value greater than seemingly-saturated brightness. That study was purely theoretical, i.e., it was conjectured by computer simulation, not with actual camera-captured data. In this paper, we formulate a precise photoelectronic charge-based sensing model, and based on that, we try to verify the above theoretical conjecture with actual camera-captured data. The experimental results successfully prove that restoring a brightness value greater than the digital count limit is possible.**

I. Introduction

The performance of image sensors has been increasing in recent years due to technological innovations. In CMOS image sensors, the reduction of dark current noise and readout noise, two of the three major noise factors in image sensors, has been affirmatively resolved [1], leaving only optical shot noise as the remaining noise factor. In general, noise harms image/video coding, image processing, video analysis, scene recognition, etc. However, the existence of optical shot noise is not always a nuisance. In [2], we have demonstrated that the presence of noise can reduce the quantization (digitalization) noise more, after averaging multiple observations, than the noiseless situation. We also have numerically shown that precise modeling of optical shot noise allows us to raise the upper limit of digital value (e.g., 255 for 8-bit sensors, 1023 for 10-bit sensors). The mathematical model used to formulate image sensing was effective but relatively simple; e.g., it was assumed that a certain integer number (no fractional number) of photoelectrons increase the digital count by one with no offset). And the study was purely theoretical. Therefore, simulation-based results were demonstrated. In [3], the variance and mean values of digital signals are measured with a real camera, and their relation is formulated considering dark current noise, readout noise, and optical shot noise. However, no connection with the number of photoelectrons nor A/D converter (ADC) properties was considered. In [4], a naïve model between the variance and average values of digital signals for a real camera is reported. However, the empirical result does not fit well in very dark and bright pixels.

This paper will formulate a more precise photoelectronic charge-based image sensing model than the former work [2-4]. Then, we experiment using an actual camera to capture the natural scene and verify the above theoretical conjecture.

II. Photoelectronic Charge-Based Sensing Model and Optical Shot Noise

Fig. 1 shows the typical image sensor model based on photon-to-electron conversion and charging. The photons pour down to the sensor of one pixel. The sensor (photodiode) absorbs the photons and emits electrons (photoelectrons). The ratio of incoming photons and outgoing electrons is called quantum efficiency. The photoelectrons (let the number be X_e) are stored in a well and read out by the ADC to yield an observed digital count (X_d) every frame period. Suppose we

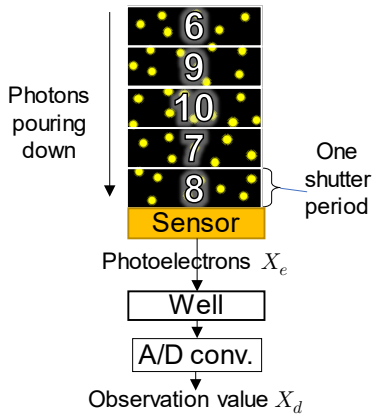

Fig. 1 Photoelectronic charge-based image sensing.

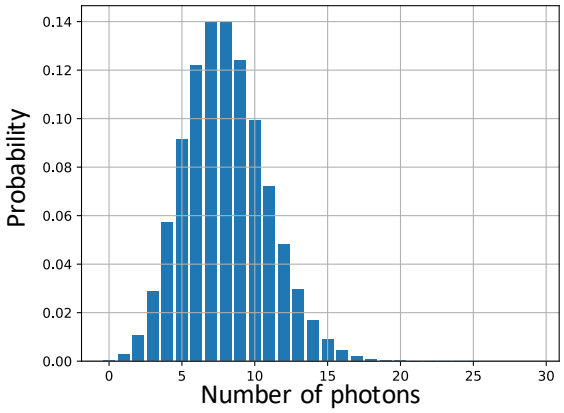

Fig. 2 Poisson distribution with mean 8.

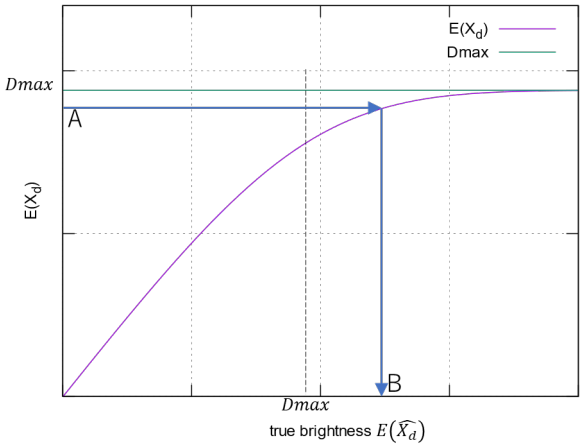

Fig. 3 True brightness vs. $E(X_d)$ and estimating process of true brightness (B) from averaged digital count (A).

have an utterly stationary light source whose average number of photons per frame is eight (8), measuring the photons flying from the source. Since photons come independently of each other, the number of photons per frame varies 8, 7, 10, 9, or 6, depending on the shooting time. This variation, called "optical shot noise, " is an unavoidable and dominant noise in digital cameras and strictly follows the Poisson distribution. Fig. 2 shows the probability mass function of the Poisson distribution with a mean of 8. Sometimes the number is zero, and sometimes the number is 20, 30, or even more. Because the number of photons obeys the Poisson distribution, the number of photoelectrons also obeys the Poisson distribution. One of the essential properties of Poisson distribution is that its mean and variance are the same. Therefore, the brighter the object is, the more noise it contains. Equation (1) shows the formulation of Poisson distribution, where X is a stochastic variable following Poisson distribution of the mean (and the variance) λ.

$$Po(\lambda, X = x) = \frac{e^{-\lambda}\lambda^{x}}{x!} \tag{1}$$

III. Precise Sensing Model

A. ADC Model and Parameter Formulation

In our preliminary experiment, it was observed that the digital count from the camera and the variance of the digital count have a linear relationship with bias. This section will formulate a precise digital count and photoelectron count model for the ADC inside the image sensor. In the following, we will assume ADC gain to be fixed to 0 dB (i.e., no gain), no tone curve, no gamma correction, and no automatic gain control.

Let an integer X_e denote the stochastic variable for the number of photoelectrons in a well to be converted to the digital count by the ADC, and let an integer X_d denote the stochastic variable associated to the digital count. The ADC property can be formulated as

$$X_d = Digital\left(\frac{X_e - b}{a}\right), \tag{2}$$

where

$$Digital(x) = \min(\lfloor x + 0.5 \rfloor, Dmax)$$

is the rounding and clipping function, a represents the average number of photoelectrons that increases the digital count by one, b represents the offset of the ADC, $Dmax$ is the maximum value of digital output. From (2),

$$E(X_d) = \frac{E(X_e) - b}{a} \tag{3}$$

$$V(X_d) = \frac{V(X_e)}{a^2} + \frac{1}{12} \tag{4}$$

are derived, where $E(\cdot)$ and $V(\cdot)$ represent the mean and variance of the given stochastic variable, respectively. Here we ignored clipping effect of $Digital(\cdot)$, but took its rounding effect into account (i.e., adding a variance of 1/12). We also know that

$$E(X_e) = V(X_e) \tag{5}$$

because X_e follows the Poisson distribution. So, we have

$$a^2\left(V(X_d) - \frac{1}{12}\right) = aE(X_d) + b \tag{6}$$

and thus, it is derived that

$$V(X_d) = \frac{E(X_d)}{a} + \frac{b}{a^2} + \frac{1}{12}. \quad (7)$$

We will confirm those relations in Section IV.

B. Estimation of True Brightness from Digital Observations

Let us consider capturing a bright object whose digital count is as high as $Dmax$. Suppose we have a real number $\lambda > 0$ and $X_e \sim Po(\lambda)$. According to (2), X_d is capped by $Dmax$.

Table I Properties of IMX547 Image Sensor [5]

Resolution	2448x2048
Pixel Size (μm)	2.74
ADC Bit Depth	12
Quantum Efficiency Mono (% at 525 nm)	67.99
Temporal Dark Noise (Read Noise) (e-)	2.49
Temporal Dark Noise (Read Noise) (DN)	16.18
Signal to Noise Ratio Maximum (dB)	39.89
Signal to Noise Ratio Maximum (Bits)	6.63
Absolute Sensitivity Threshold (γ)	4.4
Absolute Sensitivity Threshold (e-)	2.99
Saturation Capacity (Well Depth) (e-)	9748
Saturation Capacity (Well Depth) (γ)	14337
Dynamic Range (dB)	70.26
Dynamic Range (Bits)	11.67
Gain (e-/ADU)	0.15

Fig. 4 Camera and object setup. The red box roughly corresponds to the captured image (Fig. 5).

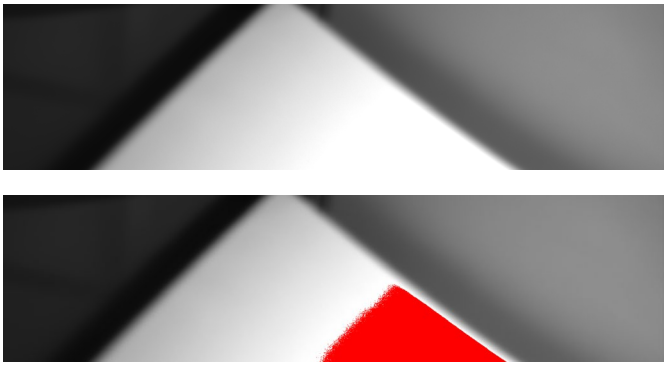

Fig. 5 Top: Captured image (averaged across frames, i.e. $EXd_{x,y}$). Bottom: same as top, constantly saturated pixels (i.e., $\forall f : P^f_{x,y} = Dmax$) are marked with red.

However, we can imagine $\widehat{X_d}$ beyond $Dmax$ based on the number of electrons fed into the well, i.e.,

$$\widehat{X_d} = \frac{X_e - b}{a}. \quad (8)$$

And its mean is

$$E\left(\widehat{X_d}\right) = \frac{\lambda - b}{a}, \quad (9)$$

which can be considered as "true brightness".

By ranging λ, $E(X_d)$ and $E(\widehat{X_d})$ can be numerically calculated based on (1) and (9). When a stationary light source is observed enough number of times, we can estimate $E(X_d)$ by averaging observed digital count. Fig. 3 shows the example of the relation between $E\left(\widehat{X_d}\right)$ and $E(X_d)$. Once the relation of those two is obtained, we can estimate the true brightness (B in the Figure) from averaged digital count (A in the Figure). Sometimes B can exceed $Dmax$. This is our proposal how to estimate true brightness from digital observations.

IV. Experimental Results

A. Camera Setup

We have conducted the experiment using real image and real sensor to validate the discussions in previous section. The camera is monochrome LUCID TRIO51S-MC whose image sensor is SONY IMX547. Some of its specifications are shown in Table I.

The experimental setup is shown in Fig. 4. We captured a static scene (Fig. 5) containing a saturated pixels (marked with red) and is used for the experiment hereafter. The focus is intentionally blurred to prevent pixel value fluctuation due to slight camera movements caused by subtle ambient vibration.

In total, 10000 frames, a frame size of 2048x512, and 12-bit pixel data were captured. According to the experiment, $Dmax$ of this camera turned out to be 4094, not 4095 (i.e., $2^{12} - 1$).

Fig. 6 shows a horizontal cross-section of the bottom line of Fig. 5, which has saturation. Fig. 7 shows the cross-section of the gray-scaled version of Fig.4, which has no saturation. Those two graphs are taken from roughly the same area to see the signal trend of the area of saturated pixels.

B. Measurement of ADC Properties

Let $P^f_{x,y}$ be the pixel value at position (x, y) of frame order f. We obtain temporal mean $EXd_{x,y}$ and temporal variance $VXd_{x,y}$ for each position (x, y). Then we obtain the level-wise average variance VXd_i for each digital level i $(i = 0,1,\ldots, Dmax)$. The formula are as follows:

$$EXd_{x,y} = Digital(mean_f\ P^f_{x,y})$$

$$VXd_{x,y} = variance_f\ P^f_{x,y}$$
$$VXd_i = mean_{x,y}(VXd_{x,y} | EXd_{x,y} = i)$$

$E(X_d)$ and $V(X_d)$ can be approximated by i and VXd_i respectively. Fig. 8 shows the linear relation of those based on actual data (i.e., Fig. 5), which coincides nicely with (7). The variance rapidly drops in very bright range (digital count > 3960). This is because most of the observation adheres to $Dmax$.

Dark range: For dark range (digital count < 250), the fitting result based on (7) was $a = 2.36398 \pm 0.003345$ and $b = 2.79738 \pm 0.6682$. Remembering that a represents the average number of photoelectrons that increases the digital count by one, $Dmax \times a = 9678.13 \pm 13.69$ is comparable with the saturation capacity (well depth), which is 9748 (cf. Table I). It is consistent with the fact that the ADC usually has less saturation capacity than well depth.

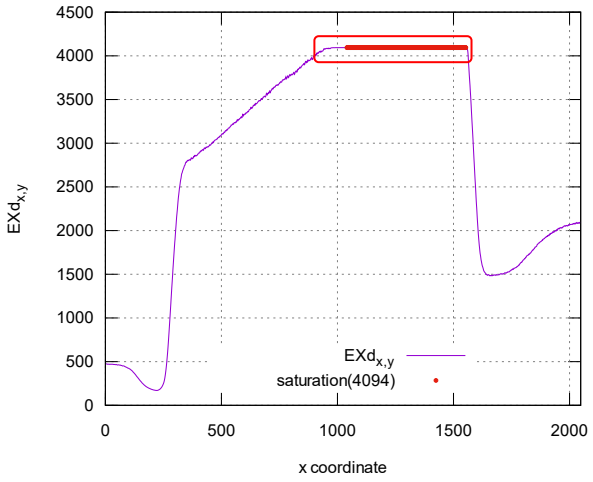

Fig. 6 Horizontal cross-section of the bottom line of Fig. 5. Red points represent saturation (i.e., all values across frames are $Dmax$). Signals in the red box area will be restored later (see. Fig. 9).

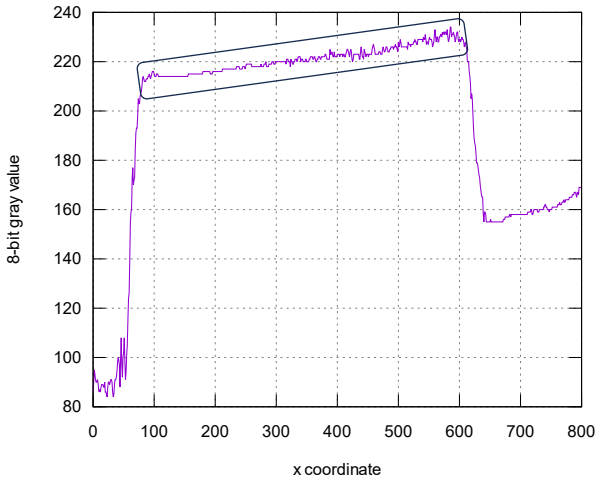

Fig. 7 Cross-section of the gray-scaled version of Fig.4, which does not precisely match the cross-section in Fig. 6; the resolution is also different. However, please note that the plateau (marked with a black box) is monotonically increasing.

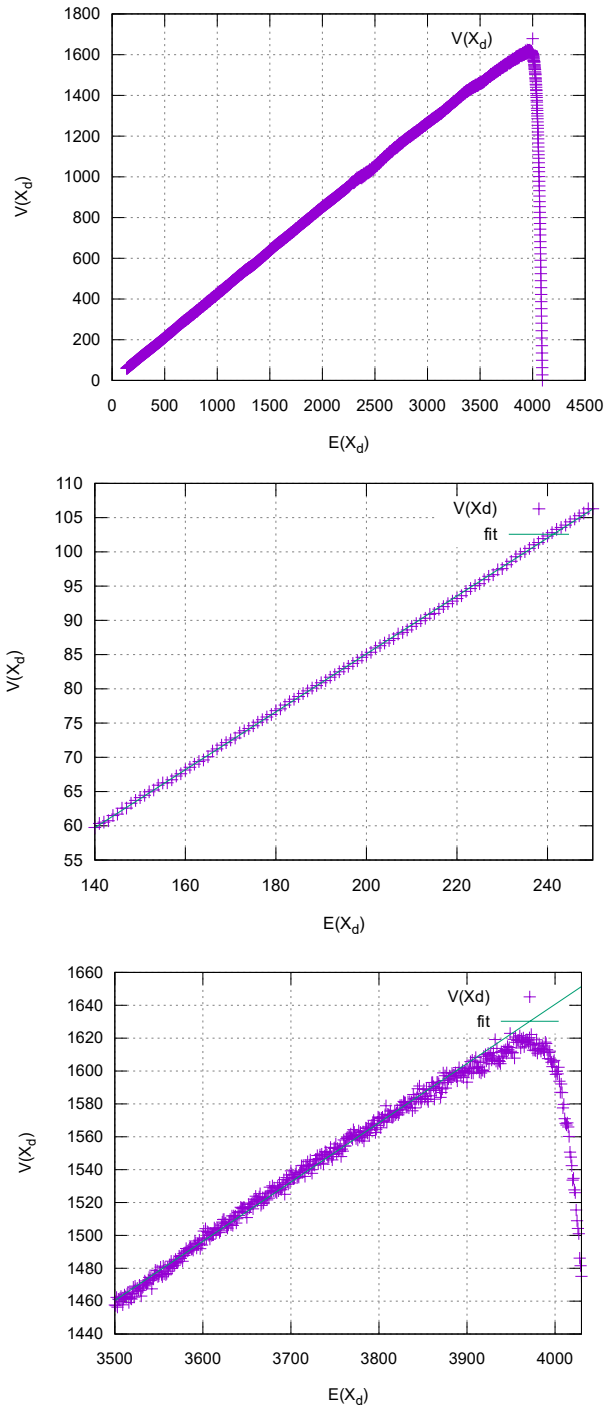

Fig. 8 Observed digital value vs. its variance. Top: whole range. Middle: dark range. Bottom: bright range.

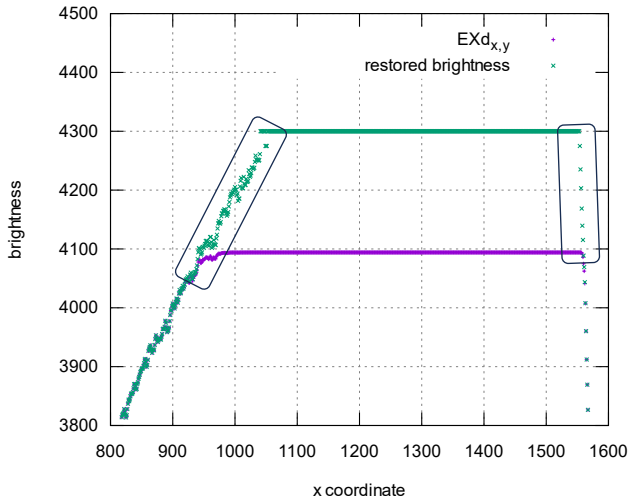

Fig. 9 Result of restoration of bright pixels (corresponding to the red box area of Fig. 6). Pixel values in black boxes are successfully restored.

Bright range: In our experiment, the bright pixels (digital count > 3500) do not precisely follow the dark pixels' ADC parameters. We suspect that the image sensor we used automatically applies some gain/offset control at the bright range. So, we fit another parameter and obtained $a = 2.77502 \pm 0.01015$ and $b = 1533.58 \pm 48.75$. The reason for the plot be more noisy than dark range's plot (Fig. 8 middle) is due to the nature of the Poisson distribution (larger mean leads larger noise variance).

C. *Restoration of True Brightness of Bright Pixels*

Based on the ADC parameters (a, b) obtained from bright range, we created a relation curve of true brightness vs. $E(X_d)$ (cf. Fig. 3) and conducted the estimation of true brightness from the data in Fig. 6 using the technique described in III.B. The maximum restoration value is chosen to be 4300. The result is shown in Fig. 9. It is clearly observed that quite a few bright pixels are successfully restored to have values greater than $Dmax$. Please note that the increasing trend seen at $800 < x < 950$ is also seen at $950 < x < 1050$ (in left black box). The same applies to the decreasing trend at $1550 < x < 1580$ (in right black box). The pixels at $1050 < x < 1550$ are *saturated*, i.e., all observed values across 10000 frames are constantly equal to $Dmax$, so there is no clue to estimate true brightness. However, if we increase the number of observations to more than 10000, we have more chance to recover more pixels.

D. *Discussion*

In our specific experiment, true brightness restoration was conducted at a flat region. However, true values of bright pixels at arbitrarily-textured region can be restored in the same manner. It should be noted that the true values of the pixels of middle brightness can practically be obtained with simple averaging along frames. Also, our proposed restoration method can coexist with high dynamic range (HDR) image acquisition because our method can expand the upper limit of each exposure of HDR image acquisition. This would be one of the applications of our technique.

V. Conclusion

In this paper, we scrutinized the temporal brightness fluctuations that light always has, and formulated precise ADC parameters which can be estimated from multiple digital camera observations. Based on those parameters, we also revealed the possibility of sensing beyond the upper limit of digital value range. The restriction of our method is, that the scene should be completely stationary – i.e., if the object moves or the illumination changes (such as fluorescent lamps) during image acquisition, our method fails.

Our future work focuses on the investigation of the restoration of dark pixel's value and to examine an analytical formulation of the relation between $E\left(\widehat{X_d}\right)$ and $E(X_d)$, which is currently empirically provided.

***Abstract*— Video frame interpolation plays an important role in video applications. This paper presents a new deep learning-based frame interpolation model under the generative adversarial networks (GANs) framework. The devised generator cascades three multi-scale sub-modules to capture coarse-to-fine visual characteristics. Furthermore, the generator is trained with an adequate loss function consisting of two adversarial and four reconstruction losses. Additional to the conventional discriminator that derives the spatial discrepancy, a new discriminator is employed to strengthen the temporal consistency among adjacent frames. The proposed method not only inherits the merit of GANs in processing speed but also produces high-quality video frames. Experimental results show that the proposed method achieves the most favorable image quality in PSNR and SSIM with a considerably short runtime compared to other state-of-the-art frame interpolation approaches.**

I. INTRODUCTION

Video frame interpolation is a technique that synthesizes intermediate frames from existing frames. Video frame interpolation finds many applications, including video creation, frame rate-up conversion, and video coding. Since the boom of deep learning, deep learning-based frame interpolation has caught much attention. Most frame interpolation networks are pixel-wise, and the most well-known approaches include kernel-based or optical flow-based ones. The kernel-based methods [1-3] derive texture effectively by aggregating neighbor pixels to estimate spatial kernels. Due to kernel size limitations, these approaches usually fail on large motions. The optical flow-based methods [4-7] derive texture effectively by aggregating neighbor pixels to estimate spatial kernels. Due to kernel size limitations, these approaches usually fail on large motions.

The Generative adversarial network (GAN) [8] is a deep learning data generation framework that iteratively trains adversarial networks, which are generators and discriminators. The generator synthesizes new data, deluding the discriminator, while the discriminator aims to recognize the corrected data. Based on that tactic, GAN has been applied in many images and video applications, including inpainting, random image generation, text-to-image translation, and video frame interpolation. Further improvement that conditions the data generation [9] with auxiliary data was proposed. Instead of only using latent vectors [10], labels, maps, and optical flow can be used as input. In video frame interpolation, GAN research also considers using attention maps, occlusion maps, and linear data as auxiliary inputs.

Considering quality and complexity, we introduce a GAN-based framework for frame interpolation comprising a generator and two discriminators (Fig. 1) without additional input requirements. The generator applies a three-scale architecture to capture multi-perspective features for deriving a frame from two adjacent ones. The discriminators consider

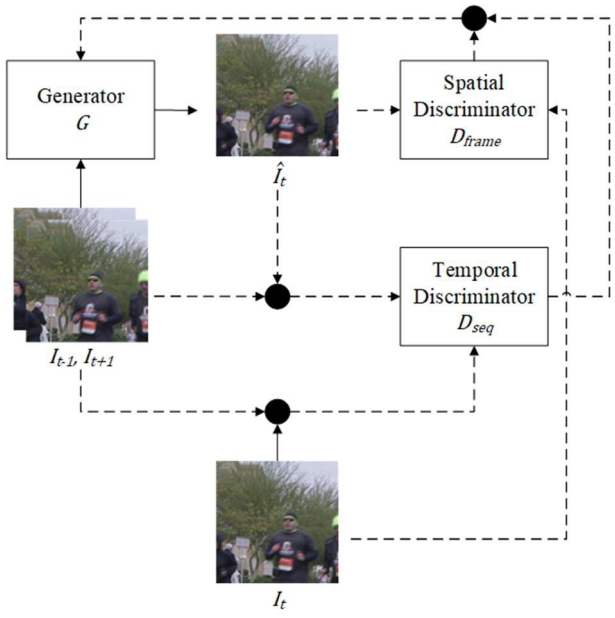

Fig. 1 The overall architecture of the proposed framework, in which two discriminators, D_{frame} and D_{seq}, facilitate a multi-scale generator G spatially and temporally. The solid and dashed arrows depict the flows of generation and discrimination, respectively.

spatial and temporal perspectives corresponding to frame-based and sequence-based models.

The main contributions of this study are summarized below:

- We design and implement a GAN-based frame interpolation framework, considering spatial correctness and temporal consistency.
- We introduce a training loss function for the generator consisting of adversarial and reconstruction loss ones to measure the reality and correctness of the output.
- We indicate each incorporated element's contribution with ablation studies and show the performance with a comparison with state-of-the-art solutions.

II. Related Works

Most recent deep learning frame interpolation solutions fall into the kernel- and optical flow-based categories. Niklaus *et al*. [1] introduced a kernel-based neural network for synthesizing intermediate frames via adaptive separable kernel estimation. Niklaus and Liu [13] manipulated optical flows and interpolation kernels with their proposed SoftSplat with forward warping operations. Besides, Liu *et al*. [4] used optical flows to copy pixels from adjacent frames for interpolation. Jiang *et al*. [5] introduced an end-to-end multi-frame interpolation network utilizing convolutional neural networks (CNNs) for jointly estimating bi-directional optical flow and occlusion mask. They also addressed the motion artifacts with visibility maps predicted by a U-Net [11]-based network.

Recently, several methods for frame interpolation have incorporated supplementary information, such as optical flows, depth maps, and occlusion maps, for high frame generation performance. Park *et al.* [7] proposed a frame interpolation network jointly estimating bilateral motion with bilateral cost volume to facilitate the optical flow estimation and dynamic filter generation network. Bao *et al.* [12] proposed an adaptive warping layer to enhance frame interpolation by integrating optical flows and interpolation kernels for motion estimation and motion compensation-driven design. From a similar point of view, Bao *et al.* [6] further used depth maps to reduce occluded objects' affection with their depth-aware projection layer. Kong *et al.* [14] introduced a pyramid frame interpolation network that refines the bilateral intermediate flow fields and features iteratively. The authors further trained IFRNet with a task-oriented optical flow distillation loss for higher performance and a geometry consistency regularization loss for enhancing structure layout. Huang *et al.* [15] introduced a frame interpolation network that utilizes intermediate optical flows with a coarse-to-fine strategy and leverages knowledge distillation from the teacher flow network.

GANs with an adversarial training strategy enable a different direction for high-quality and robust frame interpolation. GAN-based frame interpolation frameworks condition the generation to derive intermedia data by taking adjacent frames and other auxiliary data as input. Amersfoort *et al.* [16] considered a pyramid architecture to design a GAN-based frame interpolation framework. Wen *et al.* [17] proposed a multi-frame interpolation framework by concatenating two pairs of generator and discriminator aided with linear input data. Xiao and Bi [18] introduced a GANs frame interpolation framework utilizing multi-scale architecture and residual connections. Their design utilizes four pairs of generator-discriminator and incorporates attention map-based frame synthesis to enable the model to focus more on relevant regions of features based on its own estimated attention map. Tran and Yang [19] proposed a framework incorporating a two-scale generator and a discriminator to synthesize an intermediate frame from the adjacent ones.

Inspired by the previous works, the proposed method utilizes a generator for multi-perspective features and two discriminators for distinguishing spatially and temporally.

III. Proposed Methods

In this research, the proposed method aims to synthesize an intermediate frame from two given ones, as below equation:

$$\hat{I}_t = G(I_{t-1}, I_{t+1}) \tag{1}$$

Here, the target data belong to the $C \times H \times W$ vector space, in which C, H, and W represent the picture's channel, height, and width.

In the rest of this section, we describe the proposed GAN-based frame interpolation framework (Fig. 1) and explain the design for balancing generation and discrimination. We also provide a detailed description of the training loss function comprising adversarial and reconstruction loss terms.

A. Frame Interpolation Framework

Following conditional GAN-based design, the proposed method utilizes a multi-scale generator for frame interpolation and two discriminators for adversarial training. Here, the generator takes the feedback from both the discriminators, in which one considers the spatial correctness and another also pays attention to temporal consistency.

Multi-scale Generator. To explicit the multi-scale features from input and synthesize output from coarse to fine, the generator (Fig. 2) incorporates two different sub-modules deriving frames at different resolutions, as below equations:

$$\hat{I}_t^2 = G_2(I_{t-1}^2, I_{t+1}^2), \tag{2}$$

$$\hat{I}_t^1 = G_1\left(I_{t-1}^1, S(\hat{I}_t^2), I_{t+1}^1\right), \tag{3}$$

$$\hat{I}_t^0 = G_0\left(I_{t-1}^0, S(\hat{I}_t^1), I_{t+1}^0\right), \tag{4}$$

where I_t^i and $\hat{I}_t^i$ (i = 0, 1, 2) represent the existing frame and generated frame at time step t at the i^{th} level, respectively, and

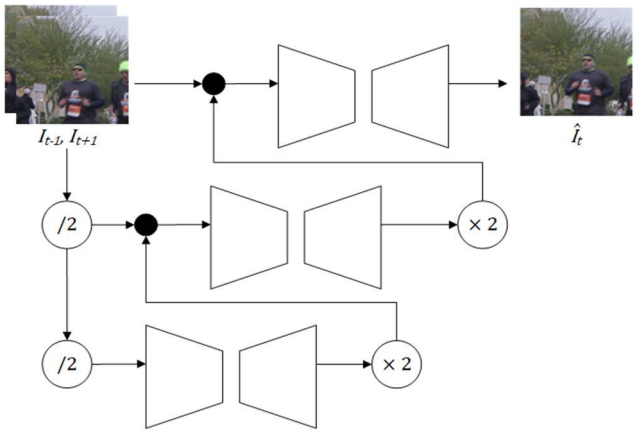

Fig. 2 The general architecture of the proposed generator.

S depicts the up-scale operation. There, the coarsest one captures the overall structure layout, and the finer one completes with more details. The finest frame $\hat{I}_t^0$ benefits from the previous inter-output $\hat{I}_t^1$ and $\hat{I}_t^2$.

All generator sub-modules share a similar backbone design following encoder-decoder architecture. Specifically, the encoder extracts features from input with a sequence of convolutional layers, batch normalizations, and Parametric Rectified Linear Unit (PreLU) [20] activation functions. Here, we use PReLU at the encoder side to reduce feature loss in the extraction process with convolution operations. Thus, the models become more robust in the deep learning environment. Furthermore, the generator is incorporated with skip connections for training efficiency enhancement and recovering spatial information by explicitly copying features between layers. Accordingly, the decoder synthesizes the output with transposed convolutional layers, batch normalizations, Dropout layers, and Rectified Linear Unit (ReLU) activation functions.

Spatial- and Temporal-Discriminators. A generated frame should contain corrected and consistent content with the adjacent ones. Therefore, we utilize two discriminators for classifying the output spatially and temporally. The first network evaluates frames individually (5), while the second considers a patch of three consecutive frames for temporal consistency (6). In this way, discrimination produces better feedback for the generation and facilitates the generation. Besides, this design improves the discrimination efficiency that helps balance the capacity and performance between generated and discriminated operations for more efficient training.

$$d_{spatial} = D_{spatial}(\hat{I}_t^0) \quad (5)$$

$$d_{temporal} = D_{temporal}(I_{t-1}^0, \hat{I}_t^0, I_{t+1}^0) \quad (6)$$

The two spatial and temporal discriminators share a similar backbone architecture (Fig. 3) that sequences convolutional layers, Batch normalizations, PReLU activation functions, and a sigmoid activation function.

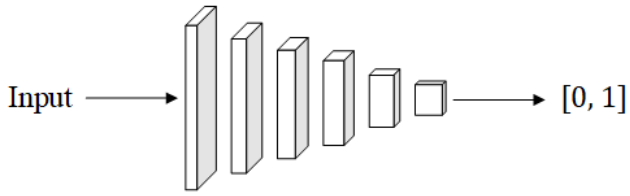

Fig. 3 The general architecture of the proposed discriminators.

B. Training Loss Function

Following the GAN-based design [8], we apply the minimax approach for training the proposed framework. As the below equation, the generator tries to minimize the classification accuracy, the term $(1 - D(x))$, with the generated data. Meanwhile, the discriminator attempts to maximize it.

$$\min_G \max_D E_{x \sim p_{data}(x)}[\log D(x)] + E_{x \sim p_g(x)}[\log(1 - D(x))] \quad (7)$$

We train the two discriminators by measuring classification accuracy with the Binary Cross Entropy (BCE) loss function. This function is also applied for measuring the video frame degradation as the adversarial loss term besides the reconstruction one, as (8), where λ_{adv} and λ_{rec} depict the non-negative weights. In practice, we apply 0.00005 for λ_{adv} and 1.0 for λ_{rec}.

$$\mathcal{L} = \lambda_{adv} \times \mathcal{L}_{adv} + \lambda_{rec} \times \mathcal{L}_{rec} \quad (8)$$

The adversarial loss term $\mathcal{L}_{adv}$ measures the feedback from the spatial and temporal discriminators, as (9), and allows the generator considers them for learning.

$$\mathcal{L}_{adv} = \mathcal{L}_{spatial} + \mathcal{L}_{temporal} \quad (9)$$

For reconstruction loss function, we refer to FI-DUSGAN [19], incorporating $\mathcal{L}_2$, multi-scale structural similarity (MS-SSIM) loss [21] $\mathcal{L}_{MS\text{-}SSIM}$, and gradient difference loss [22] $\mathcal{L}_{GDL}$ for pixel-wised generation correctness, low motion blur, and high friendliness in human vision. In this work, we add $\mathcal{L}_{census}$ to enhance the generation learning for balancing the performance between the generator and discriminators. This function measures the soft Hamming distance between ternary census transformed images with a patch size of 7×7 [23] to facilitate the generation with a more reliable constancy assumption based on the additive and multiplicative illumination changes compensation of the census transform. The proposed function is described below.

$$\mathcal{L}_{rec} = \mathcal{L}_2 + \mathcal{L}_{census} + \mathcal{L}_{MS-SSIM} + \mathcal{L}_{GDL} \quad (10)$$

IV. EXPERIMENTS

In this section, we first describe the experimental setup, including the dataset and parameters for training and implementation. Then, we evaluate the generation performance by an ablation study and a comparison with the state-of-the-art in terms of peak signal-to-noise ratio (PSNR) for pixel-by-pixel comparison and SSIM for perception-based similarity.

A. Experimental Setup

In this experiment, we train the proposed framework with the temporal frame interpolation subset of the Vimeo-90k dataset [24]. The dataset consists of several 480×256-frame patches containing three consecutive frames. Besides, we further pre-process the training dataset with random cropping and flipping operations. The target training dataset includes 51,313 128×128-frame-patches, and the testing dataset has 3,782 480×256-frame-ones.

We use PyTorch to develop the models and manipulate the training with the Adam optimizers with the recommendation parameters for implementation. Besides, we set the training batch size as 32 and the initial learning rate as 0.001 while decaying it after every 20 training epochs until reaching 10^{-7}.

We perform the experiment on the NVIDIA Tesla V100 GPU environment.

B. Ablation Study

In this ablation study, we compare various versions of the proposed framework to demonstrate the contributions of each component. As in Table I, the proposed design (5) produces the highest quality with 37.20dB in PSNR and 0.940 in SSIM. This version confirms the contribution of the modifications and the efficiency in balancing between generation and discrimination.

Table I. Ablation study on architecture and training loss function, in which the best version is highlighted in bold.

Version	Description	Loss	PSNR	SSIM
(1)	3-scale generator only	$\mathcal{L}_2$-based	36.85	0.940
(2)	2-scale-generator and seq-discriminator	$\mathcal{L}_2$-based	36.73	0.941
(3)	3-scale-generator and seq-discriminator	$\mathcal{L}_1$-based	35.75	0.928
(4)	3-scale-generator and seq-discriminator	$\mathcal{L}_2$-based	36.39	0.939
(5) Proposed	**3-scale-generator and 2 discriminators**	**$\mathcal{L}_2$-based**	**37.20**	**0.940**

Table II. Ablation study on weights of the training loss function, in which the proposed version is highlighted in bold.

Version	λ_{adv}	λ_{rec}	PSNR	SSIM
(1)	0.0001	0.5	36.84	0.938
(2)	**0.00005**	**1.0**	**37.20**	**0.940**
(3)	0.0	1.0	36.85	0.940

According to Table I, a good design GAN-based framework having efficient adversarial training will allow us to simplify the network, such as the two-scale and the three-scale one of (2) and (1), respectively. Versions (3) and (4) produce lower performance due to the imbalance between generation and discrimination. Here, the generator is more complex, and the discriminator does not have enough capability to keep the training effective. Therefore, the incorporated frame-based discriminator helps balance the generation and discrimination, enabling the proposed framework to achieve higher performance. From a different point of view, we consider replacing $\mathcal{L}_2$ with $\mathcal{L}_1$ for training the generator. However, the low-quality output of (3) shows that the mean square error-based loss function is more compatible with the proposed architecture and training loss function. In our observation, incorporating one more discriminator into (2) causes the vanishing gradients problem, and the generator fails to learn. The training problem confirms the suitability of our model designs with the applied training loss function. Besides, our study on weights of the training loss function (Table II) shows the effectiveness of the selected ones for the proposed function.

C. Comparison to the state-of-the-arts

In this section, we perform a comparison between DVF [4], SepConv [1], FI-MSAGAN [18], BMBC [7], FI-DUSGAN [19], and the proposed framework. For comparison, we retrain the compared models using a re-implemented version of FI-MSAGAN [25] and official implementations of others. Here, the proposed generator achieves the best PSNR and second-best SSIM values (Table III) with the Vimeo-90k dataset within a short runtime (9.1 ms). Overall, GAN-based methods can

Table III. Comparison between the frame interpolation methods, in which the best and second-best values are highlighted in bold and underlined, respectively.

Methods	PSNR (dB)	SSIM	Runtime (ms)
DVF	31.92	0.658	51
SepConv	35.97	0.913	115
FI-MSAGAN	35.99	0.893	26
BMBC	36.74	**0.948**	686
FI-DUSGAN	<u>37.02</u>	<u>0.940</u>	9
The proposed	**37.20**	<u>0.940</u>	9.1

(a) PSRN: 37.93dB; SSIM: 0.966

(b) PSRN: 38.40dB; SSIM: 0.952

Fig. 4 The generated output of the proposed framework.

Fig. 5 The generated output of the proposed framework (PSRN: 34.78dB; SSIM: 0.962).

achieve high-quality output with lower complexity owing to the efficient adversarial training. In our comparison, the proposed framework outperforms FI-DUSGAN by 0.18dB in PSNR and FI-MSAGAN by 1.21dB in PSNR and 0.47 in SSIM.

As shown in Fig. 4, the proposed framework synthesizes interpolated frames well in various scenarios, including frames with high contrast details with low to medium changes. On the other hand, it still fails to handle some challenging scenarios, particularly those with fast and sudden motions between frames, such as the moving cars in Fig. 5.

V. CONCLUSION

We introduced a frame interpolation framework utilizing three adversarial networks, including a three-scale generator and two discriminators. The devised generator captures coarse-to-fine visual characteristics by three-scale sub-modules with an adequate combination of loss functions. Besides a discriminator considering the quality of generated data, a temporal one is employed to guarantee consistency among adjacent frames. Thus, the proposed framework effectively balances the adversarial relationship to ensure optimal performance. Our ablation study confirmed the contribution of each designed element. The proposed design improves the PSNR by 0.35 dB without increasing complexity compared to the generator-only version. The proposed framework can derive high-quality frames in various scenarios, and it outperforms other GAN-based solutions, such as FI-MSAGAN (+3.4%) and FI-DUSGAN (+0.5%), with a similar complexity requirement. In future work, we will consider tackling more challenging scenarios, such as videos with sudden motions.

***Abstract*—High Dynamic Range (HDR) content creation has become an important topic for modern media and entertainment sectors, gaming and Augmented/Virtual Reality industries. Many methods have been proposed to recreate the HDR counterparts of input Low Dynamic Range (LDR) images/videos given a single exposure or multi-exposure LDRs. The state-of-the-art methods focus primarily on the preservation of the reconstruction's structural similarity and the pixel-wise accuracy. However, these conventional approaches do not emphasize preserving the artistic intent of the images in terms of human visual perception, which is an essential element in media, entertainment and gaming. In this paper, we attempt to study and fill this gap. We propose an architecture called *ArtHDR-Net* based on a Convolutional Neural Network that uses multi-exposed LDR features as input. Experimental results show that *ArtHDR-Net* can achieve state-of-the-art performance in terms of the HDR-VDP-2 score (i.e., mean opinion score index) while reaching competitive performance in terms of PSNR and SSIM.**

I. Introduction

The High Dynamic Range (HDR) imaging is introduced to handle the scenario where the visual content has a high ratio between the brightest and the darkest pixels [1]. HDR allows the inclusion of multiple dynamic exposures in a single visual content. Hence, if an image is in HDR, it has a wide gamut of brightness levels, i.e., there is a significant variation in light levels within a scene with high details. In other words, the well-lid and dark regions in a scene are captured with equal clarity using HDR technology. The main goal of HDR imaging is to capture the real world lighting, greater luminance distribution, brightness, detailed shadows, and radiance in a manner which is as realistic as possible and can mimic the Human Visual System and its level of perception. HDR technology has many applications, e.g., in the fields of media and entertainment [1], Augmented/Virtual Reality (AR/VR) [2], [3], gaming and visualization [2], [4], and computational photography [5]. With the increase in HDR supported hardware devices such as HDR displays, AR/VR sets, mobile screens, and cameras, researchers have tried to find ways and methods to successfully retrieve the HDR counterparts from the conventional Low Dynamic Range (LDR) content, known as inverse tone mapping.

HDR content can be created using special hardware (e.g., expensive cameras and visual sensors) and/or software (e.g., virtual environments and renderers). However, converting the existing LDR content to HDR requires unique methods and algorithms [6], [7] to expand the color gamut and dynamic range, which is usually achieved through inverse tone mapping and image enhancement. In this paper, we attempt to take an LDR image as input and create an HDR image with perceptually realistic and visually accurate information in terms of the Human Visual System represented by the HDR-VDP-2 scores (see section IV-B). This work contrasts most state-of-the-art methods that attempt to solve the problem of structural similarity of the generated HDR with respect to the LDR input. The main contributions of this work are threefold:

- We propose a CNN-based network (Section III) for HDR image content creation drawing inspiration from the method in [8]. We leverage the features from three different exposure values (EV -2, 0, and +2) and create a combined feature map for a better representation of under/over-exposed areas in the LDRs.
- We perform a thorough experimental validation with quantitative and qualitative comparisons (Sections IV and V) to establish the efficacy of our contributions.
- We present a detailed ablation study (Section VI) on the different losses used to train the network and the skip connections of the CNN layers utilized for better representation of the low-level features.

II. Related Work

Researchers have employed various Machine Learning (ML) and Deep Learning (DL) methods [7] for HDR content creation. Below, we categorize the recent relevant literature into two major buckets, i.e., image- and video-based. These buckets can be further categorized based on single and multiple exposure LDR inputs.

A. Image-based Methods

Khan et al. [8] proposed a feedback-based Convolutional Neural Network (CNN) to create an HDR image from a single exposure LDR input image. Their method uses a dense feedback mechanism based on Recurrent Neural Network (RNN) on top of a conventional CNN to obtain both low-level and high-level features. This coarse-to-fine feature

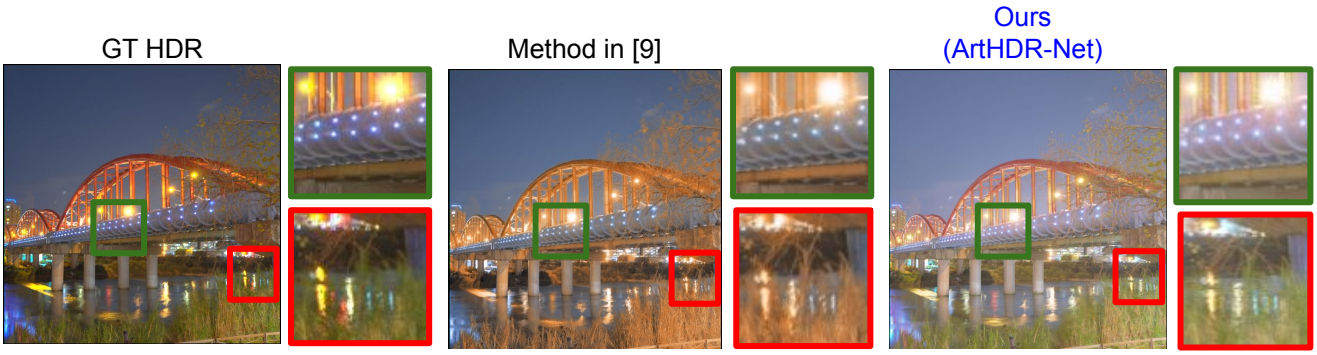

Fig. 1: Output produced by our method ArtHDR-Net compared to one of the closest state-of-the-art [9] methods in terms of HDR-VDP-2 score [10], [11]. Our method reconstructs the HDR content with better naturalness in terms of color contrast and luminance levels.

representation in various iterations leads to HDR creation at a higher quality. Phuoc-Hieu Le et al. [12] proposed a Neural Network (NN) architecture to learn and generate multiple exposures from a single image. The model can reconstruct pixel radiance and details of hallucination in different exposures by inverting the camera response. Yu-Lun Liu et al. [9] proposed a CNN architecture that learns the reverse process of camera pipeline, i.e., inverse tone mapping. The method employs three CNNs to reverse the three basic steps in camera pipeline, i.e., clipping of dynamic range, camera response function (CRF) based non-linear mapping, and quantization. Then the three sub-tasks are jointly fine-tuned to reduce the accumulated errors. Yet another interesting work [13] (although not in the DL domain) talks about an inverse tone mapping operator, which can preserve the artistic intent of the content creator in the generated HDR images i.e., the images look more realistic perceptually. Jinghui Li et al. [14] presented a novel multi-scale CNN with an attention mechanism that tackles the problems of color quantization and the loss of information in over/under-exposed regions. The method re-scales channel-wise features using a channel attention method adaptively. Another DL based method [15] proposed a novel architecture that can recover the saturated pixels of the LDR images with better quality leading to visually and perceptually better HDR images with well-preserved textures. The method employs a feature masking mechanism that limits the contribution of the features from the saturated regions of the images, which in turn reduces the checkerboard and halo artifacts of these regions. Gabriel Eilertsen et al. [16] proposed a CNN-based method that overcomes the challenges of predicting HDR pixels from complex LDR images with over/under exposed areas. Another interesting work [17] considered the low peak brightness issues and the missing of artistic intent of the existing methods. It proposed a mid-level automatic tone-mapping operator. Gaofeng Cau et al. [18] proposed a spatial and channel dimensional decoupled kernel prediction network that combines a simple module which produces preliminary HDR results and an encoder/decoder module to produce pixel-wise kernels. Finally, these two results are convolved to produce high-quality HDR images. The authors claim that the method can use the relevant information from under- and over-exposed images while avoiding pixel-wise degradation and information redundancy across channels. A work by Hanbyol Jang et al. [19] porposed a novel method of HDR generation from LDR based on histogram and color difference between HDR-LDR (multi-exposure) pairs.

B. *Video-based Methods*

Chen et al. [1] proposed a new architecture for reconstructing HDR videos from LDR counterparts based on a divide-and-conquer policy. The final framework has three components: adaptive global color mapping, local enhancement, and highlight generation. Yang et al. [20] proposed an interesting framework which is capable of utilizing two modalities of input, i.e., stacked events and the LDR frames to create a learnt latent space. The method is guided by the events to facilitate multi-modal learning for HDR creation. The method decribed in [21] proposed a Generative Adversarial Network (GAN) approach for reconstructing HDR videos from multiple exposed LDR sequences. The method starts with a denoising module to clean the LDR input and uses optical flow to align the neighbouring multi-exposed LDRs in the sequence.

C. *Positioning Our Method*

Almost all of the discussed state-of-the-art methods focus on improving the overall structural quality of the generated HDR images while preserving the original structure in the LDR inputs. However, only a handful (i.e., less than five) of the works try to tackle the problem of generating HDR images from the perspective of the Human Visual System and creating perceptually pleasing image for the human eye (see Figure 1). Most conventional methods also lack discussion of the preservation of the artistic intent [13] of the generated HDR content. In this work, we attempt to address these limitations in the current literature along with structural similarity preservation. We achieve better peak brightness with a deep CNN-based learning model along with a feedback block drawing inspiration from [8], [22] by utilizing features extracted from a single LDR image.

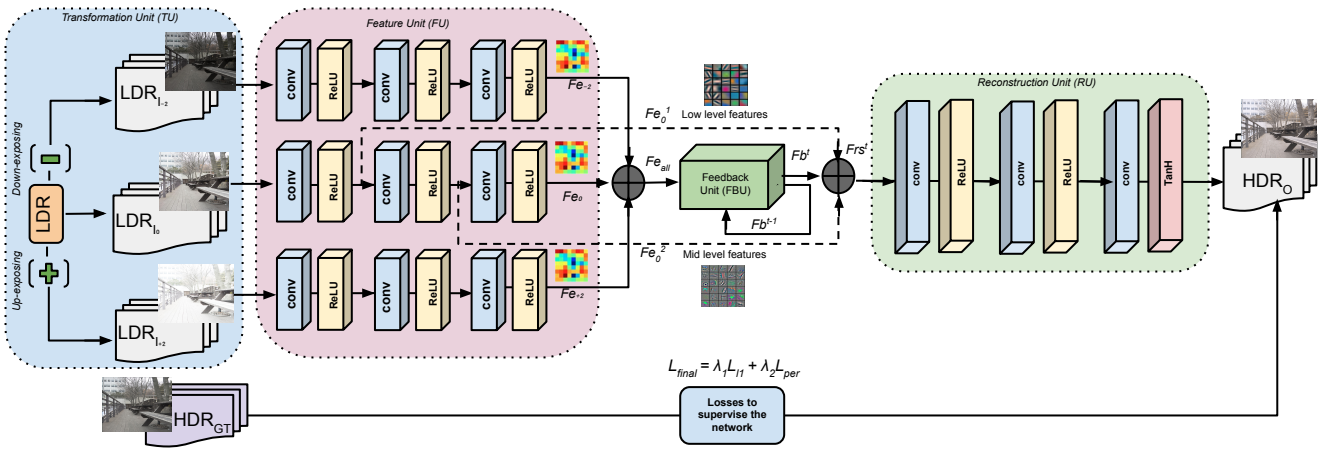

Fig. 2: Illustration of the proposed ArtHDR-Net architecture.

III. Proposed Method

This section describes our proposed architecture for HDR image creation using CNN and a feedback mechanism utilizing coarse and fine features extracted from multi-exposed versions of an input LDR image.

A. Architecture and Model

Our architecture, which we name ArtHDR-Net, comprises four basic units: a) Transformation unit (TU), b) Feature unit (FU), c) Feedback unit (FBU), and d) Reconstruction unit (RU). Figure 2 shows the overall architecture of the method.

TU is responsible for taking an LDR image as input and generating the over-exposed and under-exposed versions (EV ±2). We use an off-the-shelf method [12] to accomplish this task. Regardless of how the input image was captured, we assume that it has a middle exposure value, EV 0. The resulting multi-exposed LDRs (LDR_{I_0}, $LDR_{I_{+2}}$, and $LDR_{I_{-2}}$) are used by FU.

FU has three parallel branches for the three LDRs. Each branch has 3×3 kernels in each of the three 2D convolutional layers (conv), followed by rectified linear unit (ReLU) activation function. The three layers (in each branch) help extract three levels of features (i.e., low, mid, and high). We denote the process in FU as $func_{FU}$ and the output of FU (feature information in each branch) as Fe such that:

$$Fe_{-2} = func_{FU}(LDR_{I_{-2}}) \tag{1}$$

$$Fe_0 = func_{FU}(LDR_{I_0}) \tag{2}$$

$$Fe_{+2} = func_{FU}(LDR_{I_{+2}}). \tag{3}$$

The final feature map Fe_{all} is defined as follows:

$$Fe_{all} = Fe_{-2} + Fe_0 + Fe_{+2}. \tag{4}$$

Initially, FBU takes the Fe_{all} as input and subsequently considers the output of FBU from the previous iteration as shown in Figure 2. Similar to [23], [24], we adopt the feedback mechanism with three dilated dense blocks (having dilation rate of 3), which enhances the network's receptive field without increasing the number of parameters and computational time. This choice is made to utilize all the hierarchical features of the input LDRs. FBU also contains two 1×1 feature compression layers at the beginning and the end of each of the three dilated blocks. Each of the three dilated blocks contain four 3×3 convolutional layers with ReLU activation. This helps to reduce the number of parameters of the network and enhances the learning capability of the network. Finally, FBU starts with a 1×1 convolutional layer for compression and ends with a 3×3 convolutional layer for further processing. This supports global and local feedback mechanisms in the entire FBU as well as in the three dilated block levels. We denote the process of FBU by $func_{FBU}$ and its output by Fb such that a hidden state defined as:

$$Fb^t = func_{FBU}(Fe_{all}, Fb^{t-1}), \tag{5}$$

where t represents the iteration in the FBU.

When $t = 1$ and Fb is nil, we initialize the hidden state of the FBU with Fe_{all} only. Then we also consider the low-level features, i.e., the coarser (low and mid level) features from the first and second convolutional layers of the middle branch (see Figure 2) of FU which has LDR_{I_0}. We do this to guide the network with a set of two residual skip connections for better HDR feature representations in RU. This also helps in preserving the details and artistic intent of the generated HDR image. We denote the final output of the residual skip connections along with the output of FBU at every iteration by Frs. We represent this as follows:

$$Frs^t = Fe_0^1 + Fe_0^2 + Fb^t, \tag{6}$$

where Frs^t represents the final feature map (at iteration t) after the FBU operates on the feature output. Fe_0^1 and Fe_0^2 represent the low-level features from LDR_{I_0}, which we get

as output from the first and second convolutional layers of FU (see Figure 2).

Next, RU reconstruct the HDR image, where it takes the Frs as input in every iteration. RU is made of three 3×3 2D convolutional layers with ReLU activation (following the first two layers) and a hyperbolic tangent activation function (TanH) following the third layer (see Figure 2). We denote the function of RU by $func_{RU}$ and the output by HDR_O.

$$HDR_O^t = func_{RU}(Frs^t), \tag{7}$$

where Frs^t represents the final learned feature map at the t^{th} iteration and HDR_O^t is the final HDR image generated at iteration t.

B. Loss Functions

In this work, we calculate the losses between the tone-mapped versions of the generated HDR image ($HDR_{O(TM)}$) and ground truth (GT) HDR image ($HDR_{GT(TM)}$). This is done to avoid the high-intensity values to dominate the loss function values. We use the $\mu - law$ [25] to compress the HDRs. We employ two loss functions, namely, L1 (L_{l1}) and perceptual (L_{per}) losses, to supervise our model at every iteration t. The complete loss function is defined as

$$L_{final} = \lambda_1 L_{l1} + \lambda_2 L_{per}. \tag{8}$$

The L_{l1} loss is the Mean Absolute Error (MAE) calculated between each pixel of $HDR_{GT(TM)}$ and $HDR_{O(TM)}$. The L_{l1} loss is defined as:

$$L_{l1} = \frac{1}{n} \sum_{t=1}^{n} ||HDR_{O(TM)}^t - HDR_{GT(TM)}||. \tag{9}$$

The L_{per} loss is the perceptual loss between $HDR_{GT(TM)}$ and $HDR_{O(TM)}$ generated via the function $func_{per}$ inspired by [26]. $func_{per}$ is a VGG[1] based loss which tries to make the output closer to perceptual similarity. It is created using the ReLU activation layers of the famous 19 layer VGG network. The L_{per} loss is defined as:

$$L_{per} = \frac{1}{n} \sum_{t=1}^{n} func_{per}(HDR_{O(TM)}^t, HDR_{GT(TM)}). \tag{10}$$

We do not consider L2 loss because it is too sensitive towards outliers. We use a combination of the L_{l1} and L_{per} loss because using only the L1 loss produces visually degraded HDRs. λ_1 and λ_2 are set to 0.1 and 0.5 empirically.

IV. Experiments

We trained and tested our model on Ubuntu 20.04.6 LTS work station with Intel(R) Xeon(R) CPU E5-2687W v3 @ 3.10GHz (20 CPU cores), 126 GB RAM (with 2 GB Swap space) and 1.4 TB SSD for dataset storage. We used batch size of 10 and Adam optimizer [27] for training the model. The model was trained for 150 epochs. The learning rate of the training process was set to 2×10^{-4} at first and later adjusted to decay. We employed an iteration count of 4 for the feedback operation in FBU.

A. Datasets

We used three datasets for training and testing. Specifically, the City Scene dataset [5] (*ICCV 2017*) contains about 20K HDR-LDR pairs and ground truth HDR images. We also used the LDR-HDR pair dataset from [19] (*IEEE Access 2020*) which contains images from 450 different scenes captured using a Samsung NX3000 camera in three exposure levels (EV -2, 0, +2). This dataset contains images from indoor and outdoor environments as well as scenes containing landscapes, objects, and buildings. It also contains night scenes. Finally we used another dataset, HDR-Synth and HDR-Real from [9] (*CVPR 2020*) which contains real world LDR images and HDR counterparts (9785 in total) as well as synthetic pairs (around 500). We resized the images to 512×512 before feeding them into the model. We did an 80-20 split on the datasets for training and testing purposes.

B. Evaluation Metrics

We use three metrics to evaluate our method quantitatively. For evaluating on the basis of human level perception, we use the *High Dynamic Range Visual Differences Predictor* (HDR-VDP-2 or Q-score) [10], [11]. For structural similarity and accurate reconstruction evaluation, we use the structural similarity index measure (SSIM) and peak signal-to-noise ratio (PSNR). The HDR-VDP-2 score and SSIM are calculated on the actual GT and generated HDRs whereas the PSNR is calculated on the $\mu - law$ based tone-mapped GT and generated HDRs.

V. Results

A. Quantitative Evaluation

We evaluate our method ArtHDR-Net against three similar methods [8] (*GlobalSIP 2019*), [9] (*CVPR 2020*), and [12] (*WACV 2023*). We train and test the models on the datasets described in Section IV-A. Table I summarizes the quantitative results in terms of PSNR, SSIM, and HDR-VDP-2 (higher is better). The results confirm that our method is performing well compared to the considered state-of-the-art methods. In the case of City Scene dataset [5], ArtHDR-Net performs the best in terms of PSNR and HDR-VDP-2 scores and second best in terms of SSIM metric. On the other hand, [12] performs best in in terms of SSIM and second best in terms of PSNR scores, but the second best performer in terms of HDR-VDP-2 is [9]. For LDR-HDR pair dataset [19], once again ArtHDR-Net is best in terms of PSNR and HDR-VDP-2 scores. The method in [12] achieves top performance in terms of SSIM metric. Finally for the HDR-Synth and HDR-Real [9] dataset, ArtHDR-Net comes out best in terms of SSIM and HDR-VDP-2

[1] https://paperswithcode.com/method/vgg-loss

TABLE I: **Quantitative comparison** - PSNR, SSIM and HDR-VDP-2 attained by the proposed method and the state-of-the-art methods. The best results are in **bold**, while the second best results are underlined.

Method	City Scene dataset [5]			LDR-HDR pair dataset [19]			HDR-Synth and HDR-Real [9]		
	PSNR ↑	SSIM ↑	HDR-VDP-2 ↑	PSNR ↑	SSIM ↑	HDR-VDP-2 ↑	PSNR ↑	SSIM ↑	HDR-VDP-2 ↑
Method in [8] (2019)	32.5	0.90	67	15.2	0.66	64.5	17.1	0.71	66.7
Method in [9] (2020)	33.4	0.91	68.2	27.5	0.77	65.1	26	0.85	68
Method in [12] (2023)	34	**0.94**	68	29	**0.79**	66	**34**	0.87	67.5
Ours (ArtHDR-Net)	**35**	0.93	**69**	**30**	0.78	**66.5**	33.4	**0.88**	**68.3**

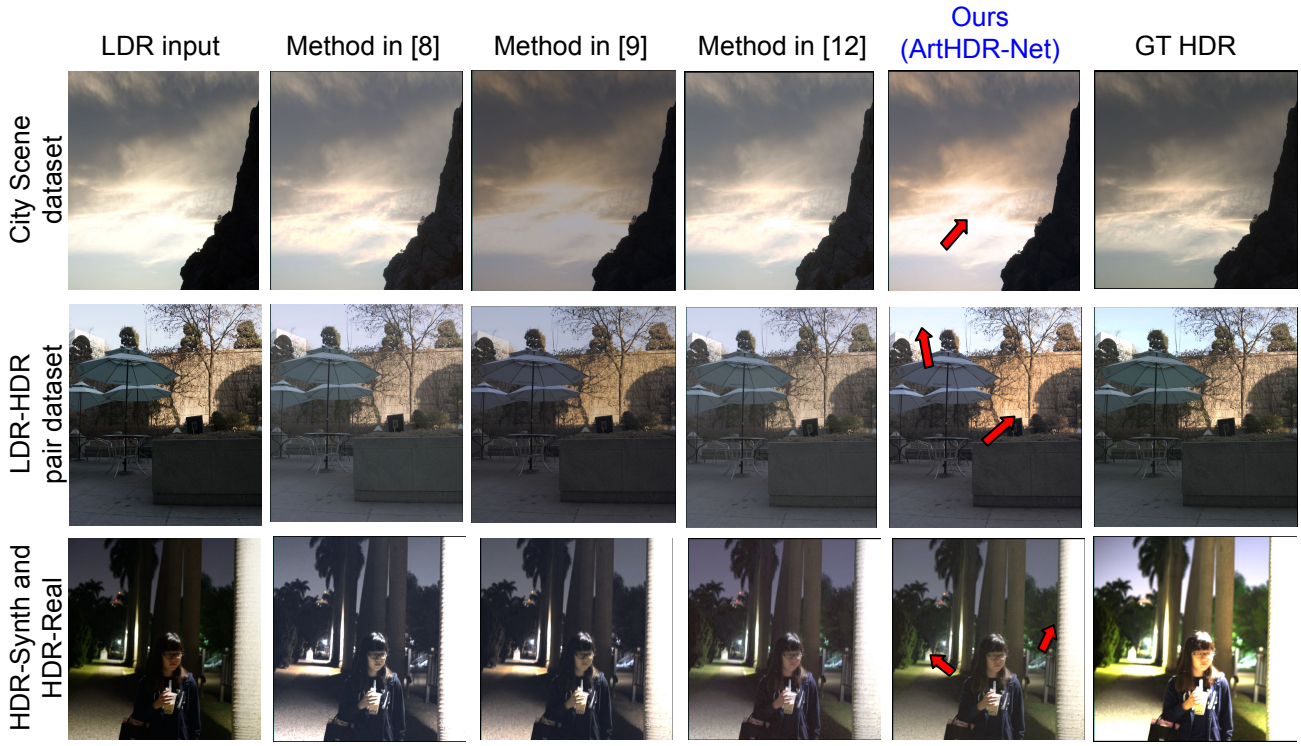

Fig. 3: **Qualitative evaluation** - Output HDR content produced by our method ArtHDR-Net and other state-of-the-art methods for the three datasets. The red arrows in our output highlight the naturalness in color and brightness, hence the artistic intent being preserved with respect to the input LDR image and the GT HDR image.

metrics whereas the method in [12] is best in terms of PSNR score. It is noteworthy that our method outperforms all the considered state-of-the-art methods and on all of the considered datasets in terms of HDR-VDP-2 score, which suggests that our method capable of reconstructing HDRs that capture the visual quality of real scenes and better represent all luminance conditions [10], [11]. The methods in [9], [12] are second best in this case. The structural similarity with respect to the input LDRs is better preserved by the method in [12].

B. Qualitative Comparison

Figure 3 depicts the qualitative comparison of our method with the considered conventional methods on the three datasets. The red arrows introduced to the images generated by our method show some sample regions which display naturalness in color and better luminance in comparison to the other methods. The methods in [8], [12] completely fail in this respect while the method in [9] gives similar results to our method, but it is more prone towards dark images. Hence, our method better represents the artistic intent of the images. Similarly, we also evaluate our method on arbitrary images retrieved from the Internet (see Figure 4). In the first row (under-exposed), we see that our method retains good color contrast and luminance compared to the other methods (yellow arrows). The methods in [8], [9] seem closer to ours but still lack in terms of luminance in some regions. In the second row (over-exposed), most methods [8], [12] fail to capture the details and artistic intent of the blue sky where the banding problem is also apparent. In contrast, whereas our method gives more natural and realistic output (red arrows). Although the method in [9] is able to give details of the blue sky to some extent, it still lacks in terms of luminance and color naturalness. The displayed GT as well as the generated HDRs from the various methods (including ours) have been tone-mapped using the algorithm in [28].

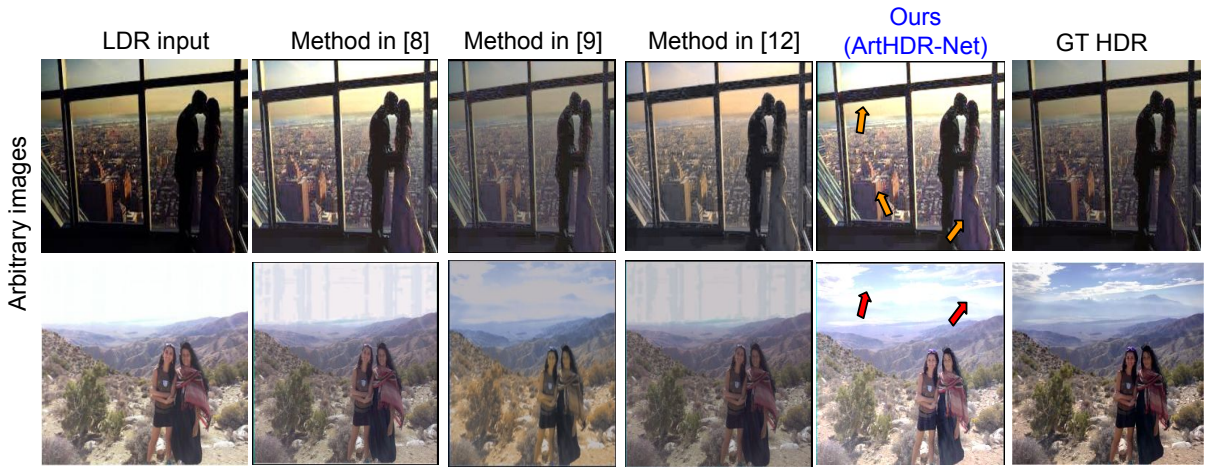

Fig. 4: **Qualitative comparison.** Comparison of our method with the considered state-of-the-art methods with respect to the input LDR and GT HDR (for images not in the mentioned datasets in section IV-A).

TABLE II: **Loss contribution** - The PSNR, SSIM, and HDR-VDP-2 achieved by using the different loss combinations. The best result is in **bold**, while the second best is underlined.

Loss	PSNR↑	SSIM↑	HDR-VDP-2 ↑
L_{l1}	36	0.931	63.5
L_{per}	35.4	0.928	66.3
$L_{l1} + L_{per}$	**36.5**	**0.942**	**67.1**

TABLE III: **Skip connections contribution** - The PSNR, SSIM, and HDR-VDP-2 achieved by using different combinations of features selected using skip connections to guide the network during the final stage in RU (see Figure 2). The best result is in **bold**, while the second best is underlined.

Fe_0^1	Fe_0^2	PSNR↑	SSIM↑	HDR-VDP-2 ↑
✗	✗	35.1	0.930	63.1
✗	✓	35.7	0.938	64.2
✓	✗	35.8	0.934	64
✓	✓	**36.5**	**0.942**	**67.1**

VI. Ablation Analysis

We experiment with the components and settings of our model to present the contributions made by of each of them in the achieved output. We create a subset of 5000 arbitrary images (collected from the three datasets described in Section IV-A) to perform the ablation experiments. Table II shows how each of the losses (see Section III-B) contributes to the final accuracy and quality of the HDR images reconstructed using our model. We see that L_{l1} contributes more towards better PSNR and SSIM values, whereas L_{per} have more impact towards the HDR-VDP-2 (Q-score). This suggests that the accuracy of the image reconstruction is mostly influenced by L_{l1}, whereas the perceptual quality is maintained by L_{per}. Finally, the combination of both losses leads to the best scores for all three metrics. Here, we also weight the losses with λ_1 and λ_2 (see Section III-B). Table III illustrates the contribution of each of the skip connections we use in our CNN architecture (see Figure 2). We observe that if we consider the skip connection Fe_0^1 only, the PSNR reaches better scores, whereas if we consider only Fe_0^2, SSIM and Q-score are better. However, if we consider both together, we get the best results for all three metrics. This implies that more low-level features improve the PSNR, while mid-level features boost up the SSIM as well as Q-score.

VII. Conclusions

In this paper, we attempt to improve the state-of-the-art HDR image generator with respect to the artistic quality of the generated HDRs from input LDRs. The quantitative results show the dominance of our method in terms of the HDR-VDP-2 which signifies that our method produces output that is visually more pleasing and appears more realistic than the other considered state-of-the-art methods. The qualitative results also support this argument. In addition, the PSNR and SSIM attained by our method are also comparable to the other state-of-the-art methods.

As future work, we intend to study the impact of multiple EV images (e.g., EV ±1, ±2, ±3 and ±4) on the feature map as well as the behaviour of the model on different EV inputs of the same image. Currently, we do not consider images with foreground motion or dynamic scenes [29]. We aim to upscale our method to videos [1], [20], [21] and dynamic scenes in the future [30]–[32]. Future work will also include the introduction of multiple tasks, such as denoising [33], deblurring, super-resolution [22], [26], and demosaicing into our framework. Finally, we plan to experiment with different loss functions and metrics [14], [15], [34], which will be more efficient in supervising the network in terms of visual quality and preservation of artistic intent.

***Abstract*—A single-image lightweight super-resolution (LSR) method was presented in our earlier work. LSR predicts the residual image between the interpolated low-resolution (ILR) and high-resolution (HR) images using a self-supervised framework. A further enhanced version of LSR, called LSR++, is proposed in this work. The improvement of LSR++ over LSR primarily lies in a new patch alignment scheme, where the spatially geometrical property of patches is exploited. Patches can be categorized into two main classes through alignment. Then, one regressor is needed for each class. Compared with LSR, LSR++ lowers the computational complexity from 3.83K to 1.71K FLOPs/pixel and the model size from 770K to 200K parameters while preserving close visual performance measured by PSNR/SSIM. LSR++ offers an attractive super-resolution method for mobile applications.**

I. Introduction

Single image super-resolution (SISR) [1] targets recovering a high-resolution (HR) image from its low-resolution (LR) counterpart. It has many real-world applications, e.g., the digital zoom-in function in mobile phones. It has been intensively studied in the last two decades. Two popular approaches are taken to tackle this problem: 1) exemplar-based methods, and 2) deep-learning (DL) methods.

For the former, patches are conventionally presented by reference vectors (known as dictionary atoms) and partitioned into multiple groups. Mappings from LR-to-HR patches are developed for each individual group. Examples include [2]–[6]. Priors can be leveraged for patch partitioning [7]. This approach has several limitations. First, the LR-to-HR mapping is based on hand-crafted features. Second, the training of the LR-to-HR mapping is time-consuming [3], [4]. Third, the quality of obtained SR images is inferior to that achieved by DL methods.

For the latter, SRCNN [8] is among the earliest ones. Substantial advances have been made since then. Examples of DL methods include [9]–[17]. Most efforts ([8]–[13]) have focused on achieving higher visual quality (namely, better PSNR and SSIM). Implementational efficiency has been explored in recent years, e.g., [14], [15]. Other SISR problems have also been examined such as unknown degradation kernels [16] and magnification with a non-integer factor [17], etc.

Although DL methods offer significant performance breakthroughs, it is challenging to implement them in mobile/edge devices due to their high computational cost and memory requirement. Implementing lightweight DL methods on mobile devices has received attention from academia and industry. Some successful results are reported in [18]–[20]. They are accomplished through better neural network architectural search and pruning but their designs appear to be tedious and ad hoc. Furthermore, all DL methods share one common shortcoming, namely, lack of mathematical transparency.

Recently, based on the green learning paradigm [21]–[25], a lightweight super-resolution (LSR) method was developed in [26] and it is reviewed in Sec. II. Patch augmentation with a flipping and/or a rotation is commonly adopted by SISR methods to enlarge the training dataset. It contributes to better quality at the expense of a higher training cost. LSR adopts patch augmentation not only in the training stage but also in the inference stage to boost the regression performance of a target pixel. That is, LSR augments its corresponding patch through flipping and rotating, conducts regression for each patch variant, and assembles the estimates by averaging.

A further enhanced version of LSR, called LSR++, is proposed in this work. The improvement of LSR++ over LSR lies in the replacement of patch augmentation with a new patch alignment scheme. Intuitively speaking, we flip and rotate a patch so that it is aligned along a certain direction. By considering the patch's symmetry in the spatial domain, we align patches into two main classes. Then, one LR-to-HR regressor is developed for each class. The patch alignment scheme reduces training and inference complexities and the model size, which is the main contribution of this paper. It is worthwhile to emphasize that the patch alignment scheme is not only applicable to the SISR problem but also other applications that need patch-wise data augmentation. It is a powerful tool in visual-based machine learning.

We conduct experiments to demonstrate the advantages of LSR++. Compared with LSR, LSR++ lowers the computational complexity from 3.83K to 1.71K floating-point operations per pixel (FLOPs/pixel) and reduces the number of model parameters from 770K to 200K. At the same time, LSR++ offers quality performance close to LSR in terms of PSNR and SSIM metrics. Thus, LSR++ offers an even more attractive lightweight SR method for mobile applications.

The rest of the paper is organized as follows. A brief review of the LSR method is provided in Sec. II. The LSR++ method is proposed in Sec. III. Experimental results are shown in Sec. IV. Finally, concluding remarks are given in Sec. V.

II. Review of LSR Method

A lightweight super-resolution (LSR) method based on green learning [24] was introduced in [26]. It follows the conventional SISR pre-processing routine: 1) transforming RGB images to the YCbCr color space and only the luminance (Y) component is processed, and 2) applying the interpolation (Lanczos) to LR images to yield interpolated LR (ILR) images. LSR contains the following three modules in cascade.

- Module 1: unsupervised representation learning
  The objective of the first module is to generate a rich and diversified set of representations in the neighborhood of a target pixel. Five types of representations are generated.
- Module 2: supervised feature learning
  The total number of representations obtained from Module 1 is around 1500. A subset of the most relevant representations can be selected based on a mechanism called the Relevant Feature Test (RFT) [25].
- Module 3: supervised decision learning
  It predicts the residual of the target pixel based on selected features through the XGBoost regressor. In the training stage, data augmentation is performed (via 90-degree rotations and flipping) to enlarge the training sample size. Furthermore, "clustering" and "prediction fusion" are adopted to boost the regression performance via ensemble learning.

There are two versions of LSR, called LSR V1 and LSR V2, respectively. All five types of representations are used in LSR V1 while only one specific type of representations is used in LSR V2. On the one hand, LSR V1 has a larger model size and a higher computational complexity than LSR V2. On the other hand, LSR V1 has better SR quality (measured by PSNR/SSIM) than LSR V2. Nevertheless, their performance differences are minor. Compared with other SISR methods, LSR V1 and V2 offer better SR quality than exemplar-based methods and comparable performance with the entry-level DL solution, SRCNN. They demand much less computational complexity measured by the floating-point operations per pixel (FLOPs/pixel).

III. Proposed LSR++ Method

A. Motivation

LSR++ inherits the same system block diagram of LSR. It follows the same high-level processing strategy: 1) patch-to-pixel residual regression, and 2) adaptive regression based on partitioned patches. It adopts the same SISR pre-processing routine and contains three processing modules in cascade (i.e., unsupervised representation learning, supervised feature learning, and supervised decision learning) as described in Sec. II.

The main difference between LSR and LSR++ lies in one aspect. That is, LSR++ employs a patch alignment scheme to achieve lower computational complexity and a smaller model size, which is the main contribution of this paper. The amount and diversity of training samples are highly related to the performance of SR methods. It is typical to use data augmentation to increase the number of training samples. For example, given N training patches, one can obtain $8N$ training patches by flipping and rotating each of them. This technique is adopted by LSR. The training complexity increases with data augmentation. Furthermore, an ensemble technique is used by LSR to increase the performance in the inference stage. That is, an input patch is flipped and rotated to get multiple variant patches in testing. The regression for the central pixel residual is conducted independently for each variant, and the predicted values of all variants are averaged to obtain the ultimate prediction.

The data augmentation technique was exploited by LSR to trade training/testing complexities for higher visual quality. Here, we propose a new method, LSR++, to preserve SR performance without data augmentation. It has the benefits of a smaller model size and a lower computational complexity.

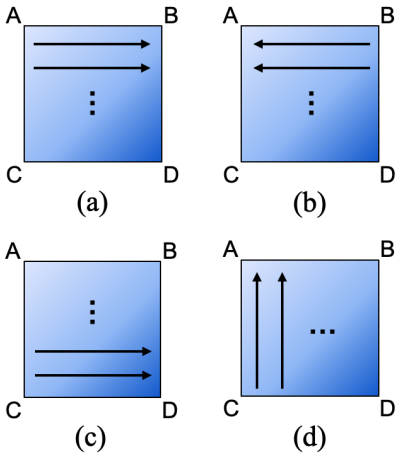

Fig. 1. Pixel access patterns on the original patch for equivalent augmented patch obtained by a) no operation, b) left-right flipping, c) top-bottom flipping, and d) clock-wise 90-degree rotation.

B. Patch Alignment

1) Implementation of Patch Flipping and Rotations: Flipping and rotating are standard ways to augment patches. They can be easily implemented by different pixel access patterns as shown in Fig. 1. "A", "B", "C", and "D" denote four corners of a patch in this figure. We can design various pixel access patterns as indicated by the arrow direction to attain an equivalent effect of data augmentation. Without loss of generality, we show adaptive pixel scanning order on the original patch to equivalently achieve three representative augmented patches via left-right flipping, top-bottom flipping, and clock-wise 90-degree rotation in Fig. 1 (b), (c), and (d), respectively. For example, if pixels are scanned from right to left in a row-wise fashion as shown in Fig. 1 (b), it is equivalent to the left-right flipping. We propose a patch alignment scheme through the adaptive pixel access patterns to achieve the same effect as patch augmentation yet without increasing the time or space consumption.

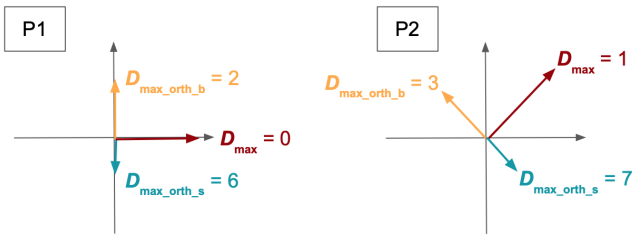

Fig. 4. Two standard templates for patch alignment: the template for P1 patches (left) and the template for P2 patches (right).

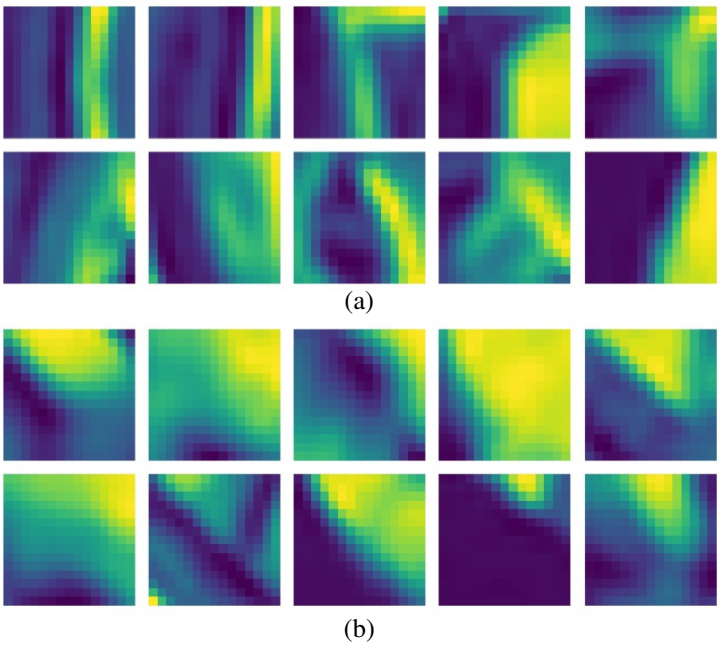

Fig. 5. Exemplary patches after patch alignment from (a) P1 patches and (b) P2 patches.

2) Patch Gradient Histogram Vector: LSR++ utilizes patch gradient histograms to achieve patch alignment. For an ILR patch of size 15×15, the horizontal and vertical gradients, G_x and G_y, are calculated by using horizontal and vertical Sobel filters of size 3×3 at each pixel. Afterwards, the gradient magnitude, r, and the gradient orientation angle, θ, are derived based on G_x and G_y. We further quantize the orientation angles into eight bins with their centers pointing to $45k$ degree, where $k = 0, 1, \cdots 7$, as the reference directions shown in Fig. 2. Given 13×13 interior points, the gradient magnitude r of pixels in their associated bins are accumulated to form an 8-D patch gradient histogram vector.

Each vector presents the quantized edge orientation statistics of a patch along these eight reference directions. Denote the gradient histogram vector dimension index by D_{old} and D_{new} for a certain gradient histogram bar before and after the rotation or flipping operation. These vectors have four properties:

- Patch gradient histogram vectors capture local edge orientation patterns. Small magnitudes in all eight dimensions indicates smooth patches. One or two larger magnitudes imply the existence of dominating edges. Otherwise, the associated patches are in a textured region.
- Patch rotation and flipping operations preserve the height and cyclic adjacency of patch gradient histogram bars as shown in Fig. 3.
- Rotation operation cyclically shifts the gradient histogram bars such that $D_{new} = (D_{old} - m)\ mod\ 8$, where m is the multiple of 45 degrees to clock-wise rotation.
- Up-down Flipping operation symmetrically shifts the gradient histogram bars such that $D_{new} = (8 - D_{old})\ mod\ 8$. The Left-right flipping can be obtained by up-down flipping followed by a 180-degree rotation.

3) Patch Alignment Algorithm: In general, patch alignment operation is performed via patch flipping and patch rotations by clock-wise 90, 180, or 270 degrees, so that patches are aligned to standard reference templates. Let D_{max} denote the dimension of the patch gradient histogram vector that has the

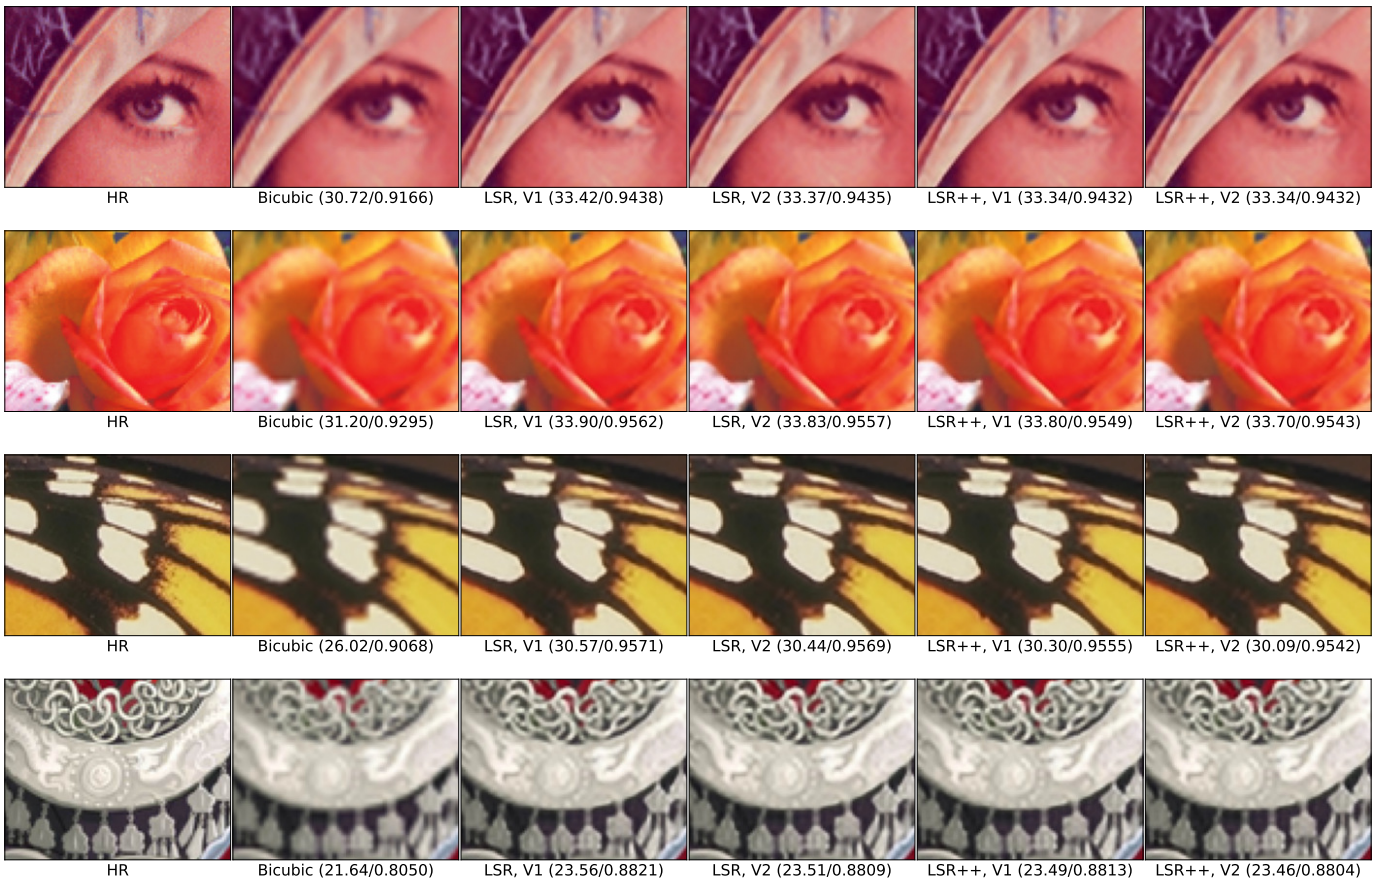

Fig. 6. Visual comparison of exemplary test SR images, where the PSNR/SSIM results are provided in brackets.

largest magnitude, and $D_{max_orth_b}$ and $D_{max_orth_s}$ represent its two orthogonal dimensions which have bigger and smaller magnitudes, respectively. Patches are first partitioned into two portions based on their D_{max}:

- Portion 1 (P1): samples with D_{max} on even indices, and
- Portion 2 (P2): samples with D_{max} on odd indices.

It is worth mentioning that patch alignment operation does not change the patch portion type. We then execute the patch alignment operation on each patch to match one of the standard reference templates in Fig. 4. Patches belonging to P1 and P2 use the left and right templates, respectively.

Patch gradient histogram properties described in Sec. III-B2 are critical to the complexity and efficiency of patch alignment. Associated re-indexing of patch gradient histogram dimensions effectively generates the updated gradient histogram after each single rotation/flipping operation. Therefore, instead of exhaustive attempts of the combination of rotation/flipping operations, one sample can be systematically aligned by the proper rotation/flipping operation sequence based on these patch gradient histogram properties. Consequently, patch alignment requires no additional complexity cost, and its high implementation efficiency is surely guaranteed.

4) Geometrical Interpretation: Geometrically, P1 and P2 patches are samples with significant gradient values along horizontal/vertical and diagonal/off-diagonal directions, respectively. Some observations are summarized as follows.

- The D_{max} direction characterizes the gradient information orthogonal to the dominant edge pattern. This is illustrated in Fig. 3 and Fig. 5.
- $D_{max_orth_b}$ and $D_{max_orth_s}$ characterize the gradient information along the dominating edges.
- The two templates shown in Fig. 4 constrain P1 and P2 samples to be aligned with vertical edges and northwest-to-southeast edges, respectively.

Through rotation and flipping operations on raw patches to satisfy the two standard reference templates, patch alignment productively summarizes the diversity of patch patterns, and therefore effectively reduces the geometrical complexity of raw patches. Accordingly, patch alignment is equivalent to data augmentation concerning the generic representation of patch patterns, while it exhibits more advanced complexity control simultaneously.

IV. Experiments

A. Experimental Setup

Only the Y channel is processed for super resolution quality evaluation. The Cb and Cr channels are obtained by the bicubic interpolation for final visualization. This is the standardized

LSR++, V2	1.71K (1X)	200K (3.49X)

experimental protocol used by all benchmarking SR papers. The results with scaling factor of 2 are demonstrated here. The BSD200 dataset [27] is adopted to train the proposed LSR++ model. The tests are performed on four datasets: Set5 [28], Set14 [29], BSD100 [27], and Urban100 [5].

Our model uses ILR patches of size 15×15 to predict the residual value of the pixel at the patch center. LSR partitions data into hard and easy samples. There is no data augmentation, no clustering, or fusion strategy for easy samples. LSR++ follows the same practice. For hard data, LSR++ adopts patch alignment to replace data augmentation in the training stage and fusion in the inference stage. Representation filters and XGBoost regressor (500 trees with the maximum depth equal 6) are learned for each of the two portions of hard data after patch alignment.

The corresponding enhancements for LSR V1 and LSR V2 are called LSR++ V1 and LSR++ V2, respectively. As described in Sec. II, the differences between V1 and V2 lie in the usage of different representations.

B. Quality Performance Evaluation

Several benchmarking SR methods listed below are considered for quality comparison.

- Exemplar Methods: SelfExSR [5], A+ [4]
- Neural Network Method: SRCNN [8]
- Green Learning Methods: LSR V1/V2 and LSR++ V1/V2

The PSRN/SSIM quality values are demonstrated in Table I, where the best and the second best are marked in red and blue, respectively. Overall speaking, their PSNR/SSIM values are similar. Note that SRCNN is the simplest DL-based method. Here we do not include advanced DL-based solutions in the table since their model sizes and computational complexity are too high to be used on mobile/edge platforms.

The averaged PSNR and SSIM degradations over four testing datasets from LSR V1 to LSR++ V1 are only 0.1dB and 0.0009, respectively. The averaged PSNR and SSIM degradations from LSR V2 to LSR++ V2 are 0.17dB and 0.0018, respectively. Such minor differences are difficult for human eyes to tell. We show four exemplary images in each row of Fig 6. The images from left to right are: HR, bicubic interpolated LR, LSR V1, LSR V2, LSR++ V1, and LSR++ V2. The quality of bicubic interpolated LR is clearly the worst. The visual quality of SR images obtained by LSR V1, LSR V2, LSR++ V1, and LSR++ V2 is difficult to differentiate.

C. Complexity Analysis

1) Training Phase: As mentioned earlier, patch alignment is equivalent to data augmentation for raw P1 and P2 patches satisfying the two standard templates. No additional data augmentation is needed. The total training time is reduced by a factor of eight. The rotation and flip can be easily implemented by various pixel access patterns as explained in Sec. III-B1.

2) Inference Complexity: One important step in LSR is the fusion operation in the inference stage. For an input patch, we generate multiple variants by rotations and flips, and ensemble the predictions from all candidates (the original input plus other variants) to yield the final estimate. Both variant generation and fusion operations are eliminated by using patch alignment in LSR++, thus leading to a faster inference speed. The inference computational complexity comparison of several super-resolution algorithms in terms of FLOPs/pixel is given in Table II. LSR++ exhibits much lower inference FLOPs/pixel values against all benchmarking methods. The detailed computation of inference complexities of LSR V1/V2 and LSR++ V1/V2 are presented in Table III in Appendix.

3) Model Size: LSR partitions patches into eight clusters aiming at grouping them with eight orientations separated by every 45 degrees. LSR++ only partitions patches into two portions. In general, LSR++ reduces its model parameters (i.e. model size) to one quarter of LSR. The comparison of number of model size with other representative SISR methods is shown in Table II. The model size of LSR++ is smaller than all benchmarking methods except for SRCNN. However, the computational complexity of SRCNN is much higher. Detailed analysis on the model sizes of LSR V1/V2 and LSR++ V1/V2 are provided in Table III in Appendix.

V. CONCLUSION AND FUTURE WORK

An enhanced version of the LSR method, called LSR++, was proposed in this work. The improvement of LSR++ over LSR lies in a new patch alignment scheme, where the geometrical property of patches in the spatial domain is exploited. Compared with LSR, LSR++ lowers the computational

complexity from 3.83K to 1.71K FLOPs/pixel and the model size from 770K to 200K parameters. At the same time, it preserves similar SR quality. LSR++ provides an attractive super-resolution method for mobile and edge computing. The patch alignment proposed in LSR++ can serve as a generic regularization process on patch diversity, which can be applied in all patch-based algorithms for the purpose of complexity control.

As to future extensions, we would like to reduce the model size furthermore. This could be achieved by replacing the XGBoost regressors with linear least-squared regression. Another possible direction is to apply LSR++ iteratively for further quality improvement. Since LSR++ has a lower computational complexity, it is acceptable to apply it more times for better visual quality.

APPENDIX

A detailed computation of the inference complexity (in terms of FLOPs/pixel) and model sizes (in terms of model parameter numbers) for LSR (V1/V2) and LSR++ (V1/V2) is summarzied in Table III. The reason for larger model parameters in Modules 1&2 of LSR++ is due to the portion-wise representation learning, while global representation filters are shared in all clusters in LSR.

TABLE III
COMPARISON OF INFERENCE COMPLEXITY (FLOPS/PIXEL) AND MODEL SIZES FOR LSR (V1/V2) AND LSR++ (V1/V2).

LSR V1/V2 Summary

Complexity	FLOPs / pixel		Model Size

***Abstract*—This paper proposes a high-quality font generation method based on StyleGAN2 and FSFont font generation model. In our previous work, we proposed a system that expresses emotions by using font changes and call it an EmoEditor (Emotion-Expressive Editor). This system uses a deep neural network based on zi2zi that is able to generate a desired rendered character by giving a fixed rendered character and a font label which distinguishes between fonts. By changing the font label, the system generates the different font characters which corresponds to several emotions. However, the system was not able to reconstruct the expected ones for our collected fonts that is needed to express emotions. Considering the rapid development of DNN technology, in this paper, we propose an extension of the StyleGAN2 model for font generation. Specifically, we enhance StyleGAN2 by incorporating an Encoder which is come from FSFont generation model and a class label input structure. By adopting a class label input, the proposed model is able to generate indicated font by users. Experimental results show that the proposed method can generate better fonts qualitatively and quantitatively than previous studies on font generation.**

I. Introduction

Text is used in various situations as a means of conveying information. One of its applications is communication. Text is used not only for communication with close friends, but also for communication with people far away, such as in the comments sections of various websites and social networking services. On the other hand, it is difficult to convey emotions over text. To address this issue, we have proposed a system that conveys emotions through font changes, which is called an EmoEditor[1]. EmoEditor uses a deep neural network (DNN) that generates fonts called zi2zi [2]. Zi2zi is a model that takes as input two data, a character image called the source font and a class label, and produces as output a character image in which the source font is changed to a font corresponding to the class label. By mapping emotions to class labels, EmoEditor changes the font based on the input emotion. The EmoEditor system can also interpolate between two fonts by using the zi2zi function. This allows users to employ emotion-expressive fonts in text, enabling richer communication compared to the use of uniform fonts. However, the zi2zi structure is not sufficient to generate fonts that express emotions, and the expected reconstruction of fonts cannot be achieved.

In recent years, significant research has been conducted on font generation. Tang proposed FSFont font generation model[3] (referred to as FSFont), which utilizes two images - a content image and a reference image - as input. Each image is processed by two different Encoders. The Content Encoder extracts the textual meaning of the font as features from the content image, while the Reference Encoder extracts font style information as features from the reference image. Considering that fonts consist of various partial elements like radicals and strokes, Tang introduced a mechanism that employs Cross Attention in the DNN to learn the partial styles of the reference image and the spatial correspondence of the components in both the content and reference images. Yangchen proposed DGFont font generation model[4](referred to as DGFont) which is based on the same concept as [3], where the content and reference images are fed into the Content Encoder and Reference Encoder, respectively. Acknowledging that the shape of the lines and strokes that form a character varies depending on the font, Yangchen adopted Deformable-Convolution [5] for the network. Deformable-Convolution allows for geometric deformation of strokes. Chi proposed CFFont font generation model[6](referred to as CFFont) which is based on DGFont. This approach takes multiple types of fonts as input content images and merges them by assigning weights to the obtained features. The loss function used in this method is not the L1 Loss between each pixel in the generated image and the correct image. Instead, it employs the L1 Loss of the histogram of the projected image in one dimension across six different directions. This enables learning that focuses on the overall shape of the characters.

In this paper, we propose a method to generate high-quality fonts based on both StyleGAN2[7] and FSFont. Our method incorporates the Content Encoder in FSFont into the StyleGAN2 model, where the output of the Encoder serves as the initial input to the Generator in StyleGAN2. In addition, we assign class label for the font which is used in training and testing, and we give this label to the Mapping network in StyleGAN2. In StyleGAN2, the generated image depends on the noise giving to Mapping network. This means that you need to search the initial noise to generate the image you want to.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Therefore, the proposed our model is able to generate indicated fonts with giving adequate class label which is regarded as a noise without searching initial noise.

The contributions of this paper are two as follows.

- We develop a method for addressing the font generation problem by utilizing the powerful StyleGAN2 model known for its ability to generate high-quality images. Through our proposed approach, we have successfully achieved high-quality font generation by leveraging class labels.
- We don't use L1 Loss as the primary loss function. To do so, we can realize the robustness of the learning process to potential misalignment issues that may arise during the reconstruction of fonts.

In section 2, we describe the DNN proposed in this paper, and in section 3, we show the conditions and results of experiments in which fonts are trained. Finally, in section 4, we summarize the results and discuss future issues.

II. Proposed Method

The proposed Generator architecture consists of two main components: an Encoder and a Decoder. In our approach, we adopt the Encoder used in the FSFont as the Encoder component, while the Decoder component is based on the StyleGAN2 Generator. The Encoder plays an important role in capturing the content and meaning of the characters in the font to be generated. It takes the content character image as input and extracts the relevant features that represent the desired font character. These extracted features are then passed to the Decoder for further processing. On the other hand, the Decoder receives the output of the Encoder, which encodes the desired font style, along with a class label. The class label serves as a guiding signal to instruct the Generator on the specific font style to be generated. By combining the encoded features from the Encoder and the class label, the Decoder synthesizes an output image where the font of the content character image is transformed to match the corresponding font style dictated by the class label.

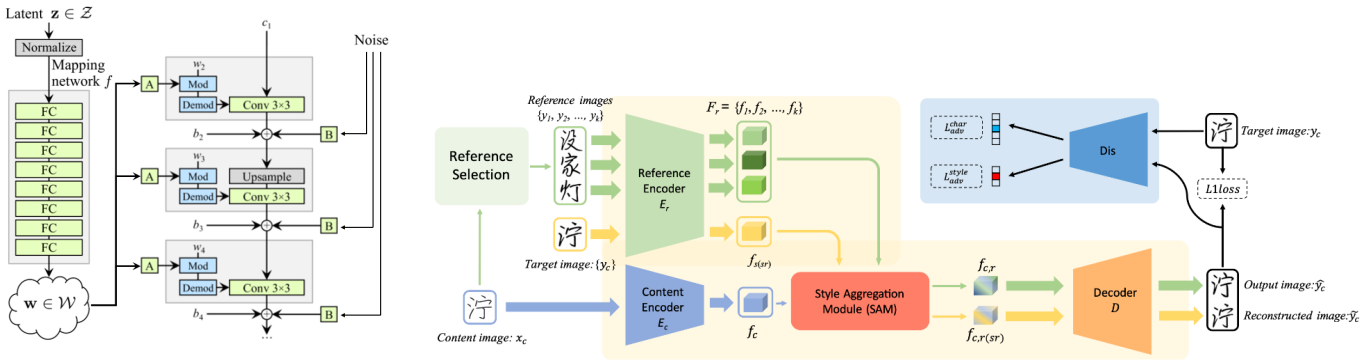
In this section, we provide a detailed explanation of both the FSFont model and the StyleGAN2 model, which form the foundational components of our proposed method. We then proceed to describe the integration of these models in our novel architecture, showcasing how they synergistically contribute to the generation of high-quality fonts with desired styles.

A. Useful two DNN models for font generation

1) StyleGAN2: StyleGAN2 is a type of Generative Adversarial Network (GAN) that has gained significant attention for its ability to generate high-quality images with controlled attributes. One of its distinguishing features is its attribute control, allowing for fine-grained manipulation of generated images. The network structure of StyleGAN2 is depicted in Fig.1(a), illustrating the flow of information within the model. Firstly, StyleGAN2 takes a noise vector, denoted as z, as input. The noise vector z is indeed mapped to the latent variable w through the Mapping Network in StyleGAN2. The Synthesis Network initially receives a 4x4 constant tensor as the first input（c_1）, which is then progressively up-sampled. During the up-sampling process, a latent variable called w is introduced, and it plays a crucial role in controlling the attributes of the generated image. By modifying the value of w during the up-sampling stages, the Synthesis Network produces an image that exhibits desired attribute variations based on the provided w.

2) FSFont font generation model: FSFont is a type of font generation model whose network structure is depicted in Fig.1(b). The network takes two types of images as input. The first type is the content image, which influences the output font character based on the characters present in the image.The second type of image is the reference image, which determines the output font style based on the style present in the image. One unique feature of this model is its utilization of Cross Attention to learn the spatial correspondence between the components of the content image and the reference image.

Specifically, Cross Attention is employed in the Style Aggregation Module, where the features of the content image serve as Query and the features of the reference image serve as Key and Value. Initially, the Query and Key are utilized to assess the similarity between the content and reference. For instance, when "盟" is used as the Query and "是" as the Key, the upper left portion "日" of "盟" is mapped to the upper part of "是," resulting in a matrix that emphasizes the pixels in the upper part of "是."



Once this matrix is obtained, the style of the part that is mapped to the Query is extracted from the corresponding Value. By extracting features from the reference image, specifically focusing on the style of the parts that exhibit similarity to the content, FSFont was able to generate a higher quality font compared to conventional methods.

B. Proposed Model

StyleGAN2 is one of powerful methods to generate high-quality images. However, to achieve the desired font character and style output, a pre-search for the character and corresponding latent variable is necessary. In the case of FSFont, in order to generate a font based on a specific content character, it is essential to pre-search for a reference character that corresponds to the content character and include it in the font to be generated.

The network architecture proposed in this paper is depicted in Fig.2. The Content Encoder used in FSFont is employed as the Encoder since it adequately reconstructs characters. In StyleGAN2, the input to the Synthesis Network was a constant value, but in this case, an Encoder-Decoder model structure was implemented by feeding the output of the Encoder into the input of the Synthesis Network.

The Mapping Network takes in noise that corresponds to class labels instead of random noise. This allows for the production of the intended font output. Additionally, we incorporated a StyleGAN2-ADA structure (Aug)[8] into our model, which aids in mitigating over-fitting by applying image augmentations to the inputs fed into the Discriminator. The

(a) The network structure of StyleGAN2 [7]

(b) The network structure of FSFont [3]

Fig. 1: Two DNN models we focused on

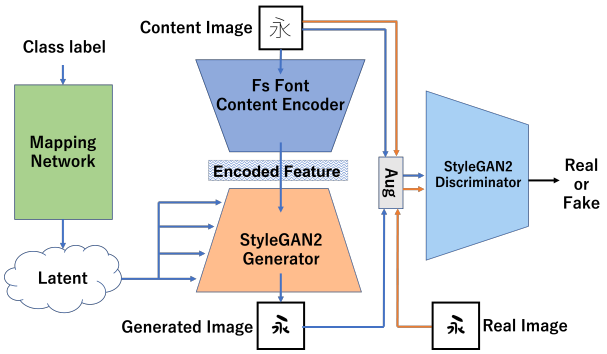


Fig. 2: Proposed Model

Discriminator receives either a combination of content images and a generator image (depicted by the blue line flow in Fig.2) or a combination of content images and a correct image (represented by the orange line flow in Fig. 2).

C. Loss Function

The loss functions utilized in this approach consist of the loss function from StyleGAN2 and the Content Consistent Loss from DGFont. The Content Consistent Loss is represented by equation (1).

$$L_{cnt} = \|f_c(I_c) - f_c(G(I_c, l))\|_1 \tag{1}$$

The f_c represents the Content Encoder, the I_c denotes the content image, the G indicates the Generator, and the l represents the class label. The equation (2) shows the entire loss function.

$$L = L_{StyleGAN2} + \lambda_{cnt} L_{cnt} \tag{2}$$

The λ_{cnt} denotes the weight of the Content consistent loss.

III. Experiments

In this section, we evaluate the model's performance in generating Japanese fonts. Firstly, we describe the training conditions, including the data set and hyper-parameters. Then, we report the training results in order of qualitative evaluation, quantitative evaluation, and font interpolation results.

A. training conditions

In this experiment, a total of ten fonts were used, consisting of one content font and nine style fonts. The font class labels and names, images are shown in Table I. For training data, a total of 2,284 hiragana, katakana, kanji, and alphabet characters were generated for each font. These images were then paired with the content font. Other training conditions were the same as those used in StyleGAN2. This includes a batch size of 32, Adam optimization method with beta1=0 and beta2=0.99, and a learning rate of 0.0025. The data set uses 128×128 gray-scale images. The output size of Content Encoder is 16×16, therefore, the StyleGAN2 network starts at 16×16.

B. Results

In order to compare our model to previous method, we selected two font generation models : zi2zi and DGFont. This is the reason why it is easy for not only our model but also these models to prepare the required data to train and test.

1) Qualitative evaluation: The comparisons of the generated fonts are shown in Table II.

From Table II(a), label 1 has blurred spikes in zi2zi and DGFont has distorted strokes in the upper part of the character, but the proposed model is able to reconstruct them well. Label 3, DGFont, has a loss of strokes, but the proposed model is able to reconstruct it. Label 7, zi2zi has blurred strokes, and DGFont cannot reconstruct triangular strokes, which is a characteristic of the font. The proposal improves on these failures. For label 8, the previous study failed to reconstruct the note shape of the top-right to bottom-left strokes, but the proposed model did. In Table II(b), zi2zi fails to reconstruct font features in labels 3, 6, 7, and 8, while DGFont fails to reconstruct strokes in labels 0 and 2, and font features in label 7. The proposed model has fewer missing strokes and reproduces font features correctly.

From on Table II(c), in label 6, the proposed model is able to reconstruct the upper left serif. In label 8, the previous study

8	utamin=plus=s6	永

(a) Generated Fonts **(b)** Real Fonts

Fig. 3: Font generation results

cannot reconstruct the note type, but the proposed model can. In Table II(d), the proposed model is the most successful in reconstructing the spikes in label 1. The proposed model can reproduce the blurring of font strokes in label 3. The proposed model can reproduce serifs in the upper left corner of the font, while the previous study cannot reproduce serifs in label 6.

A list of the font generation results is presented in Fig.3. It is evident that the generated fonts are of comparable quality to the correct fonts included in the font data.

2) Quantitative evaluation: For quantitative evaluation, we employed the perceptual metric called Frechet Inception Distance (FID) [9]. FID was proposed by Martin et al. as a measure to assess the quality of images generated by a GAN. It calculates the distance between two sets of images to quantify their dissimilarity. In order to calculate the FID, we compare two sets of images: a data set of real character images and a set of character images generated by the DNNs of each method. The process involves the following steps:

1) Compute feature vectors for the images using the image classification model Inception-v3 [10].
2) Calculate the mean and covariance of the feature vectors for each image set.
3) Compare the mean and covariance values between the two sets to determine their dissimilarity.

Considering the recommended guideline of having 10,000 or more samples in an image set for accurate FID calculation, we conducted the FID calculation using images generated with all labels instead of calculating it on a per-label basis. This approach ensures a sufficiently large and diverse set of generated images for a robust evaluation of the model's performance. Table III presents the results of the FID calculation. It is evident that our font generation method has achieved perceptually superior results compared to previous studies.

3) Font Interpolation: The font shape is interpolated by linear interpolation of the two latent variables. The interpolation formula is represented by equation (3).

$$I_{interpolated} = f_{styleGAN2}(t * f_m(l_1) + (1-t) * f_m(l_2)) \quad (3)$$

The l_1 and l_2 represents the class labels, the f_m represents the mapping network, the t represent the interpolation percentage, the $f_{stylegan2}$ represent the StyleGAN2 Generator. The result of interpolating the fonts of label 1 and label 3 is shown in TableIV. In the case of zi2zi, font collapse does not occur, but the intermediate font does not seem to reflect the characteristics of either label 1 or label 3. On the other hand, in DGFont, font collapse occurs during the interpolation process. In the proposed model, if we focus on the roof radical "宀", we can see that the spikes, which are a feature of label 1, gradually appear during interpolation. This indicates that the interpolation is more successful compared to the previous methods, demonstrating improved performance in capturing the desired font characteristics.

4) Discussions: We conducted the comparison experiment between the character images generated by our proposed model and those generated by the previous methods, which are zi2zi and DGFont. The results clearly demonstrate that our proposed model excels in reconstructing fine font features more beautifully. Remarkably, it effectively captures intricate details such as spikes in fonts with label 1, blurred letters with label 3, and musical note shapes with label 8. This achievement can be attributed to the network structure of StyleGAN2, which is adept at generating high-quality fine details in human faces. Such a structure proves beneficial for the font generation problem.

Furthermore, we observed a reduction in stroke loss and blurring of the generated fonts compared to the previous method. The utilization of L1 Loss as the loss function in the previous study tended to lead to blurring, and the misalignment of strokes in fonts with distorted strokes (e.g., label 0) resulted in unnecessary loss. In conclusion, our proposed model demonstrates the ability to generate cleaner and more practical fonts compared to the previous method. However,

TABLE III: Comparisons of FID

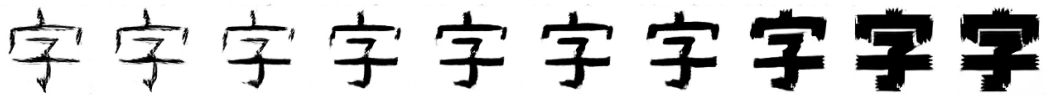
model type	FID
zi2zi	117.9732
DGFont	93.9091
Proposed model	**66.1377**

as indicated in Table II(d), there are still some issues that need to be addressed, such as the presence of unnecessary strokes in label 3, differing reconstruction in label 6 compared to the target, and insufficient feature reconstruction in label 7 and 8. Future work entails adjusting the hyper-parameters and enhancing the network structure to resolve these challenges and further improve the performance of the model.

In our previous work[1], we reduced the network size of zi2zi for the purpose of shortening the font generation time. Considering practical applications, it is better to be finished font generation as fast as possible. We compared the computational time for 1000 rendered font character generation with NVIDIA GeForce RTX 3070 GPU, and show it in Table V.

While zi2zi has a simple network structure that repeats convolutions, StyleGAN2 has a complex network structure that transforms latent variables and adjusts the weights of convolutions accordingly. This is the reason why our model takes time longer than zi2zi. Compared to DGFont, the generation

TABLE IV: Results of interpolation



t	0	1/9	2/9	3/9	4/9	5/9	6/9	7/9	8/9	1
zi2zi										
DGFont										
Proposed model										

TABLE V: Computational time for 1000 rendered font characters generation

model type	Computational time [s]
zi2zi	10.51
DGFont	18.83
Proposed model	**17.08**

time is shorter. This is because the amount of calculation of DGFont is large due to the encoding of the reference image, which procedure is not adopted our model.

IV. Conclusion

In this paper, we proposed a label-based font generation system aimed at expressing emotions through fonts. The experimental results demonstrate that by applying the StyleGAN2 network, known for its ability to generate high-quality images, to font generation, we can produce cleaner fonts compared to previous studies. However, as observed "a" of Table II(d), there still exist challenges in adequately reproducing certain fonts and characters. Improving upon this limitation is one of our future challenges.

***Abstract*—Residual blocks have been widely used in the single image super-resolution (SR), boosting the performance of SR results. The stacking of residual blocks helps to grab more information needed for the recovery of high-resolution (HR) images, but at the cost of larger model size and computational complexity. To address this problem, we propose a lightweight enhanced residual fourier transformation network (ERFTN). To ensure the network is lightweight enough while being capable of capturing both spatial and frequency information, we introduce a novel enhanced residual fourier transformation block (ERFTB) with an enhanced spatial attention (ESA) block. In addition, we adopt the contrastive loss for training acceleration without additional parameters. Extensive experiments demonstrate that our method can achieve SR performance superior to the state-of-the-art SR methods while reducing approximately half of the number of parameters (e.g., with 190K number of parameters, achieving 32.39dB in PSNR on Urban100 dataset).**

I. Introduction

Image super-resolution (SR) is frequently referred to as the process of recovering a high-resolution (HR) image from a given low-resolution (LR) image, which plays a vital role in the field of computer vision. SR has become a powerful tool in many real-world applications, such as medical image reconstruction and image quality improvement in surveillance and security fields. Given that not only the requirement of providing images with high fidelity is increasing, but also there is a growing demand of SR implementation in real-world scenarios, it is crucial to develop lightweight SR methods compatible with memory-constrained devices.

Currently, powerful deep learning techniques have been introduced into SR tasks to address the inherently ill-posed SR problems, boosting the performance of SR results from both the quantitative and qualitative views. As a pioneering work done by Dong et al. [1], the SRCNN first introduced a network structure with only three convolution layers and achieved better performance compared to traditional SR methods. Residual blocks (Resblocks), skip connections and attention mechanism had also been embedded into the network of SR models, like what EDSR [2] and RCAN [3] did, to further improve the SR performance. However, researchers noticed that for further improvements on SR performance, the network structure is not "the deeper the better", since the high-frequency details might be overlooked due to the learning bias towards low-frequency information. Meanwhile, the performance gain takes the cost of higher computational cost or memory usage, leading to limited application on low computing power devices.

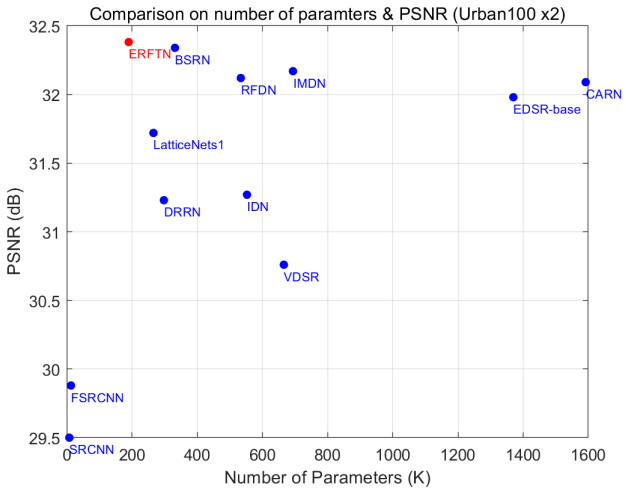

Fig. 1. Comparison on PSNR and number of parameters between the proposed and state-of-the-art SR methods on Urban100 dataset with scale factor 2.

To economize the number of parameters, deep recursive residual network[4] and distillation network [5]–[7] are introduced to SR models. However, we think that there is still space left for improving the accuracy of SR results while keeping the model lightweight with less FLOPs and fewer number of parameters.

Considering the wide use of residual blocks in the above-mentioned methods, we decide to propose a lightweight SR model, leveraging the merits of residual blocks. We design the enhanced residual fourier transformation network (ERFTN), with efficient plug-in residual blocks, enhanced residual fourier transformation block (ERFTB). The fast fourier transformation (FFT) branch in the residual blocks has shown its efficiency of capturing both high and low frequency information, as DeepRFT [8] has confirmed in the image deblurring tasks. Our proposed ERFTB combines the FFT branch with the normal convolution stream and an enhanced spatial attention (ESA) [9] mechanism, to make the SR model capable of capturing information of features in both spatial and frequency domains. Within the ERFTB, the ESA mechanism helps to enlarge the

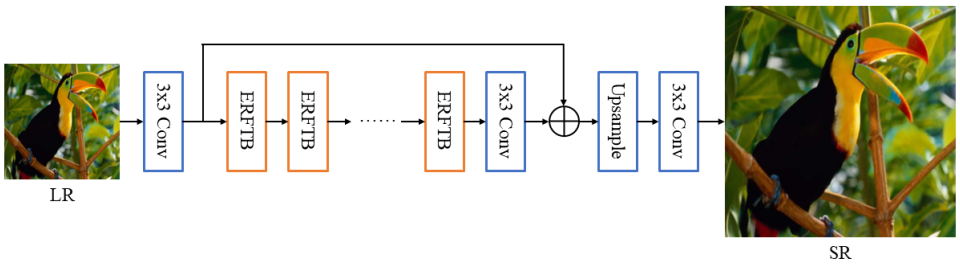

Fig. 2. The overall architecture of our proposed method ERFTN. ERFTB refers to the enhanced residual fourier transformation block.

receptive fields at the very beginning of the network without more parameters, and meanwhile, the low-frequency information is mined directly by the short skip connection structure. We also use depthwise over-parameterized convolution (DO-Conv) [10] to replace the traditional convolution layers in the residual blocks. DO-Conv could further shrink the model size and reduce the FLOPs. We additionally use a contrastive loss [11] for training acceleration, which can distinguish the positive and negative samples clearly during training.

As shown in Fig.1, the proposed method achieves better performance on PSNR while keeping the model lightweight compared to state-of-the-art methods.

II. Proposed Method

The overall architecture of our proposed method ERFTN is shown in Fig.2. We take EDSR [2] as the baseline and replace the residual blocks by our proposed ERFTB. With the simple but efficient structure, our method can achieve better SR results with fewer model storage consumption.

A. Enhanced Residual Fourier Transformation Block

We propose a new residual block Enhanced Residual Fourier Transformation Block (ERFTB), as shown in Fig.3, to replace the conventional residual blocks in the EDSR[2] baseline. ERFTB can integrate information from both spatial domain and frequency domain, supporting the SR result to be conformed to human perception and enjoy quantitative SR results improvements. ERFTB also has the merit of low computational cost, which supports the implementation of lightweight SR model.

1) Application of Fourier Transform:

Residual blocks have shown great success in computer vision problems from the low-level tasks to high-level tasks. The high-frequency information has always been treated carefully and make contributions to the SR recovering of features like edges and boundaries. However, if only the certain information is retaining, the learning bias will lead to severe distortion. Thus, it is important for the residual blocks to acquire a global learning skill.

Inspired by the success of Res FFT-Conv Block [8] in the image deblurring task and other adoption of frequency-aware network [12], we notice the ability of fast fourier transform

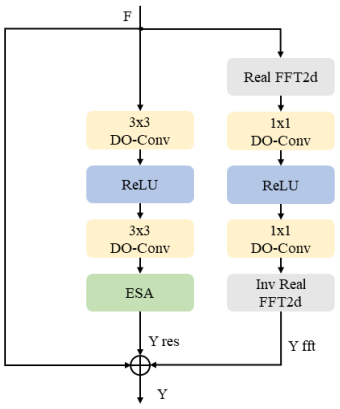

Fig. 3. Proposed ERFTB.

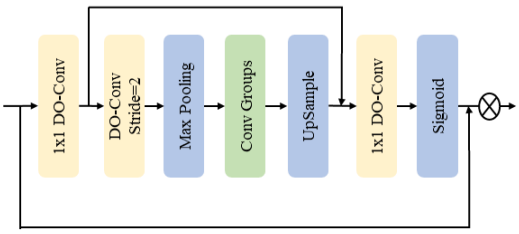

Fig. 4. Detail of ESA Block.

(FFT) [13] which can effectively integrate the frequency information without huge computations. We then produce the novel residual block ERFTB, as shown in Fig.3.

Based on the normal spatial residual stream of Conv-ReLu-Conv structure, we add the branch of FFT to compute the frequency information efficiently. Discrete Fourier Transform (DFT) is essential in the signal processing and Fast Fourier Transform (FFT) is a more efficient algorithm to count DFT according to the symmetric property of real array, and thus reduce the complexity. The 2D DFT is calculated as:

$$F(u,v) = \sum_{x=0}^{H-1} \sum_{y=0}^{W-1} f(x,y) \cdot e^{-j2\pi(\frac{ux}{H}+\frac{vy}{W})} \quad (1)$$

where j represents the imaginary unit; $H \times W$ denotes the image size; f is the input feature map and F is the output feature map. With the DFT transform, the output spectrum is

able to provide frequency from a global view.

The branch of FFT is processed as follows: First, applying the 2D FFT to the input feature $F_{input} \in \mathbb{R}^{H\times W\times C}$ to obtain the frequency spectrum $F_{fre} \in \mathbb{C}^{H\times W/2\times C}$. And then, since the real parts and imaginary parts can be separated in a complex tensor, we concatenate these two parts along the channel attention to acquire the representation of $\tilde{F} \in \mathbb{R}^{H\times W/2\times 2C}$. Subsequently, we apply Conv-ReLu-Conv to the $\tilde{F}$, and get the intermediate F_{inter} as:

$$F_{inter} = Conv(ReLU(Conv(\tilde{F}))) \tag{2}$$

where $Conv()$ denotes the 1×1 DO-Conv layers. Later, we reconstruct the complex tensor as $\widetilde{F_{fre}} \in \mathbb{C}^{H\times W/2\times C}$ by the processed real and imaginary parts as follows:

$$\widetilde{F_{fre}} = Real(F_{inter}) + jImg(F_{inter}). \tag{3}$$

Finally, we apply the inverse 2D FFT (IFFT) to $\widetilde{F_{fre}}$ to transform it back to the spatial domain, of which the output feature of FFT branch is $F_{out} \in \mathbb{R}^{H\times W\times C}$.

2) Application of Attention Mechanism:

Since the effectiveness of attention module has been proven [3], [6], [9], in this paper, we introduce the enhanced spatial attention (ESA) block to our approach. The detail of ESA Block is shown in Fig.4.

Compared to channel attention, we apply ESA Block to achieve a better performance on model complexity. ESA block is used for enlarging the receptive field quickly at the beginning of the network and ensuring the model being compact. The attention block is added to the end of each residual block, so that it should be lightweight enough, otherwise after the cascading of residual blocks, the computational cost would be overwhelming.

Note that we replace all the convolutional layers in ESA with DO-Conv [10] for a further decrease of model size. The main difference between ESA and CA is that ESA starts with a 1×1 convolutional layer, which largely reduce the channel dimensions at the very beginning, and thus keeping the whole module extremely compact. Then, a strided convolution with stride 2 and a strided max-pooling layer with large kernel size of 7×7 are used to enlarge the receptive field and to reduce the spatial size. Subsequently, the feature is processed by a group of convolutional layers, after which is an up-sampling layer and a 1×1 convolutional layer. Finally, HR features are combined directly through the skip connection when a sigmoid layer is then applied to generate the attention matrix.

The structure of ERFTB with inserted FFT branch and ESA Block, can not only reduce the number of parameters, but also bring the performance gain. Compared to ResBlocks in EDSR, the effectiveness of ERFTB is shown by the visualized feature maps in Fig.5. Our proposed method can obtain more frequency information effectively, ensuring that both high and low frequency information are adequately represented and not overlooked.

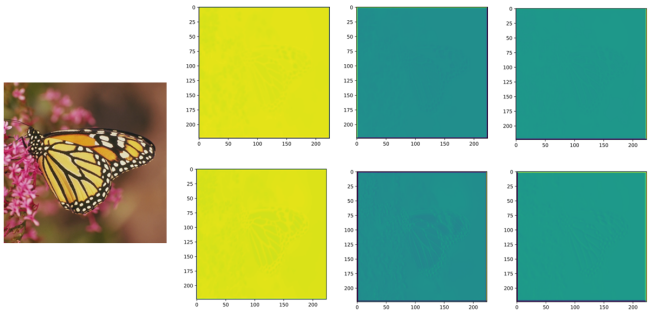

Fig. 5. Comparison of visualized feature map generated by layers 6,7 and 11 in the EDSR and ERFTN for image 'monarch' on Set 14. The upper row represents EDSR and the bottom comes from ERFTN.

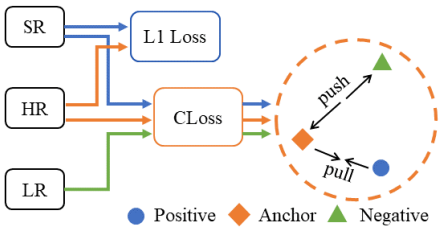

Fig. 6. The principle of contrastive loss.

B. Framework of enhanced residual fourier transformation network (ERFTN)

Learning from the prominent success of EDSR [2], we construct our framework based on the EDSR baseline for accurate and efficiency image super-resolution. As shown in Fig.2, we replace all the residual blocks by our proposed ERFTB. For a fair comparison to other state-of-the-art methods, we maintain the standard ERFTN model with 32 ERFTBs and the baseline model with 16 ERFTBs.

Depthwise over-parameterized convolution (DO-Conv)

DO-Conv [10] augment the convolutional layer with a depthwise convolution operation, which helps to achieve better performance and to accelerate the training process. To ensure the lightweight SR model could enjoy wider applications, we adopt DO-Conv without additional parameters.

Meanwhile, since the interface and receptive field of DO-Conv is the same as traditional convolutional layer, it can be easily applied in ERFTB, resulting in the same computational cost at the inference phase. We find that by employing DO-Conv, the number of parameters of our baseline with scale factor 2 can be reduced from 0.38MB to 0.19MB while achieveing slight improvements in PSNR.

C. Contrastive Loss

Normally, L1 Loss and MSE Loss are used to train SR model, of which the upper bound of the solution space is focused while the lower bound tends to be neglected. Considering contrastive loss (Closs) has already been proved to be efficient in many computer vision tasks, we introduce contrastive learning [11] into SR, which can separate the samples clearly and accelerate the training process.

Fig. 7. Visual comparison on Urban100 dataset with scale factor 4.

The specific representation of contrastive loss is shown in Fig.6. In SR, the positive sample is defined as the output of SR result, the anchor denotes the ground truth, which is the HR image, and the negative sample is defined as LR image, the Bicubic. We aim to pull the anchor closer to the positive sample while push the anchor far away from negative samples. Based on the Euclidean distance [11], Closs is calculated as:

$$L_{Closs}(W, Y, \vec{X_1}, \vec{X_2}) = (1-Y)\frac{1}{2}(D_W)^2 + (Y)\frac{1}{2}\{max(0, m - D_W)\}^2 \quad (4)$$

where D_W is the shorten notation of $D_W(\vec{X_1}, \vec{X_2})$, the Euclidean distance between two outputs; Y denotes the label, of which equals to 0 when two samples are similar and equals to 1 when two samples are dissimilar; $m > 0$ is the margin. We add a hyperparameter $\alpha = 0.1$ into Closs to control the distance between positive and negative samples in case the distance between positive samples and anchors keeps decreasing to a point where it fails to maintain the Closs to be positive. The overall loss function is as follows:

$$L = (n-t)L_1 + tL_{Closs} \quad (5)$$

where we set $n = 20$ and $t = 0.1$ based on the validation results.

III. Experiments

A. Datasets and Evaluation Metrics

Our model is trained on 800 images from DIV2K [14], which is commonly used in SR. Considering the diversity, there are various contents in DIV2K, such as people, environments, flora and fauna, handmade object, and natural scenery, etc. Four standard benchmark datasets, Set 5 [15], Set 14 [16], B100 [17] and Urban 100 [18] are used for testing. Set5 has five popular images in the field of computer vision. Set14 contains 14 commonly used images in the field of image processing. B100 contains more pictures related to real-world scenarios, like human and animals. Urban100 is a very typical dataset, which contains 100 clean images of urban environments, especially with buildings full of edges. The diversity of these four datasets helps to form an overview towards the effects of the SR model.

We compare the SR results from both qualitative and quantitative comparisons. For the quantitative part, we calculate PSNR and SSIM on the Y channel of YCbCr color space. The computational cost is evaluated by the number of parameters and FLOPs.

B. Implementation Details

In the training process, 16 images with patch size 48×48 are prepared as an input batch. Data augmentation includes random rotation by $90°$,$180°$, $270°$ and horizontal flipping. We use ADAM [19] optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 10^{-8}$. The learning rate is set as 10^{-4} and reduced to $5 \cdot 10^{-5}$ after 200 epochs. The total training stops at 300 epochs. We set the ERFTB as 16 as the ERFTN baseline, and ERFTB as 32 as ERFTN+. The model in Pytorch framework is conducted on the NVIDIA GeForce RTX 3090 GPU.

C. Comparison with the State-of-the-arts

To demonstrate that our proposed ERFTN can achieve better balance between the accuracy and efficiency, we conduct extensive experiments and compare with 11 state-of-the-arts lightweight SR methods: SRCNN [1], FSRCNN [20], VDSR [21], DRRN [4], IDN [5], EDSR-Baseline [2], CARN [22], BSRN [7], IMDN [6], PAN [23], LatticeNet [24]. The results are shown in Table 1. Meanwhile, in Table 2, we compare our ERFTN to 3 latest prominent SR model, RCAN [3], NLSN [25], ENLCN [26] on the upscaling factor 4 to show that our method can acquire notable and even higher SR results with an extremely small model size.

The quantitative results in Table 1 demonstrate the effectiveness of our lightweight model, which can achieve higher

performance with compact model size especially in large scales. We adopt a further comparison with SwinIR [27], a very powerful latest SR model. On scale factor 4, our ERFTN only uses 340KB to achieve 27.67dB in B100 dataset, while lightweight SwinIR requires 897KB to achieve 27.69dB, which demonstrates that our model can keep lightweight while achieving competitive SR results. Our performance gain is particularly clear in dataset B100 and Urban100, which shows the promising application of our model in real-world scenarios.

Fig.7 shows the qualitative comparison results on Urban100. Our proposed method is able to reconstruct the SR images which are more faithful to the ground truth with more detailed information. Especially when conducting on lines and edges,

t \ n	1	5	10	12	15	19	20	40	60	100
0.1	37.944	38.045	38.048	38.069	38.051	38.062	38.078	38.065	38.051	38.058

our method can produce lines in correct directions, while other methods may meet the problem of misleading results.

Table 3 compares the FLOPs and number of parameters cost by SR models with scale factor 2. It is obvious that our ERFTN largely reduces the FLOPs and uses the fewest number of parameters. The comparisons between other lightweight SR methods are shown in Fig.1. As a lightweight SR method, our model achieves a best trade-off between model accuracy and efficiency.

D. Ablation study

We conduct the ablation study of ERFTB on Set 5 dataset with scale factor 2 in Table 4. CA refers to the channel attention, which has commonly been used as the attention mechanism in SR models, like RCAN [3] and FADN [12]. The first and second column shows the effectiveness of applying ESA block. The adoption of DO-Conv on both FFT branch and ESA block can achieve the best results in PSNR and model size. The further implementation of Closs can introduce more performance gain without additional parameters, and what's more important, the training speed will decrease from 7.5 seconds to 5.2 seconds per epoch.

It should be noticed that the different combinations of hyperparameters in Closs will lead to different results, and sometimes even worse results. The experiments on Set 5 dataset $\times 2$ are shown in Table 5. As a result, we select n as 20 and t as 0.1 in our model. With reasonable selected parameters, the introduction of Closs could accelerate the training process and provide improvements in quantitative results.

IV. CONCLUSION

In this paper, we propose a novel enhanced residual fourier transformation network (ERFTN) for lightweight image super-resolution. The proposed enhanced residual fourier transformation block (ERFTB) with a FFT branch and an ESA attention mechanism can maintain more useful information in both frequency and spatial domain, leading to a better performance of SR results. The adoption of DO-Conv and contrastive loss can help to keep the model lightweight and accelerate the training process. We achieve satisfying trade-off between model accuracy and computational cost. Experiments on four datasets show that our method can provide promising SR results while having an extremely compact model size.

Different from other Speech2Face methods, the* ***ELEGANT*** *model performs a text grounding of the audio signal to mitigate any sources of noises (refer to § III), and to eliminate any possibility of hate speech to promote robustness and fairness in generative AI.*

***Abstract*—Existing speech driven talking face generation methods (*a.k.a* Speech2Face models) provide realistic-looking talking avatars. Yet, they are not appropriate if (1) the input speech signals are from the wild which could contain background noise; and (2) the input signal contains hate speech. In the presence of in-the-wild audio signals, the Speech2Face models do a bad lip-sync, unwanted facial movements, and sudden jitters on the head movements. While on the other hand, the Speech2Face models do not perform any reasoning on language understanding of input speech signal which could enable malicious users to translate hateful speech to a synthetic talking face promoting internet, social, and political threats. In this paper, we serve dual objectives on a single go. To the best of our knowledge, our method ELEGANT is the first Speech2Face generative model that performs a language grounding on the input speech that eliminates the transfer of spurious features originating from audio noise. Subsequently, the text embedding is associated with the speech style and passed on to a generative model with a view to learn the phoneme-viseme correspondence. In this way, our proposed ELEGANT model suppresses negative and hateful words using text embedding and also suppresses audio-specific noises using text embedding since noise-to-phoneme mapping would be random. Our experiments show that adopting the speech-denoising technique through text grounding eliminates the transfer of spurious features originating from audio noise to the vision domain. Consequently, a good phoneme-viseme correspondence leads to a comparable performances of SSIM and PSNR scores w.r.t state of the art methods.**

I. Introduction

Speech driven talking face video generation, i.e., Speech2Face, is a multi-modal generative model that translates speech signals to talking human faces with a realistic looking

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

facial expressions, head movement, eyebrow movement while lip-syncing the input speech to the generated talking face. However, we note that such Speech2Face models do not provide good generation if the input speech signals are from the wild. In the wild speech signals generally contain a lot of different types of background noises such as pure Gaussian noise, salt-and-pepper noise, etc., that a speech-capturing device such as a microphone might induce. While, surrounding noises such as wind blowing, baby crying, etc., are also considered as structured noise that comes in addition to the speakers' voices onto the in-the-wild audio. The generated talking face videos provided by the Speech2Face models do a bad lip-sync, unwanted facial movements, and sudden jitters on the head movements in the presence of noisy input speech signals. If we can still ignore such error provided by the Speech2Face generated model, any malicious user could provide harmful hate-speech audios and possibly get corresponding generated talking face. As a consequence, understanding the language of the audio should be a *must* for generating talking face videos otherwise it could harness serious ethical and societal concerns of responsible generative AI models.

To answer this question, we adopt two guiding principles:

Principle 1: ***The Speech2Face model must do away with any sources of background noises to generate talking face videos with realism and proper lip-sync without losing input audio quality*****.**
Principle 2: ***The Speech2Face model must understand the meaning of words of the spoken audio inputs to mitigate negative or hateful words that would negatively translate to talking face generation*****.**

We note that Principle 1 helps to mitigate any sources of in the wild noise [1]. Principle 2 promotes fairness in audio-driven talking face generation.

To this end, we propose a diffusion generative model based [2] Speech2Face model ELEGANT, aka End-to-end Language Grounded Speech Denoiser for Efficient Generation of Talking Face Videos, that aims to solve the challenge of talking face video generation, v, given a noisy input speech signal, s, to model $P(v|s)$. Different from the other Speech2Face models, we are first one to apply a comprehensive text grounding of the input in-the-wild audio signal, i.e., $P(v|s)P(\tilde{s}|t)P(t|\hat{s})$, where $\hat{s}$: noisy speech signal, $\tilde{s}$: reconstructed denoised speech signal through text grounding, and t: generated text from $P(t|\hat{s})$ later used by $P(\tilde{s}|t)$. Text grounding of the input signal is one of the main contributions of the paper and a novel contribution as far as we know.

We now describe each component of the $P(v|\tilde{s})P(\tilde{s}|t)P(t|\hat{s})$ model in below paragraphs:

Text Grounding of Input Audio Signal, $P(t|\hat{s})$: To do the diffusion based ELEGANT model audio to text grounding, i.e. , the methodology first gets the in-the-wild audio signal $\hat{s}$, encodes that to get the corresponding text. Hence, the ELEGANT considers the text grounding of the audio denoising as a language modeling task rather than continuous signal regression adopted by previous method [3]. The noisy speech signals are passed to the Silero based [4] speech-to-text model.

Personalized audio generation, $P(\tilde{s}|t)$: To model the $P(\tilde{s}|t)$, the generated text, t, is passed to a personalized text-to-speech decoder, $P(\cdot|t)$, that jointly trains a neural codec language model [5]. The neural codec language model provides an acoustic code matrix which is later passed to a LSTM based Grapheme-to-phoneme so as to get the phoneme sequence. Reference speech signal, i.e. the personalized audio signal, is provided to the text-to-speech decoder along with the generated text so that the decoder can learn the content and the speaker-specific styles, see Fig. [1].

Audio Driven Talking Face Generation, $P(v|\tilde{s})$: The denoised speech is then passed to the taking face generator module, i.e., $P(v|\tilde{s})$. Our methodology leverages the diffusion based "Sadtalker" [2] for the purpose of Speech2Face modeling. The Sadtalker model jointly trains identity-specific information such as pose and facial movements and a non-identity space such as texture, color, background, and facial structure information. The audio encoder of Sadtalker learns the 3D facial coefficients to represent the intermediate facial motion representation. The facial expression and head pose are generated from the audio which then are used to model final talking face video using a 3D-aware face render.

Surely, we are not the first to propose multimodal grounding. Our sister domains, such as [6] have shown promise by leveraging on the correspondence text to the image for captioning, clean audio-to-text for language modeling, and image-to-video for video understanding. However, we are the first to propose text grounding of noisy speech signals that not only denoises a noisy speech signal but retains meaningful language and emotion-specific information for a good quality audio-driven talking face generation. Our contributions are:

1. Text-Grounded Audio Driven Speech2Face Generation, to the best of our knowledge, we are the first one proposing text-grounded Speech2Face model. We show that the proposed Speech2Face model could mitigate any background noise using reasoning on language understanding of input speech.

2. Remove of Hate-speech to Promote Fairness, ELEGANT understands the language-specific information by learning a joint space of audio and text embedding. The learned joint space helps the ELEGANT model to suppress any form of negative, hateful, and biased words, thus promoting fairness.

3. High Quality Speech2Face Generation, using the 3D facial coefficients to represent the intermediate facial motion representation. The facial expression and head pose are generated from the audio which then are used to model final talking face video using a 3D-aware face render.

II. Related Work

Personalized Speech2Face models. The early research in Speech2Face is attributed to synthesizing-Obama [7] that uses more than 20 hrs of Obama's speeches. In recent years, the LSP has generated talking heads only from speech signals at over 30fps. Other works, such as [8], use audio signals to provide personalized Speech2Face generations using generative adversarial networks.

Speaker agnostic Speech2Face models. Speaker agnostic Speech2Face works such as Wav2lip [9], Audio2head [10], audio-to-face from arbitrary video generate talking faces by learning styles from a reference video and speech signals. Meanwhile, face re-enactment work [11] use a source video to style transfer the head motion to an identity.

Text grounding methods. Text grounding for audio signals [6] has shown promise by leveraging the correspondence between sound events and the captions provided. Similarly, the text grounding has shown significant improvement in video-grounded understanding [12]. Text grounding in image understanding [13] talks about the use of text descriptions that serves as an interpretation to qualitatively measure the rationality and model transparency. Similar to this, our work adapts text grounding involving semantic dependencies of text and speech signals to understand the interactions between text modality, speech, and video-specific dataset biases such as background noises, speaker head movements, non-agnostic user-specific styles, and stereotypes.

III. Methodology

Our goal is to learn the parameters of an audio-driven talking face generator, i.e.;

$$P_\theta(v|\hat{s}); v: \text{video}, \hat{s}: \text{noisy speech}, \theta: \text{parameter} \quad (1)$$

that is robust to noisy speech inputs.

Noisy Speech Signal, $\hat{s}$: We consider three major types of noisy speech, i.e. (1) background noises such as pure Gaussian noise, salt-and-pepper noise, etc., that a speech-capturing device such as a microphone might induce; (2) surrounding noises such as wind blowing, baby crying, etc., are also considered as structured noise that comes in addition to the speakers' voices onto the in-the-wild audio; and (3) the hate-speech provided by malicious user to the Speech2Face model.

The existing methods, that we discussed in Sec. II, encode both speech s and the noise ϵ, i.e., $\hat{s} = (s + \epsilon)$, that does not correctly translate the actual content of the speech and vaguely translates the noise component to the generated talking face. This produces poor-quality talking face videos with sudden head movements, bad lip sync, unnecessary eyebrow movements, and jitters in the background.

In this work, we leverages a speech denoiser $P_\psi(s|\hat{s})$ parameterized by ψ produces a cleaner version of the noisy image changing our Eqn. 1 to the following;

$$P_\theta(v|s)P_\psi(s|\hat{s}) \quad (2)$$

However, existing denoisers do not scale for in-the-wild noises or change, mask, or alter different language cues such as utterances, pauses, or emotions of spoken words. Our proposed methodology ELEGANT model considers an alternate text grounding way of denoising that poses speech denoising a language modeling task rather than a continuous speech signal regression task that provides high-quality talking face videos.

Without the loss of generality, the noisy speech signal $\hat{s}$ is first text grounded with an encoder $P_\beta(t|\hat{s})$ and then the generated text t is passed to the personalized text to speech decoder $P_\alpha(\tilde{s}|t)$. Thus, changing our Eqn. 1 to the following:

$$\begin{aligned} P_\theta(v|s)P_\alpha(\tilde{s}|t)P_\beta(t|\hat{s}) & \\ &\equiv P_\theta(v|s)P_\psi(s|\hat{s}) \\ &\equiv P_\theta(v|\hat{s}) \end{aligned} \quad (3)$$

The text-to-speech encoder $P_\beta(\cdot)$, quantizes noisy speech signals into discrete acoustic codes [4], i.e. $Encodes(\hat{s}) = C^{T\times 8}$, where C is the codec matrix, T is the downsampled uttrance length, and the 8 represents the eight codes for frame $t \in T$. The row vector of C represents eight codes of a frame, while the column vector represents the code sequence from the codebook, as shown in [5]. The discrete acoustic codes are then jointly trained with a phoneme-acoustic language model to get the text output.

The personalized text-to-speech decoder $P_\alpha(\cdot)$, on the other hand, gets the generated text from $t \sim P_\beta(\cdot)$ and provides the corresponding phoneme, i.e. $\mathbf{x} = \{x_0, x_1, \cdots, x_L\}$, using an LSTM based Grapheme-to-phoneme network [14]. Our personalized text-to-speech decoder $P_\alpha(\cdot)$ captures speaker-specific styles using clean, prompt audio of the user, see in Fig. [1]. The style prompt audio, i.e. s_{prompt}, is quantized into discrete acoustic codes, i.e. $Encodes(s_{prompt}) = \tilde{C}^{T'\times 8}$. The personalized text-to-speech decoder $P_\alpha(\cdot)$ generates the codec matrix C given the phoneme sequence $\mathbf{x}$ and the acoustic prompt matrix $\tilde{C}$, i.e.;

$$P_\alpha(C|\mathbf{x}, \tilde{C}) \quad (4)$$

The clean speech signal is generated back with a neural codec decoder that is able to reconstruct the waveform, i.e., $Decodes(C) = \tilde{y}$ where $C \sim P_\alpha(C|\mathbf{x}, \tilde{C})$. The speech modality maps syntactic and semantic representations to the text but fails to pick up audio-specific noises since noise-to-phoneme mapping is random.

Audio-driven talking face video generation, $P_\theta(v|s)$, model is inspired by the SadTalker model [2]. We assume to have a single image deep 3D reconstruction method [15] called 3D Morphable Models (3DMMs) to get the representation. In 3DMM, a face shape is modeled as a linear combination of average shape of the 3D face $F^{'}$, orthonormal basis of identity αF_{id}, and expression F_{exp}, i.e.,

$$F = F^{'} + \alpha F_{\text{id}} + \beta F_{\text{exp}} \quad (5)$$

The values of $\alpha \in R^{80}$ and $\beta \in R^{64}$ is taken from the LSFM [16] model. After that, the motion of the head pose and expression using the proposed PoseVAE and ExpNet

as described in [2]. Then, a 3D-aware Face Render [17] is used to render the 3D facial video. Similarly, one can use other Speech2Face model such as PC-AVS [18] method. The PC-AVS method modularizes the representation of human talking faces into speech content, identity space, and head pose by devising a compact pose code. This modularization is implicitly and complementarily learned within a construction-based framework using modulated convolution. Moreover, it is trained on five losses, (1) the generative adversarial loss $\mathcal{L}_{GAN}$ that provides a learning signal for overall frame by frame quality; (2) the identity loss $\mathcal{L}_i$ is a softmax cross entropy loss that preserves the identity of an actor; (3) the speech content loss $\mathcal{L}_c$ which is a contrastive loss that seeks the synchronization between audio and visual features by leveraging a negative and positive set of audio and visual feature pairs; (4) the $\mathcal{L}_{VGG}$ is the perceptual loss that relies on a pre-trained VGG network; (5) the $\mathcal{L}_1$ loss computes the $\mathcal{L}_1$ distance between the generated frames of the video and actual frames of a real video.

We note that our proposed text grounded Speech2Face ELEGANT model not only work well with PC-AVS but it can be incorporated with any other framework. In Sec. IV, we illustrate some ablation studies that shows the feasibility of using our text-grounded speech denoiser to other state-of-the-art methods.

IV. Experiments

Dataset Curation and Pre-processing: We leveraged our clean video dataset from the open source project page of [21], retaining the subjects in the video but only changed the video source. Our preprocessing involves cropping the videos in three-second clips. The noisy speech of the above mentioned videos are created following [22], wherein a noise from ten categories of Urbansound8K [23] dataset is overlaid on the clean speech signals. For each noise category of Urbansound8K, over 3000 recordings are downloaded and manual checking is done before Audacity is used to label the start and end times of every occurrence of the sound in each recording [23]. This is done with repetition to create 3 noise classes: Class0-Air conditioner noise, Class1-Car horn noise and Class2-Children playing. In addition, we have Class G-Unstructured Gaussian noise sampled using PyTorch. Unstructured noise do not require any dataset any could be generated using PyTorch packages [24]. We use Urbansound8K [23] that contains 27hrs of audio with 18.5 hrs of annotated sound event occurrences across 10 sound classes such as air conditioner, car horn, children playing, dog bark, drilling, gun shot, etc.

The Baselines Methods. For the purpose of understanding the effect of inducing noisy signals into speech signals on the talking face generation, we have broadly divided the baselines into methods that disentangle speech signals to obtain the content and speaker-specific signals and methods that do not. We run our experiments on the pre-trained models (code sourced from the respective repositories) on the videos in the wild collected as above.

- *Methods w/o Speech Disentanglement*
  1. **PC-AVS** [18] proposes pose-controllable talking face generations. The speech features and the visual features are embedded in the time-based feature space. Thus altering the speech signals will also affect the visual features.
  2. **Wav2Lip** [20] proposes an efficient lip-sync method for videos in the wild. During training, the speech encoder is tuned to generate realistic faces i.e. faces of good visual quality. Thus noisy speech features have the ability to hamper the quality of the generated faces.
  3. **Audio2Head** [10] makes use of keypoint-based dense motion fields to generate realistic and natural head movements for talking face generations. The acoustic features are used in generating the head poses and the keypoints of the facial movements.
- *Speech Disentanglement Based Methods*
  1. **Live Speech Portraits**(LSP) proposes a personalized talking face generative model. It uses APC (Autoregressive Predictive Coding) [25] to learn semantic speech embedding based on speakers' speech content. APC learns a speech based language model by trying to generate speech frames conditionally.
  2. **MakeitTalk** [19] proposes a speaker-independent Speech2Face model that provides Speech2Face videos understanding content and speaker specific features. The content specific audio features are only used to generate the lips and surrounding regions and the speaker specific features are used to generate other facial engagements.

Discussion on Quantitative Results: SSIM and PSNR are adopted to understand the generated video qualities and the results are in Table I. Four types of noises namely Noise-0: air conditioner noise, Noise-1: car honk, Noise-2: children playing, and Noise-G: Gaussian noises are overlaid on input speech signals. Our proposed text grounded speech denoiser provides comparable performaces when applied to PC-AVS, Wav2Lip, and Audio2Head, showing the efficacy of our method. Please note that the baseline denoisers are trained on custom noise categories but our method is generalizable across noises without further training on noise categories. We employ two video quality metrics, SSIM and PSNR to understand effects of noisy speech signal towards noisy video generation. Table I shows the results on four noise types. In the first three models we see that the text-grounding based denoising performs as close to a custom denoiser trained on the specific noise [22]. Interestingly, the denoisers are quite ineffective at denoising unstructured noise, as evidenced by the comparison between Denoised-G and TG-G. MakeitTalk and LSP are unaffected by noise induction as they have phoneme based speech disentanglement procedures. Methods not employing speech disentanglement use entire speech feature space to derive structural characteristics of the face. Thus small perturbation in the speech signal could be multiplied many folds translating into spurious audio-visual features. This results in unwanted jitters, and eye and hair movements.

Fig. 2: **Lip-sync qualitative comparison:** We use noisy speech signal, i.e. input with car horn noise, from Urbansound8K dataset. We note that the face generate by ELEGANTmodel is similar to ground truth. But, other methods such as **PC-AVS** [18], **MakeitTalk** [19], **Wav2Lip** [20], **Audio2Head** [10].

TABLE I: Quantitative comparison of the state-of-the-art methods. **Unaffected Models**: Since MakeitTalk [19] and LSP [21] employ speech disentanglement that dampens spurious audio-visual correlations, this results in good quality of generations. **Noise-0**: air conditioner noise, **Noise-1**: car honk, **Noise-2**: children playing, **Noise-G**: Gaussian noise, **EG**: Proposed ELEGANT model, **Denoised**: Custom denoisers trained on specific noise type [22].

between those who were _idiots_ and those who are not
between those who were _[MASK]_ and those who are not
between those who are _prospering_ and those who are not
between those who are not good and those who are not

TABLE II: **Fairness**: The language grounded speech denoiser of ELEGANTcould replace negative words, for example “idiots” either with other words or blank.

Discussion on Qualitative Results: The Fig. 2 shows a qualitative comparison among noisy audio, denoised audio, and text grounded audio (our method) of PC-AVS method. We note that other Speech2Face models have achieved bad SSIM and PSNR scores w.r.t our ELEGANTmethod. Also, the other state-of-the-art methods produce bad lip sync and eyebrow movements which are crucial for Speech2Face models.

V. Fairness of the ELEGANT model

The main job of the ELEGANT model is more than generating *only* high quality Speech2Face videos from noisy speech signals. To promote fairness in the Speech2Face domain, the ELEGANT model must understand speech signals to avoid denoising a speech signal that contains negative or hateful words; which would later be used for personalized Speech2Face videos. Similar to the work proposed in [26] that provides ways to mitigate hate words within a text document by remapping them through text embedding, ELEGANT could remap negative and hate words by leveraging the joint acoustic and text embedding. This is illustrated in Table II.

VI. Conclusion

In this work, we propose a Speech2Face model called ELEGANT that provides fair high quality audio-driven talking face videos given noisy speech or spoken signals that contains negative and hateful words. The ELEGANTconsiders understands the (noisy-)speech using a language model and suppresses any form of background noise, negative, or hateful words within the speech, thus promoting fairness in Speech2Face domain. Our experiments exhibit that adopting speech denoising technique provides high quality Speech2Face videos.

ACKNOWLEDGMENT

This research was supported in part by the Malaysia Ministry of Higher Education (MoHE)'s Fundamental Research Grant Scheme (FRGS) under the AdverSurreal project FRGS/1/2021/ICT02/MUSM/01/1. Experimentations were run on Montage, the Monash University Malaysia campus HPC platform. We acknowledge the reviewers whose comments and suggestions significantly enhanced this manuscript.

***Abstract*—Iris recognition is a prominent technique in biometric identification due to its robustness and distinctive features. However, challenges in iris segmentation, including limitation of sensors, occlusion, and inconsistent lighting, significantly impact the accuracy and efficiency of the recognition. Therefore, this paper proposes improving iris segmentation by incorporating a technique known as Unit Gradient Vectors (UGVs) into the traditional preprocessing stage. The UGVs at each pixel provide edge direction, enabling the accentuation of areas with significant directional changes. Thus, a more robust and correct edge detection from inconsistent lighting images can be obtained. An experiment was conducted using the CASIA-Iris-Lamp, which has challenging lighting conditions. Results suggest that the proposed method achieves superior performance compared to the existing method. The accuracy, false acceptance and rejection rates were improved by 2.04%, 10.00%, and 7.33%, respectively. Specifically, the equal error rate was dramatically improved by 37.78%. These promising results can contribute to advancing security and efficiency in iris recognition systems.**

I. Introduction

Biometric recognition systems offer a crucial alternative to traditional security methods reliant on passwords or physical keys. These systems leverage unique physiological or behavioral characteristics, providing intrinsic and readily accessible identity verification. Among the various biometric modalities, irises have garnered significant attention due to their superior degree of uniqueness and stability throughout an individual's life [1]. Iris recognition uses intricate patterns within the iris, the ring-shaped region surrounding the pupil, to distinguish individuals. According to its reliable and robust identification, it has been reported as exceedingly low false match rates [2].

Despite the promise of iris recognition, challenges persist. The acquisition of high-quality iris images, for instance, is often a significant hurdle. If iris images are captured with low-quality sensors, the images may be noisy, blurred, or low contrast, which could lead to identification errors and false positives. Such challenges can adversely impact the security and efficiency of various sectors that rely on these identification mechanisms.

In addition, one critical aspect of iris recognition is the accurate segmentation of the iris within an image. Segmentation involves detecting the iris's inner and outer boundaries accurately. Precise segmentation is pivotal to eliminating noise and artifacts from the surrounding eye, such as the sclera and eyelids. Inaccurate segmentation can introduce spurious features, which can significantly reduce the overall performance of the iris recognition system. However, achieving accurate iris localization is far from straightforward. Factors such as occlusion by reflections, low resolution, noises, and unpredictable lighting conditions introduce considerable difficulties. The most challenges often arise when dealing with iris images under varying lighting conditions.

Numerous segmentation methods have been proposed to improve the precision of iris localization. Traditional methods such as Daugman's algorithm [3], circular Hough transform [4], and active contour [5] employed fitting methods based on circle or ellipse shapes to localize iris and pupil regions. Recently, many image processing techniques and machine learning algorithms have been proposed [6]–[8]. Notable contributions include the application of the Hough transform and Canny edge detector [7] and the convolutional neural networks (CNNs) used for iris segmentation [8].

In the pursuit of more precise edge detection mechanisms, the utilization of unit gradient vectors (UGVs) has been proposed for accurate edge detection [9]–[11]. UGVs offer an effective way to quantify the directional changes in an image, thereby enhancing edge detection capabilities. They capture and vectorise changes in pixel intensity, facilitating the handling of intricate patterns in iris textures.

Therefore, we aim to investigate the potential of utilizing unit gradient vectors to improve the process of iris segmentation under the ongoing challenge in the field, i.e., lighting inconsistency. As a result, this study focuses on enhancing the iris localization techniques in a traditional iris recognition system. We propose a more robust method for accurately localizing the iris, thereby improving the robustness and accuracy of iris recognition systems overall. Hence, this research contributes to developing a more efficient iris recognition system applicable to real-world scenarios.

This paper is organized as follows. The traditional iris recognition process is introduced in Section II. Section III describes the proposed method. Section IV presents the experiment and result. Lastly, section V and section VI discusses and summarizes key points of this study.

II. Iris Recognition

In this section, the conventional approach used in the iris recognition process is explored, starting with the fundamental step of image preprocessing. This stage is set as the foundation for subsequent procedures, playing an essential role in determining the subsequent process of recognition.

A. Image Preprocessing

Image preprocessing comprises three steps: reflection removal, image resizing, and target pixel identification.

1) Reflection Removal: A process called "inpainting" creates the masked areas based on the surrounding image content [12]. Firstly, the mean intensity value in a neighborhood around each pixel is computed, called *adaptive thresholding*. The pixel with an intensity higher than its mean with some constant is identified as a reflection. Secondly, each connected component in the mask is labelled, and its size is computed. The components outside the threshold are removed from the mask. Lastly, morphological dilation using a specific size circular structuring element is applied to the mask to expand the areas for covering all reflections.

2) Resize Image: The width and height of the input image are reduced to two-thirds of its original size. Then, an erosion operation is applied to enhance the iris details and eliminate the noise around the boundaries [13].

3) Find Target Pixel: The local minima, a low-intensity spot in an image, is identified as a target pixel. It is a pixel or group of pixels with lower intensity values than their surrounding pixels.

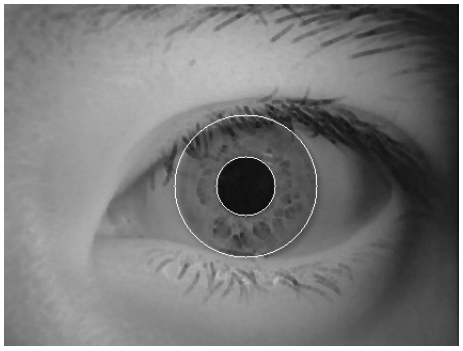
B. Iris Segmentation using Daugman's method

The traditional method lies in Daugman's algorithm, called *integral differential operator* [3]. The objective is to find a circular path within the image where the change in pixel intensity is the most dramatic. The locations of these abrupt changes in intensity typically correspond to the boundaries of the pupil or iris. The integral differential operator, the so-called Daugman values, is defined as:

$$\max(r, x_0, y_0) \left| G_\sigma(r) * \frac{\partial}{\partial r} \oint_{r,x_0,y_0} \frac{I(x,y)}{2\pi r} ds \right|, \quad (1)$$

where $G_\sigma(r)$ denotes a Gaussian filter of scale σ. r represents the radius of a circular region. x_0 and y_0 represent the coordinates of the center of the circular region. These vectors store "scores" for each potential circular boundary of the pupil and iris. The score is computed based on pixel intensity and gradient along a particular circular path at the center of the circle. Thus, the higher the Daugman values for a given circle, the more likely that the circle aligns with the edge of the pupil or iris.

Subsequently, the algorithm identifies the circle with differences in Daugman's values between consecutive radii. This circle represents the location and size of the pupil or iris, given that the abrupt change in Daugman's values between consecutive radii signifies a stark change in pixel intensity — indicative of the boundary between the iris and the sclera. For example, Fig. 1 shows the segmented area of the iris from an image in the CASIA-Iris-Lamp dataset [14].



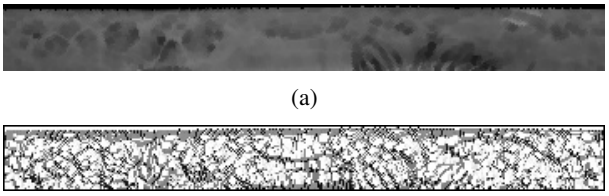


Fig. 1: An example of a segmented image from the CASIA-Iris-Lamp dataset[1] .

(a)

(b)

Fig. 2: A normalized image using Daugman rubber sheet model (a), and its feature using the local binary pattern (b).

C. Iris Normalization and Enhancement

Since to the elastic nature of the iris, pupil dilation and constriction are deformed due to changes in illumination, normalization is used to compensate for these deformations. The iris region is transformed into a fixed and consistent dimension. The size and shape variability of the iris can significantly impact the performance of the subsequent stages, i.e., feature extraction and matching.

A well-established technique is Daugman's rubber-sheet model [15]. It transforms the annular iris region from its original Cartesian coordinates into normalized polar coordinates. This transformation process, also known as "unwrapping", allows for the representation of the iris as a flexible rubber sheet, thus achieving a consistent representation regardless of pupil dilation or gaze direction.

During this unwrapping process, the coordinates of the inner (pupil boundary) and the outer (iris boundary) circles are calculated for each radial line originating from the pupil center to the iris. Each radial line is then re-sampled to a fixed number of points, creating a constant radial resolution.

The result of this unwrapping process is a rectangular block where one axis represents the change in angle around the iris, ranging from 0 to 2π, and the other axis corresponds to the radial distance from the pupil boundary to the iris boundary.

[1]Casia Iris Image Databases, Available: http://biometrics.idealtest.org

The pixel intensity values from the original image are then transferred to this new normalized representation based on their corresponding spatial location, as shown in Fig. 2a.

In addition, an image enhancement technique can be employed. For example, the histogram equalization [16] is used for adjusting the distribution of pixel intensities so that a more uniform histogram enhances the contrast of the image. It effectively reveals the complex details of the iris, making features more distinguishable and prominent.

D. Feature Extraction

Feature extraction can apply a local-binary pattern (LPB) technique [17] to generate an iris vector from the iris region. An LPB compares each pixel in the image with its neighboring pixels. A central pixel is compared with its eight surrounding pixels, forming a binary pattern. Depending on whether the central pixel's intensity is less than or equal to the neighboring pixel's intensity, a '1' or '0' is assigned, forming an 8-bit binary number (pattern) for each pixel in the iris region. The entire iris region is thus transformed into an LBP image that encapsulates the unique texture of the iris, as shown in Fig. 2b.

From the LBP image, a histogram is calculated to encapsulate the frequency of each binary pattern and encode the iris texture. The normalization of this histogram results in the formation of a feature vector, which is the input for matching.

E. Matching

The matching stage follows the feature extraction process and involves comparing the feature vectors that are derived from different iris images. The chi-square test statistic [18] is utilized for this comparison, measuring the similarity between the histograms of two feature vectors. This statistical test quantifies the difference between two histograms and provides the matching score. The lower the score, the higher the similarity between the two irises. By distinctly dividing the process into feature extraction and matching stages, the method proves to be an effective and robust solution for iris recognition.

III. Proposed Method

This section describes the proposed method based on the iris recognition processes. The proposed method is incorporated into a traditional segmentation technique which describes in Section II, to improve iris segmentation precision and to enhance the overall performance of the iris recognition system. The proposed iris recognition is shown in Fig. 3.

A. Unit Gradient Method

The preprocessing stage during the application of Daugman's algorithm involves the unit gradient method. The unit gradient vector of an image at a given pixel is a two-dimensional vector that points in the direction of the steepest increase in pixel intensity, and its length (or magnitude) is normalized to one. It is obtained by first calculating the gradients in the x and y directions (using a method such as the Sobel operator [16]), then combining it to get the gradient vector at each pixel, and finally normalizing these vectors to have a length of one.

The unit gradient vectors contain information about the direction of the edges in the image. Adding these vectors into the computation of Daugman values could help to emphasize the areas where there is a strong directional change, potentially improving the precision of the edge detection. This combined method enables a more accurate distinction between real edges and image noise, enhancing the overall edge detection results.

According to the proposed algorithm, the unit gradient vectors (UGVs) are vital to the iris recognition process. The computation of the UGVs begins with estimating gradients along the x and y axes using the Sobel operator. The gradients can be represented as:

$$G_x = \frac{\partial I}{\partial x}, \quad G_y = \frac{\partial I}{\partial y}. \tag{2}$$

In Eq. (2), G_x and G_y denote the image gradients along the x and y axes respectively, with I representing the image. The symbols $\frac{\partial I}{\partial x}$ and $\frac{\partial I}{\partial y}$ denote the partial derivatives of the image with respect to the x and y axes, respectively.

Thus, the gradient magnitude, $|G|$, can be calculated by using the Euclidean norm, shown in (3):

$$|G| = \sqrt{G_x^2 + G_y^2}. \tag{3}$$

The gradient magnitude $|G|$ measures the intensity change rate at a given pixel.

Finally, the UGVs are computed by normalizing the gradients. This is shown in (4):

$$\mathbf{U} = \frac{G}{|G|} = \left(\frac{G_x}{\sqrt{G_x^2 + G_y^2}}, \frac{G_y}{\sqrt{G_x^2 + G_y^2}} \right). \tag{4}$$

In Eq. (4), normalization ensures that each vector has a magnitude of one while maintaining the direction of the maximum change in intensity. Hence, the UGVs offer valuable edge direction information, enhancing iris segmentation's precision by adding them with the Daugman's values as shown in Eq. (5):

$$\begin{aligned} \text{Daughman_values} = \text{conv_2d}(image, x, y, mask) \\ +\text{unit_gradient_x}[y, x] \\ +\text{unit_ gradient_ y}[y, x], \end{aligned} \tag{5}$$

where the Daughman's values are the Daugman's representations at a specific polar coordinate (pre_loc_y, pre_loc_x) and radius (r − r_min). These values store "scores" for each potential circular boundary of the pupil and iris. Conv_2d is represents the result of a 2D convolution operation between the input iris image and a filter mask. Convolutions are used to extract features from images by applying a filter/mask and summing up the element-wise products. This operation is being applied to enhance the iris texture. Unit gradient represent the

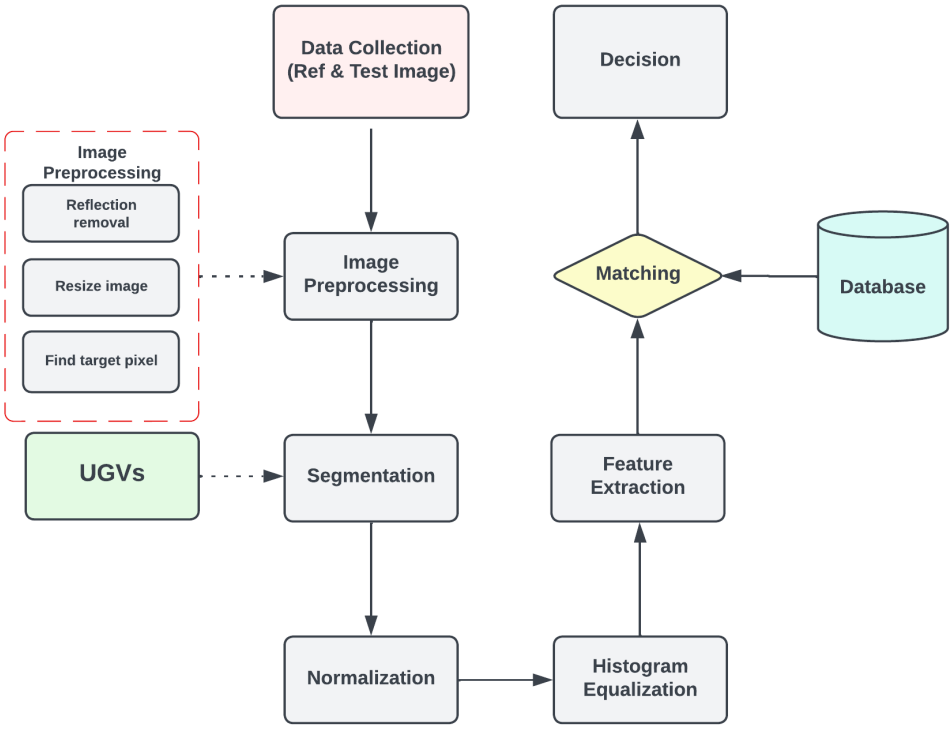

Fig. 3: A diagram of the proposed iris recognition using unit gradient vectors (UGVs).

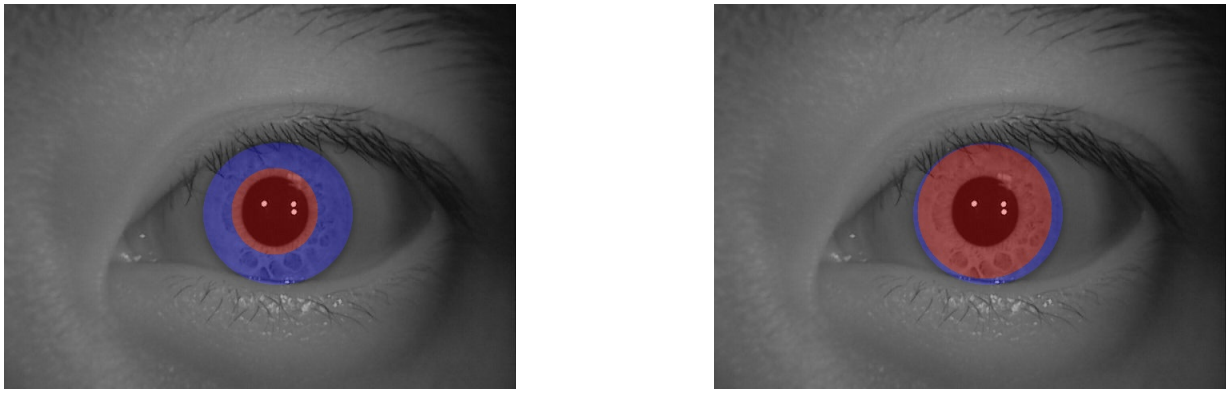
unit gradient components in the x and y directions at pixel coordinates (x, y). The gradient in the x and y directions can provide information about the direction of intensity change at a given point. Finally by adding the score with the UGVs, we could emphasize more about the area which is the boundary of the circular irises.

B. Feature Extraction

The segmented image is successfully obtained by applying the proposed method in tandem with the traditional segmentation approach. The resulting segmented images, with improved precision, are subject to feature extraction. We leverage the principles of transfer learning to extract features from the normalized images. Since the ResNet50 model is trained on the extensive ImageNet database [19], it is highly regarded for its robust performance in image recognition tasks. Therefore, we utilize the prowess of this pre-trained model in this work [20].

Note that although we have chosen to use ResNet50, the other models, such as VGG16 [21], VGG19 [22], ResNet101 [23], InceptionV3 [24], and InceptionResNetV2, also offers remarkable capabilities for feature extraction in image data, having been pre-trained on ImageNet and demonstrated their effectiveness in various contexts. The choice of ResNet50 in our current approach was motivated by its specific strengths and suitability for our task.

We customize the application of these models to the unique needs of iris recognition. The model is loaded without its top layer comprising fully connected layers. This step customizes the architecture to our task and allows us to adjust the input shape to fit the dimensions of the normalized iris images, resized to 60×360 pixels.



We freeze the weights of all layers in each base model to preserve the high-quality, pre-trained feature detectors in these models. This measure ensures the pre-existing learned features are not distorted during the training phase of our iris recognition task.

We enhance the base models by appending our custom layers, including a global average pooling 2D layer for dimensionality reduction, dense layers for learning task-specific features, and batch normalization and dropout layers for model regularization and overfitting prevention. These modifications allow the models to effectively capture intricate patterns within iris images, thereby contributing to the overall performance of our iris recognition system.

By harnessing the power of the pre-trained models, our feature extraction strategy is not only enables efficient recognition of iris patterns but also maximizes the potential of our iris recognition system.

C. Matching

The matching process compares features extracted from the previous state. For the identification task, the closet iris image is assigned to the target class against the feature of all iris images in the database. Here, the classification function is softmax. It is an adaptation of logistic regression for multiclass classification. The output layer of the transfer learning model utilized is a softmax layer, which produces

(a) (b)

Fig. 4: A comparative demonstration using an image from the CASIA-Iris-Lamp dataset: (a) illustrates the segmentation by the existing method (red circle) against the ground truth (blue circle) with IoU = 35.17%, (b) displays the segmentation by our proposed method (red circle), compared against the ground truth (blue circle) with IoU = 85.13%. The two panels highlight the differences in segmentation outcomes between the baseline and the proposed method.

a vector representing the probability distributions of each class in our database. Each element in this vector represents the probability that the input iris image belongs to the corresponding class.

For every input iris image, the class with the highest predicted probability is selected as the matching class. This selection process inherently provides a confidence score for the recognition process, offering insight into the reliability of the match.

The matching phase is deemed complete when all input iris images have been assigned a matching class from the database, effectively determining the individual's identity. The efficiency and accuracy of iris matching are significantly enhanced by using softmax classification, thereby contributing substantially to the performance of the iris recognition system.

IV. Experiment and Result

A comprehensive comparative analysis evaluates the impact of combining the UGVs with traditional segmentation techniques. The comparative framework was devised to clearly distinguish between the results achieved with and without applying UGVs.

The experiments were carried out by using the CASIA-Iris-Lamp dataset [14]. This dataset is a well-regarded benchmark in iris recognition research, and it provides a diverse range of iris images, which allows us to thoroughly test our approach under various conditions. The test set used for testing was only between $10 - 20$ % of the entire dataset.

Accuracy was the primary metric used to measure the performance of our iris recognition framework. The evaluation was carried out using the pre-trained model ResNet50 with transfer learning implemented for feature extraction. Experiments were conducted both with the standard application of these models and with the inclusion of the proposed UGVs framework in the segmentation stage.

TABLE I: Comparison between the proposed method using unit gradient vectors and the baseline for iris recognition.

Performance Metric	Baseline [3]	**Proposed method**
Accuracy	80.38	**82.02**
FAR	0.10	**0.09**
FRR	6.95	**6.44**
ERR	2.25	**1.40**

Table I shows the comparative results, providing valuable insights into the effectiveness of the proposed method. An observable improvement in accuracy is evident when the UGVs are incorporated into the segmentation process across all employed models. The baseline accuracy without the UGVs stands at 80.34%, while the proposed method using the UGVs achieves a higher accuracy of 82.02%, indicating a performance enhancement of 2.04%. A false acceptance rate (FAR), the proportion of invalid inputs incorrectly accepted, decreased marginally from 0.10% to 0.09% when the UGVs technique is employed. In the context of iris recognition, a lower FAR implies that the system is less likely to falsely identify someone, indicating that using the UGVs slightly improves the chance of rejecting an incorrect iris match by 10%. False Rejection Rate (FRR), the proportion of valid inputs erroneously rejected, reduced from 6.95% to 6.44%. This suggests that using the UGVs enhances the chance of accepting a correct iris match by 7.33%. A lower FRR means the system is less prone to reject an accurate identity. An equal error rate (ERR) is a point where both FAR and FRR are equal and serves as a convenient summary statistic. The ERR fell from 2.25% to 1.40%, indicating an overall performance improvement of 37.78% in the system when utilizing UGVs.

Simultaneously, the results revealed a reduction in table I when the UGV-enhanced segmentation method was employed.

This reduction indicates an increased model efficiency and a better generalization of unseen data, further underscoring the benefits of integrating UGVs with traditional segmentation techniques.

The enhancement was observed to extend beyond the performance metrics. Fig. 4, which illustrates a comparison of the intersection over union (IoU) with the ground truth and the segmentation, further highlights the enhancements from the proposed method. This comparison result clearly explains the effectiveness of the UGV-enhanced segmentation techniques.

Fig. 4b, where UGVs were used, the IoU score reached a high of 85.13%. This is a marked improvement compared to the score of 35.17% achieved without employing UGVs, as shown in Fig. 4a.

Our findings demonstrate that the combined approach enhances segmentation precision and provides a more robust base for subsequent feature extraction and matching processes. Improving the initial iris segmentation can significantly enhance the overall performance of iris recognition systems.

V. Discussion

Our research into integrating the use of the UGVs with Daugman's algorithm for iris segmentation has offered the potential to significantly enhance iris recognition system performance. However, as with any method, there are limitations that must be acknowledged.

One of the main limitations of our approach is observed in scenarios where the initial segmentation closely resembles the iris. In this case, our approach does not modify the circle, which could limit potential improvements. It's important to note that this behaviour is inherent to our method, which is primarily designed to improve less accurate segmentation.

Another potential limitation is observed when the approach expands the circle larger than the original size of the iris. In certain situations the circle closely resemble the iris, this enlargement could include non-iris regions, leading to a decrease in accuracy. Careful handling is required to ensure that the circle does not grow excessively, potentially including non-relevant areas in the segmentation.

Despite these limitations, our method is effective when the initial segmentation is not accurate as shown in Fig. 4a. Our approach can significantly increase the size of the circle since it provides edge direction information. If we compare the segmentation with the ground truth, the proposed method increases the intersection area as shown in Fig. 4b. This result improves segmentation accuracy and, consequently, enhances iris recognition performance.

These findings underscore the potential of our approach, despite its limitations. As with all research, understanding these limitations is key to future improvements.

VI. Conclusion

This paper presented the integration of the UGVs with a traditional segmentation technique to improve the performance of iris recognition systems. This work contributed to the iris recognition process with a more robust iris localization. The proposed method using the UGVs contained the direction information of the edges in the image. Thus, incorporating these vectors into the computation could help emphasize areas with a strong directional change, potentially improving the precision of edge detection. Specifically, our method enhances accuracy by 2.04%, reduces the FAR by 10%, and decreases the FRR by 7.33%. Furthermore, the ERR was decreased by 37.78%. These improvements contribute to more robust iris segmentation and thereby, the overall advancement of security and efficiency in iris recognition systems. However, some inaccuracies of the proposed method for iris segmentation still need refinement. In future work, we will explore a larger dataset, images from different sensors, and low-quality images.

E-mail: tsun-hin.cheung@connect.polyu.hk, enkmlam@polyu.edu.hk

***Abstract* — Automatic fact-checking plays a crucial role in combating the spread of misinformation. Large Language Models (LLMs) and Instruction-Following variants, such as InstructGPT and Alpaca, have shown remarkable performance in various natural language processing tasks. However, their knowledge may not always be up-to-date or sufficient, potentially leading to inaccuracies in fact-checking. To address this limitation, we propose combining the power of instruction-following language models with external evidence retrieval to enhance fact-checking performance. Our approach involves leveraging search engines to retrieve relevant evidence for a given input claim. This external evidence serves as valuable supplementary information to augment the knowledge of the pretrained language model. Then, we instruct-tune an open-sourced language model, called LLaMA, using this evidence, enabling it to predict the veracity of the input claim more accurately. To evaluate our method, we conducted experiments on two widely used fact-checking datasets: RAWFC and LIAR. The results demonstrate that our approach achieves state-of-the-art performance in fact-checking tasks. By integrating external evidence, we bridge the gap between the model's knowledge and the most up-to-date and sufficient context available, leading to improved fact-checking outcomes. Our findings have implications for combating misinformation and promoting the dissemination of accurate information on online platforms. Our released materials are accessible at: https://thcheung.github.io/factllama.**

I. INTRODUCTION

With the continuous growth of social media and online communication, we are experiencing a deluge of information through these channels, raising the urgent need to distinguish facts from fiction. Unfortunately, these platforms provide almost everyone with the ability to spread misinformation or fake news that often goes viral, leading to the widespread dissemination of inaccurate or false information to a global audience. Misinformation can take different forms, ranging from fabricated news stories to manipulated images or videos aimed at swaying public opinion [1].

To counteract this alarming trend, the research community is continuously developing new and innovative approaches to tackle the problem of identifying and correcting misinformation. Artificial intelligence (AI)-assisted fact-checking is one such approach and has been gaining attention in recent years [2]. It has the potential to automate the laborious and time-consuming process of manually verifying facts, while enabling quick dissemination of accurate information. With the recent rise in popularity of Large Language Models (LLMs) [3], [4] in Natural Language Processing (NLP) tasks, such as machine translation, text classification, and data extraction, they have also been used for fake news detection [5].

Despite the impressive capabilities of these LLMs, a significant limitation of these language models is their reliance on pre-existing knowledge, which may not always be up-to-date or sufficient. In the context of fact-checking, the reliance of language models solely on their internal knowledge raises concerns about their ability to accurately assess the veracity of claims, especially when faced with rapidly evolving information [6]. To address this limitation, it becomes imperative to consider external knowledge sources that provide updated and reliable information in recent fact-checking algorithms [6]–[9].

This paper aims to enhance the fact-checking capabilities of instruction-following language models by leveraging external evidence. We propose a method that combines the power of pretrained language models with the retrieval of relevant external evidence from search engines. By integrating this external evidence during the instruct-tuning process, we aim to augment the knowledge of the language model, enabling it to make more accurate predictions. The contributions of our work are summarized as follows:

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

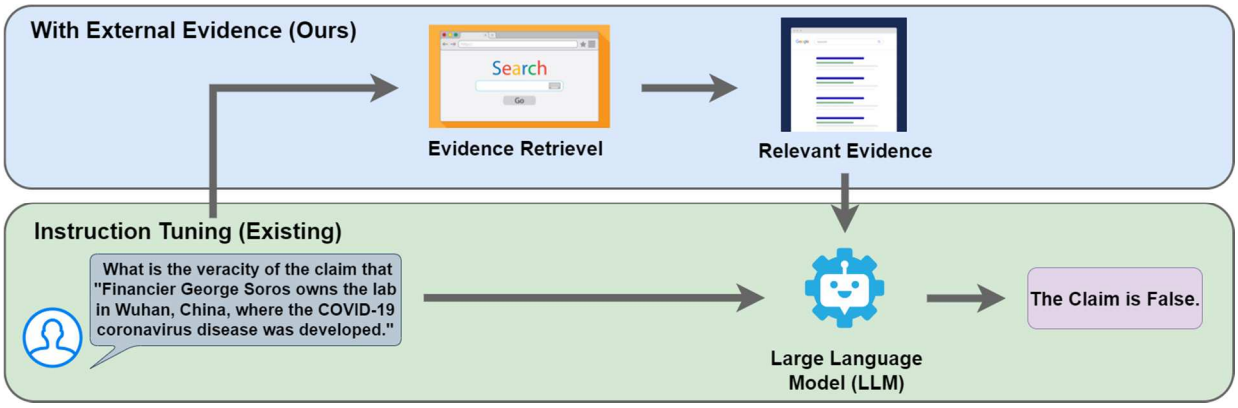

Fig. 1. Our approach for automatic fact-checking with external evidence retrieved from search engine.

- **Introducing instruct-tuned language models for fact-checking**: We propose the application of instruct-tuned language models, i.e., LLaMA, for automatic fact-checking tasks, expanding their scope beyond language generation.
- **Addressing the limitations of instruct-tuned models**: We identify the limitations of instruct-tuned language models in fact-checking due to outdated knowledge, and propose the integration of external evidence to enhance their accuracy and reliability.
- **Proposing a method for incorporating external knowledge**: We present a novel approach that combines pretrained language models with external evidence retrieval from search engines, augmenting the knowledge base for fact-checking.
- **Achieving state-of-the-art performance**: Through experiments on the RAWFC and LIAR datasets, we demonstrate that our method achieves state-of-the-art performance in fact-checking tasks.

II. Related Work

A. *Automatic Fact-Checking*

In recent years, the task of automatic fact-checking has gained significant attention due to the growing concern about the spread of false information. Many studies have been carried out using different machine learning paradigms. This section provides an overview of related works that focus mainly on machine learning-based, deep learning-based, and transformer-based approaches to automated fact-checking.

Machine learning algorithms have been widely used to build models for automated fact-checking. In traditional machine learning methods, the features are manually engineered and used to train a classifier. Several studies have explored and compared different machine learning-based methods for automated fact-checking. Hassan et al. [10] proposed a solution based on the Support Vector Machine algorithm that performs a multi-level fact-checking process on news claims. Their results indicate that the proposed solution outperforms several traditional methods in terms of accuracy.

Deep learning-based methods have been successful in many Natural Language Processing (NLP) tasks, including automated fact-checking [11]. Deep neural networks can automatically learn complex features from raw data, including word embeddings and network architectures that operate on these embeddings. In 2018, Popat et al. [12] proposed a neural network-based solution to verify claims by directly comparing them to the corresponding evidence. The model utilizes a hierarchical attention mechanism to extract relevant evidence and compares it to the given claim to make a prediction. Another study presented a fact-checking system that combines deep neural networks with natural language generation to generate explanations for the model's output [9].

The Transformer is a recent innovation in deep learning that has shown great potential in several natural language processing tasks, including automated fact-checking. Transformer-based models [13], [14] employs self-attention mechanisms that enable them to capture long-range dependencies between input tokens. Recently, several studies have demonstrated the effectiveness of Transformer-based models in automated fact-checking. For instance, Kotonya et al. [6] proposed a Transformer-based solution that operates on pairs of claims and evidence. Their model utilizes an attention mechanism that allows it to focus on the most relevant pieces of evidence when verifying a claim. The authors reported that their model achieved high accuracy on a publicly available fact-checking dataset. Another study utilized a Transformer model to predict the veracity of a claim by performing joint

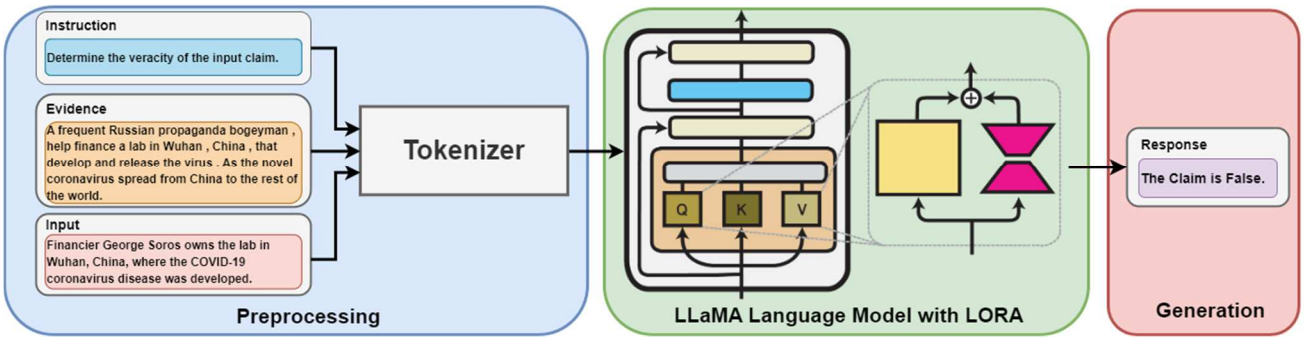

Fig. 2. Illustration of optimizing instruction-following models with external evidence using Low Rank Adaption Tuning (LORA) [22].

reasoning over both textual evidence and commonsense knowledge [15].

B. Instruction-Following Language Models

Instruction-following language models have emerged as a promising and novel approach for many NLP tasks [16]. These models can follow a set of instructions to perform a specific task, and perform classification and generation tasks.

InstructGPT [17] is an instruction-following language model that combines the power of the GPT architecture with a sequence of natural language instructions to perform a specific task. In the context of automated fact-checking, the model is presented with a claim. It then uses a set of instructions to perform verification for its output. The InstructGPT model has been evaluated on several publicly available commonsense reasoning datasets and has been shown to achieve high accuracy.

Self-Instruct [18] is an extension of the InstructGPT model that leverages self-supervised learning to improve its performance on a variety of natural language processing tasks. The model uses a simple heuristic algorithm that generates its own sequence of instructions and samples from the task pool. This self-supervised approach has been shown to improve the model's accuracy on many NLP tasks.

ChatGPT [19] is another instruction-following language model that can perform a wide range of natural language processing tasks, including automated fact-checking. The model leverages a conversational approach to fact-checking by generating questions that a human fact-checker would ask and answering them on its own. To achieve this, the model follows a set of instructions when interacting with input claims. New Bing from Microsoft[1] is a recently released industrial product that is powered by GPT and Bing search engine. However, both ChatGPT and New Bing are proprietary models, which cannot be tuned by the general public and researchers for downstream uses. Moreover, limited access to ChatGPT restricts the number of times that an account can perform fact-checking, especially for large-scale use.

Stanford Alpaca [20] is an open-sourced instruction-following language model based on the paradigm of open sequence-to-sequence model, called LLaMA [21], that is capable of performing a wide range of natural language processing tasks. In the context of fact-checking, the model can be used presented with a claim. The model derives a sequence of rules from the task specification and applies them to predict whether a given claim is factual or not. In our work, we aim to improve the fact-checking capability of LLaMA with the help of external knowledge.

C. Low-Rank Adaptation Tuning

Low-Rank Adaptation (LORA) [22] is a parameter-efficient fine-tuning method that focuses on identifying the most important neurons in a pretrained language model and updating only those neurons to improve performance on a target dataset. The "Low-Rank" component in LORA involves low-rank matrix factorization in the fine-tuning process, which compresses pretrained model parameters into a lower-dimensional space, while preserving as much of the original information as possible. The resulting lower-dimensional parameter space can be fine-tuned more efficiently and effectively using fewer target samples. In our work, we leverage the LORA tuning in instruct-tuning LLaMA, because LORA tuning can reduce GPU memory to 16 GB during tuning, when compared to 64GB during fine-tuning [20].

III. METHODOLOGY

In this section, we describe the methodology for instruct-tuning language models with external evidence for automatic fact-checking. Our proposed method consists of two key components: (1) the generation of instruction-evidence-input

[1] https://www.bing.com/new

claim samples and (2) instruct-tuning of a generative pretrained language model, i.e., LLaMA, using these samples.

A. Instruction-Evidence-Input Generation

Generation of instruction-evidence-input samples. In order to train the instruct-tuned language model, we first generate instruction-evidence-input samples. We combine the instruction, evidence, and input claim into a single sequence, with appropriate special tokens to differentiate them. The instruction provides guidance on how to incorporate the evidence for fact-checking, while the evidence consists of relevant information, retrieved from search engines, using the Google API. The input claim represents the claim that needs to be fact-checked. Similar to previous studies [8], [12], we filtered out those evidence that are from fact-checking sites or published before the claim is recorded in the fact-checking sites.

Evidence collection pipeline. Our evidence collection pipeline utilizes the Google API to retrieve relevant evidence given the textual inputs. We formulate queries, based on the input claim, and use the API to search for information from reputable sources. The retrieved evidence includes sentences or paragraphs that are likely to contain relevant information related to the claim. This external evidence serves as valuable supplementary information for the fact-checking process.

Converting factual classification to sequence-to-sequence problem. To convert the factual classification task into a sequence-to-sequence problem suitable for generative transformer models, we frame the task as text generation for automatic fact-checking. We treat the input claim as the source sequence and the fact-checking result as the target sequence. The instruct-tuned language model learns to generate a fact-checking response given the input claim and the relevant evidence. This approach allows the model to capture the nuances and context of the claim and produce more accurate fact-checking outcomes.

B. Tuning Pretrained Instruction-Following Models with External Knowledge

In this study, we instruct-tune the pretrained LLaMA [21] model using the LORA algorithm [22]. Our approach not only takes the text claim as input for factual classification, but also the retrieval evidence.

Optimization of language model. During instruct-tuning, we aim to optimize our LLaMA model's parameters θ to minimize a loss function that measures the difference between the predicted fact-check results and the ground truth of the training dataset. Suppose we have a set of input-output pairs (x, y) in the training set, where x is the instruction-evidence-input to be input to the LLaMA model, and y is the corresponding label for that claim. Suppose $f(x;\theta)$ denotes the output, i.e., predicted veracity of the input claim, of the LLaMA with parameters θ for input x. We define the loss function as follows:

$$L(\theta) = \sum(y - f(x;\theta))^2. \quad (1)$$

LORA tuning. Our goal is to find the optimal values for the parameters of the LLaMA model θ that minimize the loss function $L(\theta)$. To achieve this, we leverage the LORA algorithm, which involves a low-rank approximation of the parameter matrix θ. As a result, it reduces the number of trainable parameters and improves generalization, while preserving most of the information contained in the original parameters. Specifically, LORA compresses θ into a low-rank matrix product:

$$\Omega = UV, \quad (2)$$

where U and V are matrices of lower rank than θ. The LORA algorithm updates the parameters θ by adding a regularized factorization of θ to the existing parameters, as follows:

$$\theta' = UV, \quad (3)$$

$$\theta' = \theta + (\Omega - \theta), \quad (4)$$

where θ' is the updated parameter matrix.

IV. Experimental Setups and Results

A. Datasets

We use two publicly available datasets, namely the RAWFC [8] and LIAR [23] datasets, for evaluating our proposed approach. The RAWFC dataset is a collection of claims related to factual verification tasks, consisting of 2,012 claims with supporting evidence, labelled either true, false, and half-true, from Snopes.com. The LIAR dataset is a dataset of political statements fact-checked by PolitiFact.com, consisting of 12,836 short statements, each labelled as true, mostly true, half-true, barely true, false, or pants-on-fire. For fair comparison to other methods, we use the same split released in [8].

B. Experimental Setup

We run the experiments using the smallest LLaMA model, i.e., LLaMA-7B [21] model, in our experiment, as it is the

largest model that fits our hardware setup. We evaluate our proposed approach for automatic fact-checking using three standard evaluation metrics: Precision Scores, Recall Scores, and F1 Scores. To instruct-tune the LLaMA model, we trained the models for 3 epochs with a mini-batch size of 32. We employ the Adam optimizer with an initial learning rate of 10-4 and a linear learning decay from the initial value to 0. To avoid overfitting, we applied a dropout rate of 0.05. Our models were implemented in PyTorch [24] and HuggingFace [25]. All experiments are conducted on two GeForce RTX 2080 Ti GPUs.

C. Comparison to Other Methods

Table I and Table II provide the evaluation results of various methods on two different fact-checking datasets, i.e., RAWFC and LIAR. The methods are compared based on precision, recall, and F1-score, which are commonly used metrics to assess the performance of classification tasks. The baselines that we compared include SVM [26] , which utilizes bag-of-words features for fake news detection. CNN [23] incorporates metadata features to enhance representation learning. RNN [11] learns representations from word sequences without relying on external resources. DeClarE [12] combines word embeddings from the claim, report, and source to assess the credibility of the claim. dEFEND [7] employs a GRU-based model for veracity prediction, providing explanations. SentHAN [6] represents each sentence based on coherence and semantic conflicts with the claim. SBERT-FC [6] utilizes SentenceBERT (SBERT) for encoding and identifies fake news based on the top-ranked sentences. GenFE [9] and GenFE-MT [9] detect fake news independently or jointly with explanations in a multi-task setup. CofCED [8] is a Coarse-to-fine Cascaded Evidence-Distillation neural network for explainable fake news detection based on such raw reports, alleviating the dependency on fact-checked ones.

From Table I for the RAWFC dataset, it can be observed that traditional machine learning methods, like SVM, CNN, and RNN, achieve moderate results in terms of precision, recall, and F1-score. However, more advanced models, such as DeClarE, dEFEND, sentHAN, SBERT-FC, GenFE, GenFE-MT, and CofCED, outperform the traditional methods, particularly CofCED, which achieves the highest F1-score of 0.5107.

Interestingly, LLaMA without tuning, i.e., zero-shot prediction, performs relatively poorly compared to the other methods. However, when Instruct-tuning is applied, there is a significant improvement in performance, particularly when external knowledge is incorporated. Instruct-tuned LLaMA with external knowledge achieves the highest F1-score of 0.5565, surpassing all other methods and demonstrating the effectiveness of leveraging external evidence.

On the evaluation on the LIAR dataset, as shown in Table II, similar patterns can be observed. Traditional machine learning methods show relatively low performance, while more advanced models exhibit better results. CofCED achieves the highest F1-score of 0.2893, indicating its effectiveness in fact-checking on the LIAR dataset.

Methods	Precision	Recall	F1
SVM [26]	0.3233	0.3251	0.3171
CNN [23]	0.3880	0.3850	0.3859
RNN [11]	0.4135	0.4209	0.4039
DeClarE [12]	0.4339	0.4352	0.4218
dEFEND [7]	0.4493	0.4326	0.4407
sentHAN [27]	0.4566	0.4554	0.4425
SBERT-FC [6]	0.5106	0.4592	0.4551
GenFE [9]	0.4429	0.4474	0.4443
GenFE-MT [9]	0.4564	0.4527	0.4508
CofCED [8]	0.5299	0.5099	0.5107
LLaMA (w/o tuning) [20]	0.3350	0.3255	0.2643
FactLLaMA (Instruct-tuning w/o external knowledge)	0.5376	05400	0.5376
FactLLaMA (Instruct-tuning with external knowledge)	**0.5611**	**0.5550**	**0.5565**

Table I. Results on the RAWFC dataset.

Methods	Precision	Recall	F1
SVM [26]	0.1578	0.1592	0.1534
CNN [23]	0.2258	0.2239	0.2136
RNN [11]	0.2436	0.2120	0.2079
DeClarE [12]	0.2286	0.2055	0.1843
dEFEND [7]	0.2309	0.1856	0.1751
sentHAN [27]	0.2264	0.1996	0.1846
SBERT-FC [6]	0.2409	0.2207	0.2219
GenFE [9]	0.2801	0.2616	0.2649
GenFE-MT [9]	0.1855	0.1990	0.1515
CofCED [8]	0.2948	0.2955	0.2893
LLaMA (w/o tuning) [20]	0.1587	0.2069	0.1224
FactLLaMA (Instruct-tuning w/o external knowledge)	0.3232	0.3157	0.2998
FactLLaMA (Instruct-tuning with external knowledge)	**0.3246**	**0.3205**	**0.3044**

Table II. Results on the LIAR dataset.

Once again, LLaMA without tuning performs poorly, but instruct-tuning leads to substantial improvements.

Incorporating external knowledge in the instruct-tuning process further enhances the performance, with LLaMA, Instruct-tuning and external knowledge achieving the highest F1-score of 0.3044.

In summary, the evaluation results from both datasets highlight the superiority of advanced models over traditional machine learning methods in fact-checking tasks. The instruct-tuning approach, particularly when combined with external knowledge, consistently outperforms other methods, showcasing the value of leveraging external evidence for accurate fact-checking. These findings emphasize the importance of staying updated with the latest information and leveraging advanced techniques to effectively combat the spread of misinformation.

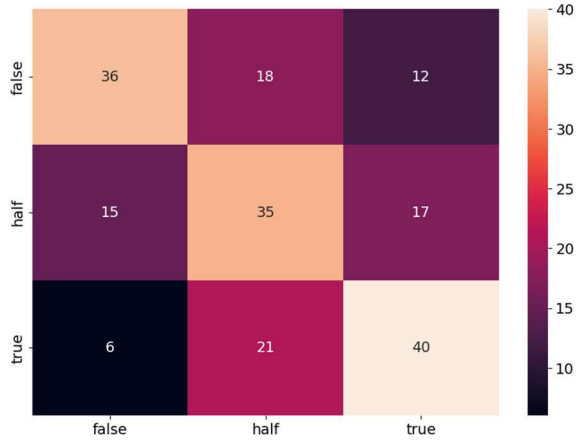

Fig.3 Confusion matrix on the RAWFC Dataset.

Fig.4 Confusion matrix on the LIAR Dataset.

D. Confusion Matrices

Figures 3 and 4 present the confusion matrices for the RAWFC and LIAR datasets, respectively. The rows and columns in the figures represent the ground-truth and predictions, respectively.

In Figure 3, it is evident that the model can effectively distinguish between the TRUE and FALSE labels. However, classifying the HALF-TRUE label proves to be more challenging for the model. This difficulty arises because both the HALF-TRUE and FALSE labels contain misinformation, albeit with differing degrees of accuracy. Moving to Figure 4, we observe that the model shows clear classification performance for the TRUE and PLANT-FIRES classes, compared to the other classes. However, it struggles to accurately classify the BARELY-TRUE, HALF-TRUE, and MOSTLY-TRUE classes. This difficulty arises from the fact that items in these classes contain a mixture of true and false information, making it a subjective task for both humans and machines to classify them accurately without specialized expertise.

V. CONCLUSION

In conclusion, this research highlights the crucial role of automatic fact-checking in combating the spread of misinformation online. While Large Language Models (LLMs) and Instruction-Following variants, like InstructGPT and Alpaca, have demonstrated remarkable performance in various natural language processing tasks, their potential lack of up-to-date or sufficient knowledge can lead to inaccuracies in fact-checking. To address this limitation, we proposed a method that combines pretrained language models with external evidence retrieval, resulting in enhanced fact-checking accuracy. By leveraging search engines to retrieve relevant evidence for a given claim, we successfully augmented the knowledge of the pretrained language model. Through instruct-tuning an open-source language model called LLaMA, with this external evidence, we achieved more accurate predictions regarding the veracity of input claims. Experimental evaluations on widely used fact-checking datasets, RAWFC and LIAR, showcased that our approach achieved state-of-the-art performance in fact-checking tasks. The integration of external evidence effectively bridged the knowledge gap between the model and the most up-to-date information available, leading to improved fact-checking outcomes. We believe our research has significant implications for combatting misinformation and promoting the dissemination of accurate information on online platforms. In our future work, we plan to generate explanations with these pretrained language models for more general use.

Auditory Representation Effective for Estimating Vocal Tract Information

Toshio Irino* and Shintaro Doan*

***Abstract*—We can estimate the size of the speakers based on their speech sounds alone. We had proposed an auditory computational theory of the Stabilised Wavelet-Mellin Transform (SWMT), which segregates information about the size and shape of the vocal tract and glottal vibration, to explain this observation. It has been shown that the auditory representation or excitation pattern (EP) associated with a weighting function based on the SWMT, termed the "SSI weight," can account for the psychometric functions of size perception. In this study, we investigated whether EP with SSI weight can accurately estimate vocal tract lengths (VTLs) which were measured by magnetic resonance imaging (MRI) in male and female subjects. It was found that the use of SSI weight significantly improved the VTL estimation. Furthermore, the estimation errors in the EP with the SSI weight were significantly smaller than those in the commonly used spectra derived from the Fourier transform, Mel filterbank, and WORLD vocoder. It was also shown that the SSI weight can be easily introduced into these spectra to improve the performance.**

Index Terms: Speaker size perception, Auditory model, Vocal tract length (VTL), Glottal vibration, Size-shape image (SSI)

I. Introduction

We can recognize phonemes pronounced by children, women, and men despite the large differences in their heights. This indicates that our auditory system can extract and identify phonemes in which variations in the pattern of formant frequencies distinguish vowel types and the fundamental frequency determines the pitch. Speaker information can also be extracted simultaneously. Speech sounds contain information about vocal tract size, which is closely correlated with speaker size [1]. Many psychoacoustic studies have been conducted on size discrimination and phoneme perception from voiced and unvoiced speech sounds (e.g., [2]–[4]; see review in [5]).

Irino and Patterson [6] proposed the Stabilised Wavelet-Mellin Transform (SWMT) as a computational theory to explain how the auditory system estimates size and shape of vocal tract separately from glottal pulse information. As explained in Section II, size estimation from voiced sounds is more difficult than from unvoiced sounds. This is because voiced speech sounds contain information about vocal tract response (filter characteristics) and glottal vibration (source characteristics) as shown in the source filter theory of speech [7], [8]. Therefore, it is necessary to effectively separate this information. An auditory model based on SWMT was proposed to explain the experimental results on size discrimination of both unvoiced and voiced speech sounds[5], [9]. It was demonstrated that introduction of a simple weighting function, referred to as "size-shape image weight (SSI weight)" (see Section II), enabled to explain the results successfully. However, the domain of previous studies was restricted to the explanation of psychometric functions derived using synthetic speech sounds. For practical applications in signal processing, it is necessary to demonstrate that the auditory model can also extract vocal tract information from natural speech sounds.

In the current study, we focus on the estimation of vocal tract lengths (VTLs) of different speakers. This is because the VTLs of sustained vowels can be accurately measured from magnetic resonance imaging (MRI) data [10], [11] and thus provide "ground truth" usable for evaluation. VTL has sometimes been estimated by "auditory motivated" models, including Mel-Frequency Cepstrum Coefficient (MFCC) [12]–[16]. Recent DNN studies [17]–[19] have also used MFCC. Although the computational power has allowed for high VTL estimation accuracy, little question has been raised as to whether MFCC is really effective for vocal tract information estimation, including speech feature extraction. We consider an effective auditory representation to answer this question.

In this paper, we first describe the problem of VTL estimation using the auditory spectrum and our approach. Then, we describe the VTL estimation method and present the evaluation results. We compared the auditory spectrum with the commonly used Fourier spectrum, the Mel filterbank spectrum [12], and the WORLD vocoder spectrum [20]. We also investigated whether introducing the SSI weight into these spectra improves the estimation accuracy. If it is the case, this simple function, which does not require any training data as in DNN, could improve the performance of many speech processing tasks.

II. Auditory process to estimate size

A. Physics of vocal tract and estimation

The main difference between the vowels of males and females lies in the differences in the VTL and fundamental frequency F_o. When VTL is shortened by a factor of $1/\alpha$, the formant frequencies F_1 and F_2 move upward to αF_1 and αF_2. On the logarithmic frequency axis, $\log F_1$ and $\log F_2$ move up to $\{\log F_1 + \log \alpha\}$ and $\{\log F_2 + \log \alpha\}$, respectively. This implies that the logarithmic scale factor, $\log \alpha$, is a constant independent of the formant frequencies. Therefore, the VTL ratio can be estimated using the cross-correlation of the log spectra corresponding to the original and shorted vocal tracts. Auditory spectra derived by gammatone or gammachirp filterbanks [21], [22] are suitable for this purpose

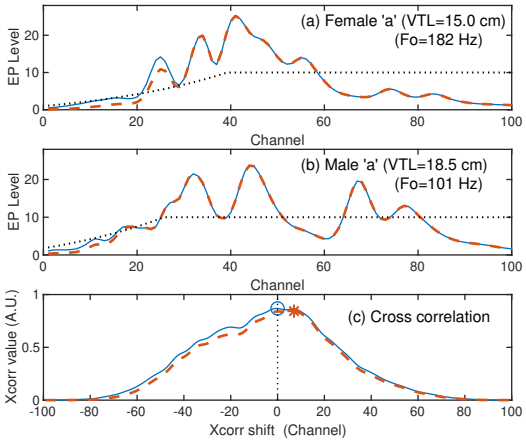

Fig. 1: Excitation patterns (EPs, i.e., GCFB outputs) of the vowel 'a' of a male (a) and a female (b) and their cross-correlation function (c). The horizontal axis for (a) and (b) is the number of GCFB channels. The vertical axis represents the EP level. In (c), the horizontal axis represents the amount of shift in terms of the channel and the vertical axis represents the correlation function value (arbitrary unit). Blue solid line: EP; black dotted line: SSI weight (see Section II-D); red dashed line: SSI-weighted EP. Circle (o) and asterisk (*) in (c) indicate the peaks in the cross correlations of the EPs and SSIweighted EPs, respectively.

because the frequency axis, $\mathrm{ERB}_{\mathrm{Nnumber}}$, is approximately a log frequency axis above 500 Hz [23]. This appears to be an easy task if the spectrum is calculated solely from the impulse response of the vocal tract. However, voiced sounds used in speech communication are derived from the convolution of the impulse response of the vocal tract and the waveform of glottal vibration [7]. This makes the estimation more difficult than expected.

B. Problem when using auditory spectrum

To be more specific, an actual female voice 'a' (VTL = 15.0 cm, F_o = 182 Hz) and a male voice 'a' (VTL = 18.5 cm, F_o = 101 Hz), drawn from a database described in Section III-A, were analyzed with a dynamic compressive gammachirp auditory filterbank (GCFB) [22], [24], [25]. The output level was averaged over a short period. This is commonly called an excitation pattern (EP) [23]. The solid blue lines in Fig. 1 show the EPs for the female voice (a) and male voice (b). The horizontal axis is the GCFB channel number, which is equally spaced from 100 to 8000 Hz on the $\mathrm{ERB}_{\mathrm{N}}\mathrm{number}$ axis [23]; this axis is effectively a logarithmic frequency axis above 500 Hz. In the female voice shown in Fig. 1 (a), prominent peaks are observed in channels 24, 32, and 41. Among these, the peak at channel 41 is associated with a formant, and the spectral shape at higher frequencies is important for VTL estimation. In contrast, the peaks at channels 24 and 32 are associated with the harmonics of F_o (182 Hz), which are resolved harmonics [23]. These additional peaks reduce the

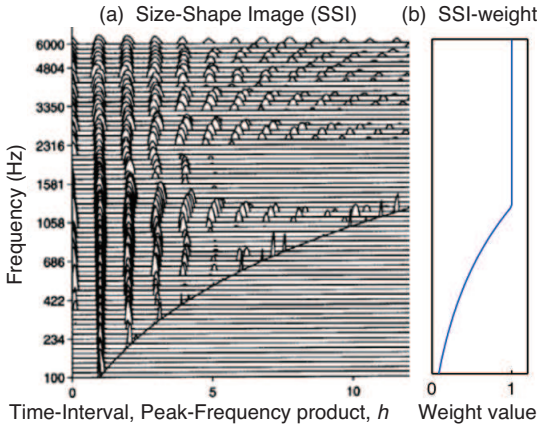

Fig. 2: Size-Shape Image and SSI weight (adapted from [9]). (a) SSI of the vowel 'o' [6]. The horizontal axis represents the product of the time interval and the peak frequency of the auditory filter. The vertical axis is the peak frequency of the auditory filter equally spaced on the $\mathrm{ERB}_{\mathrm{N}}\mathrm{number}$ axis. (b) Weighting function based on active region of SSI. (see also Fig. 8 of Appendix A).

accuracy of the VTL estimation. In contrast, for the male voice in Fig. 1(b), the peaks corresponding to the resolved harmonics are relatively small, and four formant peaks are clearly observed. The cross-correlation between the two EPs is shown by the blue solid line in Fig. 1(c). The peak (blue circle) is obtained at a shift of zero, which implies that the VTLs are the same. This estimation is obviously incorrect because the measured VTL ratio is 1.23 (=18.5/15.0). The problem lies in the fact that the resolved harmonics interfere with estimation. A similar and worse problem occured in the Mel spectrum.

C. Approach from auditory computational theory

We approached this problem using a computational theory in which the auditory system can segregate and extract information about the vocal tract and glottal vibration from speech sounds. Specifically, Irino and Patterson [6] proposed the "Stabilised Wavelet-Mellin Transform" (SWMT) which has been supported by several psychological experiments on size perception (e.g., [2], [5], [9], [26]). The SWMT process is briefly described here (see [6] for details and the upper path in Fig. 8 of Appendix A). In SWMT, the EP derived from GCFB is converted into a two-dimensional "Auditory Image (AI)" by "Strobe Temporal Integration (STI)," which is synchronized with the glottal pulse. The representation of vocal tract response is repeated at the glottal pulse rate (i.e., F_o). One cycle of the response is extracted from the AI to obtain a two-dimensional "Auditory Figure (AF)", which maximally represents information about a single pulse response of the vocal tract. This representation does not exactly correspond to the impulse response but is much closer than the usual spectrum representation obtained from repeated pulse excitation. Then, the AF is transformed into a "size-shape image (SSI)," as shown in Fig. 2(a). Here, the vertical axis represents the peak frequency of the auditory filter, f_p, and the horizontal axis is h, which is the product of the time interval and peak

frequency. SSI is a representation of the single-pulse response and eliminates the response of the adjacent pulse, which is located below the diagonal upright curve. Although it is a good method in principle, developing an STI algorithm to obtain stable images for various speech sounds is not easy. This is because estimating the strobe point or period synchrony information in the EP is a difficult task due to the variability of speech sounds (e.g., [27], [28]).

D. F_o adaptive weighting function, SSI weight

To solve this stability problem, we designed a weight function that corresponds to the area of the active part of the SSI (see also the middle block and the lower path in Fig. 8 of Appendix A). Figure 2 (b) shows a function named "SSI weight" [5], [9]. This one-dimensional function is directly applicable to EP via simple multiplication. The SSI weight (w_{SSI}) is defined as

$$w_{SSI}(f_p, F_o) \quad = \quad \min(\frac{f_p}{h_{max} \cdot F_o}, 1), \tag{1}$$

where h_{max} is the upper limit of h on the horizontal axis of the SSI and determines the area of information extracted from the SSI, as shown in Fig. 2(a). f_p is the peak frequency of the analysis filer. F_o is the fundamental frequency at the time of the analysis. When F_o is not determined, as in unvoiced sounds, setting $F_o \simeq 0$ will result in a w_{SSI} of unity across the peak frequency. The SSI weight was used to explain the results of the human size perception experiments [5], [9] and was introduced to a new objective speech intelligibility measure, GESI, to predict the simulated hearing loss sounds [29], [30]. Most importantly, the SSI weight is applicable to any spectral representation because it is a simple weighting function on the frequency axis.

E. Applying the SSI weight to EP

In Fig. 1, we apply the SSI weight (black dotted line) to the original spectrum (blue solid line) to derive the weighted spectrum (red dashed line). In particular, in Fig. 1(a), the first peak of the resolved harmonics of the female voice is effectively suppressed. The red dashed line in Fig. 1(c) shows the cross-correlation function between the SSI-weighted EPs. The peak (red asterisk) is at a shift of 6, which is approximately 1.2 times the frequency and coincides with the VTL ratio (=1.23) between the male and female. Thus, introducing the SSI weight is expected to reduce the difficulty of VTL estimation.

III. VTL ESTIMATION METHOD AND EVALUATION

A. Measured VTL data

The effectiveness of the SSI weight was evaluated using the "ATR vowel speech MRI data" [10], [11], which contains five vowel sounds, $v \{v|`a', `i', `u', `e', `o'\}$, accompanied by accurate VTLs measured from MRI images of sustained vocalizations. As it contained only 13 male prepared data points, we additionally derived six female data points [31], [32]. Therefore, we used data from 19 speakers.

B. Spectral analysis by GCFB

We used the GCFB [22], [24], [25] for VTL estimation, as described in Section II-C. It was set to process 100 channels with a sampling frequency of 48 kHz and a filter center frequency range of 100 – 8000 Hz. Upon audio input, the EP is output with a frame period of 0.5 ms, and the EP spectrogram is calculated. EPs in the range of $\pm$25 ms from the center of the speech data were averaged to obtain the spectral representation "Ep" of the vowel described above. The spectral representation "Ep_{SSI}" was also calculated by applying the SSI weight in Eq. 1 with the F_o estimated by WORLD [20].

C. VTL estimation algorithm

For each of the five vowels, the cross-correlation functions of the EPs were calculated for all combinations of the 19 speakers ($N = 19$). Between the i-th and j-th speakers, the shift in the peak position from the center, c_{ij}, was extracted using the cross-correlation function. Note that the EP was linearly interpolated in advance by a factor of 10 to make the resolution of the peak shift as a 0.1 channel. The resulting shift was assumed to be caused by the VTL difference. When the orders of i and j are swapped, the amount of shift is the same in absolute value and only the sign is reversed. Therefore, the matrix notation of all permutations is represented as

$$\begin{bmatrix} 0 & c_{12} & c_{13} & \cdots & c_{1N} \\ -c_{12} & 0 & c_{23} & \cdots & c_{2N} \\ -c_{13} & -c_{23} & 0 & \cdots & c_{3N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -c_{1N} & -c_{2N} & -c_{3N} & \cdots & 0 \end{bmatrix}.$$

The relative shift for the i-th speaker, S_i, from the average of all speakers is calculated by taking the difference between the vertical and horizontal sums of this matrix.

$$C_j^{row} = \sum_{i=1}^{N} c_{ij}, \qquad C_i^{col} = \sum_{j=1}^{N} c_{ij} \tag{2}$$

$$S_i \quad = \quad (C_i^{row} - C_i^{col})/2N \tag{3}$$

Although this equation is simple, the equivalent value was obtained using an estimation method with a generalized inverse matrix [33], [34]. Since this value is a shift quantity on a logarithmic scale, its exponent yields the VTL, L_i as

$$L_i \quad = \quad \exp(qS_i) \cdot \bar{L} \tag{4}$$

where $\bar{L}$ is the measured VTL averaged across speakers. q is a conversion coefficient that depends on the spectral representation. In this study, q was determined to minimize the squared error between the regression line, calculated from the measured and estimated VTLs for all 19 speakers and five vowels, and the 1:1 identical line.

D. Estimation results

Figure 3 shows scatter plots between the measured and estimated VTLs when using Ep (Fig. 3a) and Ep_{SSI} with $h_{max} = 3.5$ (Fig. 3b). The correlation coefficients for Ep and Ep_{SSI} were calculated for all vowels and speakers. The values were 0.71 and 0.80, respectively. Vowel labels are generally

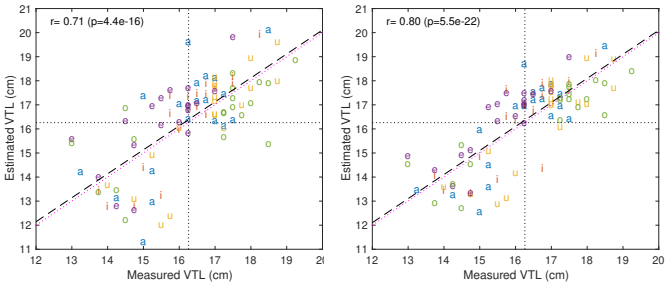

Fig. 3: Scatter plot of estimated VTL ratio against VTL measured from MRI data. The regression line was obtained using all the vowel and speaker data (dashed lines). Left: Ep, right: Ep_{SSI} with h_{max} = 3.5. Color coded for each vowel. Dotted line: 1:1 identical line.

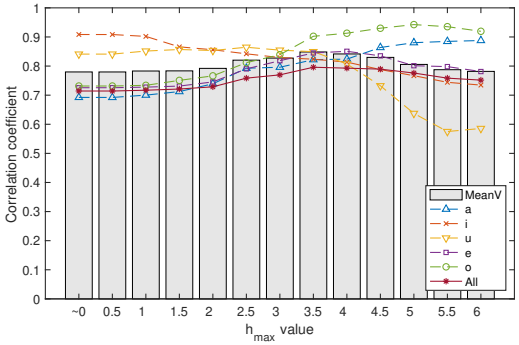

Fig. 4: Correlation coefficients between measured and estimated VTLs for various h_{max} values. Lines: Coefficients for the individual vowel ('a','i','u','e','o') and when using all vowels ("All"). Bar: mean value for the five vowels.

closer to the regression line in Ep_{SSI} than in Ep. This finding indicates that applying the SSI weight to the EP can improve the accuracy of the VTL estimation, as described in Section II-E.

1) The effect of h_{max} on VTL estimnation: Figure 4 shows the correlation coefficients between the measured and estimated VTLs calculated for h_{max} values between 0 and 6 in 0.5 steps. We assumed that the frequency response of the vocal tract filter may be best extracted by properly setting the h_{max} value to reduce the resolved harmonics in the EP shown in Fig. 4, although the h_{max} value was arbitrarily fixed at 5.0 when explaining the results of the human size perception experiments [5], [9]. It is also important to estimate vocal tract information equally well for all vowel types.

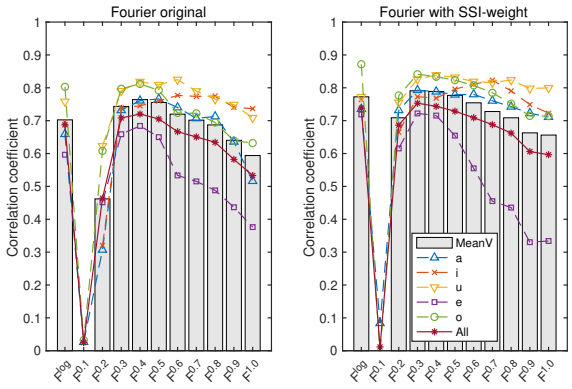
The correlation coefficients were calculated for each vowel, as shown by the lines in Fig. 4. When h_{max} was less than 3, the correlation coefficients for 'i' and 'u' (low first formant, F_1) were high, while those for 'a,' 'e,' and 'o' (high F_1) were low. This result implies that the F_o information from the resolved harmonics was not sufficiently suppressed in the low-frequency region. In contrast, when h_{max} exceeded 4, the correlation coefficients for 'a' and 'o' (high F_1) were high, and those for 'i' and 'u' (low F_1) were low. Therefore, F_1 and F_o information were excessively suppressed. The best results were obtained when h_{max} was 3.5, for which the difference between the five vowels was small, and the correlation coefficient obtained from all five vowels ('All') was the highest. In this case, information about the vocal tract and glottal vibration seemed to be properly separated regardless of vowel type.

TABLE I: Abbreviations of the compressed spectrum

spectrum	log	power, P	log+SSI	P+SSI
Fourier	F^{log}	F^{P}	F^{log}_{SSI}	F^{P}_{SSI}
Mel	M^{log}	M^{P}	M^{log}_{SSI}	M^{P}_{SSI}
WORLD	W^{log}	W^{P}	W^{log}_{SSI}	W^{P}_{SSI}

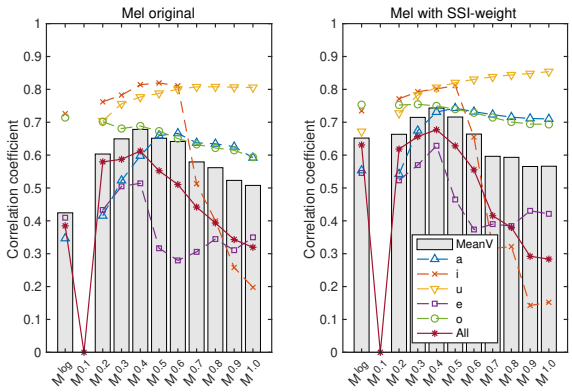
IV. Comparison with commonly used spectra

We compared the estimation performances when using the above auditory representation and commonly used spectral representations to evaluate their effectiveness. A comparison was made with a Fourier spectrum, "F," and a Mel-filterbank (MFB) spectrum [12],"M." We also included a WORLD spectrum [20],"W," because it reduces the effect of F_o by smoothing the frequency distribution and is commonly used in voice conversion as a successor of Tandem-STRAIGHT[35]. The estimation algorithm was identical to that described in Section III-C.



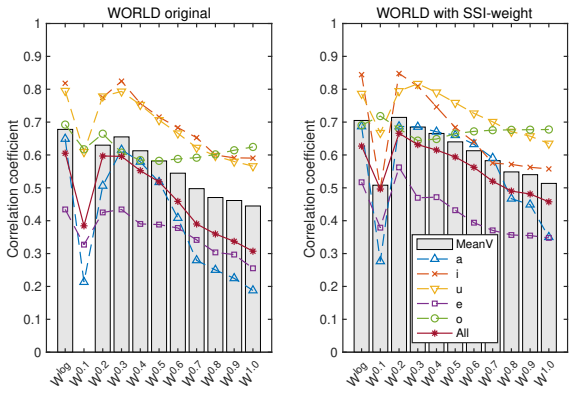
A. Calculation of the spectrum

The short-time Fourier spectrogram of the vowel sound was calculated with a frame length of 25 ms, a hamming window, and a frame shift of 5 ms. The Mel spectrogram was obtained from the STFT spectrogram with a Mel filterbank with 25 filters equally spaced on a Mel frequency axis corresponding to between 100 and 8000 Hz. The WORLD spectrogram was obtained with a default frame rate of 5 ms. Then the obtained amplitude spectrogram, $S(f_p, \tau)$, was subjected to logarithmic compression, $20\log_{10}\{S(f_p,\tau)\}$, and power compression, $S(f_p,\tau)^P \quad \{P \,|\, 0.1 \le P \le 1.0, \text{every } 0.1\}$. The compressed spectrogram in the range of $\pm$25 ms from the center was averaged to obtain the spectrum as calculated in EP (Section III-B). For the Fourier and WORLD spectra, the frequency axis was logarithmically transformed, and a spectrum with 100 channels equally spaced between $\log_{10}(100)$ and $\log_{10}(8000)$ was obtained by linear interpolation. The Mel spectrum with 100 channels was obtained from the 25-channel spectrum via linear interpolation.



As decribed in section II-D, the SSI weight improved the estimation performance when applied to the EP and was applicable to any spectrum. Therefore, the SSI weight was also applied to these spectra to investigate its effect. Table I presents the abbreviations for each compressed spectrum.

B. Effect of compression on the estimation



Initially, we sought to identify the log and exponential compressions that yielded the best VTL estimation in each spectrum. The resulting spectra are suitable for comparison with EP.

(a) Fourier spectrum

(b) Mel spectrum

(c) WORLD spectrum

Fig. 5: Correlation coefficients between the measured VTLs and the VTLs estimated from the log and power compressed spectrum. Left panel shows the result when using the original compressed spectrum and the right panel shows the result when using the spectrum with the SSI weight. Lines and bars are the same as in Fig. 4.

Figure 5a shows the correlation coefficients between the measured VTLs and the VTLs estimated from the various compressed Fourier spectra. The correlation coefficients were generally higher when using the spectrum with the SSI weight (left panel) than when using the original spectrum (right panel).The Fourier spectrum with the SSI weight F^{log}_{SSI} yielded the best correlation coefficient and a relatively small variability

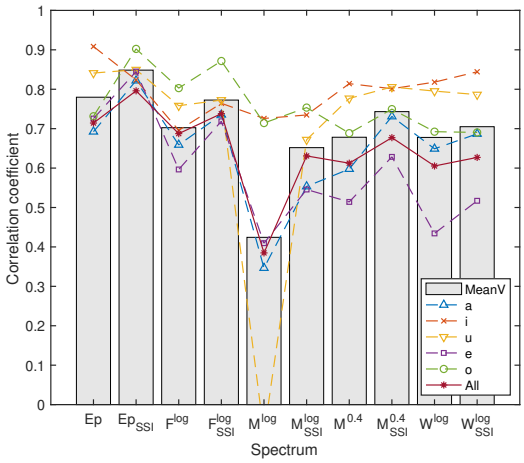


Fig. 6: Correlation coefficients derived from different spectra. Lines and bars are the same as in Fig. 4

between vowels. The F^{log} in the left panel showed high correlation coefficient although it was not the best. We used these data for comparison.

Figure 5b shows the results of the Mel spectrum. The correlation coefficients were generally smaller than those in the Fourier spectrum. The Mel spectra of $M^{0.4}$ and $M^{0.4}_{SSI}$ were the best for each panel. We also included M^{log}, which is the spectrum for the calculation of Mel-frequency cepstrum coefficient (MFCC) [12], and M^{log}_{SSI} in the comparison.

Figure 5c shows the results of the WORLD spectrum. We selected W^{log} and W^{log}_{SSI} for comparison, because they provided the best correlation coefficients on average.

C. Comparison between the EP and various spectra

Figure 6 shows the correlation coefficients for the EP and the spectra selected above. Ep_{SSI} had the highest correlation coefficient and smallest variability among the five vowels. In contrast, M^{log} had the lowest correlation coefficient. Notably, the correlation coefficient was always higher in any spectrum when introducing the SSI weight. Therefore, the SSI weight could improve the estimation of vocal tract information.

These differences were tested statistically. We performed the VTL estimation 10 times using data from 16 speakers after excluding two males and one female from the original 19 speakers at random. Subsequently, the RMS error between the measured and estimated VTLs was calculated. If the VTL estimation is sufficiently good, it should be stable and accurate even if three data points are randomly eliminated. Figure 7 shows the mean and standard deviation and the results of Tukey's HSD multiple-comparison test. The RMS error for Ep_{SSI} was approximately 1 cm, which was significantly smaller than those for the other spectra. In contrast, the RMS error for M^{log} was approximately 3 cm, which was significantly greater than that for the other spectra. More importantly, the results also demonstrate that introducing the SSI weight reduced the error in any spectrum. These reductions were statistically significant ($p < 0.05$), except for the WORLD

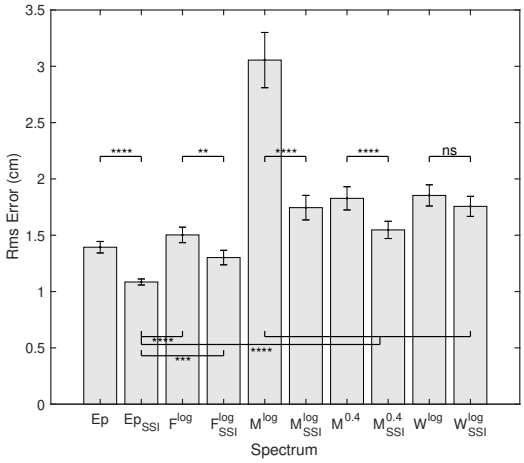

Fig. 7: Mean and standard deviation of the RMS errors in cm when the data of three speakers were randomly excluded 10 times. Tukey's HSD test: $* : p < 0.05; ** : p < 0.01; *** : p < 0.001; **** : p < 0.0001$; ns: not significant. Note that there are many other significant differences, but they are not shown here for simplicity.

spectrum. It is noteworthy that the difference between the errors of M^{log} and M^{log}_{SSI} is extremely large.

D. Some lessons from the results

Suggestions obtained from the results may serve as lessons for future speech signal processing.

1) Effective auditory representation: Many "auditory motivated" models have been proposed for various speech signal processing tasks. Most of them only introduced peripheral frequency analysis, such as the auditory and Mel filterbanks. The current results imply that such a frequency analysis is not sufficient for extracting vocal tract information. The introduction of the SSI weight improved the performance. As shown in Figs. 2 and 8, the SSI weight is a simplified version of the Size-Shape Image in the SWMT, which was proposed as a computational theory of the central auditory process. It is important to introduce knowledge of human auditory processing to derive effective auditory representation.

2) Effectiveness of MFCC: Mel-frequency cepstrum coefficient (MFCC) has been commonly used in many kinds of speech processing after its tremendous success in ASR [12]. MFCC has also been used in VTL estimation [13]–[16], even in recent DNN studies [17]–[19]. However, it has rarely been questioned whether the MFCC is an effective representation for this purpose.

The log Mel-spectrum M^{log} is a basic representation for calculating MFCC. The results in Fig. 7 imply that information about the vocal tract and glottal vibration is not sufficiently separated in M^{log}. As the discrete cosine transform (DCT) is applied across all frequency ranges, all cepstrum coefficients unavoidably contain both types of information. Therefore, the use of MFCC does not seem effective for VTL estimation, even if a state-of-the-art DNN method is used in the back-end. This is because the DNN is required to segregate both types of information embedded in the individual cepstral coefficients before estimating the VTL. Although it would be possible to use a large number of parameters to resolve this, interpretation of the internal representation could be difficult because of complexity. A modified version of the MFCC derived from the log Mel-spectrum associated with the SSI weight may improve the performance and interpretation.

3) Merit and usage of the SSI weight: the SSI weight is applicable to any type of commonly used spectra because it is a simple F_o adaptive function on a frequency axis (Eq. 1 and Fig. 2). It is not necessary to estimate F_o accurately because the SSI weight is less sensitive to the F_o value. the SSI weight can be easily implemented in any speech processing program by adding a few lines and an F_o estimation package such as WORLD [20]. Practically, it has been introduced into an objective speech intelligibility measure, GESI [29], [30], to improve the prediction of both male and female speech sounds.

V. Summary

In this study, we investigated auditory representations, which are effective for estimating vocal tract information. We proposed the use of the SSI weight which is derived from SWMT to segregate information about the vocal tract and glottal pulse from speech sounds. The auditory EP associated with the SSI weight improved the estimation of VTLs measured from the MRI data. Moreover, the estimation error was significantly smaller than when using the commonly used Fourier, Mel, and WORLD spectra. It was also demonstrated that the SSI weight can be easily introduced into these spectra to improve the performance.

Appendix A. SWMT and auditory spectrogram

Figure 8 shows the relationship between the SWMT (Stabilised Wavelet-Mellin Transform) [6], the auditory spectrogram, and the SSI (Size-Shape Image) weight introduced in Section II-D (see Appendix A in [5] for more details).

The upper path in Fig. 8 shows the signal processing of the SWMT, which is supported by several experiments on size information processing in the auditory system (for example [2], [3], [5]). This is effective in theory but has a problem when applied to practical applications. The process of strobe temporal integration for stabilization and 2-dimensional conversion in SWMT is rather difficult to implement in a computational model. To resolve this problem, we developed the SSI weight (Eq. 1) which is applicable to any spectrographic representation.

The lower path in Fig. 8 shows the analysis using an auditory spectrogram. The auditory filterbank is the same as that in SWMT. The output is processed by windowing and averaging to obtain an excitation pattern (EP). This process is simple and

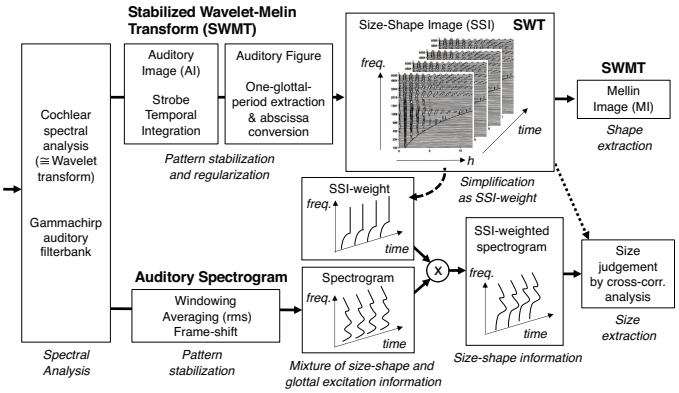

Fig. 8: Relationship between SWMT, auditory spectrogram, and SSI weight [5]. The upper path shows the SWMT process; the lower path shows the auditory spectrogram process along with the SSI weight shown in the middle block. See Appendix A.

produces a stable representation of the spectral information in the sound, although it discards the temporal fine structure that also plays an important role in the auditory perception [36]. An auditory spectrogram is a stream of EPs derived from each frame. As described in Section II, the product of the SSI weight (in the middle block) and the frame-based spectrum is suitable for extracting size information.

***Abstract*—Recently, studies of spoken term detection (STD) and spoken query STD (SQ-STD), also known as query-by-example (QbE), have been actively pursued. A representative method of QbE is posteriorgram matching using outputs of deep neural networks. However, that method requires much retrieval time and memory size. To address this difficulty, we proposed a maximum likelihood state sequence method (MLSS) for retrieval time reduction. This paper presents a proposal of two methods named "blank-cut (b-cut)" and "frame de-duplication (FDD)" to compress posteriorgram frames, by which we reduce retrieval times and memory sizes. Multiple matching scores are obtained using multiple deep learning models and architectures in the proposed methods. Then they are integrated. We achieved state-of-the-art retrieval accuracy as shown by evaluation experiments using two open test sets of about 30 hr of speech data. Furthermore, the proposed method achieved a retrieval time of less than 1 s and a memory requirement of about 1 GB. These results demonstrated the effectiveness of the proposed method.**

Index Terms: blank-cut, frame de-duplication, query-by-example, maximum likelihood state sequence, spoken term detection

I. INTRODUCTION

Along with the increasing capacity of storage media, studies of spoken term detection (STD) have been actively conducted. STD is a task that seeks specific keywords or phrases consisting of one or more words among large amounts of speech data [1–3]. In fact, NIST STD evaluation [4], Spoken Web Search (SWS) [5], QUery by Example Search on Speech Task (QUESST) [6], and NTCIR Workshop [7, 8] have been held to evaluate STD systems.

In representative conventional STD systems, speech data are first transcribed into subword sequences of text data using an automatic speech recognizer (ASR). Then, the speech data sequences are compared with those of search words (queries) using dynamic time warping (DTW) continuously at a frame level. Some misrecognition might have occurred, thereby leading to deterioration of the retrieval accuracy.

Queries of the STD system are given by text. Spoken query STD (SQ-STD) or query-by-example (QbE), whose queries are given by audio or speech, have also been conducted because of the rapid spread of smartphones and other devices. Earlier studies have also evaluated QbE systems [9–13]. A common method used for QbE is posteriorgram matching method. Posteriorgrams, sequences of posterior probability vectors for an utterance, are speaker-independent features obtained by Deep Neural Networks (DNN). When inputting a feature vector of a single frame to DNN, posterior probabilities corresponding to the states of Hidden Markov Models (HMM) or phonemes and so on per frame are obtained. These output posterior probabilities are known as posterior probability vectors. In posteriorgram matching, posteriorgrams of speech data are generated in advance. A posteriorgram of spoken query is generated when it is given. Then frame-level matching between two posteriorgrams is performed using DTW continuously. The local distance in DTW matching is obtained by computing the inner product of each posterior probability vector, and then by taking the negative logarithm of it. Posteriorgram matching [14] shows the state-of-the-art retrieval accuracy, but it requires long times and large amounts of memory because of the large dimension of posterior probability vectors. To reduce the retrieval times and memory requirements, maximum likelihood state sequence (MLSS) for a spoken query or speech data has been proposed [15, 16]. This method compresses a 3,000-dimensional posteriorgram to one dimension and then eliminates the inner product calculation. Therefore, it reduces the retrieval time. However, the retrieval accuracy of MLSS is lower than that of posteriorgram matching because of the reduction of information. For another earlier study [17], two frame forced integration (2FFI) was proposed to reduce time and memory, as well as MLSS. It reduced the number of frames in the posteriorgram by averaging two frames of the posterior probability vectors in the posteriorgram to one frame.

As described herein, we propose two compression methods to reduce time and memory. The blank-cut method removes <blank> labels. We expect that removing them will improve the retrieval accuracy by highlighting only the valid information. The frame de-duplication (FDD) method compresses similar frames to one average frame. We first evaluated these methods using the output of multiple deep learning models and then obtained matching scores that are integrated to improve accuracy. We tested the effectiveness of the proposed method and the integration of multiple models using open test collections.

The remainder of this paper is organized as follows: Section II introduces earlier studies. Section III presents blank-cut method and FDD method, proposed herein. Section IV presents

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

results of experiments conducted using the proposed method. Finally, the conclusion is presented in Section V.

II. RELATED WORK

A. *Posteriorgram matching for QbE*

Recently, deep neural networks (DNNs) have been developed and used in various fields [18]. Furthermore, in speech recognition systems, acoustic models trained with DNN are often used. Even for unspecified speakers, QbE using DNN enables highly accurate retrieval by performing frame-level matching using posteriorgrams, which are frame-by-frame posterior probabilities obtained from DNN. By using this method, the speech data are first converted into features such as filter bank (FBANK) or Mel-Frequency Cepstrum Coefficients (MFCCs), which are then input to the DNN to produce a posteriorgram. The given spoken query is also converted into features and is input to the DNN to produce a posteriorgram. The local distance matrix is then produced using the posteriorgrams of the spoken query and the speech data. By computing the inner product, the similarity of vectors in each frame of the speech data and the speech query are obtained. Then DTW matching is performed using the distance matrix, which has been distanced by taking the negative logarithm after computing the inner product [18]. However, because the posterior probability vector consists of approximately 3,000 dimensions, the creation of the local distance matrix takes a high computational cost and engenders a long search time. Furthermore, because the posteriorgram of the speech data is retained, the memory requirement increases.

B. *Spoken query / Speech data maximum likelihood state sequence method (MLSS)*

A spoken query / speech data maximum likelihood state sequence (MLSS) method was proposed to reduce the memory requirement and long retrieval time of posteriorgram matching [15, 16].

In MLSS for spoken query, a posteriorgram of the spoken query is made. The state number with the largest posterior probability value in each frame is assigned to the maximum likelihood state. Each frame is associated with a maximum likelihood state number. This number converts a posteriorgram of approximately 3,000 dimensions into a one-dimensional maximum likelihood state number series. The probability values of the posteriorgrams of speech data are taken as a local distance matrix with negative logarithms. The matrix is referenced using the maximum likelihood state series of the spoken query.

In MLSS for speech data, the posteriorgrams of the speech data are converted to a maximum likelihood state series in advance for referencing and matching. Although the retrieval time and memory requirement were reduced, the retrieval accuracy was lower than that of posteriorgram matching. Fig. 1 depicts a flow of MLSS for speech data.

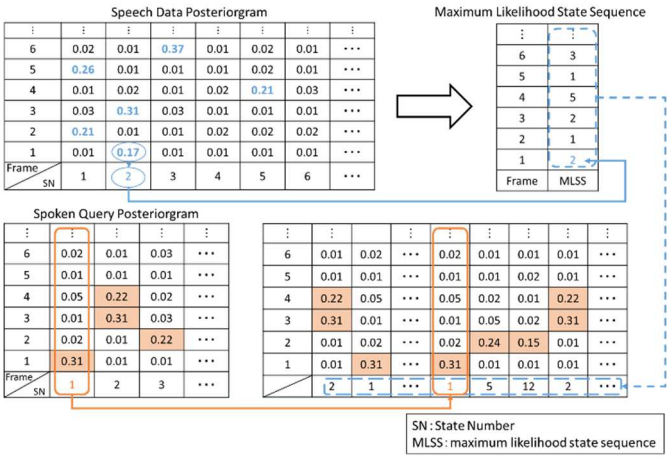

Fig. 1. Speech data maximum likelihood sequence method flow, adapted from an earlier report [16].

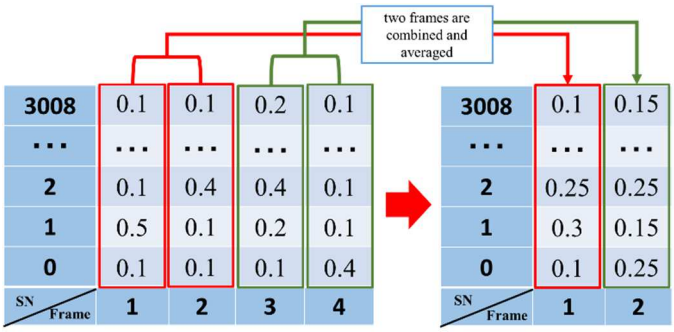

Fig. 2. Flow of two frame forced integration (2FFI) method.

C. *Two frame forced integration*

As described in an earlier report [17], a method was proposed to average the posterior probability vectors of two adjacent frames of a posteriorgram. As described in this paper, we designate it as two frame forced integration (2FFI). In this method, the posterior probability vectors of one frame and the next frame in the posteriorgram are combined and averaged. The resulting posterior probability vector is stored in a new posteriorgram. This process halves the number of frames, thereby reducing the retrieval time for matching. Fig. 2 depicts the flow of the 2FFI method.

D. *Bidirectional long short-term memory (BLSTM)*

Bidirectional Long Short-Term Memory (BLSTM) is a deep learning model that is an extension of a Recurrent Neural Network (RNN). Actually, RNN has a recursive structure by which the middle layer output returns to itself after a time delay. It is regarded as effective for learning time series data. For this reason, it is used widely in the fields of speech recognition and natural language processing.

Actually, LSTM is a model that can learn long-term dependencies by replacing the nodes in the middle layer of RNN with LSTM gates of three types. A BLSTM model uses the LSTM structure for forward propagation to the next step, makes a model for back propagation to the previous step, and integrates each output into the output layer. Compared with

unidirectional deep learning models such as simple feed forward neural networks, BLSTM can learn bidirectional features of time series data, and can thereby improve the retrieval accuracy [17].

E. ESPnet

In recent years, end-to-end learning models have been used in ASR. They reportedly provide high recognition accuracy [19]. End-to-end ASR requires no frame-by-frame correct labels, which are necessary for traditional hybrid ASR. Actually, ESPnet allows the flexible construction of models with different numbers of states corresponding to speech features such as words, subwords and other speech components. Therefore, we used ESPnet, which consists of Hybrid CTC/Attention [20] as an end-to-end speech recognizer. As a shared encoder, the same encoder is used for both CTC and Attention. The posteriorgram consisting of the posterior probability vector output from CTC is extracted and used because an earlier report [17] has described high retrieval accuracy.

F. Score integration

An important difficulty associated with MLSS method is that its retrieval accuracy is lower than that of the posteriorgram matching method because of the decreased amount of information. To resolve that point, matching with multiple deep learning models was performed; then score integration method was used for retrieval in an earlier study [17]. When using this method, the information is complemented by linear summation of multiple matching scores using Equation (1). The integration ratio of the linear summation is adjusted by weight α, for which the possible values are $0 \leq \alpha \leq 1$.

$$D_{new}(\mathrm{i}) = \sum_{n=1}^{N} \alpha_n D_n(i) \qquad (1)$$

III. PROPOSED METHOD

This section proposes blank-cut method (b-cut) and FDD to compress the posteriorgram frames used in matching. This method further reduces the retrieval time and memory requirements of posteriorgram matching and MLSS methods. Moreover, with scores obtained using the proposed method in the score integration, we propose a method that achieves high retrieval accuracy, and retrieval time of about 2 s. The memory requirement is about 2 GB for about 30 hr of speech data to be retrieved.

A. Blank-cut (b-cut)

Into the posteriorgram made from Connectionist Temporal Classification (CTC) of the Hybrid CTC/Attention architecture in ESPnet, <blank> labels are inserted to match the input and output series lengths. Assuming that <blank> labels have no valid information, we propose a method that removes <blank> labels and matches them. Flow of the b-cut method is depicted in Fig. 3. In the MLSS of posteriorgrams, removing frames

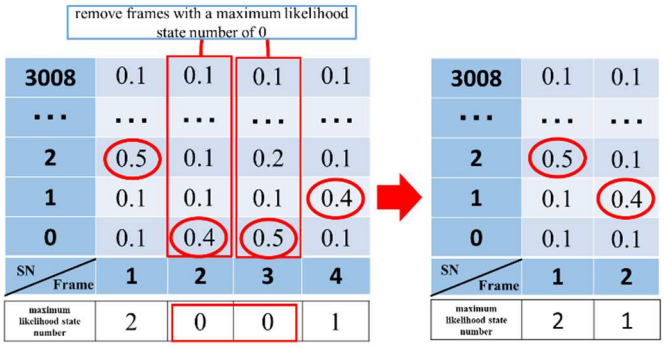

Fig. 3. Flow of blank-cut (b-cut) method.

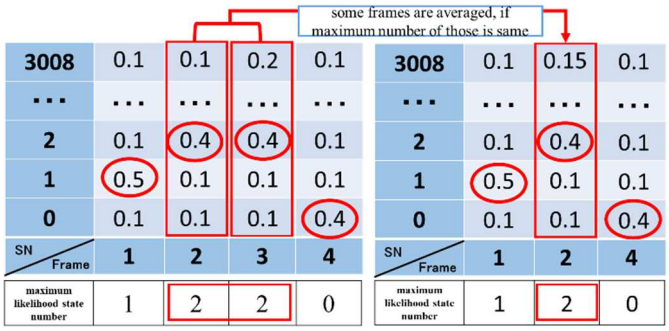

Fig. 4. Flow of FDD method.

with a maximum likelihood state number of 0, which correspond to <blank>, reduces the number of frames in the posteriorgrams, thereby reducing the retrieval time and memory. About half of the frames in the posteriorgrams obtained from CTC are <blank>. Therefore, removing them is expected to improve the retrieval accuracy by highlighting only valid information. The b-cut method is applied only to the posteriorgram obtained from ESPnet because <blank> exists only in the posteriorgram made from CTC.

B. Frame de-duplication (FDD)

The posteriorgram contains a series of frames with similar features and trends in the posterior probability vector. When local distances are made for matching, similar frames also show similar values. Therefore, even if similar frames are compressed to one average frame, the matching process is not affected markedly. The frames in the posteriorgram are reduced while maintaining the original retrieval accuracy, thereby reducing the retrieval time and memory requirement.

The FDD method flow is portrayed in Fig. 4. First, MLSS is made using the respective posteriorgrams of the spoken query and speech data. Next, each MLSS is referenced to ascertain the proportion of consecutive frames which have the same maximum likelihood state number. If frames of the same maximum likelihood state number are consecutive, then the posterior probability vector obtained by averaging multiple posterior probability vectors for those frames is stored as a new posteriorgram. If not, the posterior probability vectors of frames are stored as they are. Compressing multiple frames into a single frame reduces the overall number of frames in the posteriorgram, therefore engendering reduction of the time

necessary for local distance computation and DTW matching. Reduction in the number of retained posteriorgram frames also reduces the memory requirement. Furthermore, unlike the 2FFI method, which averages all frames by two frames, the FDD method, which compresses only frames with similar trends in the posterior probability vectors, can compress and match while preserving the features and trends of each frame's posterior probability vector.

C. Combination with score integration

Because the amount of information possessed by the posteriorgram is reduced when the proposed methods are applied, the retrieval accuracy might be lower than that of posteriorgram matching. To address this possible shortcoming, score integration using different deep learning models is applied to complement the information and to improve the retrieval accuracy. Memory requirements increase with the number of models used for score integration. However, the proposed methods reduce both retrieval time and memory during each matching. The methods are expected to maintain the memory requirement at a practical level even when using score integration.

IV. EXPERIMENTS

A. Experiment conditions

As described in this report, BLSTM and the model of ESPnet (Hybrid CTC/Attention) were trained and used for evaluation experiments. TABLE I presents the extraction conditions of speech features. The BLSTM model consists of 120 dimensional features (FBANK 40 dimensions, its ΔΔ features, and its ΔΔ features) concatenated in before and after 5 frames of one frame. Therefore, the input features are 1,320 (11 × 120)-dimensional. The input of Hybrid CTC/Attention was set to 83 dimensions, consisting of 80 FBANK dimensions and 3 pitch dimensions, as in an earlier study [17] that showed high retrieval accuracy.

The training data for each model are 2,702 lectures from the Corpus of Spontaneous Japanese (CSJ): speech of about 600 hr. The BLSTM consists of one input layer, five intermediate layers (256 dim.), and one output layer. The output layer corresponds to triphone. The number of states is 3,009 with state sharing. In Hybrid CTC/Attention, the output nodes correspond to character (3,242 dim.), syllable (261 dim.), and monophone (40 dim.), each of which has a <blank> label, an unknown state <unk> label, and a terminating <eos> label. Consequently, character has 3,245 dimensions, syllable has 264 dimensions, and monophone has 43 dimensions. For our experiments, we used a posteriorgram obtained from CTC, which has been shown to be highly accurate in an earlier study [17]. The retrieval time was measured using a personal computer: Intel Core i5-9400 CPU, NVIDIA GeForce RTX 2070SP GPU, and 16 GB RAM.

B. Test collections

TABLE II presents open test collections, called NTCIR-10 and NTCIR-12, used for the evaluation of the retrieval experiments. Because no spoken queries were provided in NTCIR-10, we recorded 100 queries uttered by 10 people. In NTCIR-10, the target speech data for retrieval were 104 lectures from the Spoken Document Processing Workshop (SDPWS), and in NTCIR-12, 98 lectures from the SDPWS. Correct answers were provided by the organizer for both NTCIR-10 and NTCIR-12. The mean average precision (MAP) was used to evaluate the retrieval accuracy.

TABLE I
Conditions for Feature Extraction

Model Architecture	BLSTM	Hybrid CTC / Attention
Feature parameter	120 dimensions FBANK (40 dims) + ΔFBANK (40 dims) + ΔΔFBANK (40 dims)	83 dimensions FBANK (80 dims) + Pitch (3 dims)
Window length	25 ms	
Frame shift	10 ms	

TABLE II
Two Open Test Collections

	NTCIR-10	NTCIR-12
Spoken documents	104 presentations, 29 hr, 40,746 utterances	98 presentations, 27.5 hr, 37,782 utterances
Query sets	Formal run: 100 (10 people)	Formal run: 113 (10 people)

C. Results obtained using proposed methods (single model)

To evaluate the proposed method, we first conducted matching experiments using the single model. In the matching experiment, we compare the normal condition with the 2FFI, b-cut, and FDD methods. Fig. 5 presents results of the matching experiments on NTCIR-10 using the BLSTM model. As described above, we use the posteriorgram matching method as the baseline because it allows detailed retrieval. Considering that it will be used together with the score integration method in later experiments, we conducted experiments on MLSS for spoken query and MLSS for speech data, which are expected to be of practical retrieval time in BLSTM. In the figure, the posteriorgram matching method is denoted as “Poste”, MLSS for spoken query as “Sq”, and MLSS for speech data as “Sd”.

In NTCIR-10, compared to Sq normal, the 2FFI method decreased MAP by about 1 pt, but reduced the retrieval time by about 2.6 s and the memory requirement by about half. The FDD method also reduced the time by about 2.6 s and memory by about half, and improved MAP by 0.2 pt. Compared to Sd normal, the 2FFI method decreased MAP by about 1.6 pt, but reduced the time by about 2.5 s and memory by about half. Similarly, the FDD method decreased MAP by about 2 pt, but reduced the time by about 2.5 s and memory by about half.

Experiments were also conducted using both the 2FFI and FDD methods. Compared to the results obtained using each method applied alone, the size of the posteriorgram can be reduced further. Then we aim to reduce the retrieval time and memory requirement further. Experiment results demonstrated that the 2FFI&FDD MAP outperformed the stand-alone MAP in both Sq and Sd, further reducing the retrieval time and

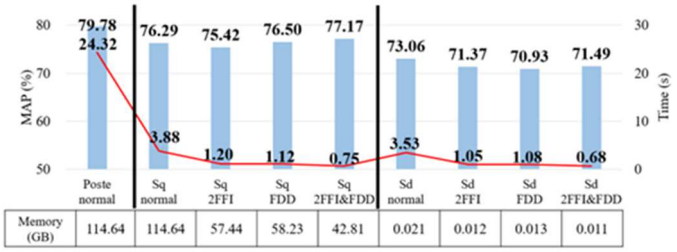

Fig. 5. Results of 2FFI method and FDD method (BLSTM: NTCIR-10).

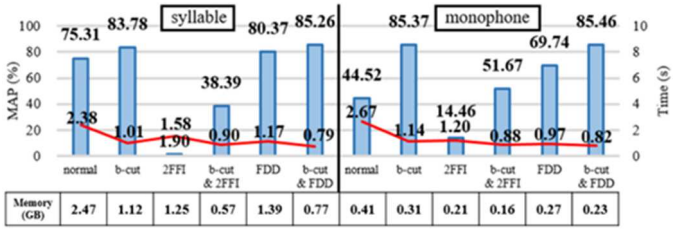

Fig. 6. Results of Posteriorgram matching using b-cut method, 2FFI method and FDD method (syllable, monophone: NTCIR-10).

memory requirements. A similar trend was observed from the NTCIR-12 experiment results.

Fig. 6 portrays results obtained from the experiments on NTCIR-10 using monophone and syllable. Monophone and syllable data have fewer dimensions in the posterior probability vector. Therefore, the retrieval time is expected to be practical even with posteriorgram matching. Therefore, we conduct experiments on the posteriorgram matching method.

In NTCIR-10 of monophone, the b-cut method improved MAP by about 41 pt, halved the retrieval time, and reduced the memory requirement by about 0.1 GB, compared to normal. The 2FFI method decreased MAP by about 30 pt, but halved both the time and memory. The FDD method improved MAP by 25 pt and halved both time and memory.

We also conducted experiments using the b-cut method in combination with the 2FFI and FDD methods. The b-cut&2FFI method decreased MAP by about 34 pt, but reduced the retrieval time by about 0.3 s and the memory requirement by half. The b-cut&FDD improved MAP by about 0.1 pt, reduced the time by about 0.3 s and memory by about 0.1 GB. Because MAP dropped markedly when the 2FFI method was applied, experiments using the 2FFI&FDD method were not conducted for monophone or syllable. The same tendency was observed from experiments with syllable in NTCIR-10 and with monophone and syllable in NTCIR-12.

The 2FFI method reduced the retrieval time and memory requirement while maintaining MAP in BLSTM, whereas MAP decreased considerably in monophone and syllable matching because the distribution of posterior probability values in ESPnet tends to be more extreme than that in BLSTM, with the posterior probability value of maximum likelihood being approximately 0.9 and the probability values of other states being almost zero. The 2FFI method buried high probability values by forcibly averaging them. In contrast, the FDD method compresses by averaging only similar frames

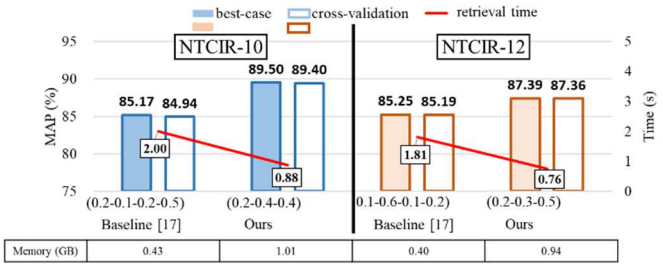

Fig. 7. Results in combination with the score integration method (NTCIR-10 and NTCIR-12).

with the same maximum likelihood state number, which reduces the previously described effects and which therefore prevents the MAP degradation. Regarding the b-cut method, we have concluded that removal of the blank part contributed to MAP improvement by coordinating the valid information. Therefore, the 2FFI&FDD method effectiveness was confirmed for BLSTM. That of the b-cut&FDD method was confirmed for monophone and syllable.

D. Results of score integration (multiple models)

Because the amount of information in the posteriorgram decreases when FDD method is applied, achieving clear improvement in retrieval accuracy compared to normal posteriorgram matching is difficult. Therefore, to complement the information of different tendencies and to improve the retrieval accuracy we apply score integration using multiple models.

Fig. 7 presents results of score integration for NTCIR-10 and NTCIR-12. The baseline is the highest MAP among the experimentally obtained results shown in an earlier study [17] that used score integration. The integration ratio is changed by 0.1. The integration ratio with the highest MAP is shown in the figure as "best-case" as a result of the experiment with all ratios. For cross-validation, results of another experiment using the highest integration ratio for one test set are shown alongside the best-case results as "cross-validation".

In NTCIR-10 at baseline, the highest MAP was found when a total of four types of matching scores were integrated. They are BLSTM (MLSS for speech data, 2FFI for only speech data), character (MLSS for speech data), syllable (MLSS for speech data) and monophone (MLSS for spoken query), in the integration ratio of (0.2 – 0.1 – 0.2 – 0.5). However, in this study, the MAP was highest when a total of matching scores of three types were integrated. They are BLSTM (MLSS for speech data, 2FFI&FDD), syllable (b-cut&FDD) and monophone (b-cut&FDD), in the integration ratio of (0.2 – 0.4 – 0.4). Compared to the baseline, the results obtained using the proposed method improved MAP by about 4.3 pt and reduced the retrieval time by about 1 s. The memory requirement increased by about 0.6 GB, but because it is only about 1 GB, it is a practical amount.

The same trend was observed for NTCIR-12. The highest MAP was observed when the baseline was integrated with the same matching scores as NTCIR-10 in the ratio of (0.1 – 0.6 – 0.1 – 0.2), whereas proposed method was integrated in the ratio

of (0.2 – 0.3 – 0.5). Compared to the baseline, our method improved MAP by about 2.2 pt and reduced the retrieval time by about 1 s. For both test sets, MAP during cross-validation was similar to that of the best case. Therefore, no bias was found among the test sets in terms of the integration ratio.

V. CONCLUSIONS

As described herein, we propose blank-cut method and FDD method to compress the posteriorgram frames. We applied 2FFI method and two proposed methods to three models and integrated their scores to obtain the best retrieval accuracy: 89.50% for NTCIR-10 and 87.39% for NTCIR-12. The retrieval time was 0.88 s for NTCIR-10 and 0.76 s for NTCIR-12, each of which was reduced by about 1 s. Although the amount of memory requirement increased from the baseline, it was only about 1 GB, which is within a practical range. The findings confirmed the effectiveness of the proposed method.

In future studies, we expect to achieve higher accuracy by introducing and integrating further multiple deep learning models.

***Abstract*—In this paper, we present a short-time fundamental frequency estimation method based on a differential equation. Fundamental frequency estimation is a popular problem in audio analysis. Particularly, the estimation from short signals has been desired in various real-time processing. The sinusoidal constraint differential equation (SCDE)-based method for realizing high-temporal resolution has been proposed for the frequency estimation of a single sinusoid or multiple sinusoids. The SCDE-based method can efficiently and accurately estimate frequency even from a short-term signal. In this paper, as its extension towards the fundamental frequency estimation, we introduce the harmonic constraint to the SCDE-based method, and propose the finite-order harmonic constraint differential equation-based method. We first derive a differential equation that any harmonic signals with harmonics up to Nth order satisfy, where the fundamental frequency is included in coefficients. Then, the fundamental frequency is estimated by minimizing an objective function expressed as the short-time integral of the squared error of its differential equation. Our experimental results show that our method outperformed the existing methods for estimation with noisy signals of 5 ms.**

I. Introduction

The frequency estimation of sinusoids has been studied as a fundamental problem in audio signal processing with various applications [1]–[7]. The fundamental frequency estimation has also been studied as a popular problem [8]–[10]. Signals such as speech and music have a harmonic structure. The frequencies with the harmonic structure are integer multiples of a common low frequency, which is known as the "fundamental frequency" or "F0". We aim to track the fundamental frequency in real time. To this end, we extend a frequency estimation method that has performed well on a short signal with high-frequency resolution.

A popular method of frequency estimation is the maximum likelihood estimation [11]–[15]. Although it can accurately estimate frequencies, it requires an iterative optimization to solve a nonconvex optimization problem. Other methods for frequency estimation have used discrete Fourier transform (DFT) [16]–[21]. Parabolic interpolation [16], [17] and spectral reassignment [18], [19] improve the estimation accuracy by taking the spectral peak. However, their estimation accuracy depends on the frequency resolution. It is difficult to estimate high resolution in a short signal.

One promising method for frequency estimation is the sinusoidal constraint differential equation (SCDE)-based method [22]–[25]. The key to this method is the use of signal derivatives. In detail, the SCDE is a differential equation that holds for a single sinusoid. The equation is independent of the amplitude and phase of the sinusoid, allowing us to estimate the frequency in a closed form from a short signal. We expanded the SCDE-based method for an arbitrary number of sinusoids [26]. Our method can accurately estimate the frequencies of all the sinusoids simultaneously from a short observed signal.

An approach to performing the fundamental frequency estimation based on the SCDE method would be applying it directly to a harmonic signal as a multi-sinusoidal signal. In this case, the frequencies of the harmonics are estimated separately. Then, by post-processing them, the fundamental frequency could be estimated. However, we consider that a more effective performance could be achieved by incorporating the harmonic structure into the model in advance.

In this paper, based on such motivation, we present the finite-order harmonic constraint differential equation (FOHCDE)-based method that uses the SCDE with the harmonic structure of signals as a constraint. Firstly, we formulate a differential equation satisfied by any harmonic signal with harmonics up to the Nth order, with the fundamental frequency incorporated within the coefficients. After that, the fundamental frequency is estimated by minimizing an objective function defined as the short-time integral of the squared error from the differential equation. Our experimental results show that the FOHCDE-based method is effective in high resolution for a small length. The proposed method can achieve a higher performance than the SCDE-based method under noisy conditions.

II. Sinusoidal Constraint Differential Equation

We previously presented a method of estimating the frequencies of multiple sinusoids from an extremely short signal [26]. In this section, we briefly explain this method based on the SCDE.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

A. Signal model

Let us consider a signal modeled as

$$x(t) = \sum_{n=1}^{N} A_n \cos(\omega_n t + \phi_n), \tag{1}$$

where t denotes continuous time, $n = 1, \ldots, N$ denotes the sinusoid index, and A_n, ω_n, and ϕ_n denote the amplitude, frequency, and phase of the n-th sinusoid, respectively. The parameters A_n, ω_n, and ϕ_n are unknown, while the number of sinusoids (N) is assumed to be known in this paper.

B. Frequency estimation of SCDE-based method

We first introduce the SCDE-based method for a sinusoid referring to [22], [23]. The SCDE-based method for a sinusoid is the basis for the SCDE-based method for multiple sinusoids and the FOHCDE-based method. In this case, the following second-order differential equation holds for any t and ω_1:

$$\frac{d^2}{dt^2} x(t) + \omega_1^2 x(t) = 0. \tag{2}$$

This equation is called the SCDE [22], [23]. Since it does not contain A_1 or ϕ_1, the frequency estimation can be performed independently of these parameters. To obtain ω_1 satisfying (2), we minimize the following objective function:

$$J(\omega_1) = \int_\Gamma \left[\frac{d^2}{dt^2} x(t) + \omega_1^2 x(t) \right]^2 dt, \tag{3}$$

where Γ denotes the range of $t \in \mathbb{R}$ in the definite integral. It has also been extended to the case with multiple sinusoids by combining the DFT and the SCDE-based method in each sub-band [22], [23]. Since spectral peaks are not separable when the signal is very short, this method is not applicable for short-time signals.

C. Multiple frequency estimation by SCDE-based method

Next, let us consider a signal with N sinusoids. The SCDE with multiple sinusoids is defined as [26]

$$\begin{aligned} &\left(\frac{d^2}{dt^2} + \omega_1^2 \right) \cdots \left(\frac{d^2}{dt^2} + \omega_N^2 \right) x(t) = 0 \\ &\Leftrightarrow c_0 \frac{d^{2N}}{dt^{2N}} x(t) + c_1 \frac{d^{2(N-1)}}{dt^{2(N-1)}} x(t) \\ &\quad + \cdots + c_{N-1} \frac{d^2}{dt^2} x(t) + c_N x(t) = 0, \end{aligned} \tag{4}$$

where c_n denotes the coefficient of the differential equation, depending on ω_n for all n. We obtain ω_n from each c_n. To optimize c_n under the SCDE (4), we minimize the following objective function:

$$J(c_0, \ldots, c_N) = \int_\Gamma \left[\sum_{n=0}^{N} c_n \frac{d^{2(N-n)}}{dt^{2(N-n)}} x(t) \right]^2 dt. \tag{5}$$

We can then estimate frequencies by solving the simultaneous equations for c_n.

III. Finite-Order Harmonic Constraint Differential Equation

A. Motivation

The SCDE-based method is applicable to any signal, including that with the harmonic structure. The harmonic structure of sound is a unique feature of voice and instruments. By introducing the constraint of the harmonic structure into the SCDE-based method, we expect to realize the fundamental frequency estimation with good accuracy, even from a short signal.

B. Signal model

Let us consider a signal with a harmonic structure. We model the signal as

$$x(t) = \sum_{n=1}^{N} A_n \cos(\omega_n t + \phi_n), \tag{6}$$

$$\omega_n = n\omega_1, \tag{7}$$

where ω_1 denotes the fundamental frequency and N denotes the finite number of harmonics included in $x(t)$. As described in Section II-A, A_n, ω_n, and ϕ_n are unknown, while N is assumed to be given in advance.

C. Fundamental frequency estimation by FOHCDE-based method

First, each sinusoid in (6) satisfies the following SCDE as in (2):

$$\left(\frac{d^2}{dt^2} + \omega_n^2 \right) A_n \cos(\omega_n + \phi_n) = 0 \quad \forall n. \tag{8}$$

From (7), the following differential equation holds for $x(t)$ with any t, N, and ω_1:

$$\left(\frac{d^2}{dt^2} + \omega_1^2 \right) \cdots \left(\frac{d^2}{dt^2} + N^2 \omega_1^2 \right) x(t) = 0. \tag{9}$$

We call this equation the FOHCDE since any harmonic signals with harmonics up to Nth order satisfies this differential equation. To estimate ω_1 that satisfies constraint (9) as much as possible, we minimize the following objective function:

$$\begin{aligned} J(\Omega_1) &= \int_\Gamma \left[\sum_{n=0}^{N} \alpha_n \Omega_1^n \frac{d^{2(N-n)}}{dt^{2(N-n)}} x(t) \right]^2 dt \\ &= \sum_{n=0}^{2N} \beta_n \Omega_1^n, \end{aligned} \tag{10}$$

where $\Omega_1 = \omega_1^2$. The coefficients α_n and β_n respectively satisfy the equations below.

$$\sum_{n=0}^{N} \alpha_n \Omega_1^n = \prod_{n=0}^{N} (1 + n^2 \Omega_1) \tag{11}$$

$$\sum_{n=0}^{2N} \beta_n \Omega_1^n = \sum_{i=0}^{N} \sum_{j=0}^{N} \alpha_i \alpha_j S_{ij} \Omega_1^{i+j} = \boldsymbol{z}^\mathsf{T} \boldsymbol{S} \boldsymbol{z} \tag{12}$$

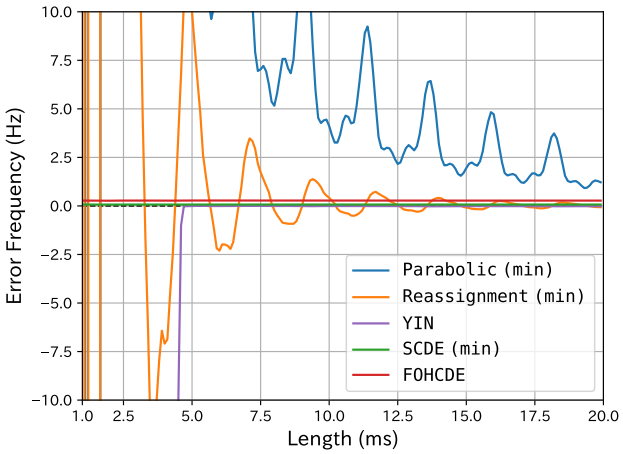

Fig. 1. Estimation error with respect to the signal length for harmonic signals whose frequencies are 440 Hz and 880 Hz.

Here,

$$\boldsymbol{z} = \left[\alpha_0 \Omega_1^0 \ \cdots \ \alpha_N \Omega_1^N\right], \tag{13}$$

$$\boldsymbol{S} = \begin{bmatrix} S_{00} & \cdots & S_{0N} \\ \vdots & \ddots & \vdots \\ S_{N0} & \cdots & S_{NN} \end{bmatrix}, \tag{14}$$

$$S_{ij} = \int_\Gamma \left[\frac{d^{2(N-i)}}{dt^{2(N-i)}} x(t) \frac{d^{2(N-j)}}{dt^{2(N-j)}} x(t)\right] dt. \tag{15}$$

Now, we find the stationary point by taking the derivative of $J(\Omega_1)$ with respect to Ω_1 and setting it to zero.

$$\frac{dJ(\Omega_1)}{d\Omega_1} = \sum_{n=1}^{2N} n\beta_n \Omega_1^{n-1} = 0 \tag{16}$$

Eq. (16) is the polynomial equation of Ω_1 with degree $2N-1$. This equation is identical to that in the original SCDE-based method [22], [23] when $N = 1$. When $N = 2$, the equation, which is a cubic polynomial, has a closed-form solution. In the case where $N = 3$ or more, (16) becomes a polynomial of degree five or higher and cannot be solved algebraically; it is still possible to compute the solution efficiently using an iterative algorithm. Finally, although any real root of the polynomial can be used as the estimate of Ω_1 that satisfies (16), we choose the one that minimizes the objective function (10) as the optimal solution.

IV. Experiments

A. Evaluation using signal length

We investigated the relationship between the signal length and the estimation error by various methods under a noiseless condition. We evaluated the following five conventional methods and the proposed method: The parabolic interpolation method [16], [17] estimates the frequency of a sinusoid by performing DFT. This method finds a frequency bin where the spectral peak is located, fits a quadratic function to the bin and its two side neighbors, and obtains the frequency estimate from the peak of the quadratic function instead of the spectral peak. The spectral reassignment method [18], [19] is also a DFT-based method, which calculates the phase derivative by using a time-differentiated window function. The number of DFT points for these methods was set to 65536 by zero padding, regardless of the signal length. The YIN method [8] is one of the methods for fundamental frequency estimation and utilizes the autocorrelation of the signal. This method utilizes the feature of a periodic signal and estimates the frequency by measuring the highest non-zero-lag peak of the autocorrelation. We also compared the SCDE-based method based on the differential equation [26]. The SCDE-based method is the one described in Section II. Since these methods estimated multiple frequencies, we took the minimum one as the fundamental frequency estimate. We used the centered difference scheme to compute the differential. We simulated a harmonic signal consisting of 440 Hz and 880 Hz, where no noise signal was added in this section. The sampling frequency was 44.1 kHz. In the YIN method, the fundamental frequency is given in advance as 40 Hz to 4000 Hz for estimation.

Fig. 1 shows the estimation error as a function of signal length. `Parabolic (min)`, `Reassignment (min)`, `YIN`, `SCDE (min)` and `FOHCDE` indicate the parabolic interpolation, spectral reassignment, YIN, SCDE-based, and the proposed method, respectively. As shown in this figure, the errors of the DFT-based methods, i.e., the `Parabolic (min)` and `Reassignment (min)` were large when the signal length was small because the frequency resolution was insufficient. The estimation accuracy of the `YIN` was significantly high, and the error was almost 0. Note that the current implementation of the `YIN` requires at least 5 ms of observation, and thus, no results are shown in Fig. 1. In contrast, the `SCDE (min)` method achieved highly accurate frequency estimation even if the signal length was very small, such as 1 ms. Since the `SCDE (min)` and the `FOHCDE` are performed in the time domain, the estimation accuracy is not affected by the frequency resolution, resulting in these remarkable results. The `SCDE (min)` was slightly better than the `FOHCDE`. One reason may be considered that the effect of errors in numerical derivatives and computations is inevitable for the `FOHCDE` because β_n in (10) is significantly large.

B. Evaluation under noisy condition

We evaluated the frequency estimation accuracy under a noisy condition. We used the root mean square error (RMSE) as a measure for evaluation. We performed 1000 trials. In this evaluation, we used the harmonic structure with two components whose frequencies were 440 Hz and 880 Hz. The signal length was 5 ms. We added the band-limited noise with bandwidths from 340 Hz to 540 Hz and from 780 Hz to 980 Hz by changing the SNR from -30 dB to 30 dB. Band-limited noise was generated by performing a DFT on a 10 s white noise signal, applying masks to specific frequency bins, and then performing an inverse discrete Fourier transform (IDFT) on the modified signal. Assuming a combination of the proposed method with a rough frequency decomposition, such as in [22]

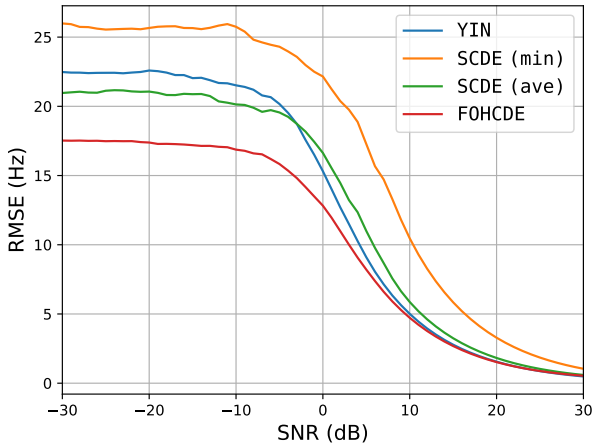

Fig. 2. RMSE for harmonic signals with two components whose frequencies 440 Hz and 880 Hz. The signal length was 5 ms.

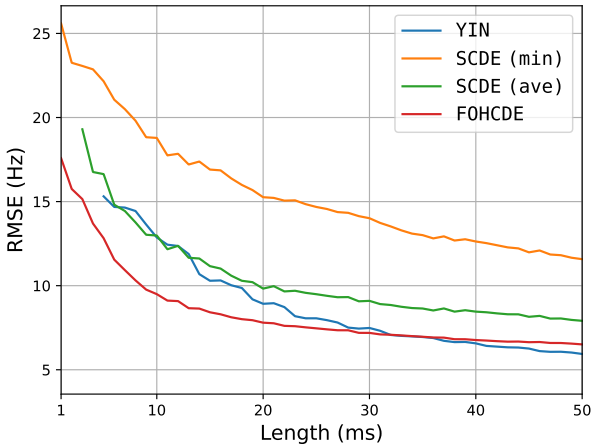

Fig. 3. RMSE of the signal length in 1000 trials. The SNR was 0 dB.

and [25], we employ band-limited noise. If the absolute error of the estimate exceeds 50 Hz, the result was excluded from the RMSE computation as gross error. Other experimental conditions were the same as described in Section IV-A.

Fig. 2 shows the RMSE as a function of SNR. We compared with the proposed method `FOHCDE` with three conventional methods: `YIN`, `SCDE (min)`, and `SCDE (ave)`. `SCDE (ave)` estimates the fundamental frequency by taking the mean of the two frequency estimates.

This figure shows that the estimation accuracy of all methods tended to improve as the SNR increased. In particular, their errors were close to 0 with high SNR. The `YIN` achieved the best performance. The `SCDE (ave)` had a higher accuracy than the `SCDE (min)`. It can be considered that the `SCDE (ave)` utilizes each sinusoid to estimate the fundamental frequency. However, the proposed method was effective for low SNR. The proposed method achieved estimation with noise robustness since the harmonic structure was added as a constraint. Gross errors occurred about 150 out of 1000 times in the `YIN` and about 15 out of 1000 times in the `FOHCDE`.

Next, we fixed SNR to 0 dB and changed the signal length. The signal length ranged from 5 ms to 50 ms. Fig. 3 shows the RMSE as a function of signal length. This figure does not have estimations in `YIN` and `SCDE (min)` for a signal of 5 ms or less since all estimates have errors greater than 50 Hz. This figure shows that all methods tended to improve in estimation accuracy as the signal length. Similarly to the result in Fig. 3, the `SCDE (ave)` had a higher accuracy than the `SCDE (min)`. The `YIN` was better than either, and its estimation accuracy was high when the signal length was sufficient. The `FOHCDE` has the smallest error for a signal of 30 ms or less.

As a result, the `FOHCDE` achieved high accuracy estimation with a small signal with noise robustness since the harmonic structure was added as a constraint. When the signal length is sufficiently large, or the SNR is high, the estimation accuracy of the `FOHCDE` is limited, which can be caused by errors in numerical derivatives. Hence, future work is needed to improve this issue by using more sophisticated methods for numerical derivatives.

V. Conclusion

In this paper, we proposed the FOHCDE-based method for estimating the fundamental frequency. We used the equation related to the differentiation of the signal and the harmonic structure as a constraint. Then, the fundamental frequency was estimated by minimizing the objective function of the FOHCDE-based method. Our experimental results confirmed that our method was more accurate than the SCDE-based method under noisy conditions, and it maintained its performance for a short signal even when the DFT-based methods did not work. In future work, we aim to avoid errors from higher-order numerical derivatives by utilizing the weighted integral method [22], [25].

***Abstract* — Tone labeling of tone sandhi and polyphones is crucial when preparing a high-quality speech corpus for constructing a Mandarin text-to-speech system. Correct tone labeling may ensure that the constructed text-to-speech system can generate a natural prosody. This paper proposes tone labeling using an iterative method with a deep learning-based tone recognizer. The experimental results showed that the proposed method could robustly label tones for syllables of tone sandhi and polyphones on a multi-speaking rate Mandarin speech corpus. Furthermore, this study found that syllables misrecognized as different tones from lexical tones may reflect the true tone realizations caused by coarticulation, location in a prosodic structure, and speaking rates. This study also provided a quantitative analysis of the relationship between labeled tones and prosodic structure to conform to the characteristics found in previous linguistic studies.**

I. INTRODUCTION

Labeling syllable tones in a speech corpus is essential for constructing a Mandarin text-to-speech (TTS) system. Correct tone labeling would help a trained TTS system to produce natural prosody, especially regarding tone sandhi and polyphone syllables. The simplest way to label syllable tones is to utilize text processors to predict proper tones from the input text. However, acoustic realizations of tone-sandhi and polyphone syllables would have some acceptable variations that cannot be predicted only from text information. Therefore, the results of tone labeling usually need to be checked manually to ensure labeling quality [1].

Although end-to-end (e2e) TTS development techniques can build high-quality TTS by constructing mapping from raw input text to spectrograms or waveforms, tone labeling for the corpora is still required because the collected speech corpora cannot guarantee sufficient text-speech training pairs to learn mappings from text to speech with correct prosody regarding tone sandhi and polyphones. Therefore, training corpora for constructing TTS systems are usually labeled with tones. The constructed e2e TTS systems operate with a front-end text processor to extract linguistic features from input text to predict *surface* tones rather than *lexical* tones [2-8].

Because tone labeling is time-consuming and labor-intensive, it is worth constructing a robust automatic tone-labeling method for preparing TTS speech corpora. In addition, tone recognition is essential for assessing the tones realized by Mandarin learners. This paper hence proposes tone labeling using a deep learning-based tone recognition method. The proposed method is examined on the Treebank multi-SR corpus - a multi-speaking rate Mandarin speech corpus uttered by a female professional announcer which has been used in the previous studies of prosody modelings [9-11].

Figure 1 illustrates the research methods used in this study. Section 2 uses the Speaking Rate-dependent Hierarchical Prosodic Model (SR-HPM) with local speaking rate modeling [9-11] to obtain prosody tags representing speech utterances' prosodic structure and the associated local speaking rates. The labeled prosody tags can help analyze the results of tone labeling.

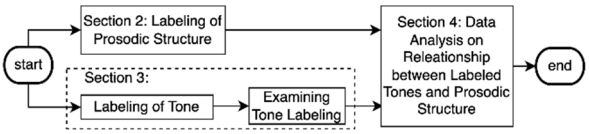

Figure 1: *Research method of this study.*

In Section 3, the tone of each syllable is labeled by a tone recognizer realized by a deep learning-based model (specifically, a transformer-based model) with input acoustic features, and a tone posteriorgram is generated by the recognizer, which is regarded as the likelihood of five Mandarin tones. We checked the tone labeled by the tone recognizer and found that the accuracy for tone labeling of tone sandhi and polyphones was quite high. In addition, we found

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

that some syllables in the corpus pronounced in different tones from lexical tones can be correctly identified by the proposed method. Finally, Section 4 provides a quantitative analysis of the relationship between the labeled tones and prosodic structure, indicating that syllables misrecognized as different tones from lexical tones may reflect the true tone realizations (i.e., surface tones) caused by coarticulation, location in a prosodic structure, and speaking rates.

The tone labeling in this study relies on the constructed deep learning-based tone recognizer. Many previous studies have constructed tone recognizers as components in computer-assisted language learning (CALL) system [12-14] or to provide auxiliary information for automatic speech recognition (ASR) [15,16]. Various deep learning models have been proposed to improve the performance of tone recognition, including DNN-HMM [17], CNN-DBLSTM [18] with an attention mechanism, CTC [19], an end-to-end method by combining CNN, Bi-GRU, Time Distributed Dense layer, and CTC [20], and an end-to-end tone classification method utilizing both a variant of Residual Neural Network (ResNet) with mel-spectrogram input and a multilayer perceptron model with context syllable segment features extracted from the force alignment results by ASR [21]. To develop a CALL system, the Goodness of Tone (GOT) inspired by the goodness of pronunciation (GOP) [22] and the soft-target tone model [14] can improve tone recognition accuracies or equal error rates for detecting mispronunciations. From the perspective of speech production, the target approximation model (TAM) [23], which extracts the underlying pitch targets for tone recognition from the surface F0 contour, was also used to improve tone recognition accuracies with BSLTM [24].

To the best of our knowledge, this study differs from the above studies in the following aspects:1) the tone recognizer functions as a tone labeler rather than a detector for a CALL or ASR system, and 2) with the prosodic structure labeled by SR-HPM [9-11], the relationship between labeled tone and prosodic structures can be investigated quantitatively. Note that the proposed transformer-based tone recognizer in this study (as will be illustrated in Subsection III.B) is new to the above-mentioned existing tone recognition methods and has not been tested with publicly available datasets. In order to check if the proposed transformer-based tone recognizer has a reasonable performance compared with the existing methods, the proposed tone recognizer was tested on a large-scale open-source Mandarin speech dataset – the AISHELL3 database [1]. The competitive tone recognition accuracies were obtained by the proposed transformer-based tone recognizer with respect to the performance reported in the previous study [21]

Although the findings related to tone labeling reported in this study are limited by the experimental results on the speech corpus uttered by only one speaker, the analyses in Section 4 may shed light on finding a tolerance for assessing tone realizations by Mandarin learners.

II. Labeling of Prosodic Structure

The experimental database in this study is the Treebank multi-SR corpus, composed of four parallel sub-corpora in four speaking rates read by a professional female announcer. The average utterance-wise speaking rates (SRs) for the four sub-corpora, from fast to slow, were 0.181, 0.198, 0.244, and 0.264 s/syllable, respectively. There are 1478 files with 203,746 syllables. The SR-HPM modeling [9] with local speaking rate estimation [10,11] jointly labels the corpus with a four-layer prosodic structure, as shown in Figure 2, and robustly estimates the speaking rate of each prosodic phrase. The four-layer prosodic structure consists of prosodic units of syllable (SYL), prosodic word (PW), prosodic phrase (PPh), and prosodic phrase group (PG), from bottom to top. Break types with specified prosodic-acoustic characteristics delimit these layered prosodic units. It has been shown that the PG-initial and PG-final prosodic phrases (PPhs) have distinctive intonation patterns. The intonation of the PG-initial PPhs was marked by an F0 reset before a rapid decline. The PG-final PPhs also possess an F0 reset, and the contour then trails to an ending with final lengthening [25]. One may find the details of break types in previous studies [9-11].

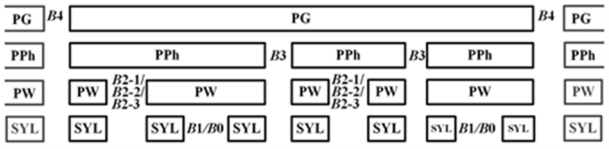

Figure 2: *Prosodic structure used in this study.*

III. Labeling of Tones

A. Iterative Tone Labeling

The experimental corpus was labeled with lexical tones and thus may contain incorrect tone labeling. Therefore, we developed a 5-step iterative tone labeling method to jointly label syllables with the correct realized tones (i.e.m surface tones) rather than lexical tones and constructed a robust tone recognizer.

Step 1 updates the target tones to train the deep learning-based tone recognizer. The target tones are set to be lexical tones for the 1st iteration, that is, iteration index *k*=1. For the other iterations, the target tones were set as the re-labeled tones.

Step 2 trains the tone recognition model that minimizes the cross entropy loss expressed by

$$\theta_k = \arg\min_{\theta} \sum_{n=1}^{N} \sum_{c=1}^{5} \hat{y}_{n,c}^{k} \log(y_{n,c}) \quad (1)$$

where *n* denotes the syllable index, c denotes the tone class, $y_n = f_\theta(x_n)$ represents the function of tone recognition with the trainable parameter set θ; x_n is the input acoustic feature for the *n*-th syllable, y_n is a 5 × 1 vector to express the output vector of the tone recognizer, $\hat{y}_n^k$ is the one-hot vector in which $\hat{y}_{n,t_n}^k = 1$ if the target tone of the *n*-th syllable is t_n.

Step 3 generates tone posteriorgram y with θ_k :

$$y = [y_1^T \quad \dots \quad y_N^T]^T \text{ and } y_n = f_{\theta_k}(x_n) \text{ for } n = 1 \sim N \quad (2)$$

Step 4 re-labels the tones of syllables by

$$t_n^* = \begin{cases} \arg\max_t y_{n,t}, \text{if } y_{n,t} \geq Th(s_n) \text{ and } s_n \in \mathcal{T} \\ t_n \quad , \text{otherwise} \end{cases} \quad (3)$$

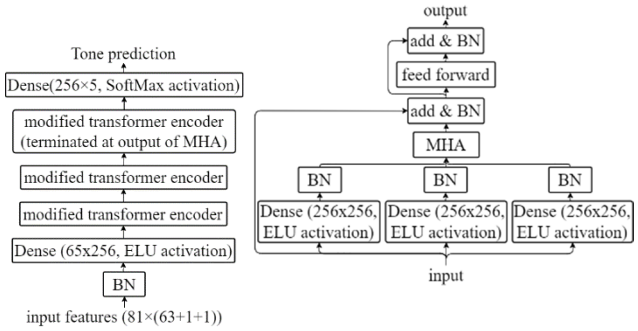
where t_n^* is the re-labeled tone, $Th(s_n)$ denotes the likelihood threshold for re-labeling, s_n denotes the linguistic features of *n*-th syllable, $\mathcal{T}$ is the set of linguistic units for tone re-labeling.

Step 5 checks a convergence of tone re-labeling. If convergence is reached, that is, $t_n^* = t_n$ for all *n*, we stop the iteration or return to Step 1 to continue training and re-labeling.

B. Set of Linguistic Units for Tone Re-labeling

The set can be categorized into four exclusive subsets:

Set 1: Tone 3 sandhi syllables, i.e., s_n with $t_n = t_{n+1} =$ T3 and $Th(s_n) = 0$. The threshold $Th(s_n) = 0$ indicates that the tone predicted by the tone recognizer is the relabeled tone, without considering its corresponding degree of likelihood. A speaker may use various tone 3 sandhi realizations to manifest syntactic or semantic conditions properly.



Set 2: Tone sandhi for $s_n \in \{$不(bù), 一(yī)$\}$ and $Th(s_n)$=0.7. The tone for *bù* could be tone 2 (T2) or tone 4 (T4), whereas the tone for yī could be tone 1 (T1), T2, or T4. Although the tones for {*bù*, yī} can be determined by their written contexts, we find that the speaker manifested much tone variation in acoustic features beyond the tone sandhi rules inferred from information extracted from the text. We thus set the threshold $Th(s_n)$=0.7 for a more reliable tone re-labeling.

Set 3: $s_n \in$ Polyphone, $s_n \notin$ Set 1, and $Th(s_n)$=0.7. We selected 26 frequent polyphone characters from a polyphone character table [26]. Each polyphone character sometimes has only one phonetic combination but may have different tones for different meanings. Parts of the polyphone character cases considered in Set 3 overlapped the cases in Set 1. For simplicity, we excluded cases with $t_n = t_{n+1} =$ T3. We also set the $Th(s_n)$=0.7 for a more reliable tone re-labeling.

Set 4: $s_n \notin$ {Set 1, Set 2, Set 3} and $Th(s_n) = 0.98$. We found that some syllables in the corpus may have different phonetic realizations than lexical tones. These syllables are usually located in specific positions of a prosodic structure, that is, sentence-initial and sentence-final positions. Parts of the tone change are caused by the idiomatic realization of tones on specific words or characters. We also found that the speaker made a few erroneous tones due to misreading or a creaky voice. Because the cases for Set 4 are rare, we set a high threshold, $Th(s_n) = 0.98$, to ensure that the re-labeling is robust.

C. Transformer-based Tone Recognizer

Figure 3(a) shows the structure of the proposed transformer-based tone recognizer implemented by Tensorflow 2.11.0 [27]. The structure consists of a batch normalization (BN) layer and a dense layer (65x512) with Exponential Linear Unit (ELU) activation, followed by a stack of three modified transformer encoder blocks. Figure 3(b) shows the structure of the modified transformer encoder block. The input of Multi-head Attention (MHA) is followed by a cascade of dense layers (256×256) with ELU activation and the BN layer. The remainder of the architecture is the same as that of a conventional transformer encoder [28]. The number of heads and key dimensions of the MHA are 2 and 256, respectively. The dimensions of the feed-forward were 512. The output is a 5 × 1 hot vector by SoftMax activation cascaded to the first dimension of the MHA in the top modified transformer encoder block, indicating the tone of the target syllable. The input of the recognizer considers syllable-based features extracted from a fixed-length speech segment with 0.81 seconds centered around the target syllable.

(a) (b)

Figure 3: *the structure of the proposed tone recognizer.*

The input features include:

1) 81×63 Mel-spectrogram: We take the 63-band Mel-spectrogram (without DC) that considers the frequency range from 0 to 2000 Hz with a 512-point FFT in a 10ms frame interval for a 16KHz sample rate. The number 81 indicates that we take the spectrogram information of 40 frames before and after the frame at the center of the target syllable.

2) 81x1 syllable boundary flag to indicate whether the frame belongs to the target syllable with binary values.

3) 81x1 frame index to mark the relative position of the frames, ranging from -40 to +40.

The proposed modified transformer encoder can achieve the same tone recognition rate as the original one with a shorter training duration, i.e., fewer training epochs to reach convergence for loss or accuracy. The training duration for the proposed modified transformer can reduce by 40% of the one taken by the original transformer encoder.

D. Performance of the Tone Labeling

We used all the Treebank multi-SR speech corpus in the tone recognizer's iterative re-labeling (or training) processing. The tone re-labeling process took two iterations to reach convergence, and each iteration took 80 epochs of approximately 85 min with Nvidia 2080ti. The Adam optimizer with a learning rate of 1.0e-5 was used to update the model parameters. In each training epoch, 10% of the corpus was randomly chosen as the validation set to avoid overtraining. We found that in both iterations, the accuracies for the training and validation sets in each epoch were similar, illustrating the robustness of the training process. The recognition accuracy for the 1st iteration with lexical tone targets was 96.1%. The accuracy reached 96.7% in converged iterations. Note that the true tone classes for the 1st iteration and 2nd iteration were lexical tones and re-labeled tones, respectively. The slight increase in accuracy was mainly attributed to the relabeling of tones for the four sets.

Table 1 presents the confusion matrix for tone recognition in the 1st and 2nd iterations. The numbers without brackets are the results of the model obtained in the 1st iteration with lexical tones as true classes. The results of the 2nd iteration that regarded the re-labeled tone as the training target are shown in the numbers within the round and square brackets. The numbers within round brackets count lexical tones as true classes, while those within square brackets count re-labeled tones as true classes. As shown in the *Count* column, the number for T2 increased from 48983 to 53845, while the number for T3 decreased from 37065 to 31766 because of tone re-labeling for tone 3 sandhi. The higher accuracies in the square brackets than those in the round brackets indicate that the proposed method can re-label the tones of syllables to obtain a more consistent or robust tone recognition model.

We then checked the performance of tone re-labeling for the speech tokens of the four sets by listening to these tokens. Two native Mandarin speakers were invited to participate in the check task. Because there are numerous syllables for tone re-labeling, we sampled 7%, 10%, 7%, and 10% of the datum for Sets 1 to 4 for the checking, respectively, with a uniform distribution for the four speaking rates. Table 2 shows the accuracies and corresponding 95% confidence intervals for labeling the four sets. The accuracies were generally high, except for polyphone and tone sandhi for "yi." We found that a few polyphone characters with low tone recognition accuracies and short durations of the syllable "yi" may degrade the performance of tone re-labeling.

Table 1: *Confusion matrix for the tone recognitions. Numbers within round brackets and without brackets are calculated when assuming lexical tones are true tone classes. Numbers in square brackets regard the re-labeled tones as true tone classes.*

		Predicted Class						
		T1	T2	T3	T4	T5	Count	Acc. %
True Class	T1	**37096** **(36576)** **[38128]**	362 (732) [520]	134 (189) [119]	413 (463) [459]	29 (74) [37]	38034 [39263]	97.5 (96.2) [97.1]

	15225	669	86.4	83.6≤ Acc. ≤88.8
Set 4: misrecognized tones with high tone posteriorgram				
	537	54	96.3	87.3 ≤ Acc. ≤ 99.5

E. Performance comparison to the previous work

In order to check the performance of the proposed transformer-based tone recognizer, we conducted a tone recognition task on the AISHELL3 speech database [1] in comparison with the existing method reported in the literature [21]. The method proposed in [21] is similar to our proposed method in that both methods utilize information from Mel-spectrogram and syllable boundary as inputs. The two methods differ in that the proposed method in [21] uses the extra linguistic feature, i.e., base-syllable type, and syllable boundaries obtained by the force alignment results according to the ASR output. The proposed method, however, uses the force alignment results according to true syllable transcription. We may neglect the differences made by the force alignments with the ASR and the true syllable transcriptions because the reported syllable error rate [21] made by the ASR was low (6.29%). The most syllable errors would be substitutional errors and the syllable boundaries obtained by the force alignment with the ASR results would be very close to the one made by the true syllable transcription. Since the literation [21] did not clearly describe the settings for the training and test datasets, we follow the document released by AISHELL3 to extract 65.6 and 9.4 hours of speech from AISHELL3 as training and test datasets, respectively. The lengths for the training and test sets are the same as the ones shown in [21]. Table 3 displays the distribution of tones, which is close to the distribution in the [21].

Table 3: *Distribution of tones for AISHELL3*

	T1	T2	T3	T4	T5	Total sample#
training	0.210	0.235	0.161	0.332	0.061	774714
test	0.217	0.234	0.158	0.335	0.053	102742

The authors of [21] displayed various accuracies with different parameters. We select the configure "+SF+C2" as the object for comparison because its length of acoustic feature is closest to our setting, i.e., 81 frames with 10ms frame intervals. To make fair comparisons, the base-syllable type information is added to the input of our transformer-based tone recognizer. Table 4 shows the result of the comparisons. As can be seen from the table that our proposed tone recognizer achieved better accuracies for T1 and T4 (accounting for 55% of data), a slightly lower accuracy for T2 (accounting for 23% of data), and lower accuracies for T3, and T5 (accounting for 22% of data). We believe that our proposed tone recognition method is competitive with the one proposed in [21] according to the compared results shown in Table 4.

Table 4: *Our method vs. results reported by [21]*

	T1	T2	T3	T4	T5
Ours	**0.931**	0.869	0.818	**0.923**	0.862
[21]	0.910	**0.874**	**0.874**	0.875	**0.916**

In addition, we apply the mechanism of tone relabeling to the training set of AISHELL3. To simplify the processing of relabeling, as long as the probability of the predicting tone class exceeds 0.5, we change/relabel the tone class. Then, two transformer-based tone recognizers were trained with the original tone labeling (denoted as the *raw model*) and the tone relabeled by the proposed method (denoted as the *relabeling model*). Table 5 shows the performances of tone recognition on the test sets of AISHELL3 by the *raw model* and the *relabeling model.* As shown in Table 5, the relabeling mechanism increased the accuracy for T1, T4, and T5, but an overall slightly lower accuracy was obtained. This result is reasonable because AISHELL3 has been labeled with surface tones, and most of the labelings were manually checked. The tone relabeling would not help improve tone recognition accuracies if the surface tones have been correctly labeled, indicating the corpus is consistently labeled in high quality.

Table 5: *Performances of tone recognition on the test sets of AISHELL3 by the raw model and the relabeling model.*

	T1	T2	T3	T4	T5	accuracy
raw	0.913	**0.871**	**0.819**	0.909	0.765	**0.879**
relabeling	**0.915**	0.864	0.764	**0.916**	**0.781**	0.872

With the results shown in this subsection, we may conclude that the proposed transformer-based tone recognizer could achieve a competitive performance to the existing method.

IV. Data Analysis

This section provides a quantitative analysis of the relationship between the labeled tones and prosodic structures for the Treebank multi-SR corpus. Note that here we analyzed the cases except for the cases of tone sandhi and polyphones. Table 6 shows the percentages of prosodic boundary types preceding and following target syllables with combinations of true and predicted tone classes. The boundaries are categorized into three types:1) intra-PW boundary with B0 and B1, denoted as "intra," 2) PW boundary with B2-1/2/3, denoted as "PW," and 3) PPh boundary with B3, B4, and Be, denoted as "PPh." Numbers in square brackets denote the number of syllables with true-predicted tone pairs. The numbers in brackets are percentages of the three prosodic boundaries.

A. Pitch Reset at PW/PPh Initial Positions

It was found that the following misrecognized cases may be caused by F0 resets that overwrite syllable tone realizations at the beginning of PWs, PPhs, or PGs:

1) The T3 syllables misrecognized as tones with higher F0 registers, that is, T4s (698 samples), T2s (643 samples), and T1s (83 samples), were more likely to follow PW or PPh boundaries than the correctly recognized T3 cases (intra:PW:PPh=63:22:15). The misrecognized cases (698+643+83 samples) were contributed by 470, 354, 218, and 382 samples, respectively, from the fast to slow sub-corpora.
2) The T4 syllables misrecognized as T1s (528 samples) were more likely to follow PPh boundaries than correctly recognized T4 cases (intra:PW:PPh=64:25:11). The 528 samples consist of 228, 139, 71, and 90 samples from the fast to slow sub-corpora.

The above two cases also show that more overwritten tone realizations with F0 resets can be observed when the SR is faster.

Table 6: *Percentages of prosodic boundary types preceding* (B_{n-1}) *and following* (B_n) *the target syllables* (s_n) *with various combinations of the true* ($\hat{t}_n$) *and predicted* (t_n) *tone classes.*

			Predicted Class t_n									
			T1		T2		T3		T4		T5	
			B_{n-1}	B_n	B_{n-1}	B_n	B_{n-1}	B_n	B_{n-1}	B_n	B_{n-1}	B_n
True Class $\hat{t}_n$	T1	intra	**55**	**68**	62	**56**	71	**31**	61	67	**87**	12
		PW	**33**	**21**	10	**37**	10	**29**	21	26	**15**	17

			[32]		[110]		[92]		[56]		[2351]	

B. Pitch Lowering at PW/PPh Final Positions

The following misrecognized cases occurred in the endings of PWs, PPhs, and PGs, manifesting the final F0 lowering:

1) The T4 syllables misrecognized as T3s (594 samples) were more likely to be followed by PW or PPh boundaries than the correctly recognized T4 cases (intra:PW:PPh=59:27:14). The 594 samples consisted of 136, 142, 97, and 219 samples, respectively, from the fast to slow sub-corpo
2) The T4 syllables misrecognized as T3s (594 samples) were more likely to be followed by PW or PPh boundaries than the correctly recognized T4 cases (intra:PW:PPh=59:27:14). The 594 samples consisted of 136, 142, 97, and 219 samples, respectively, from the fast to slow sub-corpora.
3) The T1 syllables misrecognized as tones with lower F0 registers, that is, T2s (326 samples) or T3s (108 samples), were more likely to be followed by PW or PPh boundaries than the correctly recognized T1 cases (intra:PW:PPh=68:21:11). The 326+108=434 samples were composed of 158, 104, 69, and 103, respectively, from the fast to slow sub-corpora.
4) The T2 syllables misrecognized as T3s (309 samples) were more likely to be followed by PPh boundaries than the correctly recognized T3 cases (intra:PW:PPh=66:23:11). The 309 samples were contributed by 92, 60, 63, and 94, respectively, from the fast to slow sub-corpora.

These three cases also show that F0 lowering at the end of a prosodic unit is not consistently correlated with SRs.

C. Coarticulation in PW/PPh Medial Positions

It has been observed that the magnitude of F0 is larger at edges than at medial positions, given that syllable edges have a longer duration [29]. The following misrecognized cases may have resulted from insufficient length and coarticulation.

1) The syllables with true-predicted tone pairs of T2→T1 (T2 misrecognized as T1, 260 samples) and T2→T4 (165 samples) were more likely to be followed by intra-PW boundaries that may be more likely to cause co-articulations than PW and PPh boundaries. The 260+165=425 samples were contributed by 222, 96, 49, and 58 samples, respectively, from the fast to slow sub-corpora, showing that syllables with faster SRs would be more likely to co-articulate with the following syllables.
2) Misrecognized syllables with T1→T5 (52 samples), T2→T5(54 samples), T3→T5(99 samples), and T4→T5 (83 samples) were more likely to follow the intra-PW boundaries. The 52+54+99+83=288 samples were contributed by 124, 97, 29, and 39 samples from the fast to slow sub-corpora, respectively, showing that the

syllables in faster SRs would be more easily pronounced as neutral tones (T5).

3) Articulatorily, laryngeal movements are at the physiological limit of maximum speed in medial positions; therefore, contour tones tend to be flattened. The misrecognition with T4→T1 can be explained by the insufficient length in the medial positions.

D. Small-Scale Perception Test

By investigating some tone-misrecognized samples with high likelihoods (>0.90) for nontarget tones, we suspect that they may be perceived as the predicted tones. Eighteen native Mandarin speakers without speech or hearing impairments participated in a small-scale perception test. The test was divided into three parts:1) PW/PPh initial with true-predicted tone pair T3→T4 (2 tokens), 2) PW/PPh final with true-predicted tone pair T3→T4 (1 token), and 3) PP medial with true-predicted tone pairs T2→T1 (3 tokens) and T4→T1 (4 tokens). The above 2+1+3+4=10 misrecognized tokens were used as the treatment group and randomized with the control group (20 tokens) composed of correctly predicted tokens in the same corresponding prosodic locations. Each token is an excerpted speech segment centered around the target syllable, with one preceding syllable and one following syllable. In each test of the three parts, the tones of tokens in the treatment and control groups were mutually exclusive. For example, the control group in the PW/PPh medial test comprised tokens with target syllables T1 and T3, while the treatment group consisted of T2 and T4 tokens. Eighteen subjects were asked to identify the tone of the target syllable when playing a token.

In the PW/PPh initial positions, the accuracy rates for T1, T2, and T4 were 83.3%, 88.9%, and 90.8%, respectively, whereas the accuracy rate for T3 was only 51.44%. T3 was identified with 29.36% of responses of T4. The accuracy rates for T1, T2, T3, and T4 in the PW/PPh final positions were 83.4%, 96.3%, 100%, and 94.5%, respectively. Finally, in the PW/PPh medial positions, the accuracy rates for T1 and T3 were 85.23% and 88.9%, respectively, whereas those for T2 and T4 were only 9.3% and 3.73%, respectively. T2 was identified with 72.3% of responses of T1, and T4 was identified with 72.3% of responses of T1. Put it differently, tokens with low accuracy rates in the perception test were also misrecognized by the tone recognizer. Meanwhile, the results of this small-scale perception test may indicate that the tones predicted by the proposed deep learning-based tone recognizer may reflect the actual phonetic realizations of the speaker; in corrected speech, the pitch of T3 was likely to be raised due to pitch reset in PP initial positions and was misheard as T4 by native speakers. In PP-medial positions, T2 and T4 were likely to be shortened because of insufficient length and coarticulation, such that they were misperceived as T1 by native speakers.

V. Conclusions and Future Works

This study reported the use of a deep learning-based tone recognition model for Mandarin tone labeling. Not only the labeling for tone sandhi and polyphones, but also the misrecognized cases associated with prosodic structures were investigated. In the future, conducting more tone labeling experiments on Mandarin or Chinese dialect corpora with more speaker variety and conducting more subjective tests to examine the tone identities of syllables in various prosodic contexts would be worthwhile.

Learning to Enhance the Position Embedding and Coherence

Ting-Jia Shu and Jen-Tzung Chien
Institute of Electrical and Computer Engineering, National Yang Ming Chiao Tung University, Hsinchu, Taiwan

***Abstract*—Transformer is known as a powerful learning machine for sequence-to-sequence learning. One weakness of this attention-based machine is that the attention mechanism is not sensitive to position information. The absolute position embedding lacks of the generalization to an unknown test sequence where the length is longer than those of training sequences. It becomes important to adopt the relative position embedding in transformer, but the computation load is significantly increased. This paper deals with this issue through a new relation-aware position embedding which properly characterizes the position information with the limited computation overhead where the property of position coherence is held. The merit of the proposed method is illustrated by the experiments on neural machine translation in terms of BLEU and computation time,**

I. Introduction

The attention-based model [1], [2], [3], [4], [5] has achieved a much better performance than traditional recurrent neural network (RNN) [6], [7] without attention in a variety of natural language processing (NLP) tasks [8], [9]. Transformer [1], [10], [11] has been a successful NLP machine which is based on the self-attention mechanism. The standard attention scheme lacks of a natural encoding method for word ordering. The sine and cosine positional embedding was accordingly introduced in the vanilla transformer in order to address this issue. In general, transformer adopts the so-called absolute position embedding (APE) [1], [12] which converts each position index into the corresponding position embedding. The number of word tokens in a sentence is seen as the length of position embeddings. Such a position embedding is then added to the token embedding to form the input to the model. This is an effective and simple method, but there is an insufficiency [13], [14], [15] by using this method. Namely, once there are some test sentences which are longer than training sentences or exceed the length of sequences that the trained model can handle. Figure 1 illustrates the BLEU value of test sentence versus the length of source sentence where the transformer is implemented for machine translation in the task of WMT14. To evaluate the capability of a model to face the mismatch in the lengths of training sentences, the transformer is optionally trained from the selected sentences where the length is shorter than 50 word tokens. The red curve shows the results by using the complete training sentences while the blue curve reports the BLEUs by only using the selected sentences. The gray area means the case that the test sentences are longer than the training sentences. It can be seen that the BLEU is almost the same when the sentence length is shorter than 50. But, there is a clear gap in the metric of BLEU between two models in the gray area. Obviously, the trained transformer [16], [11], [17] has an issue of generalization in representation of different lengths of sentences. To cope with this issue, there are some alternatives where the relative position embedding (RPE) [18], [19], [20], [21], [22] was proposed. RPE is basically based on the relative distance between two tokens to express the position information. The scheme of relative position embedding incorporates the position information in the self-attention mechanism [23], [24], [25]. Unfortunately, since the attention mechanism exists in each layer of transformers, this approach requires additional computational cost which is proportional to the number of stacked transformer layers [26], [27].

To enhance the relation-awareness in position embedding without too much computation overhead, this paper proposes a relation-aware position embedding by preserving the coherence in the relative position and regularizing the difference between the position embeddings for those of input tokens with the same relative distance. In the implementation, in addition to the addition of sinusoidal position embeddings and token embeddings, the inputs to the model further merge the learned relation-aware position embeddings. The proposed position embedding and coherence are evaluated by the experiments of using transformer for neural machine translation.

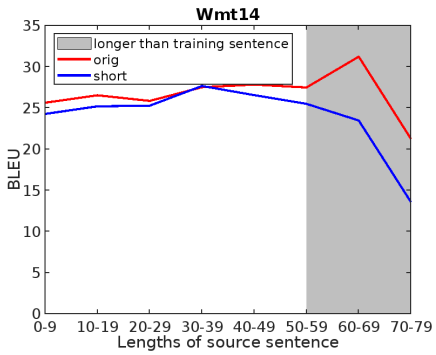

Fig. 1. BLEU value of test sentence versus the length of source sentence in a machine translation task where the transformer is implemented.

II. Position Embeddings

A. Absolute position embedding

Absolute position embedding (APE) is added with the token embedding as the input to learn the vanilla transformer. APE basically provides the information on word order in a sentence while the token embedding conveys the high-level information

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

on semantics. APE in transformer is seen as a fixed function which is composed of sine and cosine functions as follows

$$\mathrm{PE}(i,j) = \begin{cases} \sin\left(i/10000^{\frac{j}{d}}\right) & \text{if } j \text{ is even} \\ \cos\left(i/10000^{\frac{j}{d}}\right) & \text{else} \end{cases} \quad (1)$$

where i denotes the position of a token in a sequence and j denotes the dimension index for positional encoding vector.

B. Relative position embedding

Although sinusoidal position embedding does not require additional parameters and is easy to implement, the insufficiency of sinusoidal position embedding is caused when the mismatch in sentence lengths between training and test data happens. The work in [18] presented an approach based on the relative position embedding (RPE). A key difference of RPE compared with APE is made due to the circumstance that the position information of current token is encoded in a relation to those of the other tokens in the sentence. To fulfill this concept, two relative position representations are trained with the combination of self-attention [28] in a transformer. These two representations are described below.

1) Relative position representations: Basically, the edges between word tokens x_i and x_j could be used to represent the relative positional differences between two input tokens. The maximum of absolute value of a clipping distance of two tokens r is used to express the maximum of relative position in real situation. It is because that beyond a certain distance exacting the relative position information becomes useless. This method allows the model to generalize for sequence lengths which are unseen during the training phase. There are $2r+1$ unique edges $\{a_{ij}^K, a_{ij}^V\}$ which are given by [18]

$$\begin{aligned} a_{ij}^K &= w^K_{\mathrm{clip}(j-i,k)}, \quad a_{ij}^V = w^V_{\mathrm{clip}(j-i,k)} \\ \mathrm{clip}(x,k) &= \max(-k, \min(k,x)). \end{aligned} \quad (2)$$

where K and V denote the key and value in self-attention, respectively. The relative position representations $w^K = \left(w^K_{-k}, \ldots, w^K_k\right)$, $w^V = \left(w^V_{-k}, \ldots, w^V_k\right)$ are accordingly taken into account as shown in Figure 2 where $w_i^K, w_i^V \in \mathbb{R}^d$.

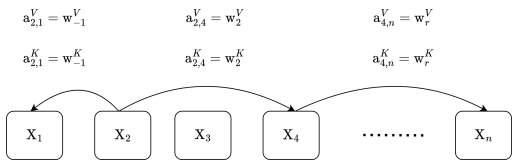

Fig. 2. Illustration for an example of the distinct edge representations between word tokens. The representations for each position relative within a clipping distance r can be learned.

2) Relation-aware self-attention: On the other hand, the self-attention in transformer was extended by considering the pairwise relations between input tokens. A relation-aware self-attention was proposed by learning two distinct edge representations a_{ij}^V and a_{ij}^K which are distinct for two individual tokens x_i and x_j. For an efficient implementation, each head for the edges for key and value $\{a_{ij}^K, a_{ij}^V\}$ is shared. After having the attention weights, the distance information is incorporated into self-attention in a form of

$$e_{ij} = \frac{x_i w^Q \left(x_j w^K + a_{ij}^K\right)^\top}{\sqrt{d}} \quad (3)$$

where w^Q is the relative position representation of query in self-attention. This distance measure is then used to calculate the attention weights for a sequence of length n via the following softmax function

$$\alpha_{ij} = \frac{\exp e_{ij}}{\sum_{k=1}^n \exp e_{ik}}. \quad (4)$$

Unlike the standard self-attention, the way of calculating latent variable z_i is not only fulfilled by multiplying the attention weights by using value matrix, but also performed by considering the distance information. To do so, the edge a_{ij}^V and value are summed and then multiplied by attention weight α_{ij}. The self-attention is modified by considering the distinct edge representation by

$$z_i = \sum_{j=1}^n \alpha_{ij} \left(x_j w^V + a_{ij}^V\right). \quad (5)$$

This modification is essential for the tasks where the information about the edge types chosen by a specific attention head is helpful to enrich encoder or decoder layers for downstream tasks. Basically, the position embedding method in [18] was developed to enhance the model generalization, but this position embedding method suffered from a relatively high amount of parameters and calculations [29], [30], [31]. In order to cope with the problem of increasing number of parameters, it was proposed [18] that the same relative position embedding for each head was shared. For an n-length sequence with h attention heads and the dimensions of each head d, the memory complexity of relative position representation was reduced from $\mathcal{O}(hn^2d)$ to $\mathcal{O}(n^2d)$ through the sharing of position embedding across individual heads. However, the overhead of training procedure was still considerable. The reduction in training time for the experiments on machine translation compared with standard transformer was only reduced by 7% in steps per second.

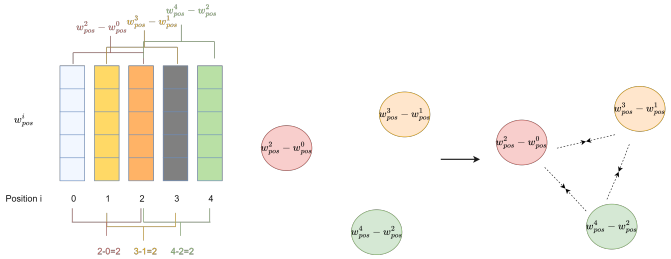

Fig. 3. Illustration of relation-aware position embedding which aims to minimize the difference between any two pairs of position embeddings with the same relative distance.

III. Relation-Aware Position Embedding

This study proposes a new relation-aware position embedding to deal with the issue of model generalization in presence of various sequence lengths without increasing computation overhead, The proposed relation-aware position embedding incorporates the relative position information into position embedding and pursues the coherence of embedding by reducing the difference between the position embeddings for those input tokens with the same relative distance. Figure 3 illustrates the key idea of this method. The relation-aware position embedding is implemented by minimizing the difference between any two pairs of position embeddings s and r with the same distance. An intuitive way to handle this issue is to introduce a learning objective

$$\sum_{s=0}^{\text{maxlen}-k} \sum_{r=0}^{\text{maxlen}-k} \left((w_{\text{pos}}^{s+k} - w_{\text{pos}}^{s}) - (w_{\text{pos}}^{r+k} - w_{\text{pos}}^{r})\right)^2 \quad (6)$$

where maxlen denotes the maximum length of sentence, k denotes the relative distance and $w_{\text{pos}} = \{w_{\text{pos}}^0, w_{\text{pos}}^1, \ldots, w_{\text{pos}}^{\text{maxlen}}\}$ denotes the relation-aware position embedding.

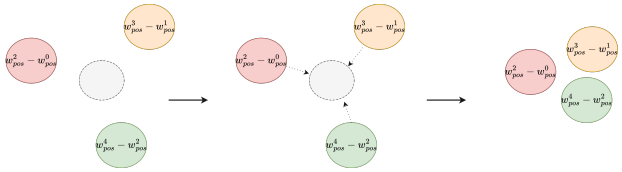

Fig. 4. Implementation of an efficient method to relation-aware position embedding with two stages. First stage is to calculate the mean of those differences between the pairs of position embeddings. Second stage is to subtract them from the distances of individual pairs.

A. Position embedding and regularization

However, such a way suffers from substantial computation overhead if the difference between two pairs of embeddings with the same distance is directly minimized. This study presents a new learning objective to pursue embedding coherence in relation-aware position embedding by first calculating the means of those differences between two position embeddings and then subtracting them from the corresponding distance between the pair of position embeddings as shown in Figure 4. The computation overhead can be considerably reduced. To learn for position embedding and coherence, the coherence objective is therefore formulated by

$$\sum_{s=0}^{\text{maxlen}-k} \left((w_{\text{pos}}^{s+k} - w_{\text{pos}}^{s}) - \frac{1}{\text{maxlen}-k} \sum_{j=0}^{\text{maxlen}-k} (w_{\text{pos}}^{j+k} - w_{\text{pos}}^{j})\right)^2 \quad (7)$$

where only one summation in two stages is used. Mean subtraction aims to promote the coherence of embedding difference. However, there will be an issue happening when calculating the average value. Considering the case of $k = 2$, the mean value is calculated by

$$\begin{aligned} \sum_{j=0}^{\text{maxlen}-2} (w_{\text{pos}}^{j+k} - w_{\text{pos}}^{j}) &= (w_{\text{pos}}^{1} - w_{\text{pos}}^{0}) \\ &+ (w_{\text{pos}}^{2} - w_{\text{pos}}^{1}) + \cdots + (w_{\text{pos}}^{\text{maxlen}} - w_{\text{pos}}^{\text{maxlen}-k}) \\ &= w_{\text{pos}}^{\text{maxlen}} - w_{\text{pos}}^{0}. \end{aligned} \quad (8)$$

It is found that the intermediate terms will be removed during the continuous addition. Some information is not counted. To prevent this insufficiency, this paper presents a learning objective by considering the square of the relation between the pair of position embeddings as follows

$$\sum_{s=0}^{\text{maxlen}-k} \left((w_{\text{pos}}^{s+k} - w_{\text{pos}}^{s})^2 - \frac{1}{\text{maxlen}-k} \sum_{j=0}^{\text{maxlen}-k} (w_{\text{pos}}^{j+k} - w_{\text{pos}}^{j})^2\right)^2 \quad (9)$$

where all difference terms are preserved in the calculation. The coherence of relative embedding is optimized to regularize the training of transformer.

In addition to formal design of learning objective, this study further extends the setting of the relative distance in the implementation as illustrated in Figure 5. Ideally, training the model with a relative distance of 1 (as shown in left subfigure) would allow the model to extrapolate the information from any pair tokens with the same relative distance. However, the actual situation may happen when the situation in right subfigure is met. We can see that although the distance between w_{pos}^2 and w_{pos}^1 is consistent with the distance between w_{pos}^2 and w_{pos}^3 but the distance to w_{pos}^1 is not double the distance to w_{pos}^3.

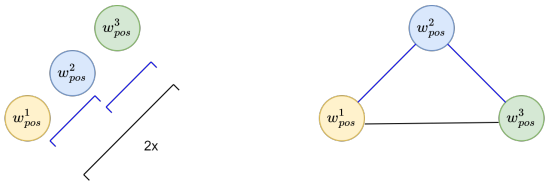

Fig. 5. (Left) An ideal case when model only needs to use the relative distance to be 1, (Right) The case that can be extrapolated to the other distances.

B. Learning objectives

The proposed method is composed of the trainable position embeddings and the transformer blocks in encoder and decoder for sequence-to-sequence learning. There are two learning objectives in the downstream task for machine translation where the parameters of position embeddings and transformer blocks are trained. In what follows, the mechanics of merging different objectives to form the training objective $\mathcal{L}$ are addressed. First of all, the cross entropy (CE) loss is formulated according to the summation of the negative conditional likelihood of output sequence given input sequence

$$\mathcal{L}_{ce} = -\sum_{x,y} \log p(y_t | y_{<t}, x) \quad (10)$$

where $x = \{x_t\}$ denotes the input string, $y = \{y_t\}$ denotes the output sequence, and $y_{<t}$ is the history of y_t at token t. Next, the second term in $\mathcal{L}$ is formed as the regularization term $\mathcal{L}_{\text{pos}}$ which is used to reflect the relative position information in position embeddings with dimension d. In Eq. (9), only a specific distance k is considered as the relative position information. Therefore, the regularization term is calculated by considering various values of k in relative position

$$\mathcal{L}_{\text{pos}} = \sum_{k} \sum_{s=0}^{\text{maxlen}-k} \Big((w_{\text{pos}}^{s+k} - w_{\text{pos}}^{s})^2 - \frac{1}{\text{maxlen} - k} \sum_{j=0}^{\text{maxlen}-k} (w_{\text{pos}}^{j+k} - w_{\text{pos}}^{j})^2 \Big)^2. \tag{11}$$

The final learning objective is constructed by using the cross entropy loss and the relation-aware position embedding loss

$$\mathcal{L} = \mathcal{L}_{\text{ce}} + \lambda \mathcal{L}_{\text{pos}} \tag{12}$$

where λ is a regularization parameter.

Algorithm 1: Training procedure for relation-aware position embedding in transformer

until *training converged*

C. Learning algorithm

Algorithm 1 shows the learning procedure for transformer encoder and decoder $\phi = \{\phi_{\text{enc}}, \phi_{\text{dec}}\}$ as well as relation-aware position embeddings. The proposed position embedding is calculated by combining the sinusoidal position embedding and the relation-aware position embedding with an annealing ratio parameter r_{pos}. Such embedding is then added by the word embedding and used to calculate the inputs $\{z_0^x, z_0^y\}$ to feed in encoder and decoder for finding the transformer output z_{out}. The objectives of training transformer parameters ϕ and relation-aware position embeddings w_{pos} based on $\mathcal{L}_{\text{ce}}$ and $\mathcal{L}_{\text{pos}}$, respectively, are then jointly optimized to fulfill the whole model for a downstream task of sequence-to-sequence learning for machine translation between English and German with the evaluation as shown in the experiments.

IV. Experiments

There are two datasets IWSLT'14 De-En (German to English) and WMT'14 En-De (English to German) [32] collected to evaluate the proposed method for sequence-to-sequence learning. The subsequent experiments were carried out by using the Fairseq toolkit [33]. For the task on WMT'14 En-De, the tokens of English sentences were first encoded into word embeddings which were then added by the mixed position embeddings from the sinusoidal position embedding and the proposed relation-aware embedding. Simultaneously, the tokens of German sentences were also encoded by using the same way so as to calculate the decoder inputs. After feeding the inputs into transformer, the encoding of English sentences as the hidden states have been decoded into those for German sentences. The overall model is then jointly optimized according to the cross-entropy loss regularized by the relation-aware position embedding loss.

A. Experimental settings

IWSLT'14 De-En translation task contained around 167K training sentence pairs and 7K testing sentence pairs. This corpus consisted of the TED talk transcriptions and their translations. In the experiments, the dataset was separated into training, validation, and test sets containing 160K, 7K, and 7K sentence pairs, respectively. On the other hand, WMT'14 En-De translation task contained roughly 3.9M, 39K, 3K of sentence pairs pairs in training, validation, and test sessions, respectively. The byte pair-encoding (BPE) [34] was applied to segment the words into subword units. In order to make the test data longer than the train data, this study removed the WMT'14 training data with the sentence length longer than 50 and the IWSLT'14 training data with the sentence length longer than 40. After removing, the WMT'14 training and test data were resized to 3.5M and 0.2K sentence pairs and IWSLT'14 training and test data were reduced to 137K and 0.8K sentence pairs, respectively. The performance of translation models were evaluated in terms of BLEU score [35]. The vanilla transformer was implemented as the baseline model. The word embedding size and position embedding size have been set as 512 for WMT'14 and 256 for IWSLT'14, respectively. The dimension of intermediate hidden layer of a feed forward network was set as 2048 for WMT'14 and 1024 for IWSLT'14. There were six encoder and decoder blocks in model configuration. To control the size of model parameters, the dimension of position embedding vector was set as 128,

and the vector was concatenated four times. The parameter r_{pos} was set as 2 and the relative distance was set from 1 to 15.

TABLE I
COMPARISON OF THE RESULTS ON WMT'14 EN-DE. THE RESULTS MARKED BY * ARE REFERRED FROM [36].

Model	Params	BLEU	Training time
Transformer [1]	61M	27.66*	–
RPR [18]	–	27.92*	–
CAPE [36]	–	27.89*	–
Transformer	66.5M	27.75	1.00
RA transformer	66.7M	**28.18**	1.009

TABLE II
COMPARISON OF THE RESULTS ON IWSLT'14 DE-EN.

Model	Params	BLEU
Transformer [1]	39.5M	34.54
RA Transformer	39.7M	**34.91**

B. Experimental results

This study implements the so-called relation-aware (RA) transformer with the proposed relation position embedding and compares the performance of machine translation using vanilla transformer [1] and RA transformer. First of all, the results of WMT'14 and IWSLT'14 tasks are shown for the case where there is no removal of training data. In the WMT'14 task as shown in Table I, the lower part shows the results of our implementation. The comparison is made in terms of the number of parameters, the BLEU and the training time relative to vanilla transformer. It is found that the proposed RA transformer obtains 0.43 absolute improvement in BLEU, spends only 0.3 $\%$ overhead of memory requirement for model parameters, and takes only 0.9$\%$ longer training time when compared with vanilla transformer. Relative to the related works including the methods called the relative position representation (RPR) [18] and the continuous augmented positional embeddings (CAPE) [36], it is found that the proposed RA transformer achieved 0.29 improvement in BLEU compared with state-of-the-art method CAPE. In the IWSLT'14 task as shown in Table II, RA transformer obtains an absolute improvement of 0.37 in BLEU score over standard transformer with very limited overhead in model size. The model size of WMT'14 is much larger than that of IWSLT'14. These results demonstrate that RA transformer considerably performs better than vanilla transformer in various tasks.

Next, the same evaluation is performed by considering the case that the pairs of long sentences are removed from training data. Total number of sentence pairs in training data is reduced. This set of experiments is to assess the generalization of the performance of BLEU when the mismatch in sentence length happens. As shown in the results on WMT'14 and IWSLT'14 as given in Table III, it is still found that the proposed RA transformer obtains higher BLEU scores than vanilla transformer in both English-to-German and German-to-English tasks. The robustness of RA transformer in presence of various lengths of sentences is illustrated. The BLEU values in Table III are lower than those in Tables I and II because the size of training data is reduced.

TABLE III
COMPARISON OF THE RESULTS ON WMT'14 EN-DE AND IWSLT'14 DE-EN WHERE THE PAIRS OF LONG SENTENCES ARE REMOVED FROM TRAINING DATA.

Model	Params	BLEU
Transformer (WMT)	66.0M	23.98
RA Transformer (WMT)	66.2M	**24.15**
Transformer (IWSLT)	39.3M	20.43
RA transformer (IWSLT)	39.5M	**20.71**

TABLE IV
COMPARISON OF THE RESULTS ON IWSLT'14 DE-EN IN PRESENCE OF DIFFERENT RANGES OF RELATIVE DISTANCES k.

Model	k	BLEU
Transformer	-	34.54
RA transformer	1 to 5	34.60
RA transformer	1 to 10	34.72
RA transformer	1 to 15	**34.91**
RA transformer	1 to 20	34.74

C. Ablation study

Following the setting of preserving all pairs of training sentences, an ablation study on IWSLT'14 DE-EN is further examined by evaluating the effect of adopting different ranges of relative distances k, i.e. considering multiple relative distances. As shown in Table IV. the highest BLEU score is achieved in case of the range of k from 1 to 15. Even only considering the range from 1 to 5, there is still slight improvement obtained by using RA transformer. These results using the proposed RA transformer are consistently better than those using standard transformer.

V. CONCLUSIONS

This paper presented a new relation-aware position embedding and combined it with traditional word embedding and sinusoidal position embedding. This new embedding brings relative position information to the transformer model where the cross-entropy loss and the relation-aware position information loss were jointly minimized. The experiments on machine translation showed that the BLEU values were increased by using the resulting relation-aware transformer compared with the vanilla transformer where the overheads in memory requirement and computation cost were relatively limited. The effect of relative distances was also evaluated. Future studies will be further extended for the other downstream tasks for sequntial learning based on transformer.

VLSI Design of Near-Lossless Image Compression using Improved LZW

Yao-Zhong Zhang[1],Chiung-An Chen*[1], Jia-Sheng Zhang[1],and Jia-Wen Wang[1], *Member, IEEE*

[1]Department of Electrical Engineering, Ming Chi University of Technology, New Taipei City, Taiwan

An improved encoding method based on Lempel-Ziv-Welch (LZW) is proposed, utilizing the advantages of VLSI parallel processing to overcome the drawback of lengthy encoding time in LZW. The improved LZW encoding method enhances the encoding efficiency by 90% and simultaneously improves the compression ratio by 30%. The near - lossless image compression process in this paper incorporates integer DCT, Huffman coding, run-length encoding, and the improved LZW encoding. Compression experiments were conducted on a Kodak image dataset, resulting in an average bit rate of 7.13 bpp (Bits Per Pixel) and a PSNR of 44.5.

Keywords—Image Compression, LZW Algorithm, Parallel

I. INTRODUCTION

With the advancement of technology, the images captured by cameras are becoming increasingly sophisticated. When photos contain richer details and colors, the amount of data needed to store them will significantly increase. The inevitably affects the speed of uploading and other processes, making image compression an essential operation. Image compression reduces the data size of images, resulting in three advantages: shortened upload and download times, moreover, storage space occupation less, and lower power consumption [1-3].

Image compression is the processing of compressing image data into smaller storage space or narrower transmission bandwidth. Traditional image compression methods typically use either lossless compression or lossy compression [4]. Lossless compression methods compress image data into smaller storage space without losing image quality, while lossy compression methods can compress image data into smaller storage space but may affect image quality. Many image compression methods have been proposed, such as JPEG [5], PNG, and GIF, and there is an increasing demand for more efficient compression methods. Therefore, the motivation behind image compression research is to develop more effective image compression techniques to meet the needs of modern applications and improve efficiency in storing and transmitting image data .

This paper aims to design an improved LZW encoding compression hardware circuit for wireless transmission. The design are significant differences between software programming languages and hardware description languages [6-7]. The former offers flexibility, rich functionality, data abstraction, object-oriented programming, diverse databases, such as C, Java, Python, MATLAB, and so on, with the latter has advantages in sequential circuits and parallel processing, achieving simultaneous processing of multiple procedures through different timing executions to increase work efficiency. Overall, the computational performance of VLSI is higher than that of software.

II. IMPROVED LZW ENCODING

Traditional LZW encoding [8-9] consists of a prefix code (P), current character (C), and a dictionary. The encoding steps are as follows: check if PC exists in the dictionary, if not, output P, add PC to the dictionary, and update P as C. If PC already exists in the dictionary, update P to the code for PC in the dictionary. Repeat these steps until the encoding is complete. As each PC signal needs to be compared with the data in the dictionary to determine if it has been encoded, the comparison time increases as the dictionary grows larger. This leads to longer encoding times for traditional LZW encoding. Taking ACABAC as an example, following the traditional LZW method, the encoded result is ACAB1. Therefore, traditional LZW encoding has two issues: a large number of entries in the dictionary (dictionary occupancy) as shown in Table 1 Part A, and empty codes as shown in Table 1 Part C.

Table 1. Traditional and improved LZW encoding methods

Part. C	Example		ACABAC		
	Traditional LZW encoding		ACAB1		
	Improved LZW encoding		121		

This paper presents improvements to the Traditional LZW encoding, as shown in Figure 2. The enhancement lies in the approach: when LZW fails to find a matching PC value within the dictionary, it incorporates that PC value into the dictionary and promptly outputs the corresponding encoding, as shown in Step2 of the Table 2. Subsequently, the next two data entries are consecutively retrieved from the buffer and designated as P and C. This ensures the correct functioning of the subsequent LZW process, as elaborated in Steps 3 to 4 in Table 2 and Figure 1. This strategic method guarantees that each key within the dictionary is used at least once, mitigating the occurrence of encoded values that remain unused, as shown in Parts B and C of the Table 1. The Improved LZW encoding technique introduces two pivotal advantages: a more compact dictionary, exemplified in Parts A and B of the Table 1; and reduced output, as shown in Part C of the Table 1. These improvements significantly elevate the efficiency of the LZW encoding process.

Table 2. Encoding steps and dictionary generation

	(Prefix, Current)	Encoded string	Dictionary		Output
			Index	Key	
Step1	(, A)				
Step2	(A, C)	AC	1	AC	1

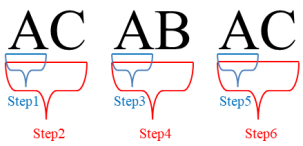

Figure 1. Steps of improved LZW encoding method using ACABAC

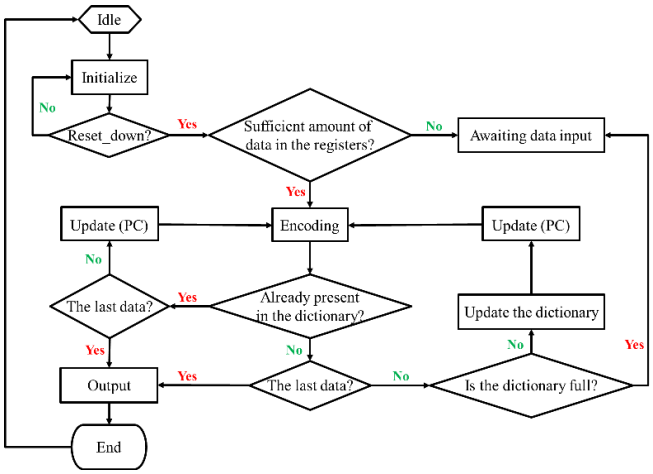

Figure 2. Flowchart of the improved LZW method

The improved VLSI design of the LZW encoding, as proposed in this paper, is illustrated in Figure 3. It consists of five modules: ***Buffer***, ***Found***, ***PC_data***, ***Code_out***, and ***LZW_Ctrl***. The *Buffer* module serves as a register, primarily designated for accessing the input data (*data_in*). The *Found* module encompasses a **Comparator**, **Counter**, **Dictionary**, and **Code_stage**, as shown in Figure 4. A comprehensive description of their functions is provided in Table 3. Notably, the signals *rd*, *we*, *en_coun*, and *en_camp* are generated by the *LZW_Ctrl* module, controlling the actions of dictionary read/write, comparator, and counter operations.

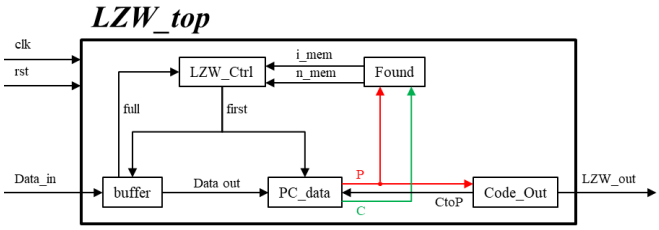

Figure 3. VLSI design of improved LZW encoding

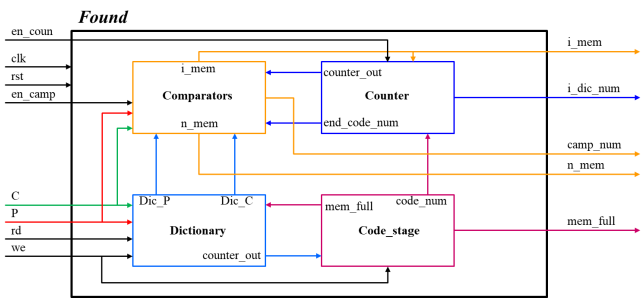

Figure 4. Block diagram of the ***Found*** module

Table 3. Description of the ***Found*** module

Found	Description
Comparators	By contrasting the current *P* and *C* values with the *Dic_P* and *Dic_C* in the dictionary, the encoding status of the PC pair is determined. This process generates the signals *i_mem* (indicating presence in the dictionary) and *n_mem* (indicating absence in the dictionary). These signals are utilized to inform the control module about the current status of whether the *PC* value is already present in the dictionary.
Counter	Based on the current number of encoded entries (*Code_num*), the selection of dictionaries for comparison by the comparator is determined. When the *i_mem* signal is high, the counter outputs the current count value, serving as the position of this *PC* pair within the dictionary, thereby generating the *i_dic_num* signal. On the other hand, *end_code_num* indicates to the comparator whether the dictionary entry being processed is the last one that has been encoded. This signal can enhance encoding efficiency when the dictionary is not fully populated.
Dictionary	The dictionary simultaneously outputs multiple pairs of *Dic_P* and *Dic_C* for comparison by the comparator, while *camp_num* indicates in which dictionary the current PC is located. The input signals *rd* and we determine whether to perform an output operation or write to the dictionary.
Code_stage	The *we* signal is used to update the current count of encoded elements. In LZW encoding, if the dictionary size is not restricted, the number of entries in the dictionary can continuously expand with the increase of data, leading to an escalation of required encoding bits. This might even surpass the size of the original data. Consequently, it is customary to set a limitation on the dictionary size (which can be tailored to specific requirements) for encoding purposes. Additionally, the state module includes a *mem_full* signal, indicating whether the dictionary module can continue writing entries to the dictionary.

The *PC_data* module, as shown in Figure 5, serves as the processing unit for *P* and *C* values in the context of LZW encoding. This module primarily makes decisions based on comparison results, determining whether to output the *P* value or transform *P* into an encoded value from the dictionary.

Within the module, *datain* represents the output value of the LZW register, and the first signal is generated by the *LZW_Ctrl* module, indicating that this is the first data entry that doesn't require encoding but only awaits the next data input. *P* and *C* signify the current *PC* values and are updated according to corresponding conditions. *in_memnum* is produced by the Found module as *camp_num*, informing us about the dictionary where this *PC* value exists. *dic_num* corresponds to *i_dic_num* in the Found module, denoting the address within that dictionary. When the comparison outcome is existence, these sets of information are used to update the *P* value.

When the *PC* value isn't present in the dictionary, the *Code_out* module outputs the current *P* value and generates the *CtoP* signal after the output completion. At this point, the *P* value is updated to *C*, while C is updated to the next data entry, creating a new *PC* value to proceed with encoding operations. Upon reaching the last data entry, the Found module similarly generates the *last_imem* and *last_nmem* signals. The former indicates the continued existence in the dictionary, while the latter signifies its

absence. When *last_imem* is at a high voltage level, the *P* value is updated to the encoded value, halting the encoding process. Meanwhile, when *last_nmem* is at a high voltage level, both *P* and *C* maintain their current states and are sequentially outputted. Subsequently, the encoding process concludes.

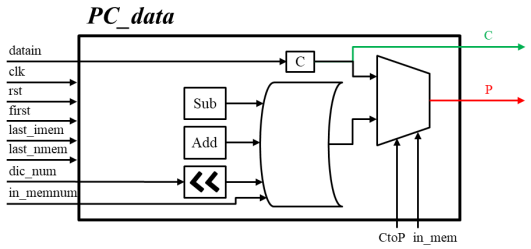

Figure 5. Block diagram of the ***PC_data*** module

The *Code_Out* module, as shown in Figure 6, encompasses several critical signals. Firstly, there's the *end_data* signal, originating from the LZW register. When this signal is set to a high voltage level, the current *P* value is outputted, and concurrently, the *end_code* signal is also set to a high voltage level, indicating the end of encoding. The we signal, on the other hand, is provided by the *LZW_Ctrl* module. When it transitions to a high voltage level, the current *PC* value is written into the dictionary, which is subsequently reset. During this time, the *P* value is also outputted to ensure error-free encoding. Simultaneously, the *CtoP* signal is raised, notifying both the *PC_data* module and the *LZW_Ctrl* module that the output has been completed, enabling them to proceed with reading the next set of data for encoding. The *rst_CtoP* signal, provided by the *LZW_Ctrl* module, resets the *CtoP* signal to prevent erroneous operations in the *PC_data* module during *PC* value updates, thus averting encoding errors.

Lastly, the *last_nmem* signal is also generated by the *LZW_Ctrl* module, signifying one of the outcomes of the final encoding. At this juncture, the *PC_data* module maintains the present state of the PC value, while the Output module concurrently outputs the *P* and *C* values. Simultaneously, the *end_code* signal is set to a high voltage level, culminating the encoding operation.

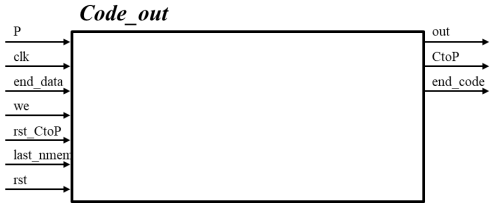

Figure 6. Block diagram of the ***Code_Out*** module

The *LZW_Ctrl* module, as shown in Figure 7, constitutes the central component of the entire control system. This module comprises ten distinct states, each with specific functionalities. To begin, when the system is in the ***IDLE*** state, it signifies an idle state. Only when the start signal is triggered does the system transition to the subsequent state, ***INIT_RAM***. In this state, the system generates the *rst_ram* signal, which serves to clear all registers. This action ensures that the results of the previous encoding do not influence the current encoding.

Following this, the system progresses to the ***CONFIRM_RAM*** state. Here, the state awaits the clearance of all registers. Once this is accomplished, the system proceeds to the *DATAIN* state. During the ***DATAIN*** state, the system awaits sufficient data accumulation in the LZW buffer (based on the full signal) to ensure an adequate amount of data for encoding. The system then advances to the ***ENCODE_START*** state. In this phase, the system unconditionally transitions to the *P_C_data* state and simultaneously issues the first signal. This signal informs the system that this is the first set of data, obviating the need for encoding and only necessitating the arrival of the second data set for input.

Within the ***P_C_data*** state, the system emits the *en_data* and *rst_CtoP* signals. The former controls the timing of LZW buffer data readouts, while the latter clears the *CtoP* signal within the Output module to prevent anomalies in the *PC_data* module during updates. Subsequently, the system unconditionally enters the ***DATA*** state and, upon the first trigger, returns to the *P_C_data* state to process the second set of data. When the *in_mem* signal surfaces, indicating the presence of a corresponding *PC* value in the dictionary, the system resets the comparator's enable signal and then proceeds to the *FOUND* state.

In all other circumstances, the system unconditionally enters the ***FOUND*** state. Within this state, the enable signals for the comparator, counter, and dictionary are activated and maintained until the comparison outcome materializes. Based on the post-comparison result, the system undertakes actions contingent on the existence of the *PC* value in the dictionary. If the *PC* value is present in the dictionary, the comparator's enable signal persists, and the *en_data* signal is set to a high voltage level, subsequently reverting to the DATA state. If the PC value is absent in the dictionary, the enable signal is deactivated, simultaneously triggering the we signal (the write signal for the dictionary module), and then progressing to the *OUTRAM* state.

During the ***OUTRAM*** state, the system awaits the completion of output from the Output module while concurrently resetting the *we* and *rst_CtoP* signals. It then reverts to the *P_C_data* state to continue with the next encoding until the LZW buffer emits the *end_data* signal. At this juncture, the final data is encoded, and regardless of the *PC*'s presence in the dictionary, the system enters the *OUTRAM* state. Depending on the scenario, either *last_imem* or *last_nmem* is emitted. The former indicates the final encoding exists in the dictionary, while the latter suggests otherwise. When the *last_imem* signal emerges, the *P* value is converted into the dictionary's address and directly outputted. Conversely, when the *last_nmem* signal is high, the *P* and *C* values maintain their present states and are sequentially outputted. Subsequently, the system enters the ***ENCODE_END*** state, wherein the *en_dicout* signal is transmitted to the dictionary module to output encoding data from the dictionary. This action primarily facilitates recovery operations by software. Upon the complete output of all dictionary data, the system returns to the *IDLE* state, awaiting the next encoding process.

III. RESULTS

In this experiment, both the traditional LZW algorithm [8-9] and the improved LZW algorithm were subjected to VLSI design for image compression. The test image used was an 8-bit color Lena image with a size of 256*256 pixels. The test data results are presented in Table 5. It is noteworthy that while the traditional LZW algorithm required 91.73 milliseconds to complete the image compression process, the improved LZW algorithm presented in this paper achieved image compression in just 0.91 milliseconds. This demonstrates a remarkable speed improvement of 100 times when compared to the traditional method. This underscores the effectiveness of splitting the dictionary into multiple smaller dictionaries and performing simultaneous comparisons in significantly mitigating the encoding drawbacks of LZW.

Table 5. Seconds for VLSI circuits of traditional and improved LZW methods in lena image compression

Method	Time (seconds)
Improved LZW	**0.91 m**
Traditional LZW	91.73 m

Table 4 presents the shift compression algorithm proposed by B. Koc, Z. Arnavut, et al. [10], using the Kodak image dataset. Table 4 shows our method achieves better compression rates compared to the approach proposed by B. Koc, Z. Arnavut, et al. The original images from the Kodak dataset and the compressed image dataset using our method (with the improved LZW encoding as the core) are shown in Figure 8. Although the PSNR value is slightly lower, it still remains at around 44dB. Therefore, our proposed compression algorithm achieves good compression rates and can be applied for faster image transmission in wireless communication.

Table 6 presents the gate count simulated by the Vivado software along with the clock frequency used in this experiment. The operation frequency employed in this experiment is 50MHz. The gate count typically ranges from LUT multiplied by 4 to 6. Consequently, the gate count in this experiment is around 17,000, which is not considered substantial in today's circuit designs. This gate count aligns with the original intent of this experiment, which is to apply it to portable electronic devices.

Table 6. VLSI design for image compression in this paper, simulated with Vivado software

Operation Frequency	LUT	Gate Count (k)
50MHz	2849	17

IV. Conclusion

This paper combines DCT, Huffman coding, run-length encoding, and the improved LZW encoding for near-lossless image compression. Due to the DCT encoding in the image compression process, it leads to a slightly lower PSNR value. However, the average PSNR value remains at 44.5. The focus of image compression is on the improved LZW encoding, which not only achieves fast encoding but also exhibits high compression efficiency. As shown in Table 5, our method demonstrates a rapid encoding rate, allowing for quick compression of each image. By effectively and swiftly compressing the images, data size is significantly reduced, as indicated in Table 4. This facilitates fast transmission in wireless communication, simultaneously reducing power consumption and extending battery life.

***Abstract* —The demosaicing process is the most critical step in image processing, this study presents a Hamilton-Adams-based algorithm for mosaic removal and image scaling. The algorithm consists of three steps: image pre-processing, image scaling, and improved Hamilton-Adams mosaic removal. The image pre-processing stage employs a mean filter to reduce high-frequency signals at the image edges, effectively mitigating the zipper effect caused by image scaling and improving image quality. The improved Hamilton-Adams method incorporates high-quality linear interpolation to achieve more accurate edge computations. In terms of image quality assessment, this paper increased 1.13 dB of PSNR, 1.19 dB of CPSNR, and 0.03 of SSIM values compared to high-quality linear interpolation with bicubic interpolation.**

KEYWORDS: Color filter array, Image pre-processing, Demosaicing, Hamilton-Adams, Image scaling

I. INTRODUCTION

Consumer electronic products commonly feature image signal processors, such as digital cameras and smartphones. This product internally incorporates a charge-coupled device (CCD) or a complementary metal-oxide-semiconductor and utilizes the color filter array (CFA) for image acquisition. Most of the CFAs use the Bayer pattern [1], as shown in Fig.1, where a group of 2×2 pixels consists of two green filters, one blue filter, and one red filter. These components selectively filter light to capture color information and achieve the reconstruction of full-color images. The Bayer CFA pattern is widely employed in consumer electronic devices due to its simplicity and effectiveness, contributing to enhancing the luminance information and overall image quality.

After capturing the image using the CFA, only one color (red, green, or blue) can be recorded for each pixel, resulting in a monochrome representation. By applying a demosaicing algorithm, such as bilinear interpolation (BI) [2], it is possible to reconstruct the RGB values for each pixel. However, this approach often leads to unnatural colors and the appearance of zipper artifacts. Other methods, such as High-quality linear interpolation (HQLI) [3] and Hamilton-Adams (HA) [4], have been proposed to mitigate zipper artifacts and provide more realistic color reproduction.

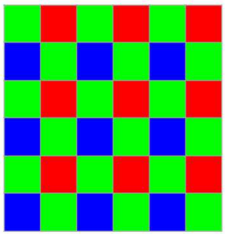

Fig. 1. Bayer format.

A. Linear interpolation demosaicing

HQLI introduces a high-quality linear interpolation demosaicing method for Bayer pattern color images. This method emphasizes the preservation and restoration of image details. Linear interpolation demosaicing is a prevalent technique that employs linear interpolation methods to interpolate the missing color values for each pixel in the image. Unlike some traditional methods that may suffer from edge blur and loss of fine details, this HQLI method can better preserve the details and edge structures of the image, providing a more realistic and clear visual effect.

This study compares the proposed method with other interpolation methods through experiments to validate its effectiveness. The experimental results demonstrate that this HQLI method produces superior results in the interpolation

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

process of Bayer pattern images, offering a more realistic and meticulous color restoration.

B. *Hamilton-Adams demosaicing*

HA demosaicing [4] describes a device for processing digital image signals acquired from a sensor. The sensor has color pixels aligned in rows and columns, where each pixel position generates at least three independent color values, but only one color value is available.

The device includes memory for storing digital image signals and a processor connected to the memory. The processor performs interpolation to obtain missing color values based on the different color values of nearby pixel positions. The processor also includes a structure for obtaining Laplacian values, gradient values, and color difference deviation values from neighboring pixels in the same column and row. Subsequently, a classifier is formulated by aggregating these values, and the preferred direction for interpolating the missing color values is determined based on the classifier. The device presents a technique for interpolating multiple designated color values within the proximity, ensuring conformity with the preferred direction.

This method presents a hardware-friendly implementation by utilizing chroma difference for blue and red channel calculation, thereby eliminating the requirement for complex multiplication or extensive memory. However, dealing with images containing intricate edges may produce slight zipper artifacts, which can be considered a limitation of the algorithm. Nonetheless, in terms of hardware implementation, it provides an efficient and straightforward approach.

The previous two methods only focus on demosaicing and cannot compress computational data, requiring extensive delays or memory storage in hardware implementation. Therefore, [5] introduces an innovative, low-complexity joint color demosaicing and digital zooming algorithm, providing an effective and high-quality solution to image processing for single-sensor digital cameras.

Traditionally, color demosaicing and digital zooming are separate steps performed using different techniques. However, the algorithm proposed in this paper adopts a novel approach by combining these two steps for improved results.

This algorithm utilizes the edge information extracted from the original sensor data to perform direct interpolation during the color demosaicing and digital zooming processes. This approach has several advantages. Firstly, it ensures the preservation of edge features in the output, thereby enhancing image clarity and details. Secondly, due to the elimination of separate information extraction processes, the algorithm exhibits lower computational complexity, enabling higher processing speeds. Most importantly, this joint processing method leverages the correlation between the two steps, resulting in more accurate results.

Method [5] demonstrates exceptional performance in generating scaled full-color images and scaled Bayer color filter array images, surpassing the conventional separate processing methods. However, a drawback of this method is its reliance on substantial computational resources during hardware implementation, which may limit its suitability for scenarios.

This study employs down-sampling, bicubic interpolation [6], and mosaic removal combined with image preprocessing to address the issue of coarse image data and ensure hardware feasibility. These techniques effectively tackle the problem of coarse image data. However, the resulting zipper effect caused by compression necessitates the use of image preprocessing to mitigate this issue. For hardware implementation convenience, this study utilizes an improved version of the HA demosaicing [4], followed by sequential steps of image down-sampling, image preprocessing, HA demosaicing [4], and bicubic interpolation [6], the flow chart is shown in Fig. 2.

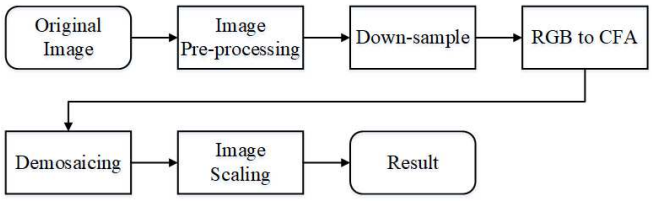

Fig. 2. Flow chart of the image processing.

II. PROPOSAL WORK

A. *Down sample*

This study utilized the Kodak dataset [7] with original image dimensions of 768×512. This study employed down-sampling to reduce the size of the images simply and efficiently. Down-sampling involves discarding every other row and column, resulting in a downsized image of 384×256, the size is one-fourth the size of the original image, and the concept is shown in Fig. 3.

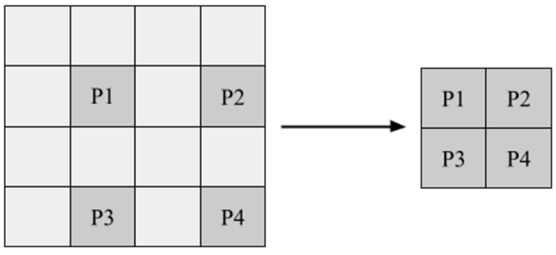

Fig. 3. The schematic diagram of down-sampling.

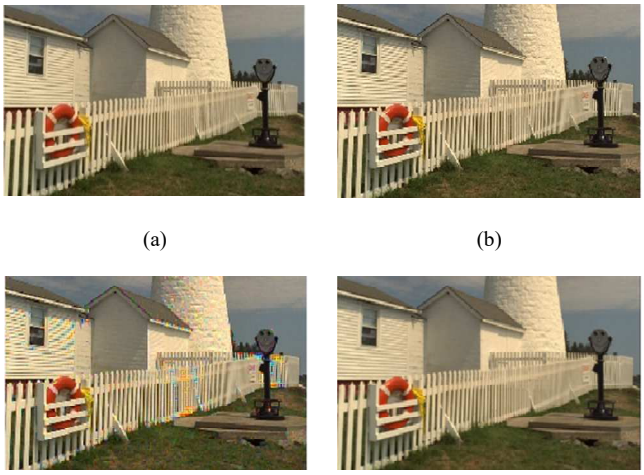


B. *Image preprocessing*

After the down-sampling process, the image loses a significant amount of pixel values, resulting in a jagged or wavy texture, as shown in Fig.4 (b). Due to the absence of a single texture direction, which is not horizontal or vertical, it becomes challenging to determine the texture direction

accurately along the demosaicing edges. This leads to the creation of zipper artifacts in the image, as illustrated in Fig.4 (c). To address this issue, smoothing the texture is beneficial for demosaicing direction determination. A low-pass filter is employed to eliminate high-frequency signals in the image, resulting in a smoother texture. The simplest low-pass filter is the mean filter (MF) [8], formula (1) calculates the average value of pixels within the convolution kernel's region and assigns this average value to the pixel at the center of the kernel. Let $g(s,t)$ represent the original image, and $f(x,y)$ denotes the image obtained after applying the mean filter. Formula (2) is M x N chosen convolutional kernel, this study uses a 3×3 size kernel:

$$f(x,y) = \frac{1}{mn} \sum_{(x,y) \in Sxy} g(s,t) \tag{1}$$

$$\frac{1}{9}\begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \tag{2}$$

(a) (b)

(c) (d)

Fig.4.(a)Original(b)Down sampling without preprocessing (c)Demosaicing without preprocessing (d)Down sampling with preprocessing.

C. *Improved Hamilton-Adams demosaicing*

This section presents the utilization of HA as the fundamental framework, augmented with algorithmic enhancements through HQLI. By integrating color difference information into HA, the computational process becomes more efficient and precise in determining edge directions. Moreover, HQLI excels in preserving fine details in smooth regions. Consequently, by combining these two methods, a three-step demosaicing approach is devised. The first step involves restoring the G pixels in the R (B) channels. To calculate the missing green pixels, the R and B channels are used. The texture on the edges is classified into vertical, horizontal, and no specific texture. According to the HA, the gradient formula for the horizontal and vertical directions is as (3):

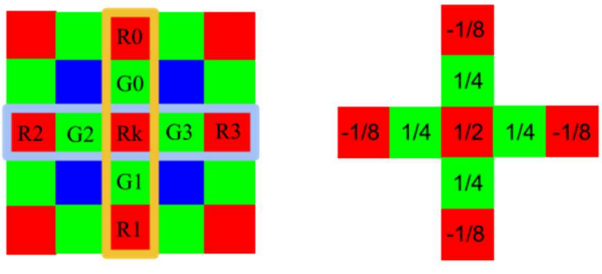
$$\begin{cases} H = |G_2 - G_3| + |2 \times R_k - R_2 - R_3| \\ V = |G_0 - G_1| + |2 \times R_k - R_0 - R_1| \end{cases} \tag{3}$$

H represents the vertical gradient, and V represents the horizontal gradient. As illustrated in Fig.5 (a), the red denotes the central point and calculated the missing green pixel value. The direction is determined by comparing the gradient values, the pixel value is computed according to the texture direction. G_k represents the missing green pixel value for the center point G_k, the calculation formula for G_k is shown in (4):

$$\begin{cases} H > V & G_k = \frac{(G_0 - G_1)}{2} + \frac{(2 \times R_k - R_0 - R_1)}{2} \\ H < V & G_k = \frac{(G_2 - G_3)}{2} + \frac{(2 \times R_k - R_2 - R_3)}{2} \end{cases} \tag{4}$$

This study replaces the calculation parameters for the direction where H equals V and no specific texture, as shown in Fig.5 (b), with those from HQLI [3], which introduces the concept that edges have greater luminance variations than chromaticity. In comparison with the BI estimation of the central red value in Fig.5 (a) to its nearest red sample, if it differs from this estimated value, it implies a significant luminance variation at that pixel. To leverage the advantages of HQLI, estimated luminance variations are added to correct the green value of Bilinear Interpolation [2]. The correction formula is shown below (5):

$$G_K = \widehat{G_k} + \Delta\alpha \times \Delta R_k \tag{5}$$



Where $\widehat{G_k}$ represents the estimated value obtained using BI, $\Delta\alpha$ is the parameter controlling the strength of this correction formula. HQLI proposes using the Wiener method to find the most suitable parameter value, and in the paper, it suggests $\Delta\alpha=1/2$ for better results. Meanwhile, ΔR_k represents the gradient of R_k at that location, used for estimating luminance changes, and its calculation formula is as follows (6):

$$\Delta R_k \triangleq R_k - \frac{1}{4}(R_0 + R_1 + R_2 + R_3) \tag{6}$$

After determining the strength parameter for the correction formula, the calculation formula for the HQLI can be expressed as follows (7):

$$G_k = \frac{1}{2} \times R_k + \frac{1}{4}(G_0 + G_1 + G_2 + G_3) - \frac{1}{8}(R_0 + R_1 + R_2 + R_3) \tag{7}$$

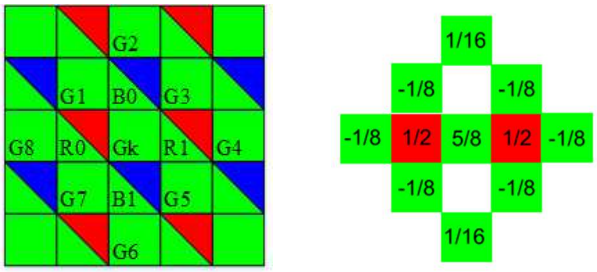
For the remaining pixels as shown in Fig.5 (a), the same procedure applies, but this time using blue as the center point instead of red to calculate the missing green pixel value.

(a) (b)

Fig.5. Using red color at the center point.

The second step involves restoring the missing red or blue

pixels in the G channel. Building upon the previous step, where the missing green pixels were already filled in, as indicated by the green triangles in Fig.6 (a), this step utilizes the parameters from HQLI to calculate the missing pixel values, as shown in Fig.6 (b). HQLI incorporates an estimated luminance change to correct the values obtained from BI. The correction formula is as follows (8):



$$R_K = \widehat{R_k} + \Delta\beta \times \Delta G_k \quad \textbf{(8)}$$

Here, $\widehat{R_k}$ represents the estimated values obtained using BI, and HQLI suggests that $\Delta\beta$ = 5/8 yields optimal results. ΔG_k denotes the gradient at that position for G_k. After obtaining the strength parameter for the correction formula, the calculation formula for HQLI is organized as follows (9) to compute the missing red pixel value R_k for the center point G_k:

$$\mathrm{R}_k = \frac{5}{8} \times \mathrm{G}_k + \frac{1}{2} \times (\mathrm{R}_0 + \mathrm{R}_1) + \frac{1}{16}(\mathrm{G}_2 + \mathrm{G}_6) - \frac{1}{8} \times (\mathrm{G}_1 + \mathrm{G}_3 + \mathrm{G}_8 + \mathrm{G}_7 + \mathrm{G}_5 + \mathrm{G}_4) \quad (9)$$

Similarly, the center point G_k is also missing blue pixel values. This case employs the calculation method mentioned in HA. B_k represents the missing blue pixel for the center point, and GB_0 and GB_1 are the restored green pixels in the B channel obtained from the previous step. The formula for computing GB_0 is shown in (10):

$$\mathrm{B}_k = \frac{(B_0 + B_1)}{2} + \frac{(2 \times G_k - GB_0 - GB_1)}{2} \quad (10)$$

(a) (b)

Fig. 6. Using green color at the center point.

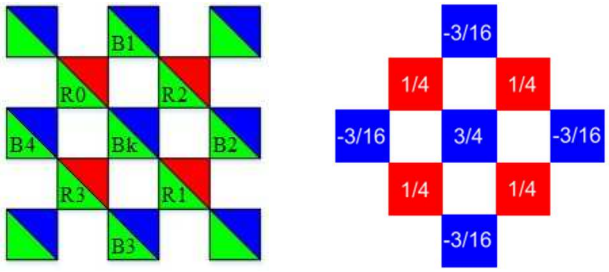
In another scenario, the pixels above and below G_k are red, and the ones to the left and right are blue. This case employs a reversed calculation method. The formula (11) can be utilized to reconstruct the missing red and blue pixels at the center point.

Furthermore, the last step is to restore the missing red or blue pixels in the B or R channel. In this step, the green channel pixels have already been restored, leaving only the red and blue channels with missing pixels, as shown in Fig. 7 (a). The transparent pixels represent points where all three channels have no missing values. The remaining texture directions for pixel points are at 45 degrees and 135 degrees, as mentioned in HA regarding the gradient calculation formula (11) for these directions:

$$\begin{cases} N = |\mathrm{R}_0 - \mathrm{R}_1| + |2 \times \mathrm{G}_k - RG_0 - RG_1| \\ P = |\mathrm{R}_2 - \mathrm{R}_3| + |2 \times \mathrm{G}_k - RG_2 - RG_3| \end{cases} \quad (11)$$

N represents the gradient in the 135-degree direction, and P represents the gradient in the 45-degree direction. RG_0 refers to the green pixel of R_0, and G_k represents the green pixel of the center point B_k. In this case, this study uses blue as the center point and calculates the missing red pixel based on the comparison of the gradient values. R_k represents the missing green pixel of the center point B_k, and the calculation formula for R_k is shown in (12):

$$\begin{cases} N > P & \mathrm{R}_k = \frac{(\mathrm{R}_2 - \mathrm{R}_3)}{2} + \frac{(2 \times \mathrm{G}_k - RG_0 - RG_1)}{2} \\ N < P & \mathrm{R}_k = \frac{(\mathrm{R}_2 - \mathrm{R}_3)}{2} + \frac{(2 \times \mathrm{G}_k - RG_2 - RG_3)}{2} \end{cases} \quad (12)$$



Instead of calculating specific directions for 135 degrees and 45 degrees, this study replaces them with the calculation parameters from the HQLI, as shown in Fig.7 (b). The HQLI incorporates an estimated luminance change to correct the values obtained from Bilinear Interpolation [2]. The correction formula is as follows (13):

$$R_K = \widehat{R_k} + \Delta\gamma \times \Delta B_k \quad (13)$$

Here, $\widehat{R_k}$ represents the estimated values obtained using BI, and HQLI suggests that $\Delta\gamma$ = 3/4 yields optimal results. ΔB_k denotes the gradient at that position for B_k. After obtaining the strength parameter for the correction formula, the calculation formula is organized as follows (14) to compute R_k:

$$\mathrm{R}_k = \frac{3}{4} \times \mathrm{B}_k + \frac{1}{4}(\mathrm{R}_0 + \mathrm{R}_1 + \mathrm{R}_2 + \mathrm{R}_3) - \frac{3}{16}(\mathrm{B}_0 + \mathrm{B}_1 + \mathrm{B}_2 + \mathrm{B}_3) \quad (14)$$

Similarly, for the remaining pixel points shown in Fig. 7. (a), the blue can be treated as the center point, and calculate the missing blue pixel values by swapping the red and blue and performing the respective calculations.

(a) (b)

Fig. 7. Using blue color at the center point.

D. *Image Scaling*

Common image enlargement techniques include bilinear interpolation [9] and bicubic interpolation (BICI) [6]. While bilinear interpolation [9] is simple to implement, it results in variations in image details. On the other hand, bicubic interpolation, although more complex in terms of algorithm, avoids the generation of jagged edges and is suitable for

handling intricate patterns. BICI calculates the pixel value of the target point based on the weighted average of the surrounding 16 pixels. The weight calculation formula is shown in (15):

$$W(x) = \begin{cases} (a+2)|x|^3 - (a+3)|x|^3 + 1 & for\ |x| \le 1 \\ a|x|^3 - 5a|x|^2 + 8a|x| - 4a & for\ 1 \le |x| \le 2 \\ 0 & other \end{cases} \quad (15)$$

x represents the pixel distance between the target point and a neighboring pixel, and adjusts the smoothness of the function, with the optimal value being -0.5. After calculating the weight values for the 16 neighboring points of the target point, the original pixel values are multiplied by the corresponding weights and summed up as follows:

$$P(x,y) = \sum_{i=1}^{4}\sum_{j=4}^{4} a_{ij} x^i y^j \quad (16)$$

P represents the target pixel value, i denotes the row number, j denotes the column number, a_{ij} represents the pixel value of the neighboring point, x^i represents the weight in the X-axis direction, and y^j represents the weight in the Y-axis direction. This process allows for image enlargement that is clearer compared to the original bilinear interpolation [9].

III. RESULTS

This study conducted tests using the Kodak dataset [7] with dimensions of 768×512, which is shown in Table 1. After simulating the Bayer CFA pattern and applying it to the down-sample, and employed an improved HA demosaicking algorithm to restore colors. Finally, this study utilized BICI. On average, this method achieved a 1.13 dB difference in PSNR compared to HQLI combined with BICI, as shown in Table 2. The noticeable differences can be observed in Fig. 8. and Fig. 9., particularly in the fenced area of Fig. 9. In addition to the proposed method for quantitative comparison, this study also attempted other approaches. The first approach involved unimproved HQLI demosaicing with bilinear interpolation and no image pre-processing. The second approach utilized unimproved HQLI demosaicing with bilinear interpolation and image pre-processing. The third approach employed unimproved HA demosaicing with bicubic interpolation and no image pre-processing. The fourth approach applied unimproved HA demosaicing with bicubic interpolation and image pre-processing. The fifth approach employed an unimproved proposed method with bicubic interpolation and no image pre-processing. The sixth approach applied the unimproved proposed method with bicubic interpolation and image pre-processing.

IV. CONCLUSIONS

This paper introduces a comprehensive image processing pipeline that integrates mean filtering [8], an improved adaptive mosaic algorithm, and bicubic interpolation for image upscaling. This procedure offers a simple yet effective approach to enhance image quality and improve visual effects. Initially, mean filtering is applied to smooth the image and reduce the zipper effect. Subsequently, the weights of parameters in the HA demosaicing [4] algorithm are adjusted using High-quality linear interpolation [3] to enhance image sharpness and color details. Finally, bicubic interpolation [6]is used for scaling, resulting in improved image quality and visual effects. This paper demonstrates excellent performance in terms of evaluation metrics while effectively addressing the zipper effect.

Regarding image quality assessment, this paper achieves a 1.13 dB increase in PSNR, 1.19 dB in CPSNR, and 0.03 in SSIM values compared to HQLI [3] combined with bicubic interpolation [6]. Although it slightly lags behind the approach proposed by Kuan-Yu Huang et al. [5] based on machine learning, the method presented in this study has greater potential for hardware implementation and can be applied to various low-complexity image processing tasks, such as image upscaling, denoising, and image enhancement.

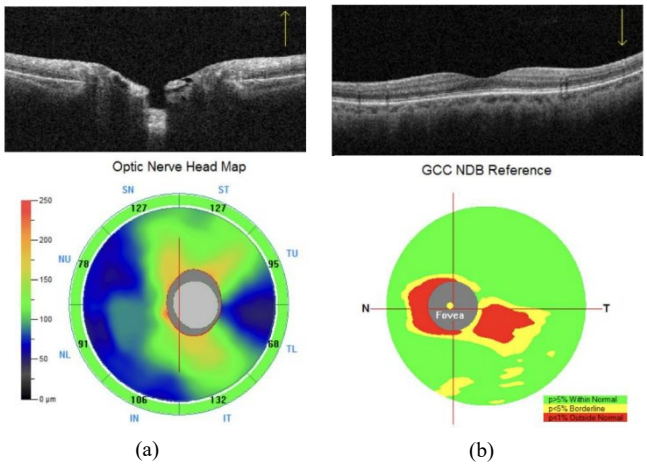
***Abstract*—With the advancement of deep learning in many computer vision applications, the development of computer-aided diagnosis systems has been focused on recently. The deep learning approaches for glaucoma assessment through fundus analysis have shown extremely high performance, especially for early detection, in many studies. In addition, researchers also found that the deep learning models detect not only the subtle changes that reflect RNFL thinning but also the morphological features that are present outside the optic disc in fundus photography. It suggests that the deep learning models have great potential for extracting detailed morphologies which may not be aware by human's vision. However, the deep learning models also suffered from the problem of poor regularization when dealing with cross-institutional datasets. That is, the model's performance dropped dramatically on the input images from different institutions. The feature extraction by deep learning models can detect detailed characteristics for distinguishing different categories; nonetheless, these detailed features also cause the overfitting problem for cross-institutional data. Therefore, in this study, we aim to verify our proposed hypothesis by the application of fundus analysis for glaucoma assessment using deep learning approaches. The features with better regularization, called robust features, were selected to reduce the influences from the non-robust features that overfit the training dataset from a specific source. With feature selection, the performance of the glaucoma assessment cross-institutional dataset can be improved from 62.7% to 81% in accuracy.**

Keywords— Glaucoma Assessment, Deep Learning Approach, Model Regularization.

I. INTRODUCTION

Glaucoma is considered one of the leading causes of irreversible blindness worldwide. It is known as the silent thief of sight since it causes vision loss or even blindness due to the progressive damage of optic nerve. As it is asymptomatic, early screening of glaucoma and the corresponding treatment are very important for patients to prevent the progression of vision loss.



(a) (b)

Fig. 1. The model of Mask R-CNN was applied to perform instance segmentation for optic cup (the enclosed area in black), optic disk (the enclosed area in light blue), and fovea (bounded area in white) in macula. The measurements of cup-disk ratio with respect to vertical height, horizontal width, and areas were computed, denoted as cdv, cdh, cda, respectively. (a) A case of glaucoma with enlarged cup-to-disk ratios. (b) A case of non-glaucoma with normal cup-to-disk ratios.

Clinically, color fundus photography, as shown in Figure 1, is one of the mandatory imaging modalities in glaucoma assessment, characterized by its convenience and relative affordability. Pathologically, glaucoma leads to the elevation of patient's intraocular pressure, which compresses the optic nerve and causes the depression of the optic disc. Such nerve fiber damage results in an enlarged cup-to-disc ratio (CDR) as it can be observed from Fig. 1-(a). In fundus analysis, the measurement of CDR is one of the factors for glaucoma assessment; however, not every glaucomatous case follows such rule. Besides, the borderline measurements of CDR may also confuse ophthalmologists in diagnosis.

On the other hand, as it is shown in Figure 2, the non-invasive imaging modality of optical coherence tomography (OCT) with high resolution 3D reconstruction of retina can provide more detailed information to compute the thickness of the retinal nerve fiber layer (RNFL) and the ganglion cell complex (GCC), which are considered the useful biomarkers in diagnosing glaucoma clinically.

(a) (b)

Fig. 2. The (a) thickness distribution maps of RNFL and (b) reference maps for GCC can be derived from OCT with high resolution 3D reconstruction of retina.

Recently, the task performance in image classification has significantly advanced as a result of the development of deep learning techniques. For fundus analysis, the deep learning models of convolutional neural network (CNN) have been widely adopted in fundus image analysis for the diseases of diabetic retinopathy (DR) [1], age-related macular degeneration (AMD) [2], and glaucomatous optic neuropathy (GON) [3-6]. These studies have shown the strength of the DCNN models to provide comparably accurate diagnostic predictions to human experts simply with the single modality of fundus images. In addition, researchers found that the deep learning models can even predict an individual's age, gender, and cardiovascular risk factors by assessing a fundus photo [7], which is extremely unlikely to be achieved by human's vision. Taking glaucoma assessment as an example, deep learning models detect not only the subtle changes that reflect RNFL thinning but also the morphological features that are present outside the optic disc in fundus photos [3]. Therefore, the main purpose of this study is to reveal the insights of the decision process by the deep learning models of DCNN in the diagnosis of glaucoma using a single modality of color fundus images.

However, researchers also found that the tasks of glaucoma assessment with the deep learning approaches suffer from the problem of poor model generalization for the cross-institutional imaging data [4-6]. As a result, even though the deep learning models have shown the extraordinary performance on a specific dataset in fundus analysis, the trained models may not be applicable on the fundus images which came from the other medical institutions due to its poor generalization. From the perspective of development, it becomes the top issue to be tackled when deploying the computer-aided diagnosis (CAD) systems.

In this study, the properties of feature extraction in deep learning approaches were mainly discussed through the tasks of fundus analysis for glaucoma assessment. We argue that the deep learning models are good at finding the detailed features which are statistically useful in classification but hard to be noticed by our vision. This kind of features is classified to the category of "non-robust features", which may be the key to success for the deep learning approaches to achieve outperformance than human experts. However, such non-robust features also overfit the dataset easily and result in the problem of poor generalization when dealing with the cross-institutional datasets. For our hypothesis, the features extracted by deep convolutional neural networks (DCNN) can be categorized into "robust features" and "non-robust features", where the "robust features" show better regularization while the "non-robust features" overfit the dataset easily for detailed characteristics [8]. Therefore, several experiments were designed to verify the abovementioned hypothesis in this study.

II. Materials and Methods

From the perspective of the development of AI-assisted systems, the AI models are supposed to maintain decent level of generalization to deal with the imaging data from different institutions or devices. Our goal is to improve the AI models' regularization property for cross-institutional data in the tasks of glaucoma assessment. In this study, we aimed to verify the poor regularization of DCNN models came from the influences of the overfitting features. Accordingly, feature selection for the robust ones can mitigate the overfitting problem successfully.

We argue that the performance of the DCNN models dropped dramatically on the cross-institutional data due to the influence of the overfitting features learned from the source dataset. Therefore, the robust features with better generalization were chosen after feature selection, mitigating the overfitting problem. To verify our hypothesis, two datasets of fundus images from different institutions were collected. The main dataset for models' training came from the Tris-Service General Hospital (TSGH). And another dataset came from the Taipei Veterans General Hospital (TPEVGH) for the purpose of evaluating the model's performance on the cross-institutional dataset. The fundus images in the main dataset were collected retrospectively from the ophthalmology clinic at TSGH. And the numbers of glaucomatous samples and non-glaucomatous samples for each dataset are listed in Table I. Another dataset from TPEVGH was randomly divided in half to become a validation set and a testing set, as listed in Table II.

Table I. Datasets of fundus images from the Tri-Service General Hospital (TSGH).

dataset	label	# fundus photos
training	Glaucoma	536
	Non-glaucoma	639
validation	Glaucoma	146
	Non-glaucoma	189
testing	Glaucoma	75
	Non-glaucoma	153

Table II. Datasets of fundus images from the Taipei Veterans General Hospital (TPEVGH).

dataset	label	# fundus photos
validation	Glaucoma	150
	Non-glaucoma	150
testing	Glaucoma	150
	Non-glaucoma	150

In the experiment, the DCNN model of ResNet50 [9] was chosen to train on the training dataset from TSGH. And the final model was determined by choosing the model's weights that reached the best performance on the validation dataset of TSGH. Then, the final model was applied on the testing sets of TSGH and TPEVGH for inference to evaluate its performance of generalization on the cross-institutional dataset.

For feature selection, the end-to-end DCNN model was decomposed into two parts: (1) convolutional layers for feature extraction and (2) fully connected layers for classification. Then, the convolutional layers and their weights were kept to perform feature extraction, and the fully connected layers were replaced by a random forest classifier for classification. For ResNet50, 2048 features were extracted from an input image through the convolutional layers. Here the classifier of random forest is to encode the relation of these 2048 features and the ground truth outputs and also estimate the feature importance. Subsequently, the validation set from TPEVGH was used to train a random forest classifier to rank all 2048 features by the feature importance. As a result, we know what features learned from the dataset of TSGH are also useful for the dataset of TPEVGH in distinguishing the glaucomatous cases, called the robust features. Finally, only some robust features were selected to train a random forest classifier on the TSGH dataset, screening out those overfitting features. And we need to check if the random forest classifier trained with the selected features can improve its performance on the cross-institutional datasets.

III. Experimental Results

From the previous two sections, the DCNN models have shown the outstanding performance in classification, capturing the detailed morphologies that surpass humans' perception. However, those detailed features that overfit the dataset may lead to poor generalization of model. In Table III, the end-to-end DCNN model trained on the TSGH dataset achieved 88.2% in accuracy on the testing dataset from the same institution, but the performance dropped to 63.3% on the cross-institutional testing set. The similar phenomenon also happened with the classifier of random forest. It means the extracted features are the bottleneck of performance. Therefore, the validation set from another institution (TPEVGH) was used to rank the feature importance for selecting the generalized features. After feature selection, even though the performance dropped about 2% on the same source dataset, it increased 18% on the cross-institutional dataset. As a result, better generalization of model can be achieved by screening out the overfitting features. Figure 3 shows the performance of the model on the cross-institutional dataset increased with more robust features selected, and it started to drop when more and more overfitting features were included.

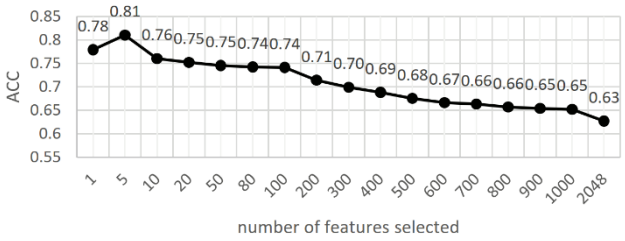

Fig. 3. The accuracy of the model on the cross-institutional dataset with respect to the number of features used in classification.

Table III. Performance comparison among different methods on the cross-institutional dataset.

Method	Data from TSGH	Data from TPEVGH
DCNN trained on TSGH data	0.882 (201/228)	0.663 (190/300)
CNL + RF (all 2048 features)	0.886 (202/228)	0.627 (188/300)
CNL + RF (5 selected features)	0.864 (197/228)	0.81 (243/300)

IV. CONCLUSIONS

In this study, we have shown the DCNN models are specialized in capturing the detailed morphologies, even those features are barely detected by our vision. On the other hand, the extracted features with detailed morphologies became the bottleneck of models' performance for the cross-institutional data, leading to poor generalization. After feature selection, the performance on the same source data may be sacrificed to trade better generalization from the perspective of CAD systems' development.

ACKNOWLEDGEMENTS

We would like to express our appreciation to the National Center for High-performance team for sharing TPEVGH fundus database in the project of MIAI-2022-M10-01.

Design of Interactive System for Acupoint Analysis Based on Augmented Reality

Chung-Yen Wei, Bo-Yuan Xu, and Yu-Xiang Zhao*
National Quemoy University, Taiwan.
*E-mail: yxzhao@nqu.edu.tw

Abstract — **In this paper, we utilize the edge computing of Jetson Nano J1010 development board and employ MediaPipe technology and acupoint mapping algorithm to display acupoints on the screen. By using a custom deep neural network (DNN) hand recognition model, we achieve augmented reality (AR) interaction with acupoints. Users can view the corresponding acupoint locations on the body and acupoint descriptions through gestures. Additionally, we develop a mobile app that enables interaction with the system via Bluetooth technology. Users can select symptoms they wish to understand, and the system will display acupoints that can alleviate those symptoms. Our team also develops an AI-based diagnostic system using the open-source conversational AI Rasa, which utilizes natural language understanding (NLU) to determine the user's intents from input on the mobile app. When the intent is related to medical content, the information is passed to a BERT model for diagnosis analysis, determining possible diseases or symptoms and providing corresponding recommended acupoints for symptom relief. This aids users in making preliminary judgments about their own conditions. All AI diagnostic information is transmitted to the server-side, where physicians can view user information through a website. By visualizing the data through charts, physicians can quickly understand the user's condition and further save medical resources. This acupoint-based healthcare system offers a safe, convenient, and efficient solution for health management, particularly valuable for individuals lacking experience and medical knowledge.**

Keywords: edge computing, acupoints, AR, AI, NLU, BERT.

I. INTRODUCTION

One of the methods for maintaining good health is acupressure. There are many specific acupoints that have the ability to treat various ailments. These acupoints not only have the effect of healing specific diseases but also help in regulating overall body functions, promoting physical fitness. However, as acupoints are distributed throughout the human body, their precise locations often require guidance from books or others, especially for beginners. We aim to enable users to easily identify the locations and functions of acupoints on their hands and heads at a glance, allowing them to effectively utilize these acupoints to alleviate symptoms in a timely manner, ultimately preventing the onset of diseases.

This system utilizes the edge computing of Jetson Nano J1010 development board and incorporates MediaPipe technology to achieve augmented reality (AR) interaction with acupoints, allowing users to view the corresponding acupoint locations on the body. We have also developed a mobile app that connects to a smart mirror via Bluetooth. Users can select symptoms they wish to understand, and the screen will provide feedback on acupoints that can alleviate those symptoms. The system also includes AI diagnosis using Rasa and BERT technology, which analyzes user input to determine possible diseases or symptoms and provides recommended acupoints for further symptom relief.

This acupoint-based healthcare system offers a safe, convenient, and efficient solution for health management, particularly valuable for individuals lacking experience and medical knowledge. The innovation of this project lies in the integration of the mobile app, AI, and AR technology, which realizes a acupoint-based healthcare solution that is more convenient and efficient compared to traditional healthcare approaches.

II. RELATED WORK

Acupoints are essential elements in traditional Chinese healthcare, and in recent years, artificial intelligence (AI) technology has made significant progress in acupoint recognition. Early approaches utilized CNN models and mathematical calculations or edge detection to infer acupoint locations [1]-[2], while now models such as MediaPipe can obtain human body coordinate points. Previous studies have used 3DMM models to display facial acupoints [3], but their complex computational requirements limit real-time operation. MediaPipe Face Mesh is a real-time facial landmark detection

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

system that uses machine learning to predict the 3D positions of 468 facial keypoints. Compared to 3DMM models, MediaPipe performs better and is suitable for running on various devices.

Recent research has also used MediaPipe for facial acupoint display [4], but with limited functionality. This paper further develops on the foundation of MediaPipe, implementing not only facial acupoint display but also hand acupoints, acupoint classification, and gesture interaction, providing users with a more comprehensive experience. In recent years, artificial intelligence has made significant progress in various fields such as natural language processing, image recognition, visual retrieval, and medical image analysis [5]-[6]. Especially in the past few years, with the rapid improvement of computer specifications and the growth of talents in various domains, the power of artificial intelligence has been strengthening year by year. The following sections will introduce the relevant technologies used in this research.

A. MediaPipe

MediaPipe is an open-source, cross-platform multimedia processing framework developed by Google [7]. It provides a set of templates for image and video processing, enabling the construction of complex multimedia applications. MediaPipe supports multiple platforms, including Android, iOS, Linux, and Windows. It offers various built-in algorithms such as face detection, holistic detection, and hand tracking, while also allowing easy extension with custom algorithms. MediaPipe can be used in various environments, such as mobile and embedded devices. Within the scope of this project, MediaPipe serves as the means to collect body pose data, resulting in the implementation of two key features: the acupoint mapping and the gesture recognition facilitated by a custom DNN calculator [8].

B. PyQT

PyQt is a framework for developing graphical user interface (GUI) applications [9]. It is based on the Qt framework, which is a cross-platform application development framework used for desktop, mobile, and embedded systems. PyQt can run on multiple operating systems, including Windows, Mac OS X, Linux, and embedded Linux, making program development on Jetson Nano much more convenient. Due to its foundation on the Qt framework, PyQt offers excellent performance. It provides efficient drawing and event handling through optimization and design, enabling the handling of large amounts of data and complex operations. Additionally, PyQt offers rich configuration and customization options, allowing the creation of unique user interfaces.

C. Jetson Nano

The Jetson Nano J1010 development board is a high-performance single-board computer introduced by NVIDIA, designed specifically for machine learning and artificial intelligence applications. Jetson Nano J1010 features NVIDIA's quad-core ARM Cortex-A57 processor and a 128-core NVIDIA Maxwell GPU, providing powerful computational capabilities. This allows it to excel in handling complex machine learning and visual computing tasks, capable of real-time processing of high-resolution images and videos. The NVIDIA GPU on Jetson Nano J1010 provides additional computing resources for accelerating machine learning and deep learning tasks. This enables the execution of complex neural network models on Jetson Nano and facilitates real-time face detection and hand recognition tasks as proposed in this paper.

J1010 is also an optimized hardware platform for AI and machine learning applications. It supports popular deep learning frameworks such as TensorFlow, PyTorch, and Caffe, as well as GPU acceleration libraries like CUDA and cuDNN, enabling efficient utilization of custom models.

D. BERT

BERT (Bidirectional Encoder Representations from Transformers) is a pre-trained deep learning model for natural language processing (NLP) developed by Google [10], extending from the Transformers [11] decoder. BERT is capable of bidirectional encoding of sentences, considering the contextual information of all words in the sentence. This allows BERT to exhibit excellent performance in various NLP tasks, including sentiment analysis, machine translation, keyword extraction, and question-answering systems.

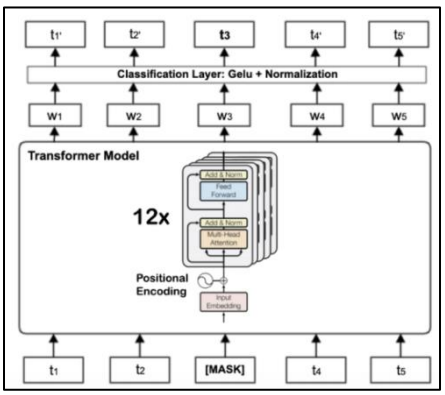

Fig. 1 BERT basic architecture diagram.

The architecture of BERT used in this project consists of 12 transformer layers (see Figure 1), which is a neural network architecture that effectively learns long-range dependencies. BERT employs a technique called adaptive learning during

training, enabling the model to dynamically adapt to different input lengths of sentences. Additionally, BERT utilizes residual connections and self-attention mechanisms [11], allowing the model to capture the relevance within sentences better. Through the BERT model, we aim to infer user diseases based on conversations and provide corresponding acupoints displayed on the human body.

E. MVC and State Machine

This paper adopts the Model-View-Controller (MVC) architecture on the software side to organize and separate different components of the application, aiming to achieve better code structure and maintainability. The Model represents the data structure, logic, and state of the application. It is responsible for handling operations, validation, persistence, and other data-related tasks. The Model does not directly interact with the user interface (View) or user interactions (Controller) but provides interfaces for them to interact.

The View is responsible for presenting the interface, allowing users to intuitively view and manipulate data. It typically represents user interface elements such as buttons, forms, charts, etc., and updates accordingly based on the state of the Model. The Controller serves as an intermediary between the Model and the View. It receives user inputs, processes user requests, and then passes the results to the Model or View as needed. It determines how to update the Model and View based on the logic of the application. In addition to the MVC architecture, this paper also utilizes a state machine to manage the different states and transitions within the application. The state machine helps define the behavior and flow of the application by representing various states and specifying the conditions and actions associated with state transitions. By adopting the MVC architecture and employing a state machine, this paper achieves a well-structured and maintainable software solution for the intended application.

III. APPROACH

A. System Architecture

In this paper, an interactive AR acupoint healthcare system is developed, which can recognize acupoints on the user's hands and head and assist users in learning and understanding acupoint knowledge. As shown in Figure 2. The system consists of four main components: the software side, the hardware side, the server side, and the mobile side. The hardware side utilizes the edge computing of Jetson Nano J1010 development board and interacts with the user through a webcam. The software side is developed using PyQt and utilizes MediaPipe to obtain the coordinates of the human body. With the help of algorithms, the obtained coordinate points from MediaPipe are mapped to the acupoints on the head and hands. This allows the display screen to show the acupoints, enabling users to learn and understand acupoint knowledge.

Additionally, the system includes an Android app that users can download. Through this app, users can conduct AI consultations and record their physical condition and related information. During the consultation, the app connects to the server side to perform AI consultations. The server side utilizes natural language understanding (NLU) to interpret user inputs and determine their physical condition. The user's information is stored on the server. Doctors can log in to the server through a web interface to quickly understand the user's physical condition and related information.

This design enables doctors to gain a faster understanding of the user's physical condition, improving diagnostic efficiency, and allows users to conveniently access medical assistance. Overall, the developed system provides an interactive AR acupoint healthcare solution, combining hardware, software, server, and mobile components to enhance acupoint learning, AI consultations, and efficient healthcare delivery.

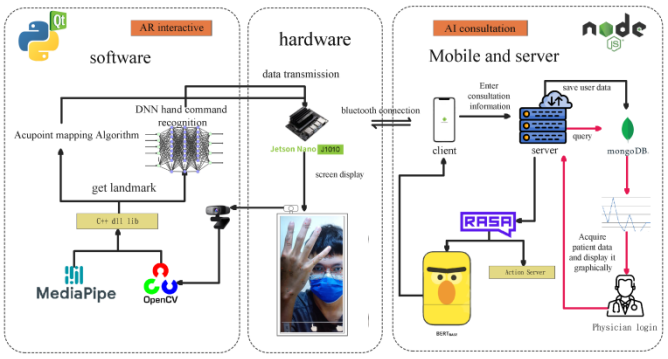

Fig. 2 System Architecture Diagram.

B. Produce Architecture

The product architecture is visually represented in Figure 3. Initially, we utilize a webcam to capture the user's hand data, which is subsequently transmitted to the Jetson Nano J1010 for processing.

In the Data Analysis phase, we leverage the hand and head landmarks provided by the Mediapipe holistic model to enable two essential features: acupoint mapping and gesture recognition. Acupoint mapping involves projecting these acupoints onto the human body, while Deep Neural Networks

(DNNs) are employed for hand gesture recognition, providing users with an intuitive means of controlling the entire system. This allows users to view the desired acupoint locations or issue commands effortlessly.

Additionally, we take measures to optimize this resource-intensive computation, resulting in reduced power consumption and lighter system load requirements. We empower users to select from our customized facial recognition models, and we implement asynchronous output for data analysis, ensuring a smoother visual interaction with their hand acupoints in augmented reality. Finally, in the front-end interaction, users can engage with and control the system with gesture interaction and mobile app.

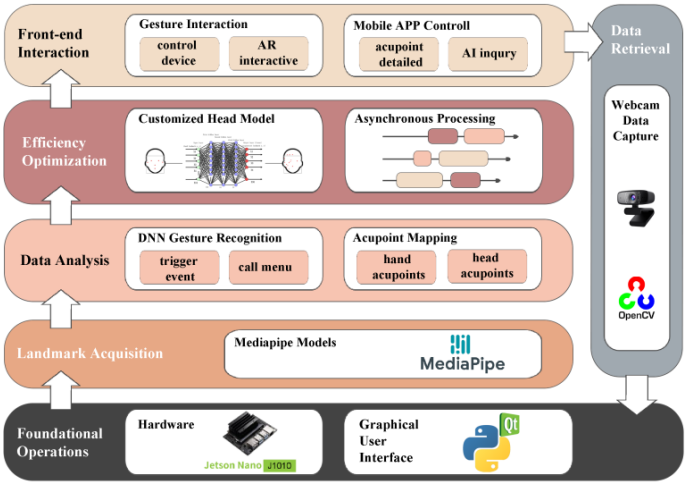

Fig. 3 Product Architecture Diagram.

C. *Acupoint Mapping*

Our hand and head localization utilize position data from a database, which includes reference MediaPipe coordinate positions, relative distances to the coordinate positions, and acupoint names. The steps for displaying acupoints can be seen in Figure 4.

We employ a custom hand acupoint mapping algorithm that utilizes various mathematical functions such as cross products, dot products. We employ the intuitive definition of the dot product in Euclidean space, which involves taking the dot product of two vectors, dividing it by the distance between the two vectors, and then applying the inverse cosine function to obtain Phi (Equation (1)), and generates transformation matrices based on the rotation amount of the base axis (Equation (2)). By comparing the relative positioning points from the database with the hand localization points provided by MediaPipe, the acupoints can be accurately displayed on the screen and scaled based on distance. The development of this custom algorithm ensures reliable acupoint mapping.

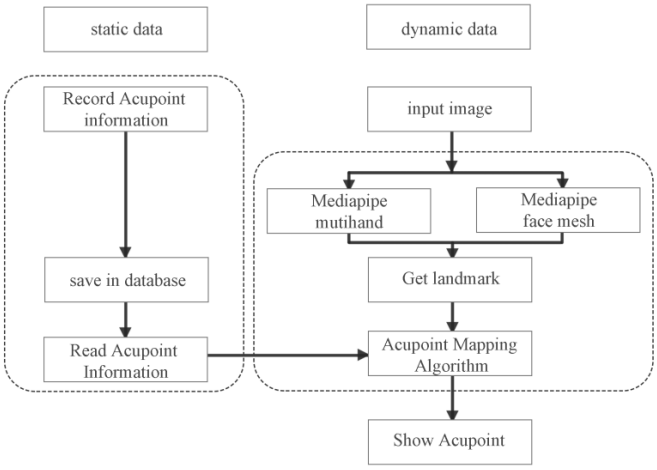

Fig. 4 Product Architecture Diagram.

$$\varphi = \cos^{-1}\frac{\overrightarrow{v_{0to9}} \cdot \overrightarrow{nv_{0to9}}}{\sqrt{(x_0-x_9)^2+(y_0-y_9)^2}\times\sqrt{(nx_0-nx_9)^2+(ny_0-ny_9)^2}} \quad (1)$$

$$where \quad \overrightarrow{v_{0to9}} = (x_0 - x_9, y_0 - y_9),$$
$$\overrightarrow{nv_{0to9}} = (nx_0 - nx_9, ny_0 - ny_9)$$

$$[\alpha, \beta] = [x,\ y] \cdot \begin{bmatrix} \cos\varphi & -\sin\varphi \\ \sin\varphi & \cos\varphi \end{bmatrix} \times z \quad (2)$$

D. *DNN Hand Gesture Recognition*

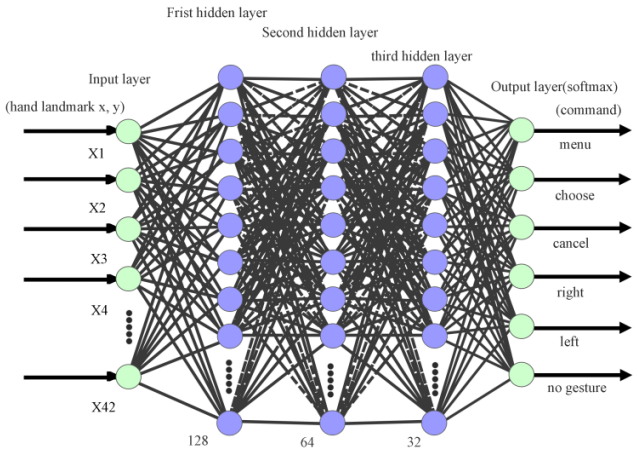

Fig. 5 DNN hand recognition model

HaGRID (Hand Gesture Recognition Image Dataset) [12] is a dataset for hand gesture recognition images. In this project, we utilize the data from HaGRID as well as custom hand data to train a DNN (Deep Neural Network) model. The dataset consists of a total of 28,304 samples. Figure 5 illustrates the DNN network. The input for this model consists

of 42 features, including the X and Y coordinates of 21 hand localization points returned by MediaPipe. Since the input features are coordinate positions, a simple three-layer DNN model is sufficient to quickly classify the current gesture into its corresponding type. The output consists of four classes: menu, choose, cancel, right, left, and no gesture. This hand gesture recognition functionality enables users to interact more conveniently with the smart mirror, enhancing the overall user experience of the product.

E. State Machine

Figure 6 illustrates the main operational logic of the state machine in the software code of this project. The purpose of this state machine is to perform a series of operations and decisions based on the landmark data returned by the hand tracking model of MediaPipe. A more detailed explanation of this operational logic is provided below.

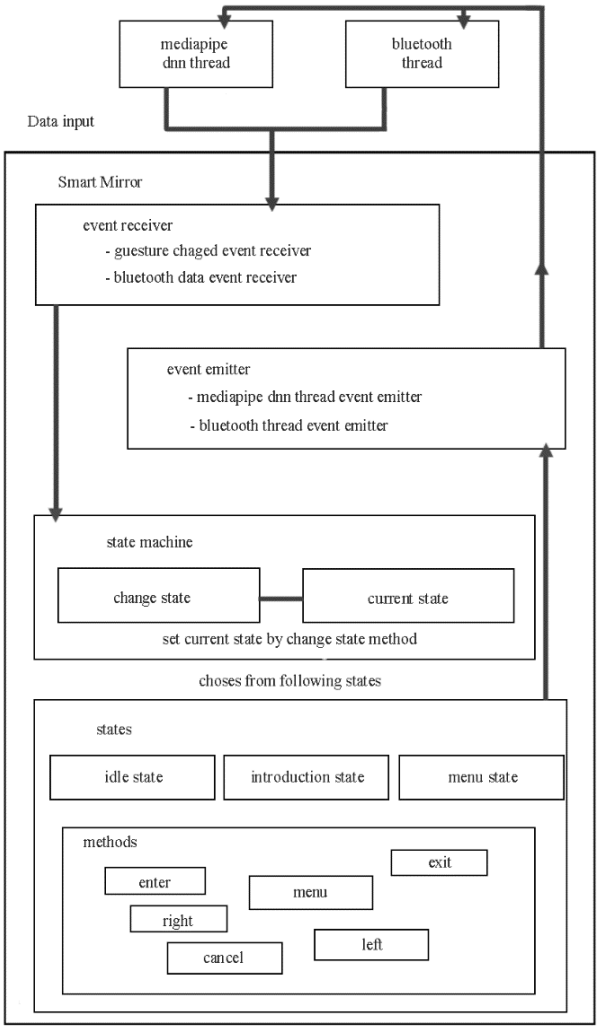

Fig. 6 Finite state machine architecture

Firstly, the system retrieves the landmark data as input from the hand tracking model of MediaPipe. Next, these input data are passed to a custom DNN model for processing. The output of the DNN model is transmitted to the main thread (smart mirror - main thread) through event functions. This design helps prevent race conditions and critical sections between different threads, ensuring the proper handling of data. Once the output of the DNN model reaches the main thread, the smart mirror evaluates the output. This evaluation may involve operations based on predefined logic or conditions. Based on the evaluation result, the state will execute the corresponding method. These methods may involve updating the display content of the mirror, adjusting mirror settings, or performing other relevant operations.

If specific transition conditions are met, the state instructs the state machine to perform a state transition. State transitions may involve entering another state or executing different operational flows. Additionally, the state can also notify the UI controller to switch UI interfaces. This allows the screen display to change based on the system's requirements and state variations. The state can also send events to other threads. These events can trigger specific operations in other threads or perform specific tasks. For example, these events can be used to control the model's activation, notifying relevant threads to execute model-related operations.

F. Mobile Bluetooth Pairing

We provide Bluetooth connectivity between the mobile device and the software side (as shown in Figure 7).

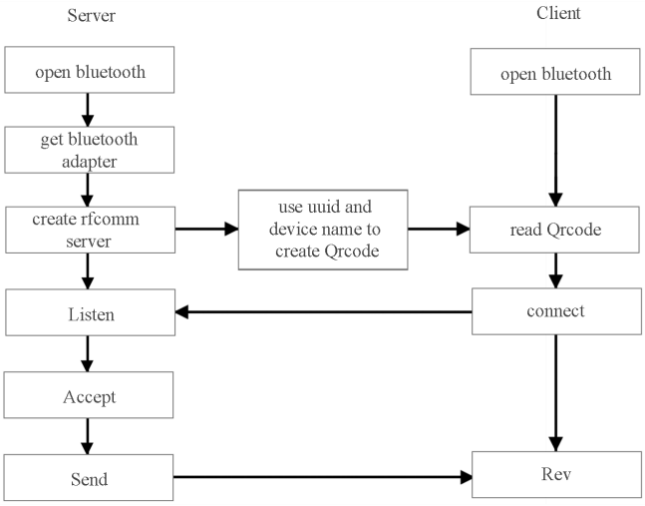

Fig. 7 Mobile phone bluetooth connection

Through Bluetooth pairing, users can conveniently view the corresponding acupoints for their symptoms and access

detailed information about the desired acupoints. When the user activates the Bluetooth pairing function, the mobile device acts as an RFCOMM server and generates a specific UUID for identification during the connection. This UUID, along with the device name, is encoded into a QR code and displayed on the mobile device. The user simply needs to place the QR code displayed on the mobile device within the field of view of the webcam. The Jetson Nano, equipped with built-in Bluetooth functionality, scans and decodes the QR code, thereby obtaining the device's MAC address and server UUID.

The Bluetooth pairing functionality transforms the mobile device into a convenient control interface, allowing users to effortlessly operate and access the desired acupoint information. This design not only provides a more intuitive and interactive interface but also enhances usability by increasing convenience.

G. *BERT AI Consultation*

BERT AI Figure 8 illustrates the AI consultation architecture of this project. We have set up our own server and built a simple chatbot on the server. We utilize Rasa to create the chatbot, and when the user's intent on the mobile device is to inquire about a disease or symptom, the BERT model trained in this project provides corresponding effective acupoints based on the user's input. The smart mirror then displays only these acupoints, allowing the user to further alleviate their symptoms.

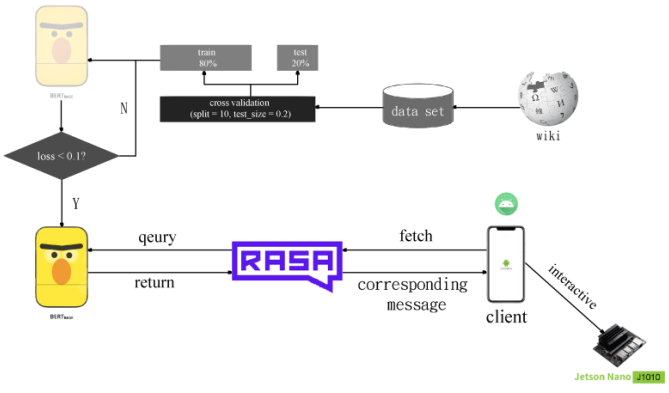

Fig. 8 Architecture Diagram of BERT AI Consultation

In this work, we employ the pre-trained BERT model, specifically the bert-base-chinese variant [13]. This model consists of 12 layers, 768 hidden units, and 12 attention heads, with a parameter size of 110MB. Before training the model, we initialize the token input of the BERT model and incorporate data collected from Wikipedia. Currently, our dataset includes dialogue information associated with 109 disease categories and symptoms related to these diseases, totaling 623 records. We use this data for fine-tuning the model, which involves connecting a new simple classifier to the last layer of BERT to identify the disease category based on the user's input.

IV. RESULT

A. *Acupoint Mapping Effect*

Our algorithm is based on the model proposed by Mediapipe and applied to hand and head acupoint mapping. Using the landmarks provided by Mediapipe, our algorithm achieves acupoint display accuracy consistent with the Mediapipe model [14], reaching up to 95.7%, when the hand is rotated or fully extended. The effectiveness of acupoint mapping can be observed in Figure 9. The hand acupoints adhere to fixed positions and do not shift due to hand rotation or other gestures. This demonstrates the accuracy and effectiveness of our acupoint mapping algorithm.

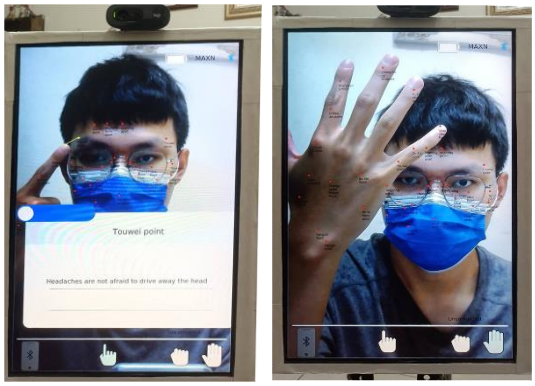

Fig. 9 Acupoint Mapping Effect Display

B. *DNN Performance Evaluation*

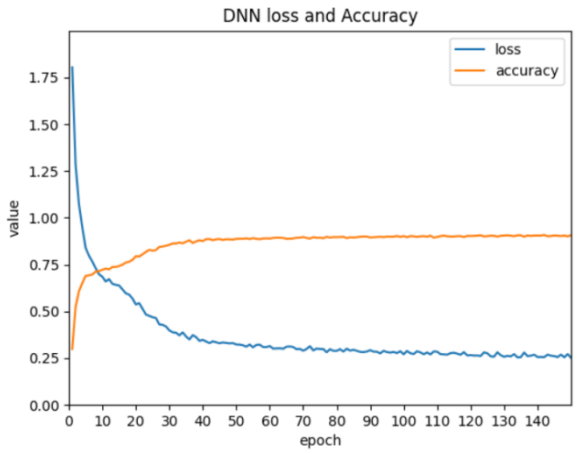

Fig. 10 DNN Hand Gesture Recognition Loss and Accuracy

$$\text{Loss} = -\sum_{i=1}^{output\ size} y_i \cdot \log \hat{y}_i \quad (3)$$

We employed DNN for hand gesture recognition with 150 epochs, a batch size of 16, and the categorical cross-entropy loss function (Equation 3). By observing the loss function during training, we can see a gradual decrease in loss and a corresponding increase in accuracy, indicating good learning performance of the model. The DNN hand gesture recognition model in this project achieved an impressive accuracy rate of up to 90%. This indicates that our model can accurately classify the user's gestures into six predefined types (menu, cancel, choose, right, left, no gesture). Such high accuracy provides reliable hand gesture recognition functionality for our application, enabling users to perform corresponding operations smoothly. Monitoring the loss function and accuracy ensures that the training process and results of the model meet the intended goals. Figure 10 intuitively illustrates the progress and effectiveness of our model training. This technology exhibits high accuracy in hand gesture recognition, providing a solid foundation for the successful implementation of this project.

C. BERT Performance Evaluation

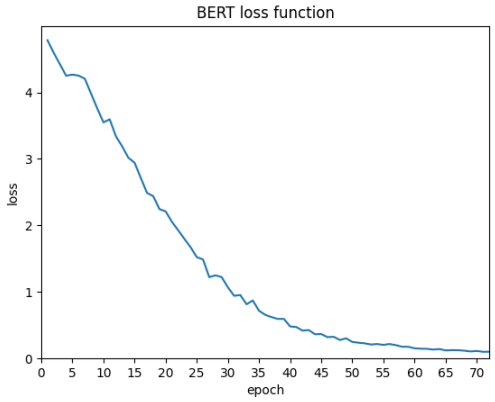

Fig. 11 BERT Loss Fuction

In this paper, we divided the dataset into an 80% training set and a 20% testing set for fine-tuning the BERT model. During the training process, we used 72 epochs and a batch size of 10. By observing the variation of the loss function in Figure 11, we can see a gradual decrease in the loss function, indicating an improvement in the model's learning performance. We terminated the training when the loss function was below 0.1. After each training session, we obtained four model metrics: Accuracy, Precision, Recall, and F1-Score. To ensure the credibility of the experiment, we performed ten-fold cross-validation, averaging the model metrics from the ten iterations as the final performance indicators. This approach helps reduce the impact of random variations in individual training sessions and provides a more comprehensive evaluation of the model's performance.

Based on our results, our model performed impressively in disease prediction, achieving an accuracy rate of nearly 80%. This means that our model can provide accurate predictions for the symptoms and disease categories entered by the user. The results in Figure 12 further validate the effectiveness and reliability of our trained BERT model in the AI chatbot for medical consultations.。

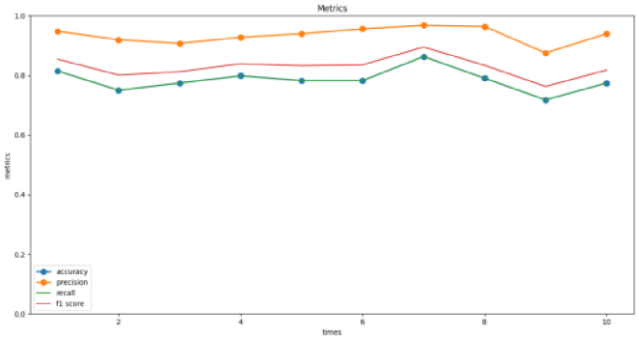

Fig. 12 Architecture Diagram of BERT AI Consultation

V. CONCLUSIONS

In conclusion, this paper has established algorithms for accurate mapping of acupuncture points, demonstrated augmented reality visualization using MEDIAPIPE, achieved hand gesture recognition using a simple neural network based on DNN, and proposed a disease analysis technique based on BERT. We have discussed the accuracy of disease inference in our study and successfully developed an embedded system, integrating the technology into JETSON NANO. This allows users to interactively explore and understand acupuncture knowledge by observing acupuncture points on the human body through our developed product.

Anomaly Detection of Rolling Element Bearings using Domain Adaptation

Hsin-Tse Lu*
* National Chengchi University, Taiwan
E-mail: owen.lu.academic@gmail.com

***Abstract*—To address manpower and equipment efficiency issues in the manufacturing industry, IoT and AI technologies are employed to collect and diagnose machine operation. Vibration analysis has been proven effective in monitoring rotating equipment and predicting abnormalities. However, when applied to large machines, a universal anomaly detection model becomes impractical, requiring numerous models for different areas, leading to management challenges.This study proposes field adaptation to align the features of two machines onto the same vector in a coordinate plane. This enables a single anomaly detection model to monitor both machines, achieving model generalization and reducing administrative costs. By adjusting the features, the same detection model can be applied to different machines, enhancing efficiency and simplifying model management in the monitoring process.**

I. Introduction

The rolling mill process is a vital component of metalworking, involving the reduction of metal stock thickness through the use of rollers[1]. To ensure uniform thinness, precise control is necessary, relying on a rolling theory-based mathematical model that considers key parameters such as rolling speed, roll gap, and rolling force. Among the critical components involved in these subprocesses are the rolling element bearings (REBs) within the rotating equipment. Monitoring the condition of REBs on the rolling mill production line is crucial to maintain product quality. However, implementing effective monitoring methods in factories faces obstacles related to label uncertainty and model unscalability. Class imbalance is a significant issue stemming from the division of REB conditions into abnormal and normal classes. This imbalance leads to costly deployments on production lines and exposes them to uncertainty. Classifiers operating under such conditions may yield misleading accuracy rates, failing to detect true positive faults and compromising the effectiveness of the monitoring solutions. Addressing label uncertainty and class imbalance is essential to enhance the implementation of monitoring methods in factory settings.

II. Methodology

The proposed approach aiming to align them by projecting them onto the same coordinate plane during training. The objective is to maximize the overlap between the two data sets. This training method requires complete data labels for the source data set, while the target data set can be unlabeled. The key process in this approach is Domain Adaptation[2], which focuses on aligning the data sets from the two fields on the same coordinate plane. The health score, defined as the density of anomalies over a fixed time period, will serve as the performance indicator in this study.

III. Results and Discussion

Before Domain Adaptation, we analyzing the model cross-validation results between Device 1 and Device 2. The obtained health score was 23.12 during normal condition and 28.23 during abnormal condition. This implies that the model fails to provide accurate alerts when Device 2 is in an abnormal condition. Conversely, when using the model trained on Device 2 to assess the normal operation of Device 1, a health score of 55.21 was obtained during normal condition and 32.45 during abnormal condition. Here, the issue of false alarms becomes apparent.

After Domain Adaptation, it was found that training the model using Device 1 as the source yielded an average health score of 1.33 during normal condition and a health score of 75.55 during abnormal condition. Similarly, training Model 1 with Device 2 as the target resulted in a health score of 2.12 during normal condition and 67.31 during abnormal condition. These outcomes indicate that both devices can derive satisfactory benefits when training the model with their respective data.

IV. Conclusions

The study utilizes domain adaptation to achieve overlap between the two sets of equipment data in the vector space. By aligning the distributions closely, a model is employed to detect the normalcy of the equipment, resulting in promising outcomes. This highlights the significance of field adaptation in achieving universality among data with similar characteristics.

Abstract — In modern medicine, X-rays play a crucial role in diagnosis and maintaining patient records. In dentistry, bite-wing radiographs are commonly used to evaluate dental conditions. However, manually positioning teeth during diagnosis can be time-consuming and labor-intensive. To address this, this study utilizes artificial intelligence (AI) to assist dentists, speeding up the diagnosis process and providing rapid reference samples. We collaborated with five experienced dentists from Chang Gung Memorial Hospital, who provided bite-wing radiographs and corresponding tooth position data for training the model. Using the You Only Look Once (YOLO) V4 model as the foundation, this research applied image enhancement techniques inspired by existing literature, including bilateral filters and adaptive Gaussian binarization. These techniques reduced noise and improved tooth contour clarity, resulting in improved model performance, reduced processing time, and approximately 7% higher accuracy compared to existing techniques. Additionally, this research proposed image enhancement method increased the model recognition speed by 60.19% compared to using the original images. The study obtained ethical approval from the Research Institution Review Board (IRB) under application number 202002030B0. Integrating AI into tooth positioning enhances diagnostic efficiency and advances AI in dentistry, contributing to more effective and efficient dental care.

I. INTRODUCTION

The rapid advancements in medical technology have driven the search for more effective and accurate diagnostic methods. Precise and fine-tuning of teeth is the future of dental applications, especially the precise positioning of teeth. Current tooth positioning techniques often use various types of deep learning models and primarily focus on symptom detection, such as the study [1] which utilizes mask-RCNN for caries symptom detection with a maximum accuracy of 92%. However, there is less emphasis on dedicated tooth positioning. Yet, tooth positioning aids dentists in understanding the location of teeth by using the FDI tooth notation system. Therefore, there is a space for development, as the reference [2], where a CNN model based on Dental Panoramic Radiograph (DPR) imaging data achieves a tooth detection accuracy of 99.7%. However, compared to DPR, bite-wing radiographs are more commonly used for diagnosis. Therefore, the purpose of this paper is to explore a precise tooth position determination method based on the bitewing sheet and using a deep learning model.

According to the reference[3], image preprocessing plays a crucial role in enhancing model training effectiveness. In this approach, we employ image enhancement techniques to optimize the data. Firstly, bilateral filtering [4] is applied, effectively eliminating noise while preserving edge information within the image. Subsequently, adaptive Gaussian binarization [5] is utilized to establish pixel relationships with neighboring regions. This process converts the image into a binary black-and-white format, often used in conjunction with filtering methods. To facilitate tooth recognition, we employ the YOLOv4 model [6], a popular CNN model renowned for real-time object detection in images. Previous iterations of YOLO, such as YOLOv1 and YOLOv2, had limitations in accuracy and recall, particularly for detecting smaller objects. YOLOv3 improved upon these limitations but required substantial computational resources. Hence, our study adopts the YOLOv4 model, which not only provides higher accuracy and speed but also integrates various optimization techniques for improved resource efficiency and ease of use. By applying the YOLOv4 model to bite-wing radiographs, we can effectively detect and localize tooth positions, enabling the extraction of individual teeth for further analysis

In view of this, the aim of this research is to explore the integration of artificial intelligence techniques into tooth positioning in dentistry. By leveraging bite-wing radiographs and the YOLOv4 model, the study will investigate how AI can assist dentists in positioning teeth accurately and efficiently. The research will focus on developing image enhancement techniques, such as bilateral filters and adaptive Gaussian binarization, to improve tooth contour clarity and reduce processing time. The dissertation will assess the impact of AI-based tooth positioning on diagnostic accuracy and processing speed, enhancing the objectivity and accuracy of diagnoses.

II. METHODS

This study proposes a solution to automatically locate and extract teeth in bitewing radiographs and build up a medical database. In the past, this task was accomplished through manual operations. In recent years, specialized algorithms have been proposed, however, pixel-based algorithms have limited capabilities in handling complex images and are prone to interference from non-teeth objects. Therefore, this study utilizes the YOLOv4 model, based on the One-Stage object detection method, to replace the approach and achieve tooth localization and cropping. The method of this study, as depicted in Fig.1, can be divided into three main steps: (1) image processing, (2) YOLOv4 model training, and (3) tooth detection for tooth localization and image cropping upon completion of the model training.

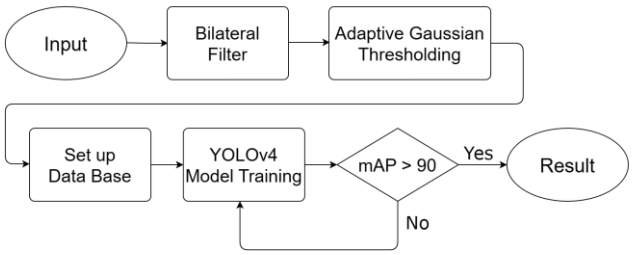

Fig. 1. The flowchart of the method of this study.

In this study, a total of 315 bitewing radiographs provided by Chang Gung Memorial Hospital in Taoyuan, were employed to execute the tasks of Training and Evaluating the object detection model. In addition, this study disregarded the irrecoverable factors such as the imaging range and photography parameters that may affect the quality of the bitewing radiographic images.

A. Image Enhancement

In the process of object detection, the localization boundaries of tooth objects are determined based on the contours of the teeth. Moreover, the brightness and shape of teeth on each individual bitewing radiograph can vary significantly. Therefore, in this study, bilateral filtering and adaptive Gaussian thresholding methods are employed to obtain a binary image with well-defined tooth contours from the bitewing radiographs. This binary image is then used for training the object detection model, enabling it to capture the characteristic contours in a visually informative manner.

1. Noise Reduction

The application of low-pass filtering techniques allows for effective blurring and denoising of images. In geometric space, common methods such as Gaussian filtering utilize the spatial relationship between pixels to apply a weighted filter based on

this relationship. Similarly, bilateral filtering takes into account both the spatial and intensity relationships of pixels. It applies a weighted filter considering the spatial distance and intensity similarity of pixels. As a result, bilateral filtering simultaneously achieves image blurring, noise reduction, and preservation of edge characteristics. This is particularly beneficial as pixels along edges often exhibit significant intensity differences. By leveraging these advantages, the utilization of bilateral filtering prior to image binarization can effectively address the issue of excessive noise being transformed into small black-and-white dots, which can potentially interfere with model learning. Moreover, this approach maximizes the preservation of edge features. The bilateral filtering process is mathematically represented by equation (2), where I(x,y) denotes the denoised pixel.

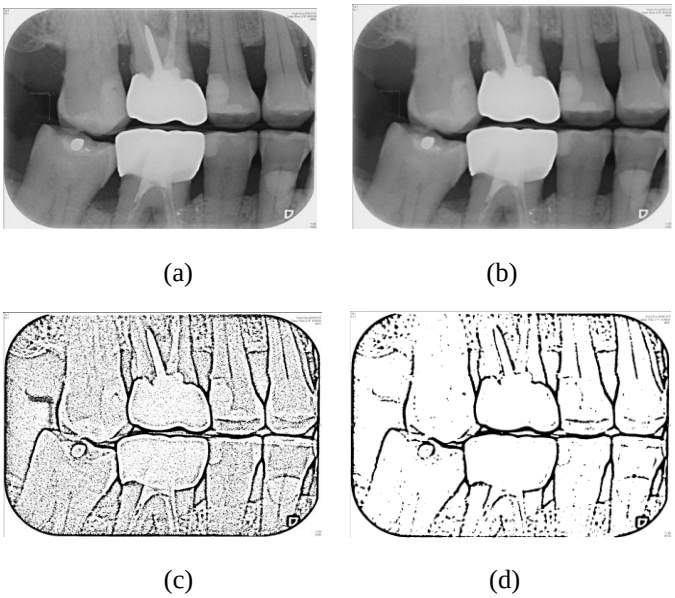
$$w(x,y,i,j) = \exp\left(-\frac{(x-i)^2+(y-j)^2}{2\sigma_s^2} - \frac{\|I(x,y)-I(i,j)\|^2}{2\sigma_r^2}\right) \quad (1)$$

$$I(x,y) = \frac{\sum_{i,j} I(i,j)w(x,y,i,j)}{\sum_{i,j} w(x,y,i,j)} \quad (2)$$

By incorporating bilateral filtering into the image preprocessing pipeline, we can enhance the quality of images for subsequent analysis, minimizing noise interference while retaining important edge information. Besides, a 13×13 kernel is used as the neighboring region for filtering in this study, and spatial parameter σ_s and range parameter σ_r are set to 3 and 100, respectively. Here, σ_s represents the standard deviation of the geometric distribution in the coordinate space, and σ_r represents the standard deviation of the photometric distribution in the color space. A larger σ_s results in a more pronounced blurring effect and an increased proportion of combined pixels from greater spatial distances. Similarly, a larger σ_r results in a more pronounced blurring effect and an increased proportion of combined pixels with greater intensity differences.

2. Image Binarization

Global thresholding, which applies a single threshold to the entire image for binarization, may result in the suboptimal conversion of details in high or low intensity regions. In contrast, adaptive thresholding calculates thresholds based on regional characteristics and performs binarization on pixels. This method helps avoid the issues mentioned above. Additionally, considering the non-original objects overlapped on bitewing radiographs, using global thresholding methods like Otsu's method [7] may introduce biases that affect the accuracy of the binarization. Adaptive thresholding, with its ability to adapt to local characteristics, can mitigate interference from external objects as well.



Adaptive mean thresholding [8][9] and adaptive Gaussian thresholding are both types of adaptive thresholding methods. The former uses the average pixel value of the neighboring pixels around the target pixel as the threshold, while the latter, like Gaussian filtering, considers the spatial relationship of pixels and uses a weighted average pixel value as the threshold as shown in equation (4).

$$g(x,y,i,j) = \frac{1}{2\pi\sigma^2}\exp\left(-\frac{(x-i)^2+(y-j)^2}{2\sigma^2}\right) \quad (3)$$

$$T(x,y) = \frac{\sum_{i,j} I(i,j)g(x,y,i,j)}{\sum_{i,j} g(x,y,i,j)} - C \quad (4)$$

$$I(x,y) = \begin{cases} 255, & I(x,y) > T(x,y) \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

In this study, we utilized a 55×55 Gaussian kernel and a standard deviation σ of 8.6. This configuration ensures that the binarization effect highlights the contours of the teeth in the image. Fig 2 illustrates the original image and the enhanced image before and after the binarization process.

B. One-Stage Object Detection

Object detection methods play a pivotal role in accurately localizing and classifying teeth, providing significant potential for handling complex patterns in practical applications. Within the state-of-the-art techniques, two main approaches stand out: two-stage object detection and one-stage object detection. The former emphasizes detection accuracy and commonly utilizes models such as the R-CNN series. The latter prioritizes inference speed by combining recognition (classification) and localization into a single step, thereby enhancing execution efficiency. Notable models in this category include the YOLO series.

With the aim of achieving real-time performance, this study adopts the YOLOv4 architecture[10], a representative model from the one-stage object detection method, as the core technology for tooth detection and model development. By leveraging the strengths of YOLOv4, this research seeks to achieve efficient and accurate tooth localization within dental imaging applications.

1. Data Distribution

In this study, the image samples were allocated randomly, following a distribution of 60% for the training set, 20% for the validation set, and 20% for the testing set. Notably, the data from the testing set was entirely excluded from the model training process. This strict separation ensures that the testing set remains independent and is not utilized in any stage of model learning. The aim of this step is to ensure that the model possesses reliable and robust generalization capabilities. Furthermore, increasing the sample size enables a larger proportion of the training set to be utilized. This offers several advantages, including enhanced model performance and an improved ability to capture diverse patterns and variations in the data. In this study, by maximizing the sample size, the richness and complexity of the training set can be effectively utilized to enhance the learning and predictive capabilities of the model.The allocated training and validation samples were processed to create the datasets available for model learning. The data distribution used in this study is shown in Table 1.

Table. 1. Quantity of bitewing images in each dataset.

Quantity of Bitewing Image in each Dataset				
Dataset	Training	Validation	Testing	Total
Bitewings	189	21	105	315

2. Data Preprocessing

Prior to model training, the data undergoes additional preprocessing steps to optimize the learning process. Firstly, the bitewing radiographs and their corresponding annotated bounding boxes are resized and padded to align with the input size required by the model. This ensures consistency and compatibility between the data and the model architecture. Secondly, data augmentation techniques are applied to the images within the training set. Random operations such as vertical and horizontal flipping, as well as mosaic effects, are introduced. These augmentations introduce variability and diversity into the training data, enabling the model to generalize better and improve its ability to handle various scenarios. Finally, to mitigate any potential bias during training, the order of the data is randomized. This shuffling process ensures that the model receives a diverse range of samples in each training batch, preventing it from learning patterns specific to the sequential arrangement of the data.

By employing these preprocessing steps, we aim to optimize the data representation, enhance the model's adaptability, and minimize any unintended biases, thereby facilitating effective and robust training of the model.

3. Model Training & Tooth Detection

After the preprocessing stage, the training of the YOLOv4 model is initiated. The architecture of the YOLOv4 model is illustrated in Figure 3. The diagram showcases a section of the model, with an input size of 416x416x3. The model incorporates various components: CSPDarknet53 [11] serves as the Backbone, Spatial Pyramid Pooling (SPP)[12], and Path Aggregation Network (PAN) [13] functions as the Neck, and YOLO [14][15]acts as the Head. Additional hyperparameters can be found in Table 2. For further context, Table 3 provides

supplementary details regarding the software and hardware equipment employed in this study.

C. Tooth Localization & Image Cropping

Utilizing a trained model for tooth detection enables the extraction of tooth positions and boundaries from bitewing radiographs. In clinical settings, dental conditions are frequently assessed by focusing on half of a tooth as a unit. Consequently, this study adopts a methodology where the detected teeth are cropped using their localization boundaries and subsequently vertically sliced into halves. The resulting teeth are then assigned sequential numbers from left to right, distinguishing between upper and lower positions based on their relative X and Y coordinates. This systematic approach facilitates the automated construction of a comprehensive medical database.

III. Results

Table 4 presents the operational guidelines for the confusion matrix, while equations (6)-(9) outline the calculation methods for these indicators. Following the aforementioned approach, the mean average precision (mAP), precision, recall, and F1-score of the YOLOv4 model were evaluated based on its prediction results utilizing a confusion matrix. Figure 4 illustrates the training process of the YOLOv4 loss function. Additionally, Table 5 displays the changes in mAP at each stage during the training process.

$$\text{Accuracy: } \frac{(TP+TN)}{(TP+TN+FP+FN)} \tag{6}$$

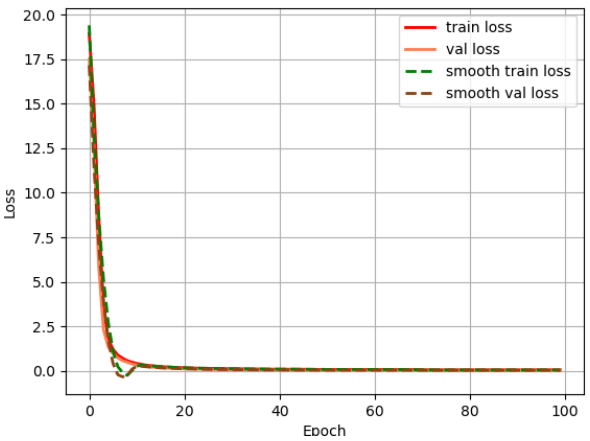
$$\text{Precision: } \frac{TP}{(TP+FP)} \tag{7}$$

$$\text{Recall: } \frac{TP}{(TP+FN)} \tag{8}$$

$$\text{F1 Score: } \frac{2\times(Precision\times Recall)}{(Precision+Recall)} \tag{9}$$

Table. 4. Confusion Matrix

	Predicted Positive	Predicted Negative
Actual Positive	TP (True Positive)	FN (False Negative)
Actual Negative	FP (False Positive)	TN (True Negative)



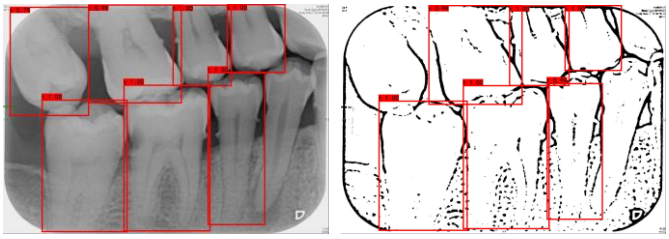


Fig. 4. Training Process for the YOLOv4 loss function.

Table. 5. The change of mAP value during the training process of this study.

Epoch	Origin Data	Processed Data
20	98.16%	97.62%
40	99.25%	98.91%
60	99.23%	98.82%

80	99.36%	98.87%
100	99.38%	99.10%

During the testing phase, we used a set of 105 untrained images as the test dataset. The mAP (mean Average Precision) value can be used to evaluate the performance of a model. When the training epoch is set to 100, using the original images as input data gets the better results. However, even when using enhancement images, the performance does not significantly decrease. The actual identification results are shown in Fig 5. According to the resulting photo, it can be observed that even though using original images captures more target objects compared to using enhancement images, there are still some instances of missing detections.

(a) (b)

Fig. 5. Recognition results through YOLOV4 (a) Original Image. (b)Enhancement Image

Based on the findings presented in Table 6 and Figure 6, it is evident that employing image augmentation techniques yields comparable performance to using original images across various metrics. Additionally, the prediction time for a single image is significantly reduced by over 61%, highlighting the efficiency and effectiveness of employing image processing techniques. Moreover, in comparison to the existing technology [16], as illustrated in Table 7, the Precision, Recall, and F1 Score exhibited enhancements of 4.85, 0.38, and 2.99, correspondingly. These experimental results demonstrate the enhanced effectiveness of the proposed technology in accurately identifying tooth positions. Furthermore, the utilization of image augmentation techniques not only maintains performance but also enhances the model's robustness by introducing variations in the training data. This ensures that the model can handle diverse dental conditions and scenarios. These advancements contribute to more reliable and effective tooth position identification in dental diagnostics.

Table. 6. Original image compared to Enhancement image.

	Original	Enhancement
mAP	99.38%	99.10%
Recall	98.43%	97.86%
Precision	98.01%	97.44%
F1 Score	98%	98%
Processing Time	0.134s	0.052s

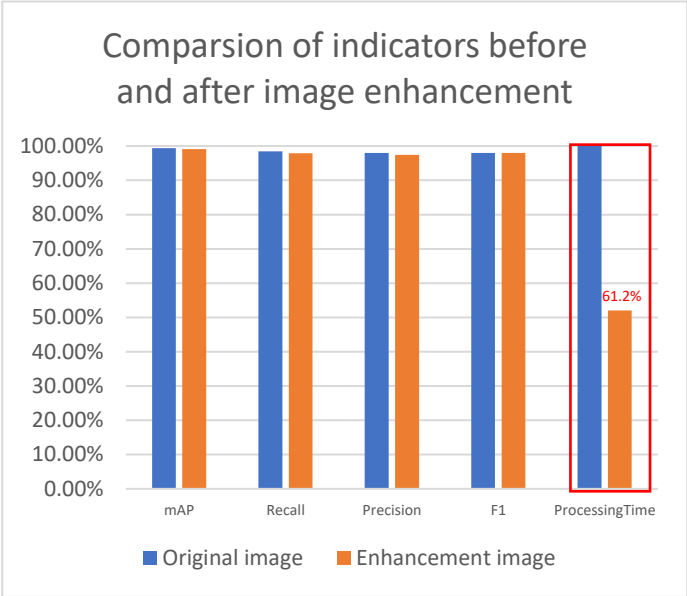

Fig. 6. Comparison of indicators before and after image enhancement

Table. 7. The comparison between the prior and this study

	This Work	Method in [16]
Precision	97.44%	92.93%
Recall	97.86%	97.48%
F1 Score	98%	95.15%

IV. DISCUSSIONS

In this study, we achieved a high mAP of 99.10% in tooth position detection using the YOLOv4 model, surpassing the performance of the Faster R-CNN model used in the existing method [16]. The YOLOv4 model demonstrated superior performance in comparison. The incorporation of image enhancement techniques, specifically bilateral filtering for noise removal and adaptive Gaussian thresholding for image binarization, played a crucial role in improving the results. Compared with the reference model [16], the model shows significant enhancement in various metrics. Precision increased

by 4.51%, recall increased by 0.38%, and F1 score improved by 2.85%. It is important to note that the reference model does not use image augmentation, which may lead to its lower mAP. Despite this minor decrease, our model maintained comparable performance, and the average processing time for predicting images was significantly reduced. The average processing time for predicting an unknown image was reduced by more than 50% compared to using original images. These results indicate that the integration of image enhancement techniques with the YOLOv4 model can effectively approximate the expertise of experienced dental professionals.

V. CONCLUSIONS

This dissertation aims to integrate artificial intelligence into bite-wing radiographs to automate the process of tooth positioning in dental diagnosis. Although the binarization process resulted in a lower level of clarity compared to the original images, it is evident that automation using AI techniques holds great potential for improving efficiency and reducing human errors in dental diagnosis. Future studies should focus on preserving more contours in binarized images while simultaneously optimizing processing time, which will contribute to the development of accurate AI models for dental condition diagnosis. The findings of this research provide a solid foundation for the advancement of deep learning models in dental diagnostics, highlighting the importance of advancing image enhancement techniques and their integration with state-of-the-art object detection models. Continued exploration in this field will lead to enhanced accuracy and effectiveness in dental diagnosis, benefiting both patients and dental professionals.

Abstract — **In the past, machine learning required centralizing the training dataset on a server or data center for training. However, due to recent concerns regarding privacy, related legal regulations, and competition among peers, this approach of uploading data to servers is not suitable in certain domains. Therefore, Google proposed 'federated learning' in 2016, which distributes the training data across different client devices. The client devices train models and upload model parameters, which are eventually aggregated on the server to generate a global model, ensuring the privacy of the training data. Traditional federated learning often faces challenges due to significant disparities in computational capabilities among heterogeneous devices. As a result, asynchronous federated learning has been introduced to improve training efficiency and reliability. The deployment of a scalable federated learning framework becomes critical, especially with the emergence of 6G communication systems, which offer low latency and high coverage, enabling services for multimedia-related applications such as autonomous vehicles, smart industries, and augmented virtual reality. Handling multi-gigabyte multimedia data to enable learning at the edge devices is of paramount importance.**

I. INTRODUCTION

The application characteristic of 6G is high coverage, which is encountered in many federated learning scenarios where a large number of devices participate in training simultaneously. For such a large number of devices, asynchronous federated learning is one solution. Through an asynchronous approach, client devices can upload their models to the server for aggregation immediately after completing training, without waiting for other devices. Therefore, the support for asynchronous weight updates in the federated learning framework becomes even more important.

II. RELATED WORKS

Federated Learning is a novel approach that enables multiple entities to collaborate on machine learning model training without directly accessing local training data. First introduced by Google in 2016, federated learning serves as a machine learning solution that meets the requirements of data privacy and communication efficiency [6, 8]. The design objective of federated learning is to ensure individual data privacy and develop satisfactory machine learning models across multiple participants or computing nodes, under lawful and compliant conditions [7, 9]. Consequently, many papers adopt the federated learning framework, where the central server collects parameters of local models from multiple nodes before aggregating them into a global model in each training round [10].

When traditional federated learning is applied to resource-constrained devices, various challenges inevitably arise [5]: (1) Unreliable heterogeneous devices: The central server waits for selected endpoints to upload the latest local models, but these endpoints may unintentionally drop out of training due to uncontrollable factors. (2) Low training round efficiency: Due to device resource disparities (device heterogeneity) and variations in training data across devices (data heterogeneity), fast devices have to wait for outdated local models uploaded from slower devices in each training round. (3) Low resource utilization: Selected devices' quality varies due to inefficient node selection algorithms. (4) Security and privacy concerns: Several attacks, including poisoning and backdoor attacks, can compromise the security of traditional federated learning. Privacy concerns arise from potential data leakage during the training process. To overcome these challenges and achieve rapid aggregation of appropriate local models to the central server, asynchronous federated learning was proposed.

The primary challenge in asynchronous federated learning for heterogeneous systems lies in efficiently maximizing resource utilization across such systems. In a survey paper [1] that collected research papers on asynchronous federated learning from 2019 to 2022, the problem of device heterogeneity was categorized into six major classes: Node Selection, Weighted Aggregation, Gradient Compression,

Semi-Asynchronous, Cluster FL (Federated Learning), and Model Split.

Among these classes, we specifically focus on Node Selection. In traditional federated learning, all nodes contribute equally to the global model. However, in asynchronous federated learning, to avoid overfitting, we prefer selecting nodes with robustness and better computational capabilities. In [2], the authors proposed a heuristic greedy node selection strategy based on the local computing and communication resources of heterogeneous nodes. This strategy iteratively selects nodes with higher contributions to participate in global model aggregation.

III. Asynchronous Federated Learning Method

This paper presents the implementation of an asynchronous federated learning algorithm using Nvidia Flare and conducts related data experiments. Building upon [4], an examination of the functionality of the NVFlare federated learning framework is performed, with a focus on comparing it with the FML system view presented in Chapter 7 of [4]. The goal is to verify whether the NVFlare framework possesses a robust architecture for practical deployment in future 6G multimedia transmission systems.

The main focus of this paper is the implementation of asynchronous federated learning on nodes. The server-side is referred to as the "Server," while the nodes participating in the federated learning training are called "Nodes." The algorithm training process is as follows:

1. Weight Initialization: The Server initializes the Global model's weights and sends the Global model to all participating clients. Upon receiving the Global model, each client immediately starts training.
2. Node Selection: After a certain waiting period, the Server calculates the contribution of each client. The contribution includes two indicators: computational contribution and network stability. The computational contribution is calculated based on the current epoch and mini-batch size of each node, while network stability is evaluated using ACK packets. The Server receives the data returned by the clients, calculates their contributions, and sorts them in descending order. The clients with the highest contributions are selected until the Server's predetermined time is reached.
3. Model Update: The Server collects the models of the nodes selected in Step 2 and performs FedAvg aggregation. Nodes that were not selected continue training. The resulting aggregated model is sent back to the nodes as the updated Global model. The contribution scores of the nodes participating in this round of training are reset to zero, while the scores of the non-selected nodes continue accumulating. This process is repeated until the Global model reaches the desired accuracy level.

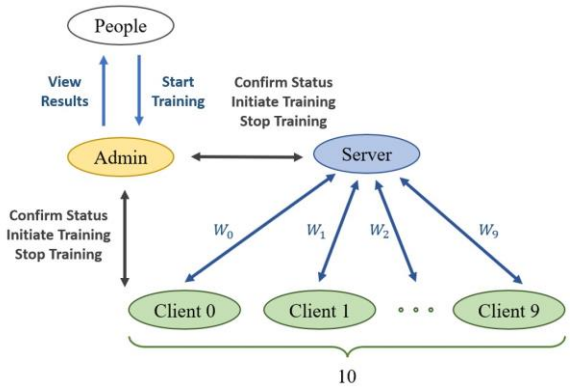

Fig. 1 Asynchronous Federated Learning Architecture.

The architecture is shown in Figure 1, and the experimental environment is set up as a POC single-machine simulation using Ubuntu Server 20.05LTS. In this study, the implementation will follow the aforementioned steps, with the network state evaluation omitted during the implementation phase. The selection of clients will be based solely on computing contributions. Figure 2 illustrates the process of the paper's implementation using NVFlare, and Figure 3 provides an explanation of the node selection process. The detailed steps of the Flare implementation are as follows:

1. The server creates a task.
2. The client requests the task.
3. The server applies the task.
4. The server waits for the client to train for 30 seconds. This time allows each client to perform its own training. In our simulation, we randomly introduce sleep functions in different clients to simulate varying computational capabilities.
5. The server uses the fire_fed_event API in Flare to send a request to all clients to stop training and upload local epoch and batch size.
6. The client uses the handle_event() API in Flare to receive the fire_fed_event and perform the corresponding actions, such as stopping training and sending parameters.
7. The client contributions are calculated, sorted, and stored as a list. The top two-thirds of the list are selected

as the chosen client nodes. For detailed steps of node selection, please refer to the next subsection.

8. The server uses the Broadcast() function to terminate the selected clients, retrieve their models, and perform model aggregation. After completion, the server broadcasts again to continue training.
9. Return to step 4 and repeat until the training completion threshold is reached.

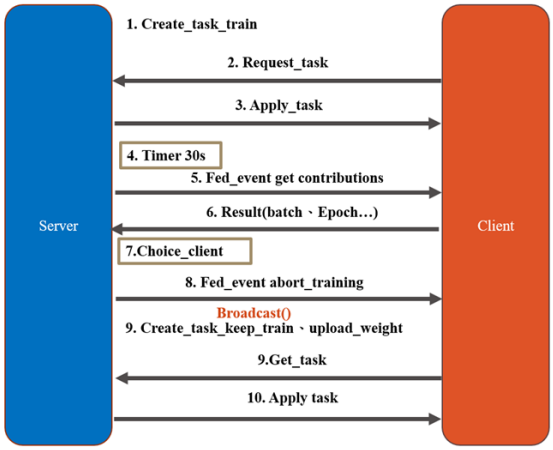

Fig. 2 Implementation Flowchart.

The detailed steps for node selection are as follows:

1. The server sets two timeouts (one for contribution and another for weights) and starts training.
2. After a certain period of local training, the client sends the local epoch count to the server for calculating the contribution. Then, it continues training. Different local epoch counts are implemented by setting different sleep times.
3. The server calculates the contribution λ of the clients received within the $timeout_{\lambda}$ period (calculated based on the local epoch count to simulate varying client computational performance). Only the clients with contributions in the top 2/3 are added to the selected list.
4. The server broadcasts a request for the selected clients to return their weights, denoted as W.
5. The server receives the W returned by the clients within the $timeout_{W}$ period.
6. The server aggregates the received W from the clients.
7. After aggregation, the server returns the updated weights, denoted as W_{new}, to the clients, completing one global round.

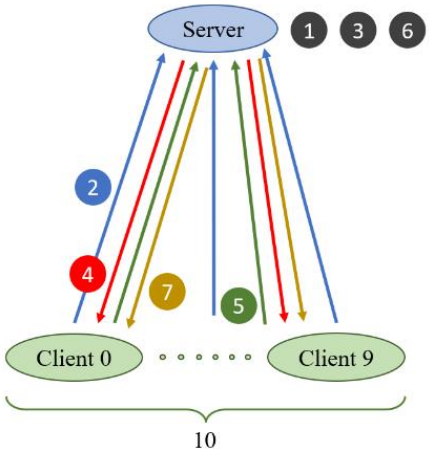

Fig. 3 Node Selection Flowchart.

To validate the approach mentioned in the reference paper, we first implemented the method described in the paper and used the provided algorithms along with a dataset for verification. For this purpose, we used the commonly used image dataset CIFAR10. CIFAR10 is a color image dataset consisting of 10 classes, with a total of 60,000 images. Among these, 50,000 images are used for training and 10,000 images are used for testing. Each image has a size of 32x32.

As described in [3], the non-IID data distribution in federated learning can be categorized into several types:

1. Non-IID on feature distribution (feature distribution skew): In domains like handwritten recognition, different individuals may have variations in stroke width, slant, etc., even when writing the same digit.
2. Non-IID on label distribution (label distribution skew): When clients are limited to specific geographic regions, the distribution of labels can vary among clients. For example, kangaroo images may only be present in clients from Australian zoos.
3. Non-IID with the same label but different feature distribution (same label, different feature): Even for the same label, the features can vary significantly across different time scales, such as day and night, seasonal variations, natural disasters, fashion trends, design trends, etc.
4. Non-IID with the same feature but different label distribution (same feature, different label): For instance, labels that reflect emotions or predict the next word can differ based on individual or regional differences.

5. Non-IID or data imbalance in quantity distribution (quantity skew or unbalance): Different clients may possess significantly varying amounts of data.

Based on the definitions of non-IID mentioned above, we chose two different types of non-IID for experimentation: non-IID in data quantity and non-IID in data labels. For non-IID in data quantity, we followed the methods described in most papers and used the Dirichlet distribution to generate the non-IID data. We adjusted the degree of non-IID using the parameter α, where larger values (>10000) indicate a more IID distribution, while smaller values (<1) represent a more non-IID distribution.

IV. Experimental Results

Parameter Settings and Explanations:

- Local training time: This refers to the duration for which each client waits to perform training in each global round.
- delay_big: It represents the waiting time for the client (simulating computational power disparity) and is directly proportional to the data size.
- delay_small: This indicates the waiting time for the client (simulating computational power disparity) and is inversely proportional to the data size.
- Dataset: CIFAR10

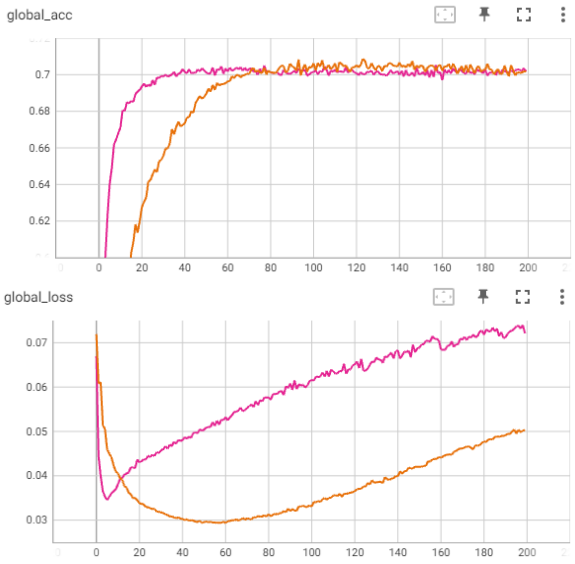

Fig. 4 Distribution: IID, local training time=5s, different local learning rate comparison..

Figures 4-7 present experimental comparisons under the IID data distribution.

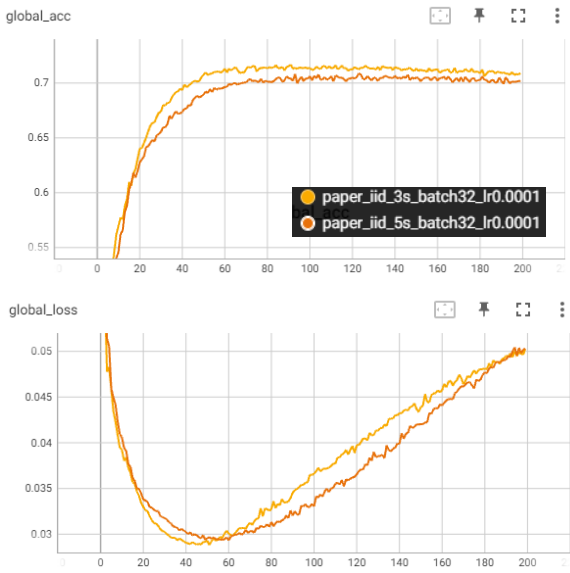

Fig. 5 IID, local learning rate = 0.0001, comparison of different local training times.

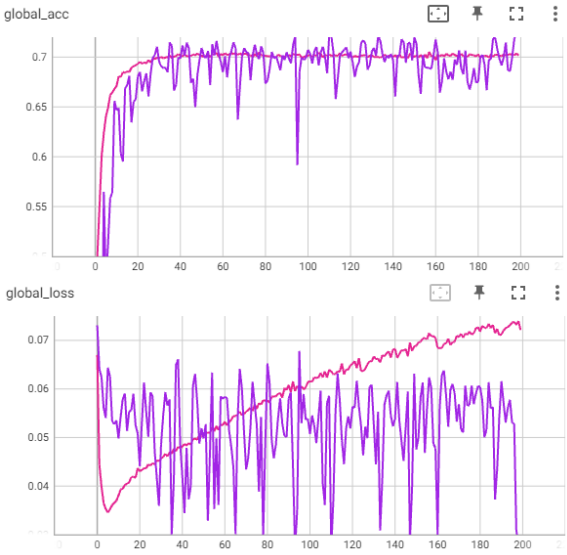

Fig. 6 IID, aggregation of the entire model approach compared to sending only model gradient.

When training machine learning models, convergence speed and accuracy are two crucial metrics. A faster convergence indicates that the model learns features and patterns more quickly, while higher accuracy implies better generalization ability. Therefore, it is essential to study and optimize these metrics.

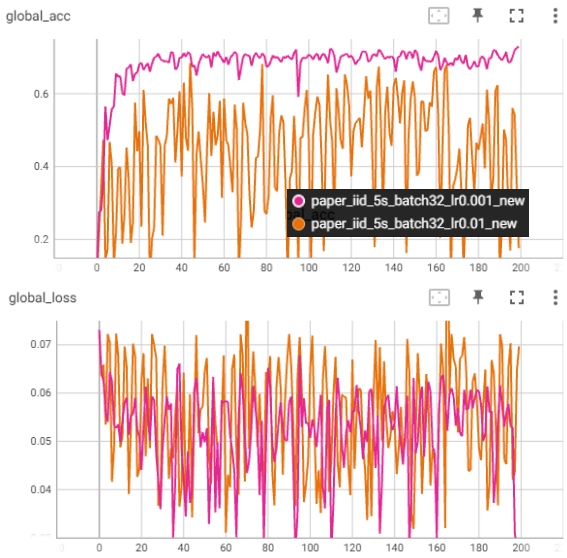

Fig. 7 IID, only send model gradient with different learning rate.

In Figure 4, we compare the performance of different learning rates under the same local training time. The results show that higher learning rates lead to faster convergence. However, when the learning rate is set to 0.001, the model exhibits severe overfitting. Overfitting occurs when the model performs well on the training data but poorly on the test data. Therefore, careful selection of the learning rate is necessary to avoid overfitting. Figure 5 compares the impact of different local training times on model performance. The results show that there is little difference between the two different local training times, and a longer local training time does not necessarily mean better performance. Therefore, we need to strike a balance between time and accuracy when choosing the appropriate local training time. In addition to the above factors such as hyperparameters and training time, we also compared different model aggregation methods. The conventional federated learning aggregation method involves returning the entire model and aggregating it. However, we explored an alternative approach of only returning the difference between the client's post-training model and pre-training model (i.e., sending only the model gradients). We aimed to reduce the global model discrepancy between different rounds using this approach.

From the experiments shown in Figures 6 and 7, we observe that under the IID data distribution, the approach of sending only the model gradients achieves similar accuracy compared to aggregating the entire model. This may be because, under the IID data distribution, the training data distributions across different clients are similar, resulting in smaller model discrepancies. However, we also found that the approach of sending only the model gradients leads to more significant fluctuations in model loss values. Therefore, the learning rate should not be too large, as it can cause excessive fluctuations during the training process, resulting in suboptimal performance.

Figures 8-11 depict the experimental results under the Non-IID (α=0.1) data distribution. Based on the results shown in Figure 8, we compare the influence of different local learning rates on model convergence under the same local training time. The results indicate that, compared to the IID data distribution, the Non-IID data distribution exhibits higher accuracy and more significant loss oscillations. This may be attributed to the unevenness of the Non-IID data distribution, which affects the global model aggregation across different rounds. Additionally, Figure 8 reveals that larger learning rates seem to facilitate model convergence under the Non-IID data distribution.

In the experiment depicted in Figure 9, we compare different model aggregation weight aggregation methods. One approach involves using the client's data volume as weights for weighted averaging of the models, while the other approach directly averages all received models. Typically, we expect that clients with larger data volumes will have better models, so using data volume weighting should yield higher accuracy. However, in the experiment shown in Figure 9, we find that using data volume weighting does not necessarily improve accuracy. On the contrary, directly averaging all received models appears to perform better.

In the experiment depicted in Figure 10, we compare the impact of different client computational capabilities on the convergence of federated learning. We simulate the performance differences among clients by making them wait for a certain period of time before starting training. In this experiment, we set three different waiting times: delay_big, delay_small, and no_suffix. Here, delay_big represents waiting time proportional to the client's data volume, delay_small represents waiting time inversely proportional to the client's data volume, and no_suffix represents all clients having the same waiting time.

From the experimental results, we can observe that delay_small leads to better accuracy. This suggests that when clients with larger data volumes upload model updates more frequently, the convergence of federated learning improves. Therefore, we can infer that allowing clients with larger data volumes to upload model updates more frequently can yield better results in federated learning. This finding will serve as a basis for our subsequent experiments.

In the experiment shown in Figure 11, we compare the aggregation methods of directly aggregating the entire model and aggregating only the gradients of the client models in the case of Non-IID data distribution. In this experiment, we find that aggregating the entire model achieves better accuracy under the Non-IID data distribution, rather than only transmitting the differences between the client models before and after training. This is different from the situation in the IID case and should be taken into account in practical applications.

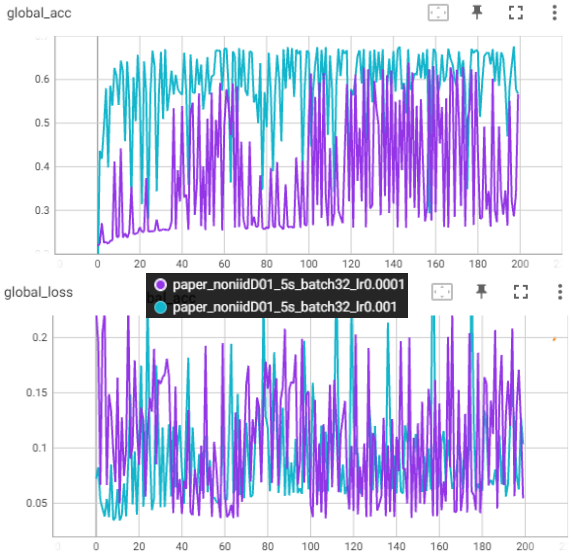

Fig. 8 NonIID, local training time=5s, different local learning rate comparison.

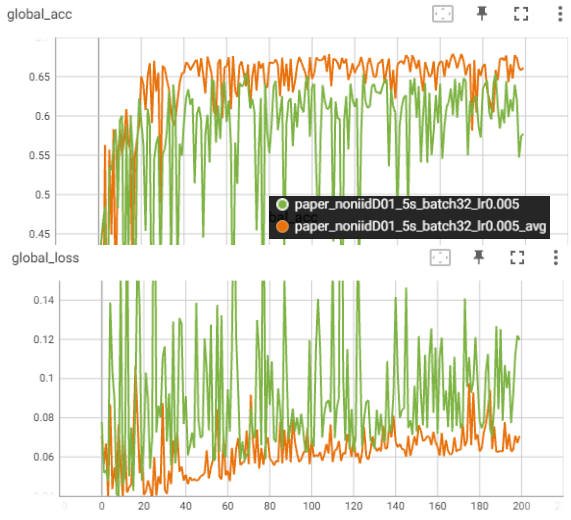

Fig. 9 Non-IID, local training time=5s, compare the aggregation results of different model aggregation weights.

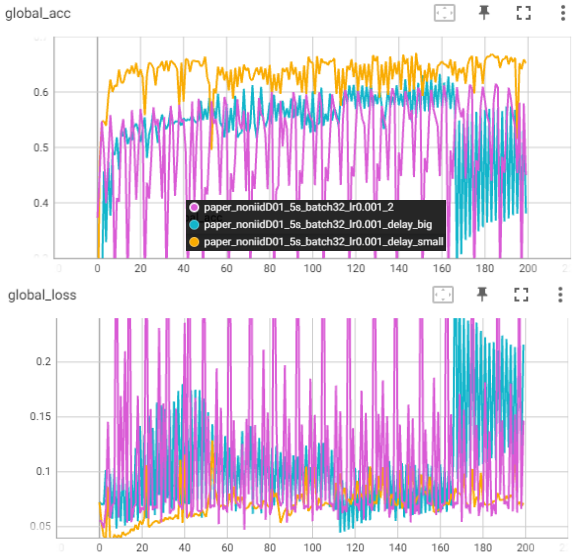

Fig. 10 Comparison of the waiting time per turn for different clients (simulating the difference in performance of different clients).

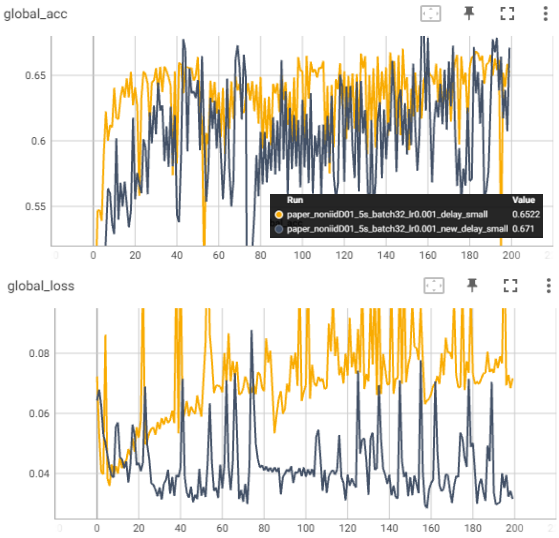

Fig. 11 Compare the performance of the direct aggregation model with that of the client-side gradient only.

V. CONCLUSIONS

In the case of asynchronous and Non-IID data distribution, we observed that the setting of the learning rate is crucial. Significant improvements were achieved by adjusting the learning rate to address the issues encountered. Both excessively large and excessively small learning rates yielded suboptimal results. Future research could explore the development of an adaptive learning rate tuner to achieve more stable training.

After fine-tuning the parameters over a period of time, we found that under well-adjusted settings, the asynchronous algorithm can achieve similar accuracy to the synchronous algorithm. This suggests that the proposed method in the paper can be effective in the context of Massive IoT and may be a promising area for future research.

From the aforementioned experimental results, it was observed that regardless of the IID or Non-IID data distribution, aggregating the entire model yields a better global model compared to aggregating only the client-side gradients. Additionally, in the investigation of using data volume as weights for model aggregation, there was no significant difference observed between the two aggregation methods in the IID data distribution. However, in the case of Non-IID data distribution, direct averaging of models can mitigate model discrepancies between different global rounds, resulting in a smoother training process.

***Abstract*— Primary brain tumors are among the ten most common causes of cancer-related death, and gliomas are the most prevalent type of adult brain tumor, accounting for 78% of malignant brain tumors. Accurate glioma subtype classification is critical to treating patients with brain tumors; however, developing an automated computer-aided diagnosis system for glioma is not trivial. This study introduces the development of an AI-assisted diagnosis system for adult glioma. There are four subtypes of glioma targeted, including Oligodendroglioma (O), Anaplastic Oligodendroglioma (AO), Astrocytoma (A), and Glioblastoma (G). Instead of directly classifying all whole-slide images into four categories, the hierarchical framework with a multi-view scheme was proposed. That is, two-stage predictions were performed. The first stage is to classify all slides into the Oligo-like and Astro-like classes by observing cells' morphologies with high magnification (x40) views by the patching approach. Subsequently, the second stage is to quantify the areas of normal vessels, hyperplasia vessels (vascular proliferation), and necrosis regions with views of lower magnification (x5, x10) by YOLO segmentation, predicting grading levels for each type. After false detection reduction, the experimental results show the quantification of vessels and necrosis regions are the valuable features to indicate grading levels, and the performance of the proposed two-stage hierarchical framework in the final 4-class predictions surpassed the approach of classifying all slides into 4 categories directly.**

Keywords*— *Glioma Diagnosis, AI-assisted Diagnosis System, Deep Learning Approaches.

I. INTRODUCTION

Adult brain tumors represent a widespread cancer classification, contributing to substantial morbidity and mortality worldwide. Data from the Central Brain Tumor Registry of the United States (CBTRUS) demonstrates that, upon histological examination, diffuse gliomas account for 68.5% of primary brain malignancies, with glioblastoma being the most fatal subtype [1]. Although advances have been made in precision diagnostics through the use of molecular data [2] and methylation status [3], histopathology continues to serve as an essential starting point. It helps to ensure more accurate precision diagnostics by reducing errors that may occur when relying solely on molecular testing methods. Consequently, our objective in this study is to establish an artificial intelligence-supported diagnostic system for the prediction of glioma histologic subtypes, such as oligodendroglioma, anaplastic oligodendroglioma, astrocytoma, and glioblastoma.

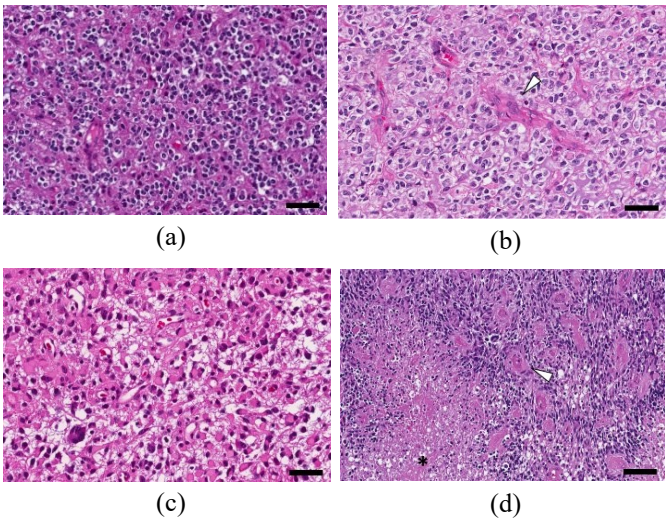

Fig. 1. The major histological subtypes of glioma found in adults encompass. (a) Oligodendroglioma, (b) Anaplastic Oligodendroglioma, (c) Astrocytoma, and (d) Glioblastoma. The arrowhead denotes endothelial proliferation, whereas the asterisk symbolizes tumor necrosis. The scale is 50 μm.

From the pathological perspective, the morphologies of glioma subtypes are somehow distinct. As can be observed in Figure 1-(a) and 1-(b), for oligodendroglioma and anaplastic oligodendroglioma, cells appear round shape nuclei with open chromatin and artifactual cytoplasmic retraction, leading to the "fried egg" appearance. On the other hand, astrocytoma and glioblastoma revealed hypercellularity with irregular and hyperchromatic nuclei in the fibrillary background, as shown in Fig. 1-(c) and 1-(d). To discriminate anaplastic oligodendroglioma from oligodendroglioma or distinguish glioblastoma from astrocytoma, the histopathologic features, like glomerular endothelial proliferation (pointed by a white arrow in Fig. 1-(c)) and tumor necrosis (the area marked with a star-shaped sign * in Fig. 1-(d)), are helpful in subtype classification. Then, the quantification of these histopathologic features can be achieved by AI technologies.

II. MATERIALS AND METHODS

In this study, a total of 646 cases of whole-slide images (WSIs) with adult glioma were collected from the database of The Cancer Genome Altas (TCGA) program [4]. There are 4 subtypes of adult glioma targeted in our experiment, which are oligodendroglioma (denoted as **O**), Anaplastic Oligodendroglioma (indicated as **AO**), Astrocytoma (shown as **A**), and Glioblastoma (denoted as **G**). Then, all WSI cases in each glioma subtype were randomly split into the training dataset and testing dataset by the ratio of 7:3. And the numbers of WSI cases for training and testing in each glioma subtype are listed in Table I.

Table I. Numbers of WSI cases in each glioma subtype's training and testing datasets.

Glioma Subtype	# training cases	# testing cases	# total cases
Oligodendroglioma (**O**)	68	29	97
Anaplastic Oligodendroglioma (**AO**)	52	22	74
Astrocytoma (**A**)	171	73	244
Glioblastoma (**G**)	162	69	231

To deal with gigapixel whole-slide tissue images, the patching approach [5, 6] that collects several patch samples from the tissue areas at a specific magnification seems easier to implement. Figure 2 shows the baseline implementation to achieve 4-subtype prediction. For each category, hundreds of patches were randomly sampled from the tissue areas in each slide at a magnification of x40, collecting training samples to learn the features of cells' morphologies. Then, for slide inference, about the same number of sampling patches were collected from the testing slide at the same magnification rate and fed into the trained model for patch predictions. The majority vote scheme from the projections of those sampling patches can determine the final predicting subtype for the testing slide.

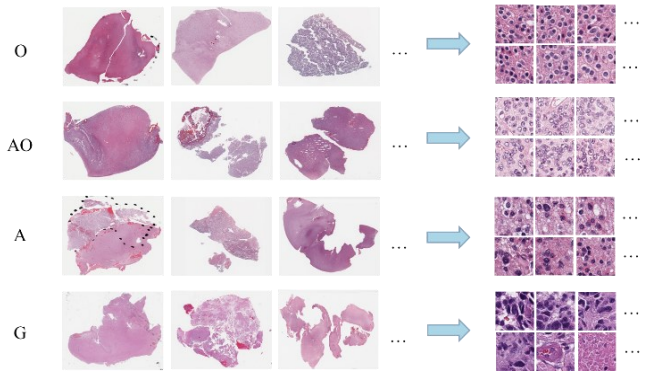

Fig. 2. The baseline implementation using the patching approach for 4-subtype prediction.

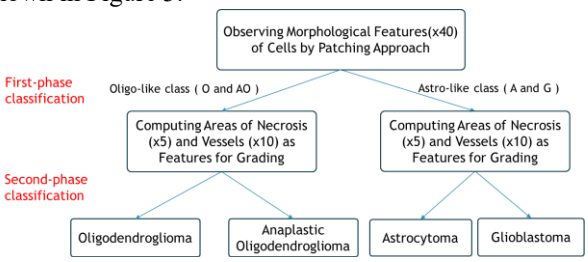
However, from the pathological perspective, features of cells' morphologies in the sampling patches at high magnification may be inadequate to evaluate the severity of cases in the Oligo-like class (including **O** and **AO**) or the Astro-like class (including **A** and **G**). Clinically, the existences of vascular proliferation (patches sampled at x10) and necrosis areas (patches sampled at x5) are crucial evidence to distinguish **AO** from **O** in the Oligo-like class or discriminate **G** from **A** in the Astro-like class. Therefore, the two-stage hierarchical framework with a multi-view scheme was proposed in this study to achieve glioma subtyping prediction, as shown in Figure 3.



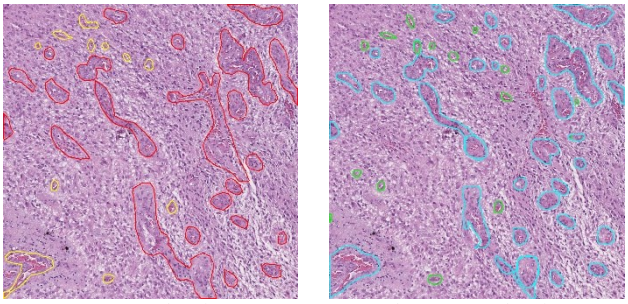


Fig. 3. The proposed framework for glioma subtyping prediction.

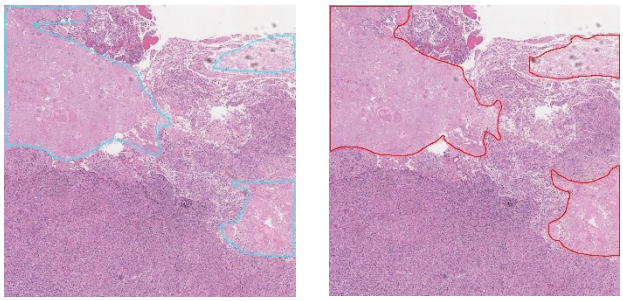
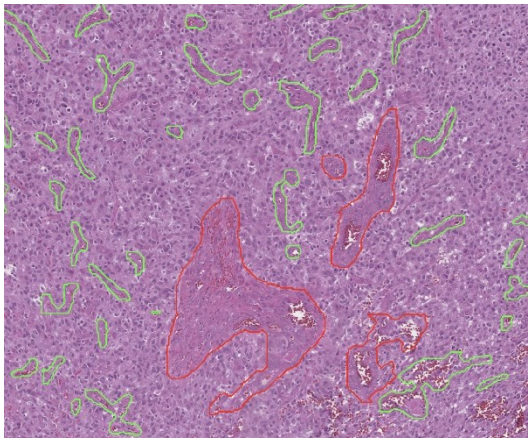
Instead of performing 4-subtype classification directly in the baseline approach, in the proposed framework, the first phase is to conduct binary classification, which categorizes all slides into Oligo-like class and Astro-like class based on cells' morphologies, using the model of ResNet50 [7]. It can be easily implemented for training data acquisition by merging the training samples of **O** and **AO** to become the training set for the Oligo-like class and merging the samples of **A** and **G** for the Astro-like class. In addition, optical density transformation [8] was applied on the sampling patches to reduce the H&E staining gaps for slides from different institutions for better regularization.



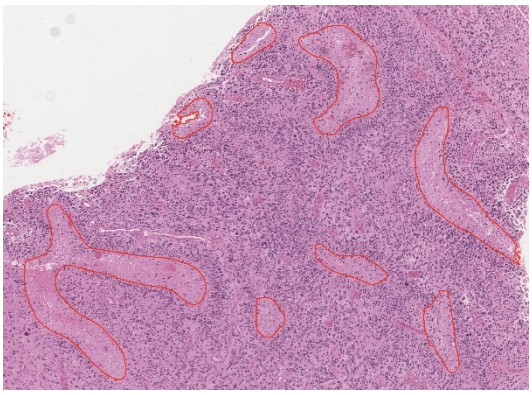
For the second phase of the proposed framework, normal vessels, vascular proliferation regions, and necrosis lesions were detected and segmented automatically by the deep learning model of YOLOv8 [8]. Patches were sampled at a magnification of x10 from the slides in the training dataset and annotated with the regions of normal vessels (in yellow) and vascular proliferation (in red), as shown in Figure 4-(a). The segmented results of normal vessels (in green) and regions of vascular proliferation (in cyan) by the YOLOv8 model are shown in Fig. 4-(b).

(a) annotated regions (b) segmented regions

Fig. 4. A patch with regions of normal vessels and vascular proliferation.



Similarly, for the segmentation of necrosis lesions, as shown in Figure 5-(a), patches were sampled from the slides at a magnification of x5 and annotated with the necrosis lesions (in cyan) to train the segmenting model. Fig. 5-(b) shows the segmented results of necrosis lesions (in red) by the trained model of YOLOv8.



(a) annotated regions (b) segmented regions

Fig. 5. A patch with regions of necrosis lesions.

Subsequently, the segmentation models for vessel regions and necrosis lesions were applied on the WSIs to scan each tile to determine if there exists vascular proliferation or necrosis lesions for the evaluation of cases' severity in diagnosis. The segmentation results for different kinds of vessel regions and necrosis lesions on the WSIs are shown in Figures 6-(a) and 6-(b), respectively.

(a) Segmented normal vessels (in green) and regions of vascular proliferation (in red) on a WSI.

(b) Segmented necrosis lesions (in red) on a WSI.

Fig. 6. The segmentation results on a WSI.

However, to obtain a perfect segmentation model that runs on hundreds of tiles over a WSI without any false positive regions of vascular proliferation or necrosis lesions is almost impossible. Moreover, the area ratio between normal vessels and regions of vascular proliferation is statistically substantial to the evaluation of severity for a case [2]. Therefore, the areas of the segmented regions of normal vessels, vascular proliferation, and necrosis lesions were computed as the features to train the logistic regression models for classification, performing 4-subtype prediction in the second phase of the proposed framework.

III. EXPERIMENTAL RESULTS

For the baseline approach that directly predicts all cases into 4 subtypes, its corresponding confusion matrix of the final prediction results is listed in Table II, and the predicting accuracy is 66.84% (129/193).

Table II. The confusion matrix of the predicting results by the baseline approach.

GT \ Prediction	O	AO	A	G
O	**3**	15	8	3
AO	2	**15**	3	2
A	5	3	**56**	9
G	0	9	5	**55**

On the other hand, for the proposed framework, the confusion matrix of the binary classification results in the first phase, in which all cases were categorized into Oligo-like class and Astro-like class, is listed in Table III. And the accuracy is about 82.9%. (160/193)

Table III. The confusion matrix of the binary classification results in the first phase of the proposed framework, using the model of ResNet50.

GT \ Prediction	Oligo-like class (O and AO)	Astro-like class (A and G)
Oligo-like class (O and AO)	**32**	19
Astro-like class (A and G)	14	**128**

Afterward, in the second phase of the proposed framework, the performance metrics in the accuracy of the logistic regression models are 98.04% (50/51) for O vs. AO and 91.55% (130/142) for A vs. G. The confusion matrices are listed in Table IV and V, respectively. As a result, the final 4-subtype prediction can be achieved by applying the patch approach using the ResNet50 model for binary classification in the first phase and quantifying the segmented areas of vessels regions and necrosis lesions as the features for further subtype

classification using the logistic regression classifiers. The confusion matrix of the final predicting results by the proposed methods is listed in Table VI, and the predicting accuracy reached 76.17% (147/193), surpassing the baseline approach's performance with 66.84% (129/193).

Table IV. The confusion matrix of the binary classification results in the second phase of the proposed framework for cases in the **Oligo-like class**, using the logistic regression classifier.

GT \ Prediction	O	AO
O	**29**	0
AO	1	**21**

Table V. The confusion matrix of the binary classification results in the second phase of the proposed framework for cases in the **Astro-like class**, using the logistic regression classifier.

GT \ Prediction	A	G
A	**71**	2
G	10	**59**

Table VI. The confusion matrix of the predicting results by the proposed framework.

GT \ Prediction	O	AO	A	G
O	**18**	0	11	0
AO	1	**13**	0	8
A	10	1	**60**	2
G	0	3	10	**56**

IV. CONCLUSIONS

This study proposed a hierarchical framework with a multi-view scheme to achieve adult glioma subtyping prediction. The experimental results implied that the areas of normal vessels, regions of vascular proliferation, and necrosis lesions computed from each slide are useful features to judge the case's severity for further subtype classification. In addition, since the over-detection of vascular proliferation and necrosis lesions is unavoidable, the classification models of logistic regression classifier trained in the second phase can alleviate the impact of those regions of false positive detection, reducing the misinterpretation cases successfully. However, a case will be misinterpreted once misclassified in the first phase. Therefore, the performance bottleneck of the proposed framework to tackle in the future is to boost the performance of binary classification for the Oligo-like class vs. Astro-like class in the first phase.

***Abstract*—Investigating the endogenous vulnerabilities of gait-based identity recognition (GBIR) is extremely important for protecting the privacy information of users stored in smart devices. In this paper, we first elaborate the poisoning attacks against the GBIR to evaluate its robustness, in which the model training process can be deliberately corrupted to manipulate its identity prediction intentionally, e.g., the illegitimate user *Alice* is misidentified as the targeted legitimate user *Bob*. To this end, we formulate a bilevel optimization problem to characterize the sequential decision-making interaction process between the attacker and the gait recognizer that is formalized by a sparse representation optimization. Further, we reformulate this NP-hard bilevel problem into a computable mixed integer program to purse a maximum-effectiveness and minimum-cost attack strategy. Finally, we perform experiments on the single- and multi-source datasets to verify the validity of our poisoning attacks in inducing the identity misrecognition.**

I. Introduction

Currently, a lot of sensitive and commercial-in-confidence data including chat records, shopping information, medical records, bank flow and so on are recorded by various smart devices [1], e.g., smartphones and wearable devices. To avoid the owners' privacy information leakage, it is critical to develop the built-in identity recognition module for implementing the identity authentication and security assurance. Due to the widespread popularity of smart devices, it is thoroughly easy to collect the user's gait data by the embedded motion sensors such as accelerometer and gyroscope. Consequently, the emerging gait-based identity recognition (GBIR) has attracted much research attention [2]–[4]. Compared with some traditional biometric information, i.e., face [5], fingerprint [6], iris [7], and voice [8], the gait has the unique advantages of that is, it can be authenticated implicitly and untouchably by more high accuracy and it is difficult to imitate explicitly.

Actually, the GBIR can be treated as a machine-learning classification task, in which the motion pattern of each individual is distinguishable and its belonging identity is recognizable intuitively. However, extensive researches [9]–[12] indicate that the GBIR is vulnerable to these adversarial impersonation attacks by the intentional impostors who can mimic the walking style of target users and even resort to the extra assistance with the similar physical shape and the speed-controlled treadmill. Furthermore, there exist a major challenge for these existing attacks to investigate the endogenous vulnerabilities of GBIR, because these strategies are heuristic in an evasion manner where only external testing samples are perturbed and the internal trained model is undisturbed, not only lacking of the strong attack effectiveness, but also taking the high attack cost. Therefore, these previous studies are limited to inspire the key secure insights to protect the user's privacy information.

To evaluate the robustness of GBIR deeply and understand its endogenous vulnerabilities well, we are motivated to elaborate the effective poisoning attacks that can cover the limitations of these aforementioned attacks. Main contributions are included as follows.

(i) We from the attacker's perspective explore the poisoning feasibility via deliberately corrupting the model training process of GBIR and intentionally manipulate its identity prediction, resulting that the illegitimate user *Alice* is misidentified as the specific legitimate user *Bob*.
(ii) We treat such a poisoning behavior as the leader-follower game between attacker and recognizer and then formulate a bilevel optimization problem to model their sequential decision-making interactions and seek for the final Nash equilibrium.
(iii) We run extensive numerical experiments on the single- and multi-source datasets to validate our proposed maximum-effectiveness and minimum-cost poisoning attacks in inducing the identity misrecognition.

II. Related Work

The brief reviews of related work are summarized below from two aspects: the advancements of existing impersonation attacks against the GBIR [9]–[12] and the applications of novel poisoning attacks in the artificial intelligent security domain [13]–[16].

1) Impersonation Attacks: The implementation strategies of impersonation attacks have evolved over the past decade [9]–[12]. Gafurov et al. [9] investigated the security of gait under two types of deliberate spoofing scenarios: friendly and hostile. Under the friendly scenario, the imitators did not make any deliberate attempt to copy the genuine user, whereas under the hostile scenario, individuals with similar physical characteristics attempted to imitate each other. The authors concluded that the imitator with similar physical characteristics or of the same gender might have a better chance of getting

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

accepted. In a follow-up, many works in Ref. [10]–[12] used sensors embedded in smart devices to capture gait acceleration and achieved gait imitation. The results are not acceptable, the reason may be that gait mimicry is a difficult task in practice and that a meticulous impersonation strategy hardly increases the chances of success of an impostor, even though they were closely physiologically paired with the victims and given live audio and visual feedback.

2) Poisoning Attacks: Besides the works mentioned earlier, poisoning attack [13]–[16] is another kind of adversarial attacks, which poisons the training templates to induce a wrongly trained model. Luis et. al [14] extended data poisoning attack approach to multi-class DNN, in which a fraction of training data are manipulated to subvert learning process. Zhu et al. [15] presented a transferable clean-label poisoning attack approach that can attack image classification system successfully without any knowledge of victim DNN via designing poison images to surround the targeted image in feature space. Huang et al. [16] devised a data poisoning attack approach that can manipulate the DNN based recommendation system to recommend attacker-chosen target items to as many customers as possible. The poisoning attack strategy can threaten the security of pattern recognition models seriously and it inspires us to absorb into our optimal attack strategy.

Till now, there is few studies considerd adversarial attacks on GBIR system. In this paper, from the perspective of attackers, we propose a poisoning attack strategy to explore the endogenous vulnerabilities in existing GBIR systems.

III. Problem Formulation

In this section, we first introduce the sparse representation optimization on the GBIR. Then, we describe the intentions of poisoning attacks and formalize its bilevel optimization model. Finally, we give the problem solving method.

A. Sparse Representation Optimization on GBIR

In general, the distinctive gait pattern can be recognized to identify its owner. Thus, the GBIR is treated as a classification task, which can be chracterized by sparse representation optimization. This includes two parts.

1) Dictionary Construction: For all c users (i.e., classes), we use their d training samples to construct a dictionary matrix D as follows.

$$D = [D_1, \cdots, D_k, \cdots, D_c] \in \mathcal{R}^{K \times d} \tag{1}$$

where $D_k = [\boldsymbol{d}_{k1}, \cdots, \boldsymbol{d}_{k\overline{m}_k}]$ is constructed by the training samples of k^{th} user, $k = 1, 2, \cdots, c$, and $\overline{m}_k$ is total number of training samples of k^{th} user, implying that $(m_k - \overline{m}_k)$ is total number of testing samples of k^{th} user, $\sum_{k=1}^{c} \overline{m}_k = d$. Often, $K \ll d$ is known.

2) L_1 Minimization: Suppose $\boldsymbol{y}$ be one of testing samples of k^{th} user. Due to the fact that both $\boldsymbol{y}$ and D_k are from the same user with the identical-distribution samples, they have high positive correlations. So, we can use a linear combination to describe the correlations between $\boldsymbol{y}$ and D_k as follows.

$$\begin{aligned} \boldsymbol{y} &= D_i \boldsymbol{x}_i \\ &= [D_1, \cdots, D_i, \cdots, D_c][\mathbf{0}_1^{\mathrm{T}}, \cdots, \boldsymbol{x}_i^{\mathrm{T}}, \cdots, \mathbf{0}_c^{\mathrm{T}}]^{\mathrm{T}} \\ &= D\boldsymbol{x} \end{aligned} \tag{2}$$

where $\boldsymbol{x} \in \mathcal{R}^d$ is a sparse vector with the maximum sparsity $\overline{m}_i$ and its non-zero elements is the coefficient $\boldsymbol{x}_i$.

Due to $K \ll d$, this is a under-determined equation system so that it exists infinite solutions. Only the sparsest solution is desired to locate the unique class of user identity. To model this sparse representation, we adopt the L_1 minimization optimization as follows.

$$\min ||\boldsymbol{x}||_1 \tag{3}$$

$$\text{s.t. } \mathbf{0} \preceq \boldsymbol{x} \preceq \mathbf{1} \tag{4}$$

$$||\boldsymbol{y} - D\boldsymbol{x}||_2 \leq \epsilon \tag{5}$$

Remark: (i) The sparse representation optimization has been widely used in the classification tasks such as voice, face recognition [17]–[19], because this only requires to construct the complete dictionary matrix rather than the time-consuming training process. (ii) A common trick is to relax L_0 minimization by L_1 in this sparse representation optimization, when considering the solving challenge that the L_0 minimization is an NP-hard problem. (iii) The expression (2) is changed into (5), due to the existence of measurement error ϵ, and thus this optimization problem is a second-order cone program (SOCP).

B. Poisioning Attack

1) Attack Intention: An example is taken to treat *Alice* as a illegitimate and *Bob* as the targeted legitimate. Keep in mind that the attack intention is the illegitimate *Alice* is misidentified as the targeted legitimate *Bob*. Specifically, the goal of poisoning attack is to inject perturbations into the training samples in order to misunderstood the model classification. Without loss of generality, D' represents the corrupted dictionary matrix and ΔD the model bias, which can be expressed as follows.

$$D' = D + \Delta D \tag{6}$$

This means that the training templates are tampered to implement the key of poisoning attacks.

2) Bilevel Optimization Model: Intrinsically, a two-player game exists between the malicious attackers and the gait recognizer. Initially, the adversary actively injects small perturbations to the training dataset to induce the identity misidentification of a GBIR system. Subsequently, the gait recognizer passively responds these false data injections. Eventually, going on many-round attack-defense competitions, two players achieve the game equilibrium point in which they have the balance of their own objectives. In brief, such a sequentially adversarial decision-making interaction process is a Stackelberg leader-follower game. Therefore, our proposed poisoning attacks can be described as an two-player adversarial game.

Generally, the bilevel optimization is an adequate framework to model such a Stackelberg leader-follower game [20]–[22].

Based on the mentioned expressions (3)-(6), we formulate a bilevel optimization problem to characterize our poisoning attacks as follows.

$$\min_{\Delta \boldsymbol{D}} \|\boldsymbol{x}_B - \boldsymbol{x}'_A\|_1 - \|\boldsymbol{x}_A - \boldsymbol{x}'_A\|_1 \tag{7}$$

$$\text{s.t. } \|\Delta \boldsymbol{D}\|_0 \leq \beta K \tag{8}$$

$$\|\Delta \boldsymbol{D}\|_2 \leq \beta \|\boldsymbol{D}\|_2 \tag{9}$$

$$\min ||\boldsymbol{x}||_1 \tag{10}$$

$$\text{s.t. } \|\boldsymbol{y}_A - (D + \Delta \boldsymbol{D})\boldsymbol{x}'_A\|_2 \leq \epsilon \tag{11}$$

where $\boldsymbol{y}_A$ is the testing sample from *Alice* and β is the threshold factor.

We note that $\boldsymbol{x}_A$ and $\boldsymbol{x}_B$ are the specified sparse vectors used to accurately locate the identity index of *Alice* and *Bob* without any attack, respectively. We use the corrupted sparse vector $\boldsymbol{x}'_A$ to locate the *Alice*'s identity index under poisoning attack. In this leader-follower game, the upper-level leader is the attacker who focuses on designing optimal attack strategy to induce the identity misidentification, and the lower-level follower is the gait recognizer who aims at the accurate identity identification.

C. Problem Solving

The bilevel optimization problem is NP-hard, because the bilevel architecture raises a extremely huge solution space to cause the intractable computation, as investigated in our publication [23]. To solve our bilevel problem efficiently, we use Lagrangian dual of SOCP in [24] to solve the lower-level optimization problem. Finally, we adopt these mentioned duality theory to reformulate a single-level SOCP as follows.

$$\begin{aligned}
&\min_{\Delta \boldsymbol{D}} \|\boldsymbol{x}_B - \boldsymbol{x}'_A\|_1 - \|\boldsymbol{x}_A - \boldsymbol{x}'_A\|_1 \\
&\text{s.t.} \|\Delta \boldsymbol{D}\|_0 \leq \beta K \\
&\quad \|\Delta \boldsymbol{D}\|_2 \leq \beta \|\boldsymbol{D}\|_2 \\
&\quad \|\boldsymbol{y}_A - (D + \Delta \boldsymbol{D})\boldsymbol{x}'_A\|_2 \leq \epsilon \\
&\quad \mathbf{1} + D^{\mathrm{T}}\boldsymbol{\nu} - \boldsymbol{\eta} = \mathbf{0} \\
&\quad\quad ||\boldsymbol{\nu}||_2 \leq \lambda \\
&\quad\quad \boldsymbol{\eta} \succeq \mathbf{0} \\
&\quad \mathbf{1}^{\mathrm{T}}\boldsymbol{x}'_A \leq -\epsilon\lambda - (\boldsymbol{y}_A + \Delta \boldsymbol{y}_A)^{\mathrm{T}}\boldsymbol{\nu}
\end{aligned} \tag{12}$$

We notice that (12) can be run in a powerful mathematical program solver Gurobi [25], which can obtain a near-globally optimal solution to accurately recognize the user identity.

IV. Experiments and Evaluation

A. Experiment Settings

To verify the validity of our model in different gait data, we use two public datasets as experiment data. Concretely, PubData1 is from [26], including single-source gait signals with 50 subjects; and PubData2 is from [27], including multi-source gait signals with 56 subjects. After the gait data signal reprocessing, we extract 126- and 264-dimension gait signal features from PubData1 and PubData2 to produce the dictionary matrices and testing examples, respectively. These details are referred to our publication [27].

B. Evaluation Metric

In this work, we present seven evaluation criteria to quantify the perturbation magnitude level as follows.

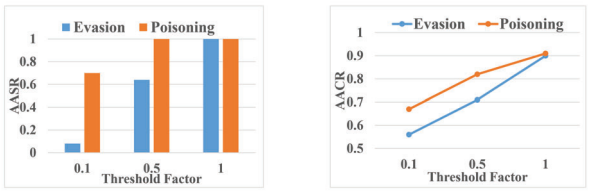
(i) Average attack success rate (AASR): the average successful attack in the 100-round experiments;

(ii) Average attack confidence rate (AACR) of successful attack: $\frac{\sum_l \max\{\boldsymbol{x}_A\}_l}{100}$, which is to evaluate the average attack confidence of successful attack;

(iii) L_0-relative cost (RC): $\frac{\|\Delta \boldsymbol{D}\|_0}{m}$, which is to measure the sparsity of perturbations;

(iv) L_1-absolute cost (AC): $\frac{\|\Delta \boldsymbol{D}\|_1}{\|\boldsymbol{D}\|_1}$, which is to measure the absolute cost of perturbations using L_1-norm;

(v) L_1-RC: $\frac{\|\Delta \boldsymbol{D}\|_1}{\|\boldsymbol{D}_A - \boldsymbol{D}_B\|_1}$, which is to measure the relative cost of perturbations using L_1-norm;



(vi) L_2-AC: $\frac{\|\Delta \boldsymbol{D}\|_2}{\|\boldsymbol{D}\|_2}$, which is to measure the absolute cost of perturbations using L_2-norm.

(vii) L_2-RC: $\frac{\|\Delta \boldsymbol{D}\|_2}{\|\boldsymbol{D}_A - \boldsymbol{D}_B\|_2}$, which is to measure the relative cost of perturbations using L_2-norm;

C. Evaluation Experiments

1) Attack Experiment on PubData1: In this experiment, we evaluate the performance of poisoning attack strategy on PubData1 with different threshold factor β. Each experiment is repeated for 100 times. The evasion attack approach is compared with our method. The average results are shown in Fig.1 and Table I.

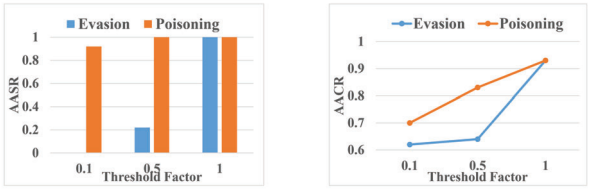
Fig. 1 shows the changes of AASR and average AACR for the testing samples of *Alice* under the evasion and poisoning attack strategies against PubData1. We can see that the AASR under these two attack strategies present the increasing trending till 100% and the AACR rises up to 90%, as the threshold factor β changes from 0.1 to 1. These results illustrate that the gait recognizer of GBIR system is really susceptible to these adversarial attacks to misidentify *Alice* as *Bob*. Also, we can find that the AASR and AACR of poisoning attack strategy are higher than that of evasion attack strategy. Even though given the slight attack resources, that is, the threshold factor β is assigned 0.1, the AASR remains above 70% and the AACR is over 68% under the poisoning attack strategy. These results indicate that poisoning attack strategy is more effective than evasion attack strategy.

(a) AASR (b) AACR

Fig. 1. Experiment Results of AASR and AACR with PubData1.

Table I mainly lists the results of L_0-RC, L_1-RC, L_2-RC, L_1-AC, and L_2-AC for the testing samples of *Alice* under

TABLE I
THE RESULTS OF ATTACK COST FOR *Alice* ON PUBDATA1



Threshold factor	Strategy	Original Label	Present Label	Variable	L_0-RC	L_1-RC	L_2-RC	L_1-AC	L_2-AC
0.1	Evasion	Alice	Alice/Bob	$\Delta \boldsymbol{y}_A$	9.99%	7.75%	9.04%	3.02%	4.67%
		Bob	Bob						
0.1	Poisoning	Alice	Alice/Bob	$\Delta \boldsymbol{D}_A$	6.66%	5.07%	6.35%	2.29%	3.01%
		Bob	Bob	$\Delta \boldsymbol{D}_B$	9.99%	7.61%	9.11%	2.81%	3.69%
0.5	Evasion	Alice	Alice/Bob	$\Delta \boldsymbol{y}_A$	36.63%	42.91%	46.72%	16.72%	18.89%
		Bob	Bob						
0.5	Poisoning	Alice	Bob	$\Delta \boldsymbol{D}_A$	9.99%	43.23%	47.17%	16.65%	18.79%
		Bob	Bob	$\Delta \boldsymbol{D}_B$	49.95%	47.22%	49.02%	17.64%	19.79%
1	Evasion	Alice	Bob	$\Delta \boldsymbol{y}_A$	16.65%	78.56%	85.17%	35.88%	39.34%
		Bob	Bob						
1	Poisoning	Alice	Bob	$\Delta \boldsymbol{D}_A$	13.32%	83.30%	91.72%	34.72%	39.93%
		Bob	Bob	$\Delta \boldsymbol{D}_B$	69.93%	86.10%	88.51%	36.73%	39.76%

the evasion and poisoning attack strategies against PubData1. Table I also shows the label change before and after attacks. If the original label *Alice* is identified as the present label *Alice/Bob* (marked in blue color), this means that only partial attacks are successful for 100-time testing experiments. The red color *Bob* means *Alice* is identified as the present label *Bob* with 100%.

In Table I, we observe that the possibility of successful attack (marked in red color) increase as the threshold factor increases from 0.1 to 1. This confirms that the more attack resources are consumed, the higher attack cost is spent. When the threshold factor is 0.1, poisoning attack strategy can achieve higher attack successful rate shown in Fig. 1 with small attack cost, compared with evasion attack. When the threshold factor is 0.5, the attack successful rate of poisoning attack can achieve 100% with only modifying less than half of the features.

2) Attack Experiment on PubData2: Fig. 2 shows the results of AASR and AAC for the testing samples of *Alice* under the evasion and poisoning attack strategies against multi-source PubData2. We observe that the values of AASR and AACR under these two strategies increase gradually, as the threshold factors are assigned from 0.1 to 1. At the same time, we also see that the AASR and AACR of poisoning attack strategy are higher than that of evasion attack strategy. Even though the threshold factors are assigned 0.1 to allow an imperceptible attack resource, the AASR remains above 90% and the AACR is over 70% under poisoning attack strategy. These results indicate that the gait recognizer is readily deceived to cause the identity misidentification and poisoning attack strategy is the more effective than evasion attack strategy, which are also verified in the testing experiment against single-source PubData1.

Table II mainly lists the results for the testing samples of *Alice* under the evasion and poisoning attack strategies against PubData2. Compared with PubData1, similar results are achieved in PubData2. The poisoning attack is more efficient than evasion attack with different threshold factors. When the threshold factor is 0.1, poisoning attack strategy can achieve higher attack successful rate of 90% shown in Fig. 2 with small attack cost, while the attack successful rate of evasion attack is 0. These results illustrate that poisoning attack

(a) AASR (b) AACR

Fig. 2. Experiment Results of AASR and AACR with PubData2.

which attacks the models is relatively more serious than that of attacking the testing samples. Compared with the single-source PubData1 (totally 132 features), the multi-source PubData2 (totally 264 features) is easier to be attacked, the reason may be that in PubData2, more invalid features are extracted from different sources that may affect the robustness of the model. In the future, we will consider some strategies such as feature selection, to increase the robustness of GBIR model.

V. CONCLUSIONS

In this paper, we propose a generalized bilevel optimization framework to model the poisoning attacks against the GBIR to study how *Alice* is misidentified as the legitimate user *Bob*. Numerical experiments in the single- and multi-source datasets verify that poisoning attack is the more efficient than evasion attack. In the future, we will make more efforts on the study of how to defense the poisoning attacks.

***Abstract*—As the Internet of Things (IoT) continues to evolve, WiFi devices are becoming increasingly ubiquitous in our everyday lives. This proliferation of devices has paved the way for innovative technologies such as device-free passive indoor tracking using WiFi devices. For device-free passive WiFi sensing, the Doppler Frequency Shift (DFS) extracted from fine-grained Channel State Information (CSI) phase has been widely adopted for estimating target motion velocity. Nevertheless, due to the presence of random phase offsets in CSI and the fact that many IoT devices have only one WiFi antenna, utilizing CSI phase for calculating DFS is usually unfeasible. In this paper, we present a novel Single Antenna WiFi Tracking (STrack) system that estimates DFS using CSI amplitude, eliminating the need for DFS symbols to directly participate in velocity calculation. Extensive experimental results indicate that STrack outperforms state-of-the-art indoor tracking systems, with a median velocity error of 1.49cm/s, and a median direction error of 12.41°, a median positioning error of 48.529cm.**

I. Introduction

Passive human tracking technology has gained significant attention in recent years due to its potential applications in various fields. It can monitor activities of elderly individuals who are at risk of falls or other health issues with little privacy concerns [1]. It is also applied for in-home security systems, where it can efficiently detect and track intruders. Existing devices that utilized for passive human tracking can be generally categorized to WiFi devices [2], [3], cameras [4], [5], and Ultra Wide Band (UWB) devices [6], etc. Compared with other devices, WiFi-based ones are cost-effective and privacy-friendly, which can be deployed widely in smart homes [7].

In device-free passive WiFi indoor tracking technology, the Doppler Frequency Shift (DFS) extracted from fine-grained Channel State Information (CSI) is a widely adopted technique for estimating target motion velocity [8]. Channel State Information (CSI) is obtained from the physical layer of the device [9], with each antenna capable of capturing the corresponding CSI data. However, the CSI obtained by each antenna contains a random phase offset, which hinders the direct extraction of Doppler Frequency Shift (DFS) information from the CSI. One common approach to eliminate random phase offsets is to employ conjugate multiplication [10] or division [11] of the CSI data of the two antennas. This method requires that the WiFi device has at least two antennas operating in the same frequency band, while not all WiFi devices meet this requirement. In the realm of the Internet of Things, single-antenna WiFi devices [12], [13] are employed to meet the requirement for low-cost hardware.

In this paper, we delve into passive human tracking using IoT devices equipped with only one antenna. Our core idea revolves estimating the DFS utilizing the CSI amplitude. This approach enables us to achieve target tracking while avoiding the unsolvable CSI phase offset problem. Nonetheless, since the amplitude of CSI is a set of real numbers, the utilization of amplitude-based estimation for DFS presents a challenge in determining the DFS symbols, which can only take positive values in the calculation. This will lead to wrong estimation of velocity direction. In previous work, Widar [2] exploits the continuity of motion to determine a unique direction of motion. This judgment method relies on the last speed estimation, which is not reliable for random motion. According to the principle of Fresnel zone [14], WiDir [15] uses the frequency difference of different subcarriers to analyze the timing of all subcarriers to obtain the symbol information of DFS. However, this method also exhibits certain limitations. Specifically, in instances where the angle between the direction of motion and the transmitter-receiver link is small, the accurate estimation of the DFS symbol becomes difficult.

In order to tackle the challenge of losing DFS symbols during estimation, we propose a new velocity estimation framework for single-antenna devices, termed STrack, which capitalizes on the observation that smart homes frequently accommodate multiple IoT devices within a single room. In this framework, initially, we compute unsigned DFS from the CSI amplitude collected by each WiFi device. Then, these unsigned DFSs are employed to calculate the complete set of feasible velocities. Finally, the actual velocity is extracted from the array of potential velocities using both the K-means algorithm and a novel weighting algorithm. Our main contributions can be summarized as follows:

1) We establish a model relating CSI amplitude and motion velocity by quantifying the length variation of the dynamic path, which can be used to measure and analyze the changes in CSI amplitude corresponding to different velocities.
2) We use multiple unsigned DFS to jointly estimate the

*Dongheng Zhang is the corresponding author.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

velocity of the target, and design a weighted estimation algorithm to judge the authenticity of the velocity.

3) We developed a single antenna WiFi tracking system (STrack) that accurately tracks the trajectory of a target. Through extensive experimentation, we have demonstrated that STrack outperforms other state-of-the-art algorithms, with a median velocity error of 1.49cm/s, and a median direction error of 12.41°, a median positioning error of 48.529cm.

II. Velocity Estimation Model

In this section, we present the model between CSI amplitude variation and target motion velocity.

A. CSI-Velocity Model

In device-free passive WiFi tracking, the position of receiver and transmitter is usually fixed, so the signal path from transmitter to receiver can be divided into two parts: dynamic path and static path. Static paths include direct paths (Line-of-Sight) and paths reflected by stationary objects. The dynamic path is introduced by the moving target in the environment. We define the single tone signal sent by the transmitter as $X(f_0, t_0) = ae^{j2\pi f_0 t_0}$ at time t_0, where f_0 is carrier frequency. The signal received by the receiver is $Y(f_0, t_0) = a'e^{j2\pi f_0(t_0-\tau_s)}$, where τ_s represents the time interval for the wave to travel from the transmitter to the receiver. τ_s is a fixed value because the distance between transmitter and receiver is fixed. The measured CSI with only static path can be expressed as

$$H_s(f, t_0) = \frac{Y(f, t_0)}{X(f, t_0)} = \frac{a'e^{j2\pi f(t_0-\tau_s)}}{ae^{j2\pi f t_0}} = Ae^{-j2\pi f\tau_s}, \quad (1)$$

where $A = a/a'$ is amplitude of CSI.

In the dynamic path, the length varies depending on the motion of the target. To establish the relationship between the time interval τ_d and the target's velocity, we aim to determine how changes in the target's velocity impact the duration τ_d.

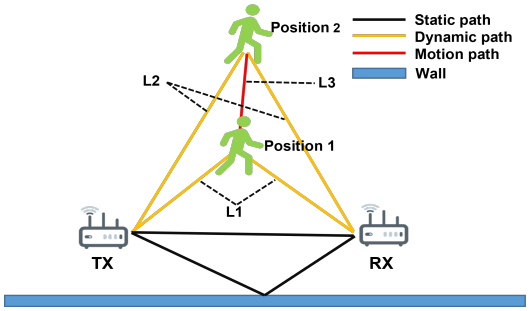

Fig. 1. Schematic diagram of static path and dynamic path generated by target motion. L_1 represents the reflected path length of the wave when the target is at position 1, and L_2 represents the reflected path length of the wave when the target is at position 2. L_3 represents the distance of the target movement

We assume that the magnitude and direction of the target's velocity are constant in a short period of time $\triangle t$. As shown in Fig. 1, the target starts from position 1 and moves to position 2 after $\triangle t$ seconds. When the target is in position 1, the CSI of the receiving end can be expressed as $Y(f_0, t_0) = a'e^{j2\pi f_0(t_0-\tau_{d1})}$, where $\tau_{d1} = L_1/c$, c is the speed of light, and L_1 represents the reflected path length of the wave when the target is at position 1. Similarly, when the target is in position 2, the CSI of the receiving end can be expressed as $Y(f_0, t_0) = a'e^{j2\pi f_0(t_0-\tau_{d2})}$, where $\tau_{d2} = L_2/c$. Now, we need to find the relationship between L_1, L_2, V (velocity magnitude) and θ (velocity direction). As shown in Fig. 2, we

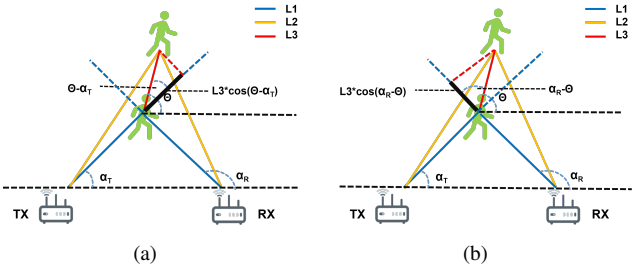

Fig. 2. Schematic diagram of motion displacement decomposition. Figure (a) represents the component of the target motion displacement (L3) on the TX-Target vector. Figure (b) represents the component of the target motion displacement (L3) on the Target-RX vector.

use the sum of the components of the target displacement length in the Target-TX and Target-RX directions to approximately replace the change in the signal propagation path length. The target displacement length can be expressed as : $L_3 = V * \triangle t$. We get the following formula:

$$L_2 = L_1 + V * \triangle t * (cos(\theta - \alpha_T) + cos(\theta - \alpha_R)). \quad (2)$$

α_T is the Angle of departure (AoD) and α_R is the Angle of arrival (AoA). Thus, when the target is in position 2, the signal of the receiving end can be rewritten as:

$$\begin{aligned} Y(f, t_0) &= a'e^{j2\pi f(t_0-L_2/c)} \\ &= a'e^{j2\pi f(t_0-(L_1+V*\triangle t*(cos(\theta-\alpha_T)+cos(\theta-\alpha_R))/c)}, \end{aligned} \quad (3)$$

the CSI of a dynamic path can be expressed as:

$$H_d(f, t_0) = Ae^{-j2\pi f((L_1+V*\triangle t*(cos(\theta-\alpha_T)+cos(\theta-\alpha_R))/c)}. \quad (4)$$

It should be noted that in the derivation of [11], DFS can be expressed as:

$$f_D = -f * V * (cos(\theta - \alpha_T) + cos(\theta - \alpha_R))/c, \quad (5)$$

and we assume that L_1 is constant over a short estimation period. So we can get that:

$$H_d(f, t) = Ae^{-j2\pi(f*L_1/c-f_D*t)}. \quad (6)$$

In practical indoor environments, CSI is the superposition of channel responses of static path and dynamic path, which can be expressed as:

$$H(f, t) = \sum_{i\in P_s} A_i e^{-j2\pi f\tau_s^i} + \sum_{j\in P_d} A_j e^{-j2\pi(f*L_j/c-f_D*t)}. \quad (7)$$

Where P_s is the set of all static paths and P_d is the set of all dynamic paths.

B. CSI Amplitude-Velocity Model

In commodity WiFi devices, since the time of transmitter and receiver is not completely synchronized, there will be a time-varying phase offset $e^{-j\phi_{offset}}$ in every CSI measurement [16], [17]. So, a complete CSI can be expressed as:

$$H(f,t) = e^{-j\phi_{offset}(t)}(H_s(f) + \sum_{j \in P_d} A_j e^{-j2\pi(f*L_j/c - f_D*t)}). \tag{8}$$

This time-varying phase offset has a severe effect on estimating DFS. Fortunately, we find that the CSI amplitude is not affected by random phase offset. According to [17], CFR power can be expressed as:

$$\begin{aligned} \mid H(f,t) \mid^2 = & \sum_{j \in P_d} 2 \mid H_s(f) A_j \mid cos(2\pi(\mid f_{D_j} \mid *t + f * L_j/c) \\ & + \phi_{sj}) + \sum_{\substack{n,m \in P_d \\ n \neq m}} 2 \mid A_n A_m \mid cos(2\pi((f_{D_n} - f_{D_m})t + f(L_n - \\ & L_m)/c) + \phi_{nm}) + \sum_{j \in P_s} \mid A_j \mid^2 + \mid H_s(f) \mid^2 . \end{aligned} \tag{9}$$

According to Eq. 9, the amplitude of CSI is the sum of a set of cosines and constant offset values, where the frequency of cosines is the absolute value of DFS. Therefore, we only need to calculate the frequency of the CSI amplitude in a short time to get the absolute value of the DFS caused by the target motion. When the target moves in a fixed direction away from the transmitter-receiver link, the variation of the CSI amplitude is depicted in Fig. 3. It was observed that the CSI amplitude waveform resembles a cosine waveform, where the variation decrease with the increase of dynamic path length.

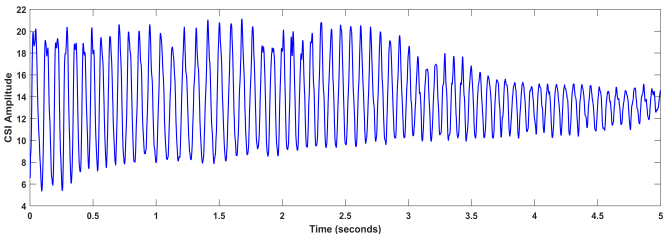

Fig. 3. CSI amplitude waveform resembles a sum of cosine and constant offset values. As the distance of the dynamic path increases, the impact of the dynamic path on the CSI amplitude decreases.

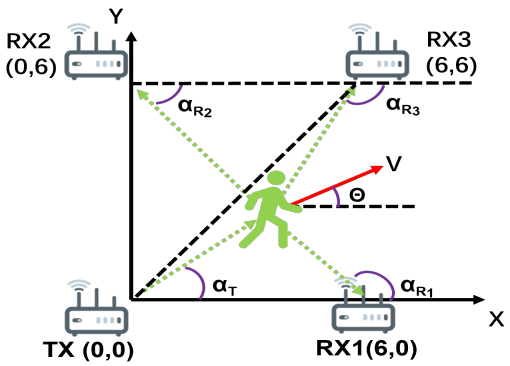
III. Joint Estimation of Motion Velocity Using Multiple Unsigned DFS

The utilization of CSI amplitude for DFS calculation results in the inevitable loss of DFS symbols, which are crucial in accurately computing motion velocity. In this section, we present a novel method to calculate motion velocity using unsigned DFS. This approach effectively prevents velocity estimation errors resulting from the loss of DFS symbols.

As we rely on the CSI amplitude for DFS estimation, the actual symbol of DFS is not directly available to us. Therefore,



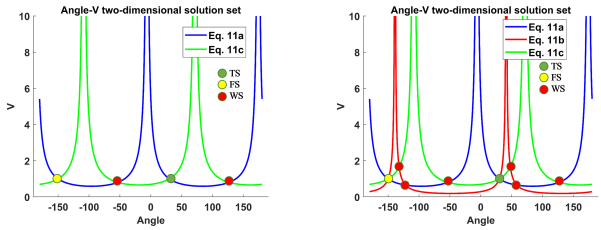


Fig. 4. Multiple decives (1 transmitter, 3 receivers) jointly estimate the moving velocity of the target

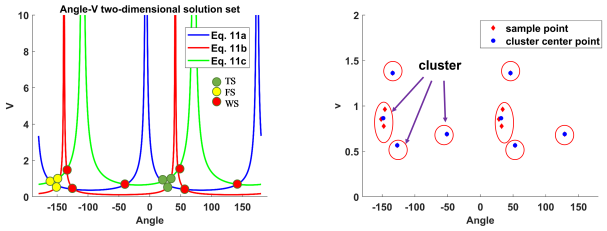
(a) (b)

Fig. 5. In Figure (a), the blue line represents all solutions satisfying Eq. 11a. The green lines represent all solutions satisfying Eq. 11c. In Figure (b), green, yellow, and red thick dots represent True solution (TS), Flase solution (FS), and Wrong solution (WS), respectively.

the relationship between DFS extracted from CSI amplitude and target velocity is as follows:

$$\mid f_D \mid = \mid f * V * (cos(\theta - \alpha_T) + cos(\theta - \alpha_R))/c \mid . \tag{10}$$

According to Eq. 10, DFS is not only determined by the velocity of target movement, but also determined by the position of transmitter, receiver and target. As shown in Fig. 4, combing the DFS measured from multiple different receivers, we have the follwing equations



$$\mid f_{D_1} \mid = \mid f * V * (cos(\theta - \alpha_T) + cos(\theta - \alpha_{R_1}))/c \mid \tag{11a}$$
$$\mid f_{D_2} \mid = \mid f * V * (cos(\theta - \alpha_T) + cos(\theta - \alpha_{R_2}))/c \mid \tag{11b}$$
$$\mid f_{D_3} \mid = \mid f * V * (cos(\theta - \alpha_T) + cos(\theta - \alpha_{R_3}))/c \mid \tag{11c}$$

When combining any two equations in Eq. 11, we can get 4 different velocities as shown in Fig. 5(a), where the intersection of the two curves are the estimated velocity.

As shown in in Fig. 5(b), the True Solution (TS) could satisfy the constraint of all equations, which is the intersection of all three curves. Meanwhile, since the DFS symbol has been lost, there is another False Solution (FS) which has the same absolute value but opposite direction compared with TS. The rest of the intersections are Wrong Solutions (WS). To achieve accurate velocity estimation, we utilize the distribution difference between TS and WS and the direction disparity between TS and FS to determine which intersection is the actual velocity.

A. Differentiate between TS and WS

To distinguish TS and WS, we have noted that since TS can satisfy all equations, a natural approach is to solve Eq. 11. However, due to the estimation error of DFS, it is difficult to directly estimate the solution of TS from all equations in Eq. 11. To resolve this problem, we have noted that by combing any two equations in Eq. 11, we can obtain all possible solutions as shown in Fig. 6, where the possible solution of TS forms clusters while WS distribute randomly. Hence, we can adopt K-Means algorithm to find the largest cluster as the estimation of TS.

(a) (b)

Fig. 6. In Figure (a), TS and FS are gathered together, WS is scattered. In Figure (b), The red dots represent all the solutions computed by Eq. 11. The blue dots represent the center points of the clusters.

K-means is a commonly used unsupervised clustering algorithm [18]. Its basic idea is to find a scheme to divide K clusters through iteration, so that the loss function corresponding to the clustering result is minimized. The loss function can be defined as the sum of squared errors of each sample from the center point of the cluster to which it belongs:

$$Loss(c,u) = \sum_{i=1}^{M} \parallel x_i - u_{c_i} \parallel^2, \tag{12}$$

where M is the total number of samples, x_i is the i-th sample, c_i is the cluster to which x_i belongs, and u_{c_i} is the center point of cluster c_i.

As depicted in Fig. 6(b), the K-Means algorithm utilizes all points within the velocity set as sample points, and subsequently divides points with closer distances into the corresponding clusters. However, due to the aggregation of all TS, and the scattering of WS, all TS are consolidated into a single cluster, while WS is divided into multiple distinct clusters. Similarly, FS is assigned to its own cluster. The determination of the cluster that divides TS or FS is based on considering the cluster with the highest count of sample points. Hence, the number of clusters, K, in the K-means algorithm is a important hyperparameter.

In a scenario where there is one transmitter and N receivers, we can derive N equations similar to Eq. 10. By combining any two equations, we obtain $M = C_N^2 = N*(N-1)/2$ combinations, each of which yields 4 distinct solutions. Consequently, there are a total of $L = 4M = N*(N-1)*2$ solutions. Theoretically, TS manifests as a set of identical solutions, which constitutes 1/4 of the original solution set, and so does FS. On the other hand, WS manifests as a set of distinct solutions, accounting for 1/2 of the original solution set. Therefore, the number of clusters should be $K = L/2+2 = N*(N-1)+2$. After selecting the cluster with the largest number of sample points, we find the sample point closest to the cluster center as the velocity to be distinguished, denoted as (V^*, θ^*). Note that since the size of the cluster for TS and FS are the same, we cannot distinguish TS and FS based on the number of sample points in the cluster.

B. Differentiate between TS and FS

To distinguish TS and FS, we develop a weighted discrimination algorithm based on Widir [15] to effectively identify and select the desired TS. According to the Fresnel Zone principle, for two different sub-carriers, the wavelengths are λ_1, λ_2 respectively, When the movement of the target is close to the transmitter-receiver link, the fluctuation first appears in the subcarrier with longer wavelength, and then appears in the subcarrier with shorter wavelength. On the contrary, when the target is far away from the transmitter-receiver link, fluctuations first appear on the subcarriers with shorter wavelengths and then on the subcarriers with longer wavelengths. By analyzing the time delays on different subcarriers, we can assess the temporal order of fluctuations across the subcarriers [19]. Based on this sequence, we can estimate the DFS symbol. However, the accuracy of this method is limited, particularly when the angle between the motion direction and the transmitter-receiver link is small. Fortunately, we find out that for the velocity obtained through clustering, whether it corresponds to TS or FS, maintains a consistent angle with all transmitter-receiver links which can be employed to mitigate the loss of precision. Consequently, we can assign weights on the estimated DFS from different RXs based on the angle, which could improve the accuracy for the DFS symbol.

Thus, we develop a weighted discrimination algorithm. Initially, We utilize time delay analysis [15] to ascertain an initial DFS symbol for each RXs. Subsequently, the symbols estimated by each RXs are weighted and combined to obtain the final estimated DFS symbol. The weight is determined by the angle between the direction of velocity and the transmitter-receiver link. Finally, we leverage the estimated DFS symbol to differentiate between TS and FS.

IV. Tracking System Implementation

In this section, we introduce the implementation details of the proposed system. As shown in Fig. 7, the system is composed of three modules: CSI Acquisition and Processing, Velocity Estimation, Target Location Tracking.

CSI Acquisition and Processing: We utilize one WiFi transmitter and at least three receivers for CSI acquisition. In addition, in order to ensure the fairness of the comparison with other algorithms, all transmitting and receiving devices use mini-computers with Intel 5300 network cards. We set the working frequency band of the WiFi signal to 5G Hz, where the DFS generated by human body movement is in the range of 0-75 Hz. The mini-computer equipped with a 5300 network card has three antennas, and we only use the CSI data obtained

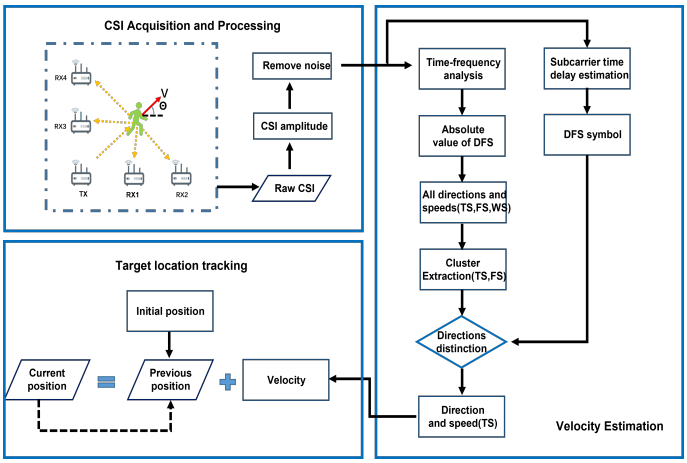


Fig. 7. System overview of STrack.

by the first antenna to complete subsequent calculations. The CSI data obtained by the remaining antennas is utilized for the calculation of other algorithms. we use the CSI data of the first and second antennas to implement PITrack [11]. We use all antennas to implement Widar2.0 [20]. To suppress random noise, we pass the signal through S-G filter [21].

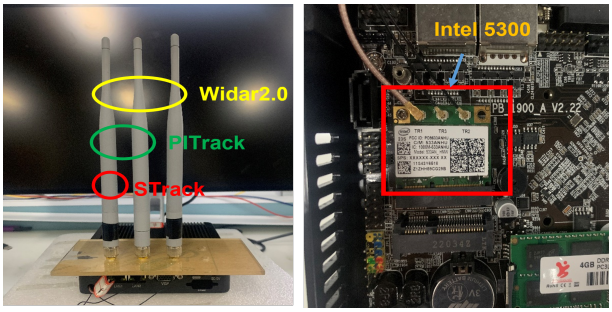

Fig. 8. Devices for experiments.

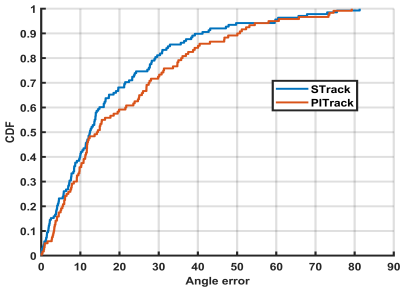
Velocity Estimation: We use the CWT algorithm [22] to extract the time-frequency spectrum from the CSI amplitude of all RXs. We then estimate the DFS from the time-frequency spectrum. Finally, we utilize the proposed algorithm to achieve velocity estimation.

Target Location Tracking: It can be seen from Eq. 5 that DFS is closely related to the speed of target motion and the position of the target at the previous timestamp. This requires us to know the initial position of the target motion in advance. With the initial position, we then calculate new positions based on the velocity estimation.

V. Experiments

In this section, we conduct extensive experiments under various settings and compare the results with state-of-the-art algorithms (PITrack [11] and Widar2.0 [20]). To assess the performance of STrack, we design experiments to evaluate its capabilities in three key aspects: velocity direction estimation, velocity magnitude estimation, and localization accuracy. We also conduct experiments in different environments to verify the robustness of the proposed framework.



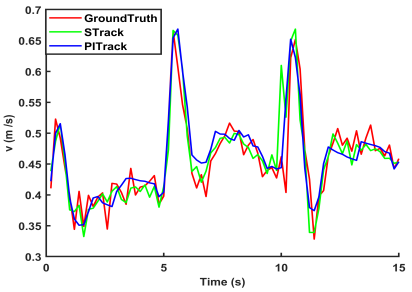


Fig. 9. CDF of velocity direction estimation error.

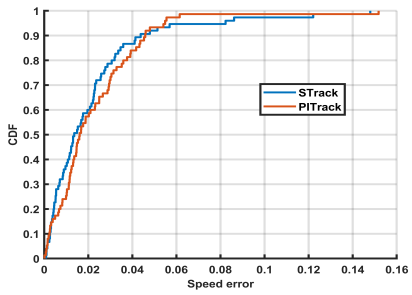
Velocity Direction Estimation: Direction estimation is crucial for device-free passive indoor tracking. The volunteer starts from a fixed position and move towards different directions, and conducts 13 sets of experiments along different directions, and each set of experiments is repeated 3 times. As shown in Fig. 9, the accuracy is slightly better than that of PITrack. The STrack direction estimation has a median error of 12.41° and an average error of 17.93°. PITrack has a median error of 14.22° and an average error of 21.31°. It worth noting that while the performance of STrack and PITrack is close, STrack can be deployed on IoT devices with single antenna, while PITrack requires 2 antennas to suppress random phase offset.



Velocity Magnitude Estimation: In experiments for direction estimation, we let the subject moves in a straight line at a fixed angle to ensure a constant direction of motion. However, maintaining a constant velocity magnitude during the exercise is challenging, necessitating a tool to collect motion velocity in real-time. To achieve this, we installed a Intel RealSense Tracking Camera T265 on the mobile platform, which can obtain a three-dimensional velocity information every 0.1s. In the experiment, we control the mobile platform to move in a fixed direction, record the velocity of movement in real-time, and then convert the three-dimensional velocity into a one-dimensional velocity to obtain the actual velocity required. As shown in Fig. 10(a), the velocity magnitude estimation with STrack is consistent with ground-truth with better accuracy than PITrack. As shown in Fig. 10(b), when the mobile platform moves at an angle of 90°, the median errors of STrack and PITrack are 1.49cm/s, 1.67cm/s, and the average errors are 2.16cm/s, 2.26cm/s, respectively.

Location Estimation: As shown in Fig. 11, the median positioning errors of STrack, PITrack, and Widar2.0 are 61.325cm, 66.114cm, and 135.47cm, respectively. In order to show the tracking performance of our system more vividly, we require volunteers to move according to the specified trajectory ('N', Triangle, Rectangle), as shown in Fig. 12, the red dotted line is the ground truth, and the black solid line is the trajectory calculated by the system , through comparison, we can find that the trajectory estimated by the system has a high degree of coincidence with the ground truth, which demonstrates the effectiveness of the proposed system.

Impact of Environments: The above-mentioned experiments were all carried out in an open room with few reflection paths. To verify the impact of environments, we conduct experiments in two environments (Corridor and Meeting room). The corridor is 8m long, 2m wide, and the sensing range is 2m*6m. The meeting room is 12m long, 8m wide, and the sensing range is 5m*5m. Volunteers are also asked to walk according to the prescribed trajectory. As shown in Fig. 13 , whether in the corridor or in the meeting room, the trajectory

Fig. 13. In corridor and meeting room scenarios, STrack can still work effectively.

VI. CONCLUSION

In this paper, we present STrack, a new Single Antenna WiFi Tracking system that estimates DFS using CSI amplitude. In this framework, we first compute unsigned DFS from the CSI amplitude collected by each WiFi device. Then, these unsigned DFSs are employed to calculate the complete set of feasible velocities. Finally, the actual velocity is extracted from the array of potential velocities using both the K-means algorithm and a novel weighting algorithm. Extensive experimental results indicate that STrack outperforms state-of-the-art indoor tracking systems, with a median velocity error of 1.49cm/s, and a median direction error of 12.41°, a median positioning error of 48.529cm.

E-mail: kaikai.wang@mail.utoronto.ca, dimitris@comm.utoronto.ca

***Abstract*—In this paper, we propose the SEformer, an efficient dual-path conformer neural network for speech enhancement. The proposed SEformer is comprised of an encoder, a decoder and dual-path conformer blocks in between. First, the encoder receives the noisy speech waveform to generate the speech features. Then, each proposed dual-path conformer block employs a temporal and frequency conformer in parallel to simultaneously extract temporal and frequency features of speech sequences, which are then fused by a transformer block for contextual representation. Finally, the decoder transforms the contextual speech features into a mask to filter out noise-related information of noisy speech, generating the estimated clean speech. Experimental results on the benchmark dataset exhibit that our SEformer yields a competitive performance to existing state-of-the-art methods while containing the fewest model parameters (about 590k).**

I. Introduction

Speech enhancement is a task aiming to improve the quality of corrupted speech by removing the noise-related information, which has become an indispensable stage in various applications like automatic speech recognition (ASR) and hearing aids. Recently, deep neural networks (DNNs) emerged as mainstream approaches to efficiently improve the performance of speech enhancement systems. Depending on the types of input signal, DNN-based speech enhancement can be categorized into Time-Frequency (T-F) and Time domain methods. In T-F domain, DNNs receive the image-like spectrum features of noisy speech as input to estimate the clean one, where the spectrum is obtained by implementing the short-time Fourier transform (STFT) on the speech waveform. For example, some DNN-based models such as neural networks (CNNs) [1] and recurrent neural network (RNNs) [2], exclusively estimate the clean magnitude from the noisy one, and reuse the phase information for reconstruction stage. However, it is sub-optimal to neglect to denoise the phase of noisy speech since it can provide extra information for better speech quality. Afterwards, various works focus on modeling both magnitude and phase information for improving the performance of speech enhancement [3]–[5]. For instance, the imaginary and real part of speech spectrum is first packed together to avoid the shortage of magnitude and phase information, and then passes through DNN-based models for predicting the clean imaginary and real spectrogram [3], respectively. Instead, the complex-value CNN is proposed to simultaneously enhance magnitude and phase of noisy speech by using more complicated structure [4].

Differing from T-F domain methods, the time-domain methods directly extract the clean speech from noisy one, which operates on the one-dimensional speech sequences. For the purpose of extracting the contextual information of long-range speech sequences, some works utilize encoder-decoder frameworks to map the inputs into the compressed features via an encoder, and then recover features back to enhanced speech through a decoder [6], [7]. To further extract the long-range dependencies of speech sequences, various DNN-based modules are inserted between the encoder and the decoder, including dilated CNN module [8], RNN module [7], and attention-based modules [9], [10]. Unlike T-F domain methods implementing on the spectrum with harmonic characteristics, time-domain methods generally involve more model or computational complexity to extract the contextual features of speech waveforms for remarkable performance.

To extract the contextual information of long-range speech sequences, some recent works adopt transformer neural network as a backbone or a component of speech enhancement system, where the transformer is originally proposed in [11] to address the long-dependency problem with self-attention mechanisms, and has been widely used in natural language processing (NLP) [12], computer vision (CV) [13], and speech processing tasks [14]–[16]. Authors of [14] introduced the Gaussian-weighted self-attention into transformer to pay more attention to the closer speech frames and less attention to the distant ones, significantly improving the performance of speech enhancement. Authors of [15] and [16] adopted two transformers to successively perform the local and global feature extraction for contextual representation, efficiently improving the performance of speech separation and enhancement. Furthermore, a convolution-augmented transformer named as Conformer [17] is proposed to efficiently leverage the local property of CNNs and the global characteristics of transformers for learning the contextual representation in speech recognition. Inspired by this, authors of [18] proposed a SE-Conformer for speech enhancement in the time domain, where the conformer is followed by the encoder for further extracting contextual features which are then passed through a decoder for speech reconstruction. Different from [18], authors of [19] adopted a two-stage conformer collaborating with generative adversarial network into speech spectrum, achieving an impressive performance of speech enhancement.

Despite various methods have been proposed to improve the performance of speech enhancement, it is still challenging to efficiently extract the long-range dependencies of speech

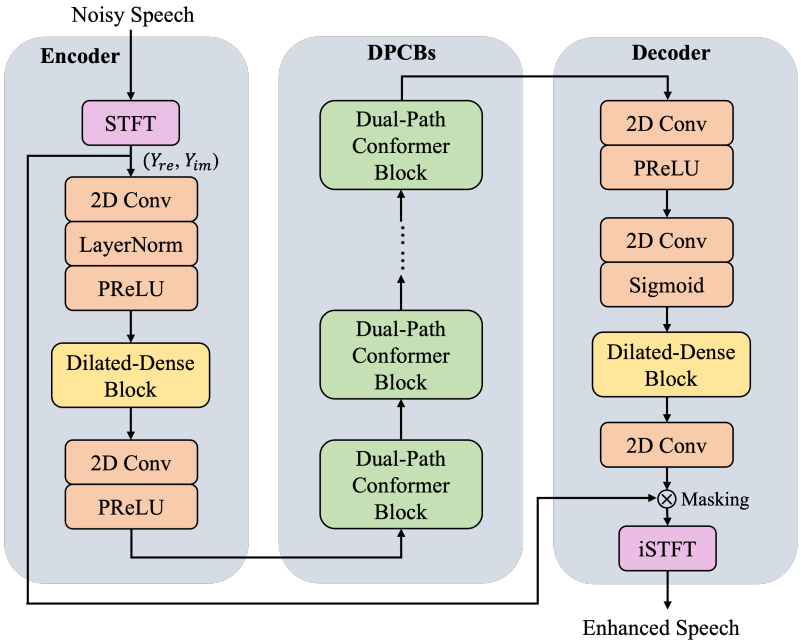

Fig. 1: Overview of proposed dual-path conformer neural network (SEformer)

sequences. By leveraging the facts that the two-stage extraction efficiently reduces the complexity of processing long-range speech sequences [20], and the conformer effectively learns the contextual information of input signals [17], we here propose a lightweight, simple but efficient SEformer for T-F domain speech enhancement. Our experiments on the benchmark dataset show that the proposed SEformer yields competitive performance to state-of-the-art denoising systems while employing the lowest model parameters.

II. Proposed Architecture

In this section, we propose a dual-path conformer, called SEformer, for speech enhancement in the T-F domain. As shown in Fig. 1, SEformer includes an encoder, a decoder and dual-path conformer blocks in between.

A. Encoder

The encoder is used to transform the input noisy speech waveform into speech features via an STFT operator, an input convolution block, a dilated-dense block, and an output convolution block. First, the noisy speech waveform s undergoes the STFT operator to obtain the spectrum with plural representation $Y = Y_{re} + jY_{im}$, where $Y_{re} \in \mathbb{R}^{B\times T\times F}$ and $Y_{im} \in \mathbb{R}^{B\times T\times F}$ denote the real and imaginary components of speech spectrum, respectively, and T and F mean the the dimension of time and frequency, respectively, and B is the batch size. Next, the real and imaginary parts are stacked together along the new channel dimension, constructing the input of model $S \in \mathbb{R}^{B\times 2\times T\times F}$. Then, the channel number of S is increased from 2 into 64 by the input convolution block using 64 $1*1$ convolution kernels attached with layer normalization and PReLU non-linearity activation. In the following, to obtain the rich feature representation, a dilated-dense block [16] is used to achieve the feature propagation and increase the receptive field with reduced parameters by using 4 depth-wise separable convolutions [21] with dense connection and dilated operation. Finally, the output convolution block compresses the channel number of the features from dilated-dense block to form the input of conformer blocks $H \in \mathbb{R}^{B\times 32\times T\times F}$ via 32 kernels of size $(1, 1)$ followed by PReLU activation operation, which aims to avoid the overflow of memory caused by the computational complexity.

B. Dual-path Conformer Block

The proposed dual-path conformer blocks consist of conformers and transformer-based fusors to extract the contextual information of speech features. The vanilla transformer has three important components such as positional encoding (PE), multi-head self-attention (MHSA), and feed-forward network (FFN). Compared with transformer, the conformer structure contains two macaron-like FFN layers sandwiching the convolution block and the MHSA [17], where the convolution block is inserted between MHSA and the second FFN for learning local information. More specifically, in the beginning, the input is processed by a half-step FFN consisting of two fully-connected (FC) layers for passing through MHSA. In MHSA, the input is first transformed into three different feature representations including Queries (Q), Keys (K) and Values (V) by three learnable linear matrixes with multiple times. Then, each query is multiplied by all keys in the dot-product manner, generating the attention weights after the softmax operation. Next, attention weights are multiplied with values to get the attention of each head. Finally, the attentions of all heads are packed together to form the output of MHSA

by a linear projection. In the following, a convolution module is employed to learn the local relationship of speech features, which is comprised of point-wise and depth-wise convolutions, normalization, and non-linear activation operations as shown in Fig. 2. Finally, the outputs from MHSA are processed by a second half-step FFN to extract abundant information. Due to the fact that the self-attention neglects the order information of sequential signals, the PE is adopted in the beginning of MHSA for adding position information.

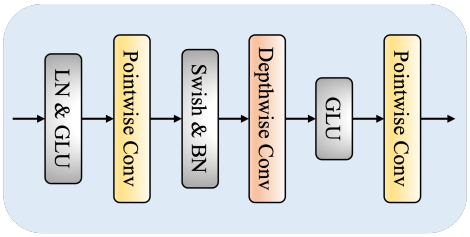

Fig. 2: Convolution module in conformer

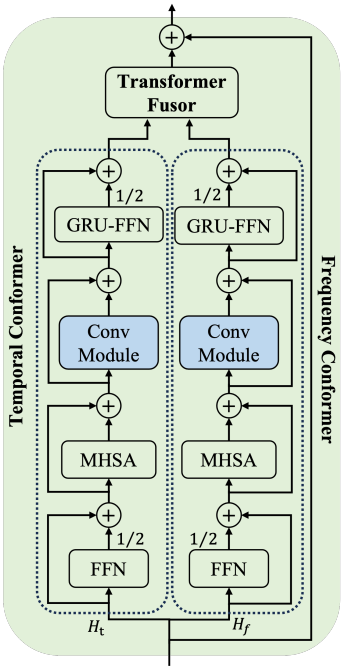

Fig. 3: Proposed dual-path conformer block (DPCB)

Each dual-path conformer block (DPCB) is comprised of a temporal conformer, a frequency conformer, and a transformer fusor as shown in Fig. 3, where the temporal and frequency conformers are employed to simultaneously extract temporal and frequency information of speech, and the transformer fusor is used to merge the generated temporal and frequency features for better contextual representation. Different from vanilla conformer and transformer, we here modify these two structures in some aspects: first, we omit the positional encoding module commonly used in conformer and transformer; Second, to learn the positional information, we employ the GRU-augmented FFN after MHSA in both conformer and transformer, where the first FC layer is substitute by a bi-directional GRU layer to track the positional information of speech signals.

During each DPCB procedure, given the compressed features $H \in \mathbb{R}^{B\times 32\times T\times F}$ generated from the encoder, the permutation first operates on the dimension of features to yield two types of features $H_t \in \mathbb{R}^{(B\times F)\times T\times 32}$ and $H_f \in \mathbb{R}^{(B\times T)\times F\times 32}$ with different dimension shape. Next, the frequency conformer operates on the H_f along the dimension F to extract the frequency dependency of each independent speech frame. Simultaneously, the temporal conformer performs on the H_t along the dimension T to aggregate the temporal dependency of various speech frames. Subsequently, the transformer fusor is used to merge the generated features from the temporal and frequency conformers by considering frequency features as queries, and temporal features as keys and values, yielding the contextual representation of speech features. The whole procedure in each DPCB can be denoted as follows:

$$Mid_{cf}(H_f) = Conv_{cf}(MHSA_{cf}(MLP_{cf}(H_f))) \quad (1)$$
$$Conf_f(H_f) = GRU\text{-}FFN_{cf}(Mid_{cf}((H_f))) \quad (2)$$
$$Mid_{ct}(H_t) = Conv_{ct}(MHSA_{ct}(MLP_{ct}(H_t))) \quad (3)$$
$$Conf_t(H_t) = GRU\text{-}FFN_{ct}(Mid_{ct}(H_t)) \quad (4)$$
$$H_{context} = Transformer(Conf_f(H_f), Conf_t(H_t)) \quad (5)$$

where $Conf_f$ and $Conf_t$ denote the frequency and temporal conformer, $GRU\text{-}FFN_{cf(ct)}$, $Conv_{cf(ct)}$, $MHSA_{cf(ct)}$ and $MLP_{cf(ct)}$ are the GRU-augmented FFN, convolution block, multi-head self-attention and vanilla FFN in frequency or temporal conformer, and $H_{context}$ is the contextual features from DPCB. Note that, in our implementation, the group normalization is added after each conformer for better training, and the residual connection is utilized in each DPCB to mitigate the gradient vanishing issue.

C. Decoder

The decoder receives the contextual features $H_{context} \in \mathbb{R}^{B\times 32\times T\times F}$ from DPCBs to estimate a mask which is used to filter out the noise-related information of noisy speech features. First, 64 1^*1 convolution kernels followed by PReLU activation are used to recover the feature channel of $H_{context}$ back to be the same as the one of H. Then, the values of features are then squeezed between 0 and 1 by adopting a gated convolution [22] consisting of a 1^*1 convolutions followed by a $Sigmoid$ activation function. Next, a dilated-dense block followed by 1^*1 convolution are employed to decrease the feature channel of $H_{context}$ to 2, creating a mask $M = [M_{re}, M_{im}] \in \mathbb{R}^{B\times 2\times T\times F}$, whose complex-valued

TABLE I: Comparison results of our proposed model with other methods on the dataset [23]

representation is $M = M_{re} + jM_{im}$. In the following, the produced mask will be applied into the input $Y = [Y_{re}, Y_{im}]$ to obtain the enhanced real and imaginary spectrograms, which are eventually proposed by iSTFT operator for reconstruction of clean speech waveform. The overall masking procedure can be denoted as follows:

$$Y \cdot M = (Y_{re}M_{re} - Y_{im}M_{im}) + j(Y_{re}M_{im} + Y_{im}M_{re}) \quad (6)$$

$$E_{re} = Y_{re}M_{re} - Y_{im}M_{im} \quad (7)$$

$$E_{im} = Y_{re}M_{im} + Y_{im}M_{re} \quad (8)$$

$$x = iSTFT(E_{re}, E_{im}) \quad (9)$$

where M_{re} and M_{im} denote the masks for real and imaginary spectrograms, respectively, and E_{re} and E_{im} mean the real and imaginary of enhanced spectrogram, respectively, and $iSTFT$ is the inverse STFT operator, and x is obtained the enhanced speech waveform.

III. Experiments

A. Dataset

Our experiments are conducted on the VoiceBank-Demand dataset [23], a benchmark dataset commonly used for speech enhancement task, including 11572 utterances from 14 females and 14 male speakers for training, and 824 utterances from one male and one female speakers for testing. Both trainset and testset are comprised of pairs of noisy and clean speech, where the noisy speech of trainset is the mixture of clean speech of trainset and 10 types of noises (8 types of noises chosen from DEMAND dataset [32] and 2 types of artificial noises) at 0 dB, 5 dB, 10 dB, and 15 dB SNR levels, and the acquisition of noisy speech in testset is achieved by corrupting clean speech from testset with 5 types of noises not used in trainset at SNR levels of 2.5 dB, 7.5 dB, 12.5 dB, and 17.5 dB.

B. Evaluation Metrics

To assess the quality of enhanced speech with respect to clean speech, some evaluation measurements are used to evaluate the model performance by operating on the enhanced and clean speech, including perceptual evaluation of speech quality (PESQ) [33] ranging from -0.5 to 4.5, and short-time objective intelligibility (STOI) [34] constrained between 0 to 1; In addition, three mean opinion scores (MOSs) [35] fluctuated between 1 and 5 are employed for subjective evaluation, like CSIG for signal distortion, CBAK for noise disturbance, and COVL for overall quality of enhanced speech.

C. Experimental Setup

All speech utterances are re-sampled to 16 KHz in both the trainset and testset. We randomly choose a 3-second speech clip from each utterance in the trainset, and maintain the length of testing utterances unchanged. To obtain the speech spectrum, a 320-point STFT operator applies a Hann window with a 20ms duration and a 10ms stride into each speech clip, resulting in the 161 frequency bins in the spectrum. Considering the hardware resource, we use 3 dual-path conformer blocks, where the input feature dimension is 32, and 4 attention heads and 64 hidden units are used in each multi-head attention block and GRU-augmented FFN block, respectively. By following the training strategy of [16], the Adam optimizer [36] is adopted to update model parameters for 100 epochs, in which the maximum L2 gradients is constrained within 5 for alleviating the explosion of gradient through gradient clipping. The learning rate is first warmed up to $4e^{-4}$, and then multiplied by 0.98 every two training epochs. For loss functions, we adopt a loss composed of the time and T-F domain to expect the proposed model to learn abundant knowledge from different aspects [16], which can be formulated as follows:

TABLE II: Evaluation results among reference models with various conformer blocks

Model	Domain	PESQ	STOI(%)	CSIG	CBAK	COVL	Para.(Million)	MACs(G)
SEformer (ours)	T-F	**3.19**	**95**	4.42	**3.62**	**3.84**	0.59	28.94
SEformer_A	T-F	3.13	**95**	4.42	3.61	3.80	**0.58**	27.89
SEformer_C	T-F	3.13	**95**	4.42	3.61	3.81	**0.58**	27.89
SEformer_V1	T-F	3.14	**95**	**4.43**	**3.62**	3.81	0.59	28.94
SEformer_D	T-F	3.01	**95**	4.30	3.53	3.67	0.73	**18.95**

$$Loss = \alpha * Loss_{time} + (1 - \alpha) * Loss_{frequency} \quad (10)$$

where $Loss_{time}$ is the mean square error (MSE) between the clean and enhanced speech waveforms in time domain, and $Loss_{frequency}$ is the frequency-domain loss to improve the speech intelligibility and perceptual quality, which calculates the distance between the clean and enhanced speech spectrum, α is a tuneable parameter to control the weight of two losses, which is configured as 0.6 in our all experiments.

D. Experimental Results

Table I exhibits the comparison results of our SEformer and some existing methods conducted on the VoiceBank-Demand dataset. Generally, our SEformer achieves a competitive performance to existing models in all evaluation measurements while involving the fewest model parameters (around 0.59 million). First of all, compared with all existing time-domain methods, our SEformer attains a superior PESQ improvement from 1.97 to 3.19. Besides, SEformer further has a 0.23 PESQ improvement based on TSTNN using two-stage feature extraction with cascaded structure while involves fewer model parameters and lower multiply-accumulate operations (MACs), presenting the superiority of proposed dual-path conformer with inner fusion mechanism. Compared with the SE-Conformer using vanilla conformer, the proposed SEformer yields better performance than most evaluation scores except for CSIG. In addition, SEformer achieves the highest STOI (95%) and MOSs scores compared with all time-domain methods.

Moreover, SEformer achieves competitive performance compared with state-of-the-art methods in T-F domain. More specifically, our SEformer achieves better evaluation results than T-GSA using the transformer with modified self-attention mechanism. Despite CMGAN achieves the better enhancement performance than SEformer, it adopts adversarial learning and possesses three times more parameters than SEformer. Differing from other methods, our SEformer is a simple but efficient enough architecture which is free from data augmentation technologies or complicated design.

Through observing the comparison results between proposed models and existing speech enhancement systems shown in Table I, our SEformer is efficient in modeling long-range speech sequences while having the lowest model parameters. This implies that our proposed dual-path conformer block with inner fusion mechanism can effectively capture the temporal and frequency information of speech sequences, and achieves the interaction between temporal and frequency features for attaining strong contextual information.

E. Ablation Study

We present some comparison models to demonstrate the effectiveness of various components of our model. First, to further explore the efficiency of proposed DPCBs, we construct two different conformer blocks, where the first one exclusively substitutes the transformer fusor with average operation named as DPCB_Avg, the second one uses the temporal and frequency conformers with cascaded structure named as DPCB_cascade. Second, to probe the sensitivity of transformer fusor on location of temporal and frequency features, we make temporal features as queries, and frequency features as keys and values for undergoing the transformer fusor, named as DPCB_V1. To make a fair comparison, we use 4 DPCB_Avg, 4 DPCB_cascade and 3 DPCB_V1 to separately replace the original DPCBs, leading to three reference models with the similar parameters to SEformer, namely SEformer_A, SEformer_C, and SEformer_V1, respectively, as shown in Table II. Finally, to investigate the effect of speech features with decreased spatial size on the performance, we introduce a down-sampling layer and an up-sampling layer into encoder and decoder, respectively, and adopt 4 DPCBs in middle, yielding the reference model called SEformer_D.

As shown in Table II, our SEformer using proposed DPCBs attains the best results in most evaluation metrics. Especially, both SEformer_C using cascaded structure and SEformer_A using averaging operation obtain the inferior performance than SEformer, indicating that dual-path extraction with conformer can efficiently extract temporal and frequency information and dynamically fuse them for better contextual representation of long-range speech sequences. In addition, by comparing with SEformer_V1, proposed SEformer achieves the similar evaluation scores, showing that the denoising performance of SEformer would not be affected by the position of temporal and frequency features in passing through the transformer fusor. Finally, despite the SEformer_D with down-sampling operation involves the fewer model parameters, its performance shows a significant drop in all evaluation metrics, which implies that adopting sufficient spatial resolution of speech features is crucial for conformer blocks to learn the contextual relationship among speech sequences.

IV. Conclusions

In short, we proposed an efficient SEformer system for T-F domain speech enhancement, which adopts the dual-path conformers with inner fusion mechanism to simultaneously extract temporal and frequency features for better contextual representation of speech sequences. The comparison results with recent state-of-art methods indicate that our SEformer achieves competitive performance and contains the fewest model parameters. In future work, we continue to modify the self-attention mechanism of conformer and transformer with reduced computations like linear-complexity attention [37], achieving the trade-off between the denoising performance and computational complexity. Besides, it is worth evaluating the performance and robustness of our proposed SEformer on more challenging datasets with low SNR environments.

***Abstract*—Speech emotion recognition (SER) helps machines behave and communicate in a more human-like way, thus has attracted extensive attention from industry and academia. Traditional SER algorithms usually discard the phase information in the speech spectrum. However, phase information plays an important role in many speech-related tasks according to recent speech-processing researches. In the SER area, the pre-trained Wav2Vec 2.0 model reached SOTA performance, still, no attention was paid to the complex information in speech. In this paper, we propose a novel framework utilizing both the real and the imaginary parts of the complex feature obtained by speech short-time Fourier transform to improve the SER performance. Specifically, we construct a deep complex neural network (DCNN) to handle the information in the speech complex feature, and then the DCNN is fused with the Wav2Vec 2.0 model to enhance the SER performance. Experiment results show that the proposed framework benefits from the compensation of DCNN and obtains nearly 1 percent performance improvement over model Wav2Vec 2.0 in terms of accuracy and F1.**

I. Introduction

Speech emotion recognition (SER) is an essential research branch of artificial intelligence. With SER, human-computer interaction becomes smoother. Besides, SER is also helpful for emergency discovery, fraud detection, psychological comfort, etc.

Speech in digital signal view is a complex wave composed of a bunch of sine waves with different frequencies and amplitudes. Therefore, short-time Fourier transform (STFT) was usually adopted to analyze the frequency domain feature information of the speech, which was proved useful fed to an emotion classifier [1][2][3][4]. There were many speech spectrum related features in SER research literature, where different spectral representations of speech were used as the input for deep learning models, including Mel-frequency Cepstral Coefficients (MFCCs), Mel-scaled spectrogram, Chromagram, Spectral contrast feature, logMel spectrogram and Tonnetz representation[5] [6] [7], etc. All these spectrum-related features could be extracted via Librosa audio library[8]. The spectrum feature based SER algorithms often used multi-time-scale method or multi-scale area attention with varied granularities to enhance the flexibility towards temporal variations[6][7]. In [9], Gammatone Frequency Cepstral Coefficients (GFCC) was proposed as a potentially better representation of speech signals for emotion recognition, which was also adopted in [10]. The key point for the success of GFCC was the usage of additional voice features. Many works [11][12][13][14][2] used MFCC as the input feature of a deep neural network to recognize the speech emotion and achieved good performance. In [15], short-time log frequency power coefficients (LFPC) was used to represent the speech signals. In previous SER works, most classifiers took features coming from the frequency spectrogram as the input, which contained only the amplitude part of the outcome of STFT, however, the phase information was neglected.

To compensate for the phase information ignored by frequency spectral features in audio-related tasks, deep complex neural network (DCNN) considering both the real and imaginary part of the speech complex feature was proposed in [16], where the building blocks and architectures for deep learning were based on complex-valued operations and representations. Based on this work, many researchers studied the advantage of complex deep neural networks in speech, music, or even biomedical signal processing tasks. In [17][18][19], models incorporating well-defined complex-valued building blocks were proposed to deal with complex-valued spectrograms to solve the difficulty of estimating the phase of clean speech during speech enhancement. In [20], several complex-valued activation functions were implemented for magnetic resonance imaging (MRI) reconstruction and that helped to achieve better performance than real-valued networks. Though complex deep neural networks are now extensively used in speech-related tasks, to the best of our knowledge, it has not been explored for the recognition of speech emotion. According to the experience of speech reconstruction, when a speech segment is modified with phase information, one can apparently hear the difference, which may influence the emotion of the speech. Inspired by this phenomenon, we investigate whether complex feature containing phase information is helpful for speech emotion recognition in this paper.

Recently, pre-trained speech models such as Wav2Vec 2.0 provided very effective acoustic feature extraction methods and were proven to have sound effects in many speech-related tasks. Wav2Vec was first proposed in [21], which trained the model on large amounts of unlabeled audio data and the resulting representations were then used to improve acoustic model training. Then Wav2Vec 2.0 was proposed in [22] which used a self-supervised learning approach to learn audio representations and trained both continuous context representations and discrete quantized representations. Wav2vec and Wav2vec 2.0 both provided outstanding pre-

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

training methods for speech, but Wav2vec 2.0 was proved superior to Wav2vec in TIMIT Phoneme recognition and other related tasks. Besides, Wav2Vec 2.0 was also helpful in SER[23][24]. Particularly, [25] improved the performance of SER on IEMOCAP to 70.83 percent in terms of UAR, which we take as the benchmark of our SER study.

In this work, we use the DCNN model which takes all the speech complex features into account as a supplement to Wav2vec 2.0 in the task of speech emotion recognition. The contribution of the work is concluded as follows: 1) This work is the first to emphasize and use the speech complex feature information in the task of SER to the best of our knowledge; 2) The proposed SER framework reaches the SOTA performance on IEMOCAP and RAVDESS and brings nearly 1 percentage performance improvement in terms of accuracy and F1.

II. Method

In this section, the SER model based on a deep complex neural network is firstly introduced. We then review Vanilla fine-tuning Wav2Vec 2.0[25], which is the baseline of our work and serves as one of the basic models in the proposed model. Finally, we introduce the details of the proposed SER framework, namely an enhanced Wav2Vec 2.0 model, which inherits the advantages of high-quality speech representation of Wav2Vec 2.0 and the full use of phase information of the deep complex neural network.

A. Deep Complex Neural Network (DCNN)

In [16], the deep complex neural network was proposed to process speech signals, and was proved beneficial for tasks such as music processing, speech enhancement, etc. In this work, we try to implement DCNN in speech emotion recognition, which has not been investigated in previous SER works.

In the DCNN of this work, a deep complex convolution network is implemented to extract the speech features and a linear layer is followed to classify the emotion category. The detailed architecture is pictured in Fig. 1. Firstly, a short-time Fourier transform (STFT) module is used to deal with 20 ms speech fragments and obtain the complex spectral feature which contains the real part and the imaginary part. Then the same complex convolution block modules are concatenated 5 times to extract more expressive features from the output of the STFT module. Then follows a global average pooling module to fuse the information coming from different speech fragments into a specified length, which is 256 in our work. Finally, a linear module is taken as the classifier, of which the output length is consistent with the number of emotion categories. Concretely, the complex convolution block contains three function layers: convolution2d, LeakyReLU, and batch normalization layer, which follow the rules of complex-valued calculation and are presented below.

B. Complex-valued Convolution

Suppose we are convolving a complex filter matrix $\mathbf{M} = \mathbf{X}+i\mathbf{Y}$ by a complex vector $\mathbf{v} = \mathbf{a}+i\mathbf{b}$, where $\mathbf{X}$, $\mathbf{Y}$ are real-valued matrix and $\mathbf{a}$, $\mathbf{b}$ are real-valued vectors. The outcome of the complex convolution is

$$\mathbf{M} * \mathbf{v} = (\mathbf{X} * \mathbf{a} - \mathbf{Y} * \mathbf{b}) + i(\mathbf{Y} * \mathbf{a} + \mathbf{X} * \mathbf{b}). \quad (1)$$

This equation gives an important role to associate real convolution with complex convolution. The implementation details are presented in Fig. 2.

C. Complex Global Averaging

Global averaging is an operation to reduce the dimension of the extracted features to a more expressive vector, which also helps to unify the speech feature size to the channel size no matter what length the incoming speech is. In real-valued global averaging, it is simply calculating the average value of each channel. But for complex-valued global averaging, the average values of both real and imaginary parts are calculated separately. Besides, the complex global averaging in our work is followed by the linear classifier, of which the input should be a real-valued vector. So, the complex global averaging module is where we combine the real part and the imaginary part of the complex feature. After global averaging calculation, we calculate the real-valued power of the complex value of each channel.

The other modules of the complex-valued neural network such as complex LeakyReLU are of simple calculation, which is performed separately on the real and imaginary parts of the complex value.

D. Vanilla Fine-tuning Wav2Vec 2.0 on SER

In [25], the authors implemented Vanilla fine-tuning Wav2Vec 2.0 and reached the SOTA performance in the field of SER. The Wav2Vec 2.0 model extracts unsupervised speech features by multi-layer convolutional neural network taking raw speech signals as the input. Under the default setup in Wav2Vec 2.0 encoder, the CNN contains 7 layers of which the step sizes are (5,2,2,2,2,2) and the convolution kernel widths are (10,3,3,3,2,2). As the number of output channels of the last convolution in the encoder is set to 512, a 512-dimensional speech feature is generated for every 20ms speech. To utilize Wav2Vec representation to speech emotion recognition, Vanilla fine-tuning Wav2Vec 2.0 processes the final contextualized embedding generalized by Wav2Vec 2.0 using a global average pooling across the time dimension, and then classifies the emotion using the ReLU activation followed by a full connection layer. Concretely, the global average pooling unifies the length of the speech feature embedding extracted by the Wav2Vec 2.0 model to 768 regardless of the input speech length.

E. Complex feature information enhanced Wav2Vec 2.0

Fig. 1 presents the framework of the proposed model, which is composed of model Wav2Vec 2.0 and model DCNN. The two basic models both take a speech signal as the input and the recognized emotion category probability as the output. Though Wav2Vec 2.0 is of strong representation ability, it does not pay attention to the phase information of the speech, which is exactly what the DCNN model can compensate for.

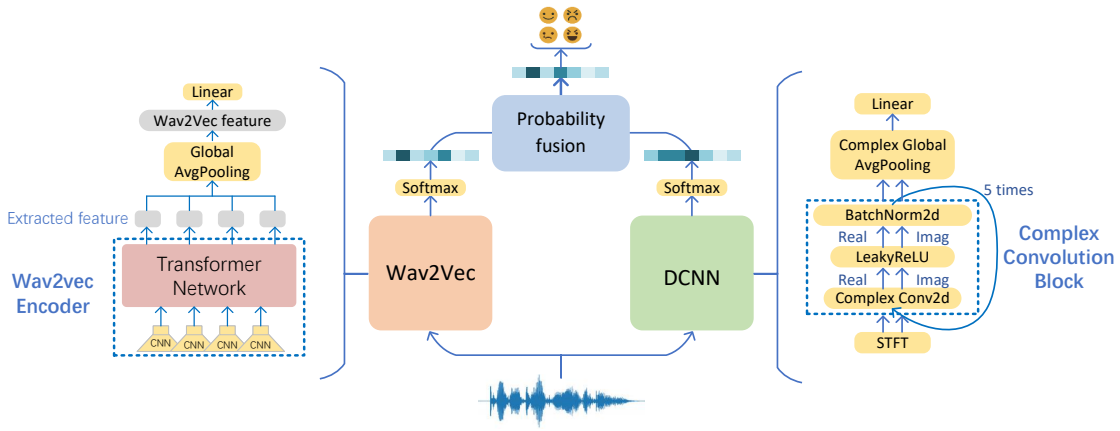

Fig. 1. Framework of the proposed complex feature information enhanced Wav2Vec 2.0

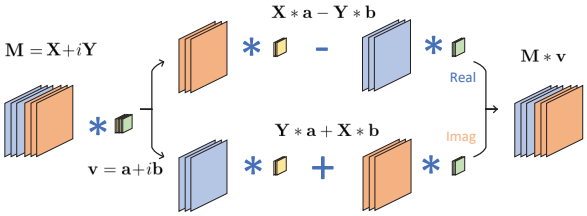

Fig. 2. Complex convolution

Specifically, for a certain speech signal input, the DCNN model provides the probability of the emotion category, $Prob_{DCNN}$, which is obtained by a softmax layer after the output of the linear classifier, $output_{DCNN}$. The calculation is as follows:

$$Prob_{DCNN} = softmax(output_{DCNN})$$

The outcome probability of DCNN $Prob_{DCNN}$ is then fused with the outcome probability of Wav2Vec 2.0, $Prob_{w2v}$ in the proportion of α:

$$Prob_{Fusion} = Prob_{w2v} + \alpha Prob_{DCNN}$$

The compensated outcome probability of the model $Prob_{Fusion}$ is then used to decide on the emotion category, Emo:

$$\begin{aligned} Emo &= argmax(Prob_{Fusion}) \\ &= argmax(Prob_{w2v} + \alpha Prob_{DCNN}) \end{aligned}$$

Therefore, the proposed enhanced Wav2Vec 2.0 model can better consider the phase information corresponding with both the real and imaginary parts of the speech complex feature when recognizing speech emotion.

III. Experiments and Results Discussion

This section introduces the datasets used, and then the experimental setup is elaborated, after that the experiments and the results are presented and discussed.

A. Dataset

Two datasets in the field of speech emotion recognition, IEMOCAP and RAVDESS, were considered to prove the advance of our proposed method. The two datasets are described below.

IEMOCAP. Interactive Emotional Dyadic Motion Capture is a popular dataset for evaluating SER systems. It contains five recording sessions, each with one male speaker and one female speaker. Following the popular setup with previous SER works, we used the default labels provided by IEMOCAP, except that the "excited" category was merged with "happy" due to its sparsity in the dataset. Finally, only four emotion categories were considered: neutral, sad, angry, and happy. After that, the amounts of examples labeled 'neutral', 'happy', 'anger', 'sad' were 1708, 1636, 1103, 1084, respectively. The total amount of speech in IEMOCAP is about 7 hours. In this work, we only used the speech modality.

RAVDESS. Ryerson Audio-Visual Database of Emotional Speech and Song dataset is a validated multi-modal dataset of emotional speech and song. This gender-balanced dataset consists of 24 professional actors, each performing 104 unique vocalizations with emotions that include: happy, sad, angry, fearful, surprise, disgust, calm, and neutral[26]. Each actor enacted 2 statements for each emotion: "Kids are talking by the door" and "Dogs are sitting by the door." These statements were also recorded in two different emotional intensities, normal and strong, for each emotion, except for neutral (normal only). Actors repeated each vocalization twice. There are a total of 1440 speech utterances and 1012 song utterances. In this work, we only used the speech part.

B. Experimental setup

We cross-validated the models on the two datasets. As for IEMOCAP, we split the dataset by leaving one session out as the test set, and the remaining four sessions were used for training. As for RAVDESS, we split the dataset into six equal subsets according to the speaker ID and chose one subset as the test set while the rest subsets as training data.

Under this setup, we performed every experiment with multi-fold cross-validation. The experimental results presented the average value of cross-validation. Four metrics were used to evaluate the performance, including unweighted accuracy rate (UAR), weighted accuracy rate (WAR), micro-F1, and macro-F1.

We carried out three experiments in this work. Experiment 1 compared several models, including deep complex neural network (DCNN), Wav2Vec 2.0 (w2v) and the enhanced w2v model (EnW) by the compensation of DCNN, which utilized both the real and the imaginary parts of the speech complex feature. The structure of model EnW was presented in Fig. 1, and the fusion proportion α in EnW was set to 1 in our experiments. As for model w2v, we followed the Vanilla fine-tuning Wav2Vec 2.0 method described in [25]. Experiment 2 was the ablation experiment carried out to check the SER performance when only using the real part or the imaginary part information of the speech complex feature. For convenience, DCNN model using only the real part or the imaginary part information of the complex feature was respectively represented by DCNN_R and DCNN_I, and EnW_R and EnW_I was short for the enhanced w2v model by the compensation of DCNN_R and DCNN_I. Model DCNN_R and DCNN_I were similar in structure with DCNN, but DCNN_R and DCNN_I did not need any complex operation and only extracted the speech embedding from the real or imaginary part of the speech complex feature using convolutional neural network. In experiment 3, we also compared the proposed complex feature information enhanced model EnW with the SOTA models in SER, including WavLM Large, HuBERT Large, and data2vec Large of which the performance and model size all came from SUPERB [27]. The models compared in one table were under the same experimental setup.

C. Experimental results and discussion

Experiment 1 explored the SER performance of DCNN and w2v, as well as the proposed model EnW in order to see the auxiliary effect of speech complex feature on emotion recognition. Then in experiment 2, we carried out ablation experiments where half of the speech complex feature was neglected to reflect the importance of using all speech complex information in SER. In experiment 3, we compared the proposed complex feature information enhanced SER model, EnW with the SOTA models in terms of UAR and parameter quantity used.

Table I and Table II show the speech emotion recognition results of models using speech complex feature on IEMOCAP and RAVDESS respectively. One can observe that the w2v model pre-trained on very large speech datasets outperforms the DCNN model which is only trained on the limited training set of certain datasets. Nevertheless, the proposed model EnW achieves more superior performance than w2v model. This reveals that although the DCNN model is not so desirable in SER, the complex feature information extracted by DCNN is still helpful to improve the SER performance.

Table III and Table IV show the results of ablation experiments only using half part of the complex feature on IEMOCAP and RAVDESS. One can observe that: 1) The model DCNN_R or DCNN_I using only the real or the imaginary part of the complex feature information could not perform better than DCNN which uses all the speech complex feature; 2) EnW_R or EnW_I outperforms w2v; 3) Models using half part of the complex feature have similar performance. Specifically, DCNN_R and DCNN_I have similar performance, so are EnW_R and EnW_I; 4) EnW_R or EnW_I neglecting half part of the speech complex feature still fails to meet the performance of EnW. The results reveal that the real part and the imaginary part of the speech complex feature contain equally important information and both real and imaginary part are necessary to achieve superior performance for the SER model.

TABLE I
SPEECH EMOTION RECOGNITION RESULTS OF MODELS USING SPEECH COMPLEX FEATURE ON IEMOCAP

Model	UAR	WAR	micro-F1	macro-F1
DCNN	0.5494	0.5225	0.5557	0.5094
w2v	0.7083	0.6945	0.7055	0.6953
EnW	0.7146	0.7011	0.7124	0.7021

TABLE II
SPEECH EMOTION RECOGNITION RESULTS OF MODELS USING SPEECH COMPLEX FEATURE ON RAVDESS

Model	UAR	WAR	micro-F1	macro-F1
DCNN	0.3501	0.3806	0.3017	0.2707
w2v	0.7624	0.7639	0.7727	0.7609
EnW	0.7721	0.7729	0.7809	0.7704

It should be noted that although the real part and the imaginary part of the speech complex feature are different, the model using the real part of the complex information has a similar performance with the one using the imaginary part. This can be explained by the similarity of the two parts in a large-scale receptive field. Fig. 3 shows the comparison of the real part and the imaginary part of the STFT result of a speech. It can be observed that the two parts are different in detail, but are similar on a larger scale. In fact, the real part and the imaginary part are both correlated with the spectrum, which means a large number in the real part is likely to correspond to a large imaginary number, and vice versa.

The superior performance of the proposed model EnW in experiment 1 and experiment 2 are consistent on the two datasets, which shows that EnW has certain generalization performance, and complex feature containing both the real part and the imaginary part really has an auxiliary effect on SER.

Table V shows the comparison of our proposed model EnW with the existing SOTA pre-trained model in SER. The results come from [27] where the experimental setup is the same as in our work. The comparison terms are limited because the experiment in [27] was only carried out on IEMOCAP in terms of UAR. It can be observed that the accuracy of SER of our model EnW outperforms the other SOTA models and uses much fewer parameters at the same time. The superior performance is inseparable from the use of the whole speech

complex feature.

IV. CONCLUSION

Traditional SER works ignored the complex feature information in speech and that could lead to insufficient use of information. This paper proposes a method using complex feature information to enhance SER performance, where the deep complex neural network is constructed to compensate Wav2Vec 2.0 model. Experiment results demonstrate that the proposed method achieves the best performance compared with other SOTA methods, which proves the auxiliary effect of the complex feature in SER. Besides, the ablation experiment results indicate that the real part and imaginary part of the speech complex feature are equally necessary to achieve a superior SER performance.

In future work, we will explore other information fusion methods to enhance Wav2Vec 2.0 using speech the complex feature in view of the good SER performance of the proposed model in this paper.

***Abstract*—Named Entity Recognition (NER) from speech is usually implemented through a two-step pipeline that consists of (1) processing the audio using an Automatic Speech Recognition (ASR) system and (2) applying an NER tagger to the ASR output. In this paper, we incorporate *pinyin*[1] — spelled sounds of Chinese characters — into the pipeline NER from Chinese speech, aiming to improve the NER performance through two steps. First, we take the pretrained model ChineseBERT to embed pinyin, as well as glyph and char, as the input of NER tagger. Second, we introduce homophone noises into training data for NER tagger, as homophone errors most likely exist in ASR output for Chinese speech. Using the two-step pipeline method with pinyin incorporated into the NER tagger, the $F1$ score is improved by nearly 1% absolute points in the experiment on the AISHELL-NER dataset, which is a significant improvement in the field of NER. And the $F1$ score outperforms the current state-of-the-art (SOTA) result on the AISHELL-NER dataset by 0.4% absolute points, despite the slightly worse Character Error Rate (CER) of our ASR.**

I. Introduction

Named Entity Recognition (NER) is a fundamental information extraction task and plays an essential role in Natural Language Processing (NLP) applications such as information retrieval, question and answering, automatic text summarization, machine translation and knowledge graphs [1]. The goal of NER is to extract predefined specific entities from sentences and identify their correct types, such as *person* (PER), *location* (LOC), *organization* (ORG). NER has been well studied in the context of written languages [2].

Recently, NER from speech has been actively studied in the Spoken Language Understanding (SLU) field [3]. As illustrated in Fig. 1, it is usually implemented through a two-step pipeline that consists of (1) processing the audio using an Automatic Speech Recognition (ASR) system and (2) applying an NER tagger to the ASR output. Although the works in [4]–[6] have shown the capability of the End-to-End (E2E) approach for NER from French, English and Chinese speech, the two-step pipeline NER approach achieves the best $F1$ score on the Chinese speech dataset AISHELL-NER [6].

In Chinese, its characters are a written form of an ideographic symbol, and pinyin is a romanization system that uses the Latin alphabet to spell Chinese characters phonetically. For example, 妈 (means mum) is a Chinese character, and `ma1` is its pinyin, where the number 1 denotes the first tone among the four tones used in pinyin.

In this paper, we incorporate *pinyin* of Chinese characters into pipeline NER from Chinese speech. First, in order to embed the pinyin as part of the input of NER taggers, we use the off-the-shelf pretrained model ChineseBERT [7] as the encoder. ChineseBERT incorporates *pinyin*, as well as *glyph* and *char*, of Chinese characters during language model pretraining on large-scale unlabeled Chinese corpus, and achieves state-of-the-art (SOTA) performances on a wide range of Chinese NLP tasks. Second, as the training data for the NER tagger is almost error free while the ASR output contains errors or

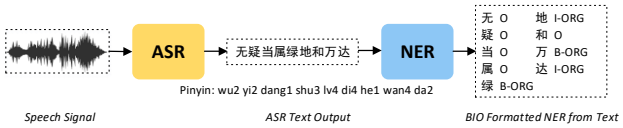

Fig. 1. Two-step pipeline NER from Chinese speech. The text of this ASR output has 9 Chinese characters with 2 named entities (绿地 for Greenland and 万达 for Wanda, which are the names of two Chinese companies), and the text means "Undoubtedly Greenland and Wanda".

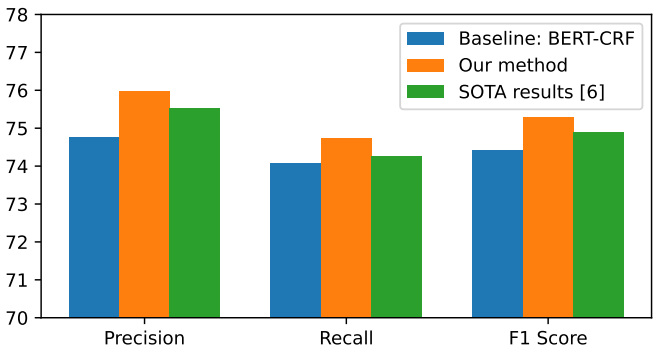

Fig. 2. Precision, Recall and $F1$ scores of the baseline pipeline method, our method and the SOTA results on the test dataset of AISHELL-NER [6].

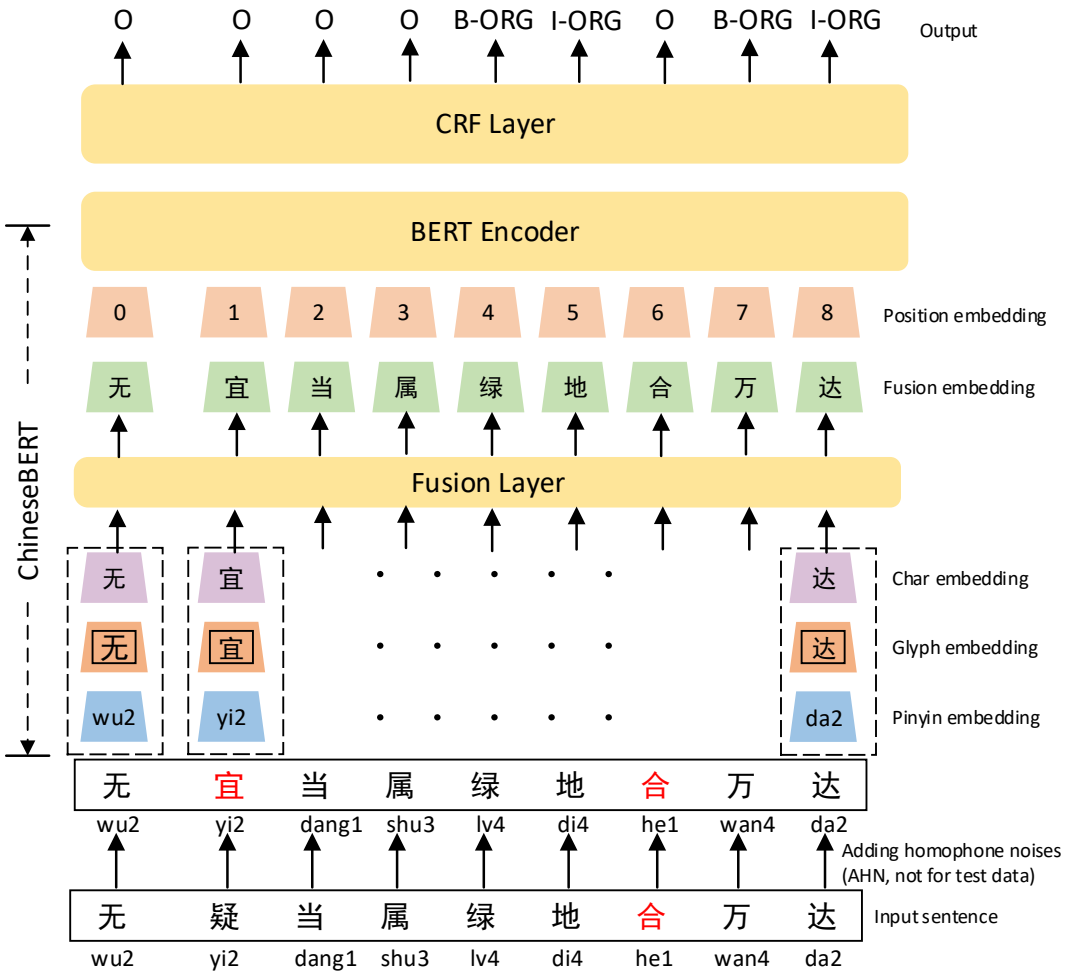

Fig. 3. NER tagger model architecture with three components AHN (adding homophone noises), ChineseBERT and CRF.

noises, we introduce homophone noises[2] into the training data to improve the robustness of the NER tagger.

To verify the effectiveness of our method, we adopt the classical ASR architecture Conformer [8] and NER architecture BERT-CRF where BERT is replaced by ChineseBERT, and test the two-step pipeline method by adding homophone noises (AHN) on the AISHELL-NER dataset [6], which is publicly available for NER from Chinese speech with three Named Entity (NE) categories (PER, LOC and ORG). Experimental results demonstrate that the $F1$ score is improved by nearly 1% absolute points (a significant improvement in the field of NER) with *pinyin* and outperforms the SOTA result in [6] by 0.4% absolute points (despite the slightly worse CER of our ASR outputs), as illustrated in Fig. 2.

Our contributions are summarized as follows:

- To the best of our knowledge, we are the first to propose to use *pinyin* for NER from Chinese speech.
- Besides the off-the-shelf pinyin embedding method, we propose to introduce the homophone noises into the NER training data to make better use of pinyin.
- By using pinyin information, our two-step pipeline method outperforms the best result on the dataset AISHELL-NER by 0.4% absolute points in $F1$ score.

II. Related Work

NER from speech could be divided into two categories [4]–[6], i.e., two-step pipeline approach and E2E approach.

The two-step pipeline approach consists of processing the given audio on an ASR system and then feeding the transcribed ASR outputs to the NER tagger, as illustrated in Fig. 1. Although ASR and NER have been well studied in their respective fields [8]–[12], there is little research on how to better combine ASR and NER for better results.

[2]Homophone errors are very common in Chinese ASR output because a great number of Chinese characters have the same pronunciation but different written forms.

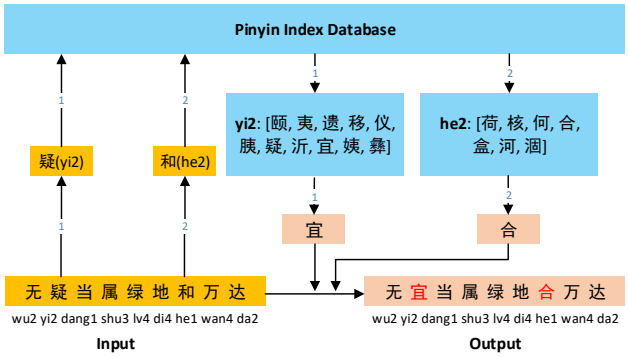

Fig. 4. Example of adding homophone noises for a Chinese sentence: the two characters 宜 (yi2) and 帝 (di4) are used to replace the two selected characters 疑 (yi2) and 地 (di4) to add homophone noises.

Lately, the E2E approach for NER from French [4], English [5] and Chinese [6], [12] speech has been proposed. Entity-aware ASR (EA-ASR) is adopted to predict NEs during the decoding process, where special tokens are added to the ASR vocabulary list to annotate NEs in the transcriptions, such as [] for PER, () for LOC, and <> for ORG. However, this method requires annotating new datasets where new NE types or new languages are introduced, and cannot directly use the existing annotation data for ASR and NER. More importantly, it is pointed out in [6] that the two-step pipeline approach gets better results than the E2E approach for NER from Chinese speech.

III. Methodology

As illustrated in Fig. 1, the two-step pipeline method (ASR + NER Tagger) is used in this paper, and the details are described as follows.

A. ASR

E2E ASR systems based on neural networks have seen large improvements in recent years. Since Transformer and Convolution Neural Network (CNN)-based model are more promising than RNN/LSMT for ASR on various corpora [13], [14], we build the ASR components with convolution-augmented Transformer-based encoder-decoder architecture [8], which has achieved SOTA accuracy in a list of benchmark datasets such as LibriSpeech. The encoder is enhanced with Convolution Neural Network (CNN), namely, Conformer [8], which maps the input sequence of audio features to a sequence of hidden states by a convolution subsampling layer and a number of conformer blocks. A conformer block is composed of four modules stacked together, i.e, a feed-forward module, a self-attention module, a convolution module, and a second feed-forward module at the end. The decoding process is enhanced with the joint CTC/attention approach and the Transformer-based Language Model (LM).

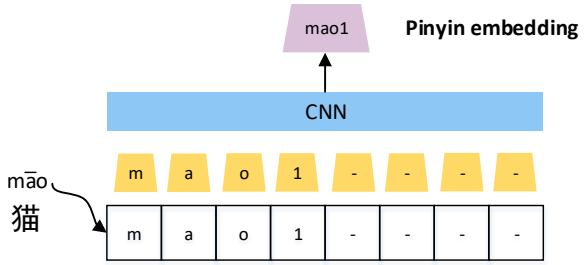

Fig. 5. Example for inducing the pinyin embedding of Chinese character 猫 (cat) with pinyin mao1 (a CNN with width 2 is applied to the sequence of Romanized pinyin letters, followed by max-pooling to derive the final pinyin embedding) [7].

B. NER Tagger

The NER tagger model architecture is illustrated in Fig. 3, which consists of three components: AHN (adding homophone noises), ChineseBERT, and CRF.

1) AHN: First, we generate a pinyin index database for 3,500 common Chinese characters[3] with the open-source pypinyin[4] package. For each entry in the database, its key is a pinyin, and its value is a list of Chinese characters with the same pinyin as the key. Fig. 4 shows two such entries with key values yi2[5] and he2[5] and with the corresponding value lists [颐, 夷, 遗, 移, 仪, 胰, 疑, 沂, 宜, 姨, 彝] and [荷, 核, 何, 合, 盒, 河, 涸]. The pinyin for the characters in the first list is yi2, and that for those in the second list is he2.

Second, we randomly select characters from a given sentence with a specified probability, and search the pinyin index database with the pinyin of the selected characters. Then, for each selected character, it will be replaced by a random selection from the searched entry value. So we achieve the addition of homophone noises in the given sentence. Fig. 4 provides an example for this process: the two characters 疑 and 和 are randomly selected from the given sentence, and are replaced by the two characters 宜 and 合 from the two entries with key values yi2 and he2. Since the two Chinese characters (宜 and 和) have the same pinyin as but different written forms from the two characters (疑 and 合), the homophone noises are successfully added for the given sentence, i.e., from input 无疑当属绿地和万达 to output 无宜当属绿地合万达.

It should be pointed out that the characters in NEs of the given sentence need not be selected for AHN, since homophonic NEs are not considered correct. And it should be noted that AHN is only used for training and development data, not for test data.

2) ChineseBERT: ChineseBERT is a pretrained Chinese language model which incorporates both glyph and pinyin embeddings of Chinese characters into model training [7]. The

[3]https://github.com/kaienfr/Font/tree/master/learnfiles
[4]https://pypi.org/project/pypinyin/
[5]2 denotes the second tone used in pinyin.

TABLE I
STATISTICS OF AISHELL-NER

	# Sentence	w/ NE	# PER	# LOC	# ORG
Train	120,098	40,839	15,842	20,693	21,455
Dev	14,326	5,173	1,902	2,588	2,731
Test	7,176	2,376	898	1,330	1,165

TABLE II
CER (%) OF CONFORMER ASR

CER (%)	Dev	Test
Conformer ASR (our)	4.59	4.99
Conformer ASR [6]	4.42	4.75

TABLE III
CER (%) ON THE SENTENCES WITH AND WITHOUT NES

	Number	CER (%)
Sentences with NEs	2,376	6.73
Sentences without NEs	4,800	4.02

glyph embedding is obtained based on different fonts of a Chinese character, and the pinyin embedding is obtained by a CNN model with width 2 on the pinyin sequence of a Chinese character. Fig. 5 provides a pinyin embedding example for Chinese character 猫 (cat) with pinyin `mao1`.

As illustrated in Fig. 3, for each Chinese character, its char embedding, glyph embedding and pinyin embedding are first concatenated, and then mapped to a D-dimensional embedding through a fully connected layer to form the fusion embedding. The fusion embedding is then added with the position embedding, which is fed as input to the BERT model.

As it is common that a character in Chinese ASR outputs is wrong but its pinyin is correct, we use ChineseBERT as the encoder for our NER tagger to improve its robustness.

3) CRF: Conditional Random Field (CRF) [15] is very effective for NER in both statistical machine learning and deep learning. Therefore, after obtaining all the character representations from ChineseBERT for a given sentence, we feed the representations into a CRF output layer, which can be seen as a char-level classifier over the NER label set.

IV. EXPERIMENTS

In this section, we evaluate the performance of our two-step pipeline method for NER from Chinese speech.

A. Experimental Setup

All the experiments are carried out on AISHELL-NER [6] dataset[6], which is built upon the open-source Chinese speech corpus AISHELL-1 [16] (150 hours training set, 10 hours development set and 5 hours test set). Table I gives the numbers of sentences that contain NEs and the detailed statistics of NE numbers for each category in AISHELL-NER.

The Conformer ASR model is built with WeNet [17] and makes use of both the joint CTC/attention decoding and LM. The parameter settings are same with [6]. The encoders have 4 attention heads with 2048 linear units. They stack 12 layers of encoder blocks, and their output size is 256. The decoders use the same configuration, except that they have only 6 layers. SpecAugment is used to randomly apply time and frequency masking blocks to log mel-filterbank features. Speed perturbation with factors of 0.9, 1.0 and 1.1 is also applied to Conformer, resulting in 3-fold data augmentation. The CNN module of the Conformer encoder uses a kernel size of 15. These ASR models are trained with the Adam optimizer, with the learning rate set to 0.0005 and a linear warmup scheduler. During decoding, the width of the beam search is set to 5.

TABLE IV
NER RESULTS FOR AISHELL-NER

		Precision	Recall	$F1$
Ground-Truth Text	BERT-CRF	**94.45**	**93.75**	**94.10**
Best result in [6]		75.54	74.27	74.90
Conformer ASR	BERT-CRF	74.77	74.08	74.42
Conformer ASR	+ChineseBERT	74.54	**74.76**	74.65
Conformer ASR	+AHN	**75.97**	74.64	**75.30**

The NER tagger ChineseBERT-CRF is trained on the BIO formatted text with AHN (the probability of AHN for each character is set to 0.05). ChineseBERT-base[7] (12 layers of 12 attention heads and the hidden size of 768) is selected for experiment. We also train two NER taggers ChineseBERT-CRF and BERT-base-CRF without AHN for comparison. The three NER taggers are optimized by AdamW [18], with the learning rate set to 0.00003 and a linear warmup scheduler. The training epoch number is set to 5, and the batch size is set to 64.

In addition, the results of the pipeline approach in [6] are chosen for comparison with our method.

Similar to the works [4]–[6], we choose the commonly used metrics Character Error Rate (CER) [19] and $F1$ score [20] to evaluate ASR and NER respectively.

B. ASR Results

The results of CER of our ASR model Conformer on dev and test datasets are reported in Table II, and the results from [6] are listed for comparison. From Table II, it could be seen that under the same model and parameter configuration, our results are very close (only slightly worse) to [6]. Therefore, the output of our ASR is reliable for the NER tagger.

In addition, we report the CER of the sentences with and without NEs from the test dataset in Table III. It could be seen that the CER of sentences without NEs are much smaller than that of sentences with NEs (4.02 vs. 6.73), which indicates that it is more difficult to correctly identify NEs in ASR and entity correction is very necessary after ASR.

C. NER Results

For the two-step pipeline method, the ASR model outputs the speech transcriptions, and then the NER tagger predicts the NEs. Table IV provides the results (*precision*, *recall*, and $F1$ *score*) of the three NER taggers (BERT-CRF, ChineseBERT-CRF with or without AHN) on the outputs of our Conformer

[6]https://github.com/Alibaba-NLP/AISHELL-NER

TABLE V
MAXIMUM RECALL RATES OF DIFFERENT NE CATEGORIES FOR NER MODELS FROM OUR ASR RESULTS

NE Categories	Total	Correct	Maximum Recall
PER	898	501	55.79
LOC	1,330	1,175	88.35
ORG	1,165	978	83.95
ALL	3,393	2,654	78.22

TABLE VI
RESULTS IN DIFFERENT NE CATEGORIES

		Precision	Recall	$F1$
Ground-Truth Text	PER	95.61	94.65	95.13
+	LOC	94.88	96.17	95.52
BERT-CRF	ORG	93.02	90.30	91.64
Conformer ASR	PER	56.80	53.51	55.11
+	LOC	83.16	85.25	84.19
ChineseBERT-CRF-AHN	ORG	81.79	78.97	80.35

ASR. Meanwhile, the results of BERT-CRF on ground-truth text and the best results in [6] are also included.

In Table IV, the result of the NER tagger BERT-CRF on the ground-truth text is much better than that on the ASR output. This is because the errors in ASR output affect the NER. And it could be seen that ChineseBERT is slightly better ($F1$ score 74.65 vs. 74.42) than BERT for NER from the ASR output, which indicates that pinyin embedding is useful for NER. And when AHN is introduced to train the NER tagger, the improvement gets a very significant boost ($F1$ score from 74.65 to 75.30). Therefore, by incorporating *pinyin* into the NER tagger, the $F1$ score could be improved by nearly 1% absolute points ($0.88\% = 75.30\% - 74.42\%$), which is a significant improvement in the field of NER. And when compared with the current SOTA results in [6], although the CER of our ASR is slightly worse than [6] (CER 4.99 vs. 4.75), our NER tagger could still get a better result ($F1$ score 75.30 vs. 74.90).

In a word, from the above comparison results, pinyin is indeed beneficial to NER from Chinese speech.

In addition, we report the maximum recall rates of different NE categories from our ASR outputs of the test dataset in Table V, where "Correct" represents the number of correctly identified NEs in ASR outputs and "Total" represents the number of NEs in ground-truth text. The recall rates are calculated by "Correct/Total", which are the theoretical maximum recall for NER models. From Table V, the recall rate for PER is the lowest (55.79%). This is because there are a lot of homophones and polyphones in Chinese, especially for person names. For example, the PER NE 姚明 (`yao2 ming2`) has the same pronunciation and same pinyin as the PER NE 姚鸣 (`yao2 ming2`), which makes ASR really hard to recognize the correct PER NE from Chinese speech.

We also report the results of different NE categories for NER models on ground-truth text and ASR outputs in Table VI. Although the results on ASR outputs significantly lag behind those on ground-truth text, especially in the PER category, their recall rates are close to the recall rates in Table V (53.51% vs. 55.79% for PER, 85.25% vs. 88.35% for LOC, and 78.97% vs. 83.95% for ORG). This shows that our pipeline method is very effective for NER from Chinese speech and further improvement of NER requires entity correction to break the recall bottlenecks.

TABLE VII
NER RESULTS FOR DIFFERENT AHN PROBABILITIES

AHN Probability	Precision	Recall	$F1$
0.00	74.54	**74.76**	74.65
0.05	**75.97**	74.64	**75.30**
0.10	74.93	74.11	74.52
0.15	74.92	73.55	74.23

D. Parameter Study

In this section, we study the probability parameter of AHN for each character. Four NER taggers with the architecture ChineseBERT-CRF are trained with the AHN probability varying from 0 to 0.15 (with step 0.05). The results of the four NER taggers on the same ASR output of AISHELL-NER test data are shown in Table VII.

From Table VII, it could be seen that the $F1$ score is the best when the probability of AHN takes the value 0.05, which is very close to the CER of ASR (4.99%). We guess that the error distributions of the training and test datasets for NER taggers are very consistent in this probability setting, so that the results of NER are the best. Therefore, it could be a good choice if the AHN probability for NER tagger takes the CER value of ASR.

E. Discussion

Essentially, incorporating *pinyin* into pipeline NER from Chinese speech is a data argumentation method for NER tagger, which tries to make training data and test data consistent in error distribution by introducing AHN.

A straightforward method is to train or fine-tune NER tagger by using the text of ASR output, which could also make the NER tagger robust. However, when this way is adopted, additional annotated NER data (namely, NE-tagged ASR outputs) is required to train or fine-tune the NER tagger so as to keep the CER consistent with that obtained using testing data. Furthermore, when the ASR model is upgraded, new training data needs to be annotated to retrain the NER model, which is costly.

In contrast, when homophone noises (independent of ASR outputs) are used, the training data for the ASR model can be used to train the NER model, not requiring additional annotated NER data. And when the ASR model is upgraded, we only need to tune the noise hyper-parameter according to the CER of the ASR model to retrain the NER model, during which additional annotated NER data is not required either.

In a word, using homograph noises is much more economic than using the text of ASR output.

V. CONCLUSION

In this paper, an important information *pinyin* of Chinese character is introduced to the two-step pipeline method (ASR

+ NER Tagger) for NER from Chinese speech. The pretrained model ChineseBERT is used to embed the pinyin to the input of an NER tagger, and the homophone noises are introduced to the training data of NER tagger. From the comparison results on the AISHELL-NER dataset for NER from Chinese speech, the $F1$ score of the NER tagger with architecture BERT-CRF could be improved by nearly 1% absolute points (a significant improvement in the field of NER), and the $F1$ score of our method outperforms the current SOTA result by 0.4% absolute points despite the slightly worse CER of our ASR. In addition, the choice for the AHN probability is discussed.

***Abstract*—End-to-end speech translation (ST) directly translates the source speech to the target text, following a typical encoder-decoder framework. However, it has shown that the conventional ST encoder is mainly used to extract long but locally attentive acoustic features, which may lead to a lack of global semantic features. In this work, we therefore propose to integrate a semantic decoder into the speech translation (SD-ST) model, where the semantic decoder can generate text-like features with more global semantic information analogously to the machine translation system (MT). We also investigate different strategies to ensure length consistency between text-like features and text sequences. Experimental results show that the proposed SD-ST model achieves the best BLEU score on the 40-hour subset of the Fisher Spanish English dataset and a comparable BLEU score on the MuST-C dataset. Furthermore, it is shown that the SD-ST model can even perform zero-shot ST.**

Index Terms: End-to-end speech translation, semantic information, encoder-decoder, speech recognition.

I. Introduction

Speech translation (ST) aims to translate speech in the source language to text in the target language. Conventional ST systems usually follow a cascaded paradigm consisting of two subtasks: automatic speech recognition (ASR) and machine translation (MT) [1]. This cascaded model in principle suffers from error propagation and latency problems [2]. Recently, many end-to-end ST approaches have been proposed to tackle these problems [3]–[5], which can be considered as a joint task of ASR and MT. However, the end-to-end ST methods suffer from the scarcity of paired speech and text data [6]. Traditional pre-training methods use a large amount of paired data to train ASR and MT models, then separately initialize the ST encoder and decoder and finally fine-tune the ST model with a small amount of parallel data [7]–[9]. However, this encoder-decoder structure cannot learn sufficient semantic information or reorder feature sequences, which are required for practical translation applications [10], [11].

This study defines semantic information as the relationship between words and the meanings of sentences. Therefore, the semantic information is mainly conveyed through text and learned by the MT model. To improve the modelling capacity of global semantic information, the MT encoder can be integrated into the ST model, such that the ST is decomposed into two subtasks: ASR and MT. For example, in [11], [12], the MT encoder is placed between the ST encoder and decoder, where [11] uses an adapter and [12] shares weights between the CTC classification layer and the embedding layer to maintain semantic consistency. In [13]–[15], an external model is additionally used to extract semantic and contextual information. Although the MT-integrated ST methods show the superiority over conventional encoder-decoder based counterparts, there exist two major limitations. 1) **Limited semantic information**: The learned semantic information is rather limited even if the acoustic features are further processed by the pre-trained MT encoder. This is because the desired input to the MT encoder are text sequences that are significantly different from the acoustic feature sequences, leading to a bias in the acquisition of semantic features. On the other hand, the semantic modeling module is insufficiently constrained when fine-tuning, which might forget or lose the original semantic information. 2) **Length inconsistency**: The acoustic feature sequences contain too much redundant information, and the sequence length is much longer than that of the text sequence [16]. This inconsistency makes it difficult to learn the alignment relation between the pre-trained decoder and encoder.

In this work, we propose to use a semantic decoder to generate text-like feature sequences, which are shown to be more fruitful in terms of semantic information and can ensure the consistency between feature and text lengths. We first train an MT model and regard the hidden-layer features therein as text features. Then, we build a semantic decoder that uses the attention mechanism to search for similar pronunciation units and aggregates acoustic features based on the text features. Further, we compute the L_1 loss at the token level between the aggregated acoustic and text features to generate text-like features. Finally, the text-like features are constructed as a sequence, which turns out to match the text sequence from the perspective of length. Experimental analysis shows that the generated text-like feature sequences can not only preserve sufficient acoustic information for ASR, but also contain more semantic information that is beneficial for ST. Our experimental results show that the proposed model achieves the best BLEU score on the 40-hour subset of the Fisher Spanish English dataset. On the MuST-C En-De dataset, the proposed model achieves a BLEU score comparable to previous baselines and it also shows the applicability to zero-shot speech translation.

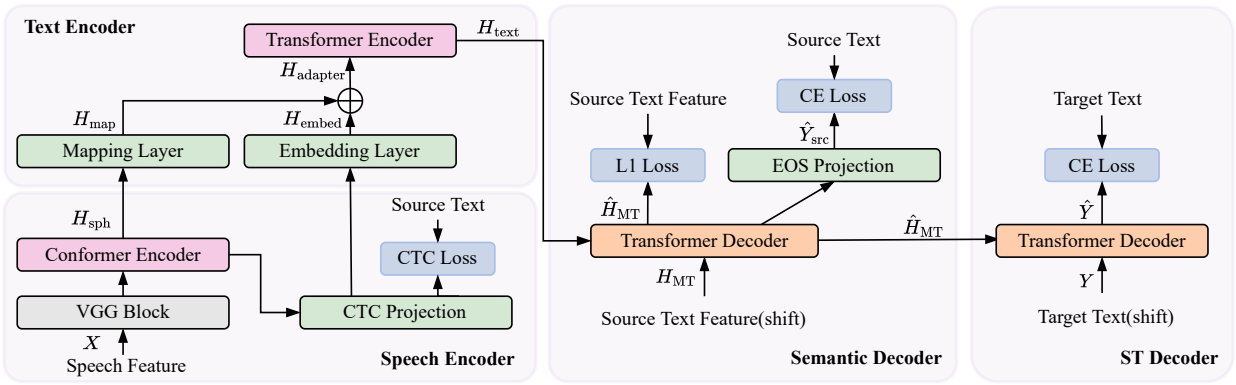

Fig. 1. The overview of the proposed SD-ST model, which reduces to the SATE model with a removal of the semantic decoder and becomes identical to the E2E-ST model by removing both the text encoder and semantic decoder.

II. Preliminaries

In this section, we will present two classic ST models: E2E-ST and SATE, which are the basis of the proposed method.

A. End-to-end speech translation (E2E-ST)

The conventional end-to-end ST model can be built by combining the speech encoder and ST decoder modules. The speech encoder extracts the acoustic feature $H_{\text{sph}} = \{h_1, h_2, ..., h_N\}$ from the raw speech feature sequence $X = \{x_1, x_2, ..., x_U\}$, where U and N denote the lengths of the speech feature and extracted acoustic feature, respectively, i.e.,

$$H_{\text{sph}} = \text{Enc}_{\text{sph}}(X), \tag{1}$$

Based on the hidden feature H_{sph} and the text sequence $Y = \{y_1, y_2, ..., y_M\}$ in the target language, the ST decoder generates the translation result $\hat{Y} = \{\hat{y}_1, \hat{y}_2, ..., \hat{y}_M\}$, where M denotes the length of the text sequence in target language. The training objective can be the cross entropy between the translation result and the true text, given by

$$L_{\text{E2E-ST}} = -\log P(\hat{Y}|Y, H_{\text{sph}}, \theta^{\text{sph}}_{\text{enc}}, \theta^{\text{ST}}_{\text{dec}}), \tag{2}$$

where $\theta^{\text{sph}}_{\text{enc}}$ and $\theta^{\text{ST}}_{\text{dec}}$ are trainable parameters of the speech encoder and ST decoder, respectively. From the viewpoint of multi-task learning, ASR can be included as an auxiliary training task, e.g., by adding an additional ASR decoder to minimize the cross entropy loss [17], [18] or the CTC loss L_{CTC} [19]. The resulting training loss function for joint ASR and ST can thus be written as

$$L = \lambda \cdot L_{\text{CTC}} + (1 - \lambda) \cdot L_{\text{E2E-ST}}, \tag{3}$$

where λ is the balancing weight.

B. Stacked acoustic-and-textual encoding (SATE)

In order to address the lack of semantic learning capability of the E2E-ST model, the SATE [11] model stacks the speech encoder and text encoder to encode acoustic and semantic information from raw speech features. The SATE model uses an adapter architecture to fit the output of the speech encoder to the expected input of the text encoder, which is given by

$$H_{\text{adapter}} = H_{\text{map}} + H_{\text{embed}}, \tag{4}$$

where

$$H_{\text{map}} = \text{ReLU}(W^{\text{map}} \cdot H_{\text{sph}} + b^{\text{map}}), \tag{5}$$

$$H_{\text{embed}} = W^{\text{embed}} \cdot P_{\text{ctc}}, \tag{6}$$

$$P_{\text{ctc}} = \text{Softmax}(W^{\text{ctc}} \cdot H_{\text{sph}} + b^{\text{ctc}}), \tag{7}$$

where W^{map}, W^{ctc}, W^{embed}, b^{map}, b^{ctc} are the parameters for the mapping layer, the CTC projection layer, and the embedding layer, respectively. Then the text encoder is used to generate a representation for translation, i.e.,

$$H_{\text{text}} = \text{Enc}_{\text{text}}(H_{\text{adapter}}), \tag{8}$$

and the training objective functions for the entire model are similar to E2E-ST. The parameters of the text encoder Enc_{text} can be initialized using off-the-shelf pre-trained MT encoders, which enables the text encoder to generate features containing semantic information. However, the semantic modeling capability would be rather limited due to the catastrophic forgetting in the absence of external supervision. Moreover, there might exist an inconsistency between the sequence lengths of the features generated by the text encoder and the desired feature for the ST decoder.

III. Semantic decoder based E2E-ST

In order to enhance the semantic modeling capability for ST, in this section we propose a semantic decoder based E2E-ST model as shown in Fig.1 consisting of four modules, i.e., speech encoder, text encoder, semantic decoder and ST decoder.

A. Semantic decoder module

The purpose of the semantic decoder module is to refine the semantic information and remove redundant noisy information. As shown in Fig.1, the semantic decoder is composed of several transformer layers and an optional projection layer

which is used to predict the end of the sentence. During training, the input to the semantic decoder is the text feature H_{MT}, which is encoded by the pre-trained MT model as

$$H_{\mathrm{MT}} = \mathrm{Enc}_{\mathrm{MT}}(Y^{\mathrm{src}}), \tag{9}$$

where $Y^{\mathrm{src}} = \{y_1^{\mathrm{src}}, y_2^{\mathrm{src}}, ..., y_V^{\mathrm{src}}\}$ is the text in the source language at a length of V and $H_{\mathrm{MT}} = \{h_1^{\mathrm{mt}}, h_2^{\mathrm{mt}}, ..., h_V^{\mathrm{mt}}\}$. The semantic decoder predicts the text-like features using H_{MT} and H_{text} and then computes the L_1 loss at the token level as

$$\hat{H}_{\mathrm{MT}} = \mathrm{Dec}_{\mathrm{semantic}}(H_{\mathrm{MT}}, H_{\mathrm{text}}), \tag{10}$$

$$L_{\mathrm{semantic}} = \frac{1}{V}\sum_{i}^{V}\left|\hat{h}_i^{\mathrm{mt}} - h_i^{\mathrm{mt}}\right|, \tag{11}$$

where $\hat{H}_{\mathrm{MT}}$ is generated in a teacher-forcing fashion when training and $\hat{H}_{\mathrm{MT}} = \{\hat{h}_1^{\mathrm{mt}}, \hat{h}_2^{\mathrm{mt}}, ..., \hat{h}_V^{\mathrm{mt}}\}$.

B. EOS prediction

The semantic decoder generates text-like features in an autoregressive way when decoding, so the exact position of the end of sentence (EOS) needs to be predicted. An inaccurate EOS position would cause the loss of useful features or redundant information contained in the generated features. For this, we consider two EOS prediction methods in this section.

Direct prediction: Let at step t of decoding the feature predicted by the semantic decoder be represented by $\hat{h}_t^{\mathrm{mt}}$. We directly normalize $\hat{h}_t^{\mathrm{mt}}$ and determine the index corresponding to the largest value as the EOS position, i.e.,

$$EOS_{\mathrm{pos}} = \mathrm{argmax}(\mathrm{Softmax}(\hat{h}_i^{mt})). \tag{12}$$

Projection network prediction: Inspired by the text-to-speech method [20], we use a single-layer projection network to project the text-like features into the dictionary space of the source language. The projection network is shown on the top of the semantic decoder module in Fig.1. We believe that it helps the text-like feature retain links to the source text. Specifically, the decoding steps of the semantic decoder will be completed in case the text-like feature is projected as an EOS token, i.e.,

$$P_t^{\mathrm{src}} = \mathrm{Softmax}(\mathrm{Proj}_{\mathrm{eos}}(\hat{h}_t^{\mathrm{mt}})), \tag{13}$$

$$EOS_{\mathrm{pos}} = \mathrm{argmax}(P_t^{\mathrm{src}}), \tag{14}$$

where $\mathrm{Proj}_{\mathrm{eos}}$ is the EOS projection network and P_t^{src} is the probability distribution at step t of decoding. The training objective is to minimize the cross-entropy loss between the predicted token and the text in the source language, given by

$$L_{\mathrm{eos}} = -\log(P_t^{\mathrm{src}}|\theta_{\mathrm{dec}}^{\mathrm{semantic}}). \tag{15}$$

C. Loss function

The proposed SD-ST model generates translation sequences using the text-like features $\hat{H}_{\mathrm{MT}}$ and is optimized by minimizing the cross-entropy loss, which is given by

$$L_{\mathrm{SD-ST}} = -\log P(\hat{Y}|Y, \hat{H}_{\mathrm{MT}}, \theta_{\mathrm{enc}}^{\mathrm{ST}}, \theta_{\mathrm{dec}}^{\mathrm{semantic}}, \theta_{\mathrm{dec}}^{\mathrm{ST}}), \tag{16}$$

where $\theta_{\mathrm{enc}}^{\mathrm{ST}}$ represents the parameter set for the speech and text encoders. The proposed SD-ST model is trained in a multi-task form, where the objective function can be formulated similarly to (3) as

$$\begin{aligned} L = \lambda \cdot L_{\mathrm{CTC}} + \alpha \cdot L_{\mathrm{semantic}} + \beta \cdot L_{\mathrm{eos}} \\ + (1 - \lambda - \alpha - \beta) \cdot L_{\mathrm{SD-ST}}, \end{aligned} \tag{17}$$

where λ, α, β are set to tradeoff the ASR-related CTC, semantic decoder and EOS prediction losses.

IV. Experiments

A. Experimental setup

The experiments are conducted on two often-used ST datasets, e.g., the Fisher Spanish-English (Es-En) dataset[1] [21] and MuST-C dataset [22]. For the Fisher Es-En dataset, we select the same 40 hours of speech as in [23]. For the MuST-C dataset, we select the English-German (En-De) language pair, which contains 408 hours of speech. We add external 18M sentence pairs from Opensubtitle2018[2] En-De translation dataset to the MuST-C experiment. For evaluation, we use the standard Fisher dev, Fisher dev2 and Fisher test sets in Fisher Es-En language pair, and use tst-COMMON set in MuST-C En-De language pair. The data pre-processing and model configuration keep the same for both datasets.

The ESPnet toolkit [24] is used to pre-process the data. We consider the 80-dimensional log-Mel filterbank coefficients and 3-dimensional pitches as the speech features, which are normalized using the mean and variance. The utterances that have more than 3000 frames or 400 words are removed. The speech data are augmented by applying speed perturbations with factors of 0.9 and 1.1 and the SpecAugment technique [25]. For text data, we tokenize the bilingual text and use Sentencepeice[3] to learn a joint source and target subword vocabulary. The vocabulary size is 1000 for Fisher Es-En language pair and 8000 for MuST-C En-De language pair.

The model configuration and hyper-parameters keep the default settings of "fisher callhome Spanish" recipe in ESPnet [24] (version 202205). The speech encoder is a 12-layer conformer with 2 additional VGG convolution blocks, and the text encoder, semantic decoder, and ST decoder each contain a 6-layer transformer, respectively. The self-attention module comprises 256 hidden units, 4 attention heads, and the FFN module has 2048 hidden units. The dropout and label-smoothing rates are set to be 0.1. The models are optimized using the Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and the inverse square root learning rate schedule.

The model training involves two phases: 1) training the speech encoder, the text encoder and the semantic decoder modules, where the speech and text encoders are initialized by ASR and MT models, respectively, and 2) training the entire SD-ST model, where the model parameters from the first stage are used for initialization except that the ST decoder is initialized by the MT model. During inference, the semantic

SD-ST-Large	-	173	**27.9**

TABLE III
THE BLEU SCORES ON FISHER DEV/DEV2/TEST SETS WITHOUT THE EOS PROJECTION NETWORK OR THE SEMANTIC DECODER MODULE.

Model	Params(M)	dev	dev2	test
SD-ST	60.5	38	39.2	38.4
- EOS projection network	60.3	37.2	38.4	37.4
- Semantic Decoder	50.5	36.4	37.7	36.3

decoder generates text-like features in an autoregressive way and predicts the EOS position. Then, the ST decoder generates translation results based on text-like features with a beam size of 10. We report 4-references case-insensitive detokenized BLEU score on Fisher dev/dev2/test sets and 1-reference case-sensitive detokenized BLEU score on MuST-C En-De tst-COMMON set.

B. Experimental results

First, we show the ST performance in Fig. 2 in terms of hyper-parameters, where $\lambda \in \{0.1, 0.2, 0.3\}$, $\alpha \in \{0.1, 0.2, 0.3, 0.4, 0.5\}$ and $\beta = 0.1$. The parameter ranges are chosen based on pre-experiments. It is clear that the choice of $\{\lambda = 0.2, \alpha = 0.1, \beta = 0.1\}$ can result in a better BLEU score, which is thus used for the following experiments on both Fisher Es-En and MuST-C En-De datasets. Table I shows the

TABLE IV
THE WERS AND LENGTH GAP ON FISHER DEV, WHERE WER OF ASR-CTC IS CALCULATED BY REMOVING THE BLANK AND REPEATED SYMBOLS IN THE PREDICTED SEQUENCES.

Model	Beam	WER	Length gap
ASR-ED[24]	1	32.9	1.31
ASR-ED[24]	5	32.1	1.31
ASR-CTC[24]	-	34.3	1.52
SD-ST	1	33	1.34

translation performance of the SD-ST model on Fisher Es-En dataset in comparison to other baseline methods. It is clear that the proposed SD-ST model outperforms the best published approach (i.e., Phone [26]) and improves the BLEU scores by 3.5 and 5.4 on Fisher dev and test sets, respectively. Note that the Phone method [26] uses the LSTM network as the backbone, resulting in less parameters. To be fair, the E2E-ST, E2E-ST-Large[4] and SATE models are also compared, which are trained using the same experimental configuration and have a comparable model size as the SD-ST model. The results show that our method still outperforms the E2E-ST, E2E-ST-Large and SATE models and achieves the best performance on the Fisher Es-En dataset.

Table II shows the translation performance of the SD-ST model on MuST-C En-De dataset in comparison to previous methods that can enhance the semantic information for ST. It is clear that our SD-ST model achieves a BLEU score of 27.2 which is comparable to previous methods, while we use fewer model parameters and speech data. Further, our SD-ST-Large[5] model achieves 27.9 BLEU score. Moreover, we try to use only the paired speech and text data of the source language for one-stage model training mentioned in Section IV-A, and then initialize the ST decoder of the SD-ST model with pre-trained MT decoder, i.e., zero-shot inference. As shown in Table II, our zero-shot SD-ST model achieves a BLEU score of 21.5, implying a potential in the zero-shot case.

In order to analyze the impact of the semantic decoder and the EOS projection network, we evaluate the performance of the proposed SD-ST model with a removal of each module in Table III. We can see that both the semantic decoder and the EOS projection network are indispensable functional modules that can effectively improve the BLEU scores. For

[4]The E2E-ST-Large model has an 18-layer Conformer module.
[5]The SD-ST-Large model has hidden size of 512 and 8 heads in attention module.

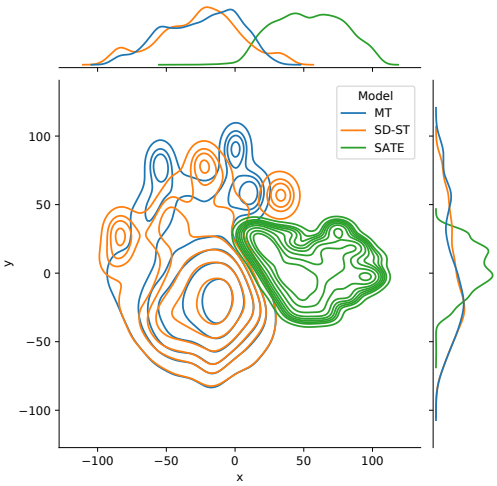

Fig. 3. Bivariate KDE contour plot of features generated by MT, SD-ST and SATE (SD-ST without the semantic decoder).

the prediction of EOS positions, the direct prediction (i.e., removing the EOS projection network) performs worse than the EOS projection network, which reveals the necessity of the proposed EOS projection method.

Further, in order to analyze the impact of the proposed semantic decoder module on the issues of limited semantic information and inconsistent length, similarly to [29] we use t-SNE[30] to compress the high-dimensional features into a 2-dimensional space. Then we show the bivariate kernel density estimates [31] (KDE) contours to visualize different features in Fig.3, where the average-pooling over the dimension of time is applied on the features. It is clear that the features generated by the MT encoder overlap with those generated by the semantic decoder of SD-ST, while they are further away from those generated by the text encoder of SATE. This implies that the semantic decoder is beneficial for generating text-like features that are rich in semantic information. In addition, with the EOS projection network in the semantic decoder, we can predict the text sequence in the source language and then compute the WER. Table IV shows that the WER calculated using the output of the semantic decoder module is comparable to the WER of the general ASR models that are trained based on default settings of ESPnet. Moreover, we calculate the length gap which measures the difference between the length of the text sequence and that of the feature or token sequence generated by each model (the length gap is averaged at sentence level). We can see that length gap of the SD-ST model is only around 1 token (subword) and comparable to ASR models that are used for the cascaded ST. We can therefore conclude that the text-like features generated by the semantic decoder not only retain sufficient acoustic and semantic information, but also maintain length consistency with the text sequence.

V. Conclusion

In this paper, we proposed a speech translation model called SD-ST, which uses a semantic decoder to generate text-like features that are rich in semantic information. The text-like features can be converted to a textual sequence as well, which is comparable to the ASR models in terms of WER. Consequently, ASR can be seen as a by-product of the proposed model. It was shown that the text-like features can preserve sufficient acoustic/semantic information and maintain length consistency with the text sequences. The semantic decoder proposed in this paper can be further investigated in future work to enhance the robustness of its text-like features to improve the translation performance in different scenarios.

***Abstract*—Tibetan is a distinctive and culturally rich language spoken by millions of people across the Tibetan Plateau and surrounding regions. Exploring the application of speech recognition technology to Tibetan has special significance for preserving language diversity and fostering cultural integration. Moreover, Tibetan comprises a multitude of distinct dialects, which present a hurdle for reusing speech recognition models. In low-resource dialect tasks, conventional approaches endeavor to transfer well-trained models from linguistically akin languages to the target. However, recent studies have shown that an indiscriminate fine-tuning of all parameters may disrupt the feature extractor of the pre-trained model, leading to catastrophic forgetting. This paper introduces an innovative fine-tuning method grounded in model adaptation. Aimed at training automatic speech recognition (ASR) models within the constraints of limited training data and cross-dialect transfer, our novel approach refines a select group of language-specific parameters, leading to robust performance. These parameters, signified by a sparse binary mask identical to the model, circumvent the need for additional parameters. Experiments conducted on two downstream low-resource Tibetan languages show that our proposed methodology outperforms the traditional fine-tuning and adapter based fine-tuning.**

I. Introduction

Influenced by history and geography, Tibetan has gradually evolved various dialects and accents, and it is widely believed that there are more than twenty different spoken forms. Generally speaking, there are three main dialects of Tibetan language: Amdo Tibetan, Khampa Tibetan, and U-Gtsang Tibetan. Due to the linguistic diversity of Tibetan and the problem of limited data, the application of Tibetan speech recognition technology trails behind [1], [2].

Automatic Speech Recognition (ASR) has made remarkable progress with the development of deep learning. Transformer-based [3]–[5] models greatly benefit from a large number of training parameters. Despite this, in scenarios where data resources are restricted, the potential for enhancements remains somewhat hampered. For some low-resource languages, fine-tuning speech recognition models trained on other dialects within the same language family has become a more effective paradigm [6]–[9]. Meanwhile, Choosing an appropriate fine-tuning strategy holds significance in bolstering the model's generalization ability [10], [11].

The advantages of neural networks in transferring knowledge between linguistically related languages are evident, primarily due to the efficiency of adaptation depends on various factors, including the distribution differences between the source and target languages [12]. In the presence of insufficient target data that fails to capture the acoustic diversity, the conventional fine-tuning approach may suffer from issues such as low generalizability and catastrophic forgetting. These challenges arise due to the high complexity and data sensitivity of the Transformer-based architecture [13], [14].

To mitigate these limitations, researchers have explored alternative strategies to alleviate the issue of knowledge forgetting during the process of transfer learning. For instance, one approach is to use L2 regularization to constrain the divergence between the model's weights and the pre-trained weights [15]. Furthermore, substituting some model parameters stochastically with their corresponding pre-trained parameters can also produce effects similar to regularization [16]. Another prevalent technique hinges on adapters, which can add additional intermediate layer parameters and fine-tuned while keeping all the pre-trained parameters frozen [17]–[19]. Nonetheless, the disadvantages of adapters remain distinctly noticeable. On the one hand, adding adapters for each task will lead to a sharp increase in model size. On the other hand, the adapter module itself requires a large amount of target language data for training, rendering the incorporation of intricate network configurations superfluous in scenarios of data paucity. Recent endeavors within the realm of Natural Language Processing have turned to sparse fine-tuning techniques as a surrogate to adapters, abstaining from the introduction of any additional structure [20], [21]. This not only curtails computational expenditure but also retains the performance supremacy of pre-trained models.

To better adapt pre-trained model to target low-resource Tibetan dialects, we proposed an effective fine-tuning method inspired by the Lottery Ticket Hypothesis (LTH) [22], which only fine tune the most task-related parameters within a subnetwork of the full model. The crux of the matter currently resides in discerning these precise parameters. In particular, there are two variations of this method: the first one discovers the subnetwork by measuring the differences between the upstream and downstream tasks, while the second one selects the most important parameters for the downstream task based on their gradient information. In comparison to the original idea, our approach diverges in two main facets. Firstly, LTH primarily focuses on the compression of large models, while

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

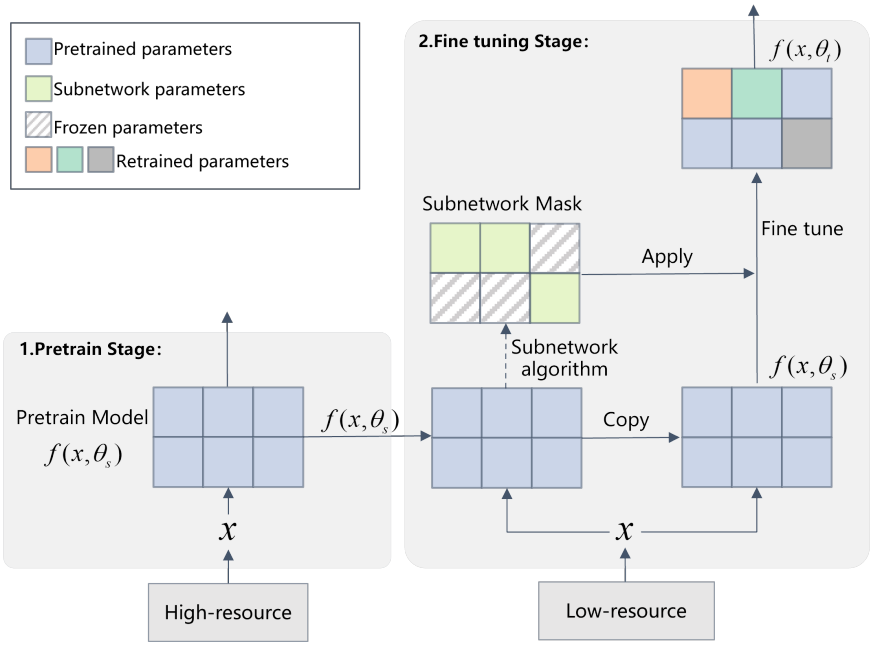

Fig. 1. Overview of the fine-tuning algorithm proposed in this work: Firstly, we train the model on high-resource corpus, and the pre-trained model is represented as function $f(x, \theta)$. Then, we obtain a mask to represent the corresponding language-specific subnetwork, where the green blocks symbolize trainable neurons, and the white blocks denote frozen ones. Finally, retrain the network using mask.

our proposed approach preserves all parameters of the network and avoids any pruning that may affect model accuracy. Furthermore, the parameters of the subnetwork extracted by the original LTH are determined by their significance in the pre-training task, which may not be applicable in transfer learning due to the potential mismatch between upstream and downstream tasks.

The rest of this paper is organized as follows. In Section 2, the proposed two fine-tuning strategies are introduced. Section 3 shows the experimental settings and evaluation results. The conclusions are in Section 4.

II. Proposed Methods

In this section, we mainly introduce our proposed cross-lingual transfer-learning methods based on language specific sparse fine-tuning, as shown in Figure 1.

A. Lottery Ticket Hypothesis

The Lottery Ticket Hypothesis (LTH) illustrates that a sparse subnetwork within a fully dense network is capable of being trained in isolation from initialization to achieve high accuracy, as shown in Figure 2.

Recent works have leveraged unstructured pruning technology to compress large pre-trained models based on the Lottery Ticket Hypothesis [22]. These methods only need to update a specific sparse sub-network and prune the remaining weights, achieving high sparsity with minimal performance degradation [23]–[25]. In different tasks or models, it is necessary to conduct multiple experimental iterations to identify an optimal "winning tickets" subnetwork. For instance, during the fine-tuning stage, a mask is typically applied, consisting of absolute values such as a set of ones and zeros. Usually, the subnetwork is identified by training a model on the source language and pruning the weights with the smallest magnitudes. This iterative pruning and re-training process may need to be executed numerous times to achieve an optimal compressed model.

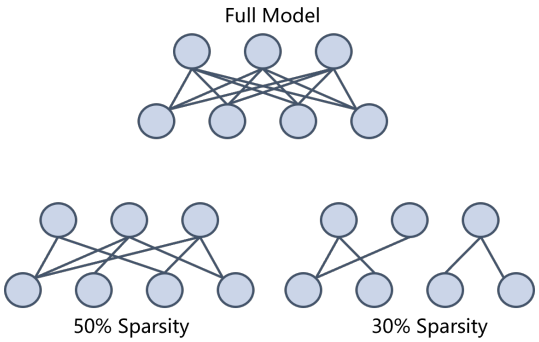

Fig. 2. Compared to a full model, a sparse subnetwork has only a few parameters trained.

B. Sparse Fine-tuning Method

This work investigates the generalization capability of sparse fine-tuning techniques in cross-dialect transfer learning, specifically in the domain of speech recognition for languages with limited resources. Consider a generic neural network parameterized by function $f(x, \theta)$ with initial parameters $\theta = \theta_0$ and input x. The output from the forward pass is $y = f(x, \theta)$. The parameters in full fine-tuning strategy would be updated

as follow:

$$\theta_{t+1} = \theta_t - \eta \frac{\partial \mathcal{L}(\theta_t)}{\partial \theta_t} \tag{1}$$

Where $\mathcal{L}(\theta_t)$ is the loss function. $\frac{\partial \mathcal{L}(\theta_t)}{\partial \theta_t}$ represents the gradients corresponding to the model parameters θ_t, and η is the learning rate. Our objective is to determine a subnetwork with a sparsity $S \in [0, 1]$. To achieve this, we consider a pruning mask consisting of a series of ones representing the subnetwork and replace the rest with zeros. This is illustrated as follows:

$$M_t^i = \begin{cases} 1 & \text{if } \theta^i \in P^t \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

P^t represents a series of weight parameters considered to be activated at iteration t. i is the i-th weight, and M is the subnetwork mask used to update parameters at each backpropagation. Usually, P^t is obtained from the top-K proportion of weights θ_t based on their magnitude. This process can be described as follows:

$$P^t = \left\{ i \mid \theta_t^i \in \mathrm{TopK}(\theta_t) \right\} \tag{3}$$

Then we update the parameters with the following equation:

$$\theta_{t+1} = \theta_t - \eta \frac{\partial \mathcal{L}(\theta_t)}{\partial \theta_t} \odot M_t \tag{4}$$

C. Language Specific Transfer

The selection of subnetworks is often crucial for sparse fine-tuning methods. In this paper, we proposed two variants methods for obtaining a set of target language-specific parameters from the backbone network, as shown in Algorithm 1. One method is based on weight amplitude difference, and the other is based on the gradient of the neural parameter.

Algorithm 1 Framework of our fine-tuning method.

Require:

$\mathcal{L}()$: learning objective of model;
θ_s : the pretrain neural model weights;
S : Sparsity of subnetworks;
subnetwork($TopK(|\theta_s - \theta_t|), S$) : different strategies of subnetwork extraction amied at downstream language are implemented (if using fisher method, the first input parameter is $TopK(\mathbf{H})$;

Ensure:

Initialize model, Start fine-tuning stage:
while in epochs **do**
  if Calculate mask **then**
    M_t= subnetwork($TopK(|\theta_s - \theta_t|), S$).
  end if
  Update θ_t using Mask.
  $\theta_{t+1} = \theta_t - \eta \frac{\partial \mathcal{L}(\theta_t)}{\partial \theta_t} \odot M_t$
end while

Weight-Difference Fine-tuning(differ): First, the pre-trained model is thoroughly fine-tuned on the downstream language. θ_s on the source language and θ_t on the target language represent the neural network parameters before and after fine-tuning. The parameters are sorted by importance according to specific rules, which can be calculated by the greatest absolute difference $|\theta_t^i - \theta_s^i|$. i is the i-th weight. Those parameters with the largest difference in the above formula are trained in the next step on downstream language, and the remaining parameters will be frozen. We use a mask M to distinguish the two types of parameters. Precisely, the K in Top-K function corresponds to the sparsity setting S at the beginning.

Second, the model re-fine-tuning on the target language, and this time, the mask M given by the previous step is used. Parameter updating is similar to equation (4). Notice that the L1 regularization is applied in this work to encourage more robust parameter updating.

Gradient based Fine-tuning(fisher): Fisher Information [26] determines the update direction in natural gradient descent, which is a nonlinear function of the weights and data [27]. As described below, the Fisher is usually given by a hessian matrix:

$$\mathbf{H} = E_X[J^T J], J = \frac{\partial \mathcal{L}(\theta_t)}{\partial \theta_t}, \tag{5}$$

where H is Hessian Matrix, and J denote the gradient matrix of the model. Given the task-specific training data D, we use the diagonal elements of the empirical Fisher Information Matrix (FIM) to estimate the task-related importance of the parameters , as described in [21]. We derive the Fisher information for the i-th parameter as shown in (6):

$$\mathbf{H} = \sum_{j=1}^{|D|} \left(\frac{\partial \log p(y_j \mid \mathbf{x}_j; \theta)}{\partial \theta^{(i)}} \right)^2 \tag{6}$$

We rank all parameters based on their Fisher Information, assuming that those with higher Fisher Information are more important for the target task. Then, we use the Top-K function to select the highly relevant parameters to form the subnetwork. During the back propagation process, only the parameters in the subnetwork are updated by gradients, while the other non-subnetwork parameters are frozen.

TABLE I
STATISTICS OF ANNOTATED LANGUAGE DATASETS.

Dialect	Size (Hours)			Speakers	Utterances
	Train	Dev	Test	Total	Total
Am-do	133.1	5.8	2.1	114	113643
U-Gtsang	4.6	2.2	2.3	8	7892
Khampa	5.1	2.5	2.4	8	7996

III. TASK DESCRIPTION AND BASELINE SYSTEMS

A. Dataset

We employ a comprehensive Tibetan dataset, including Amdo, U-Gtsang, and Khampa. The corpus is recorded in a serene environment, and sentences are employed in everyday discourse. The data acquisition process employed a monophonic

recording setup with a sampling rate of 16 kHz and 16-bit quantization. The speakers who participated in the recordings were youthful denizens hailing from Tibetan regions, aged between 18 and 23. The duration of each audio is generally within ten seconds. Subsequently, the datasets were segregated into 'train', 'dev' and 'test' splits for training and validation correspondingly for all datasets. The size details of the dataset are presented in Table I.

B. Baseline system description

We utilize Transformer[3] based ASR model implemented in SpeechBrain [28]. In order to better evaluate the performance of our proposed method on models with different numbers of parameters, we designed two Transformer models with different model size. For the transformer-small, the encoder has 12 layers and the decoder has 6 layers with width 256. For the transformer-large, the encoder has 16 layers and the decoder has 8 layers with width 512, and other parameters are exactly the same. Each layer includes multi-head attention and fully connected layer. We extract 80 dimensions fbank features (windows with 25ms size and 10ms shift). Except for the mentioned parameters, all other settings are exactly the same as in this work.

IV. Experimental results

TABLE II
WORD ERROR RATE (WER) FOR CROSS-DIALECT FINE-TUNING FROM AM-DO TO U-GTSANG AND KHAMPA.

Model	Params (M)	Method	Khampa		U-Gtsang		Avg
			Dev	Test	Dev	Test	
Transformer (Small)	27.3	vallina	14.08	14.22	23.60	24.46	19.09
		fisher	14.18	14.43	24.27	24.86	19.43
		diff	14.02	14.20	22.14	22.47	**18.20**
Transformer (Large)	87.5	vallina	12.62	13.30	23.45	24.91	18.57
		fisher	10.30	11.65	21.20	22.28	16.35
		diff	10.26	10.93	19.76	20.02	**15.24**

We compare our proposed two fine-tuning strategies: diff and fisher, to vanilla fine-tuning (update all parameters). As shown in Table II, our proposed methods outperform vanila fine-tuning, achieving a relative reduction in WER ranging from 5% - 18%. In particular, the 'diff' method exhibits superior efficacy on U-Gtsang and Khampa compared to 'fisher'. Upon comparing the experimental results of the 'Transformer (Small)' model with those of the 'Transformer (Large)' model, , it can be observed that as the model's parameter size increases (from 27.3M to 87.5M), the advantages of the sparse fine-tuning method become more pronounced.

TABLE III
COMPARED TO OTHER SPARSE FINE-TUNING METHODS

Method	Khampa		U-Gtsang		Avg
	Dev	Test	Dev	Test	
vallina	12.62	13.30	23.45	24.91	18.57
topk	13.37	13.92	23.38	24.26	18.73
random	20.17	21.45	31.34	37.64	27.65
adapter	18.04	19.11	28.66	30.58	24.09
diff	10.26	10.93	19.76	20.02	**15.24**

We further compare our proposed method with other sparse fine-tuning techniques, such as topk (selecting subnetwork from the pre-trained model), random (randomly selecting parameters as subnetwork), and adapter-based methods, employing Transformer (Large) as the foundational model. As exhibited in Table III, the experimental results indicate 'diff' method is superior to other sparse fine-tuning methods. Moreover, it suggests that obtaining task-specific sparse subnetworks from the target domain enables a more precise depiction of the target domain's characteristics, thereby avoiding the necessity for extensive data transformation or alignment between the source and target domain.

TABLE IV
THE EXPERIMENTAL RESULTS OF FUSING KNOWLEDGE REPRESENTED BY VARIOUS METHODOLOGIES.

Method	Combination Type	Khampa		U-Gtsang		Avg
		Dev	Test	Dev	Test	
vallina	-	12.62	13.30	23.45	24.91	18.57
fisher	-	10.30	11.65	21.20	22.28	16.35
diff	-	10.26	10.93	19.76	20.02	**15.24**
diff + fisher	union	10.41	11.09	20.05	20.53	15.52
	intersection	10.40	11.23	20.51	21.38	15.88
diff(30%) + topk(10%)	union	10.02	10.27	19.82	20.13	**15.06**
	intersection	10.73	11.49	21.14	21.68	16.26

To analyze whether there is a correlation between the knowledge encapsulated in the subnetworks extracted using different sparse fine-tuning methods, we conducted experiments utilizing distinct combination techniques (union and intersection) and employ Transformer (Large) as the foundational model. As shown in Table IV, compared to using the diff method alone, there is a slight degradation in performance when combining the two variants of the method proposed by us (diff and fisher). However, by conjoining the knowledge derived from the source domain ('topk') and the target domain ('diff'), the efficacy of the model can be further enhanced.

As Figure 3, to investigate how diverse levels of sparsity may impact the fine-tuning efficacy, we varied our target sparsity rate to span from 10% to 100%. Notice that the sparsity denotes the trainable weights compared to the entire model. We analyze the effect of sparsity on both low-resource datasets and found that lower degrees of sparsity result in greater enhancements compared to higher levels of sparsity. Meanwhile, the model achieved its highest accuracy in low-

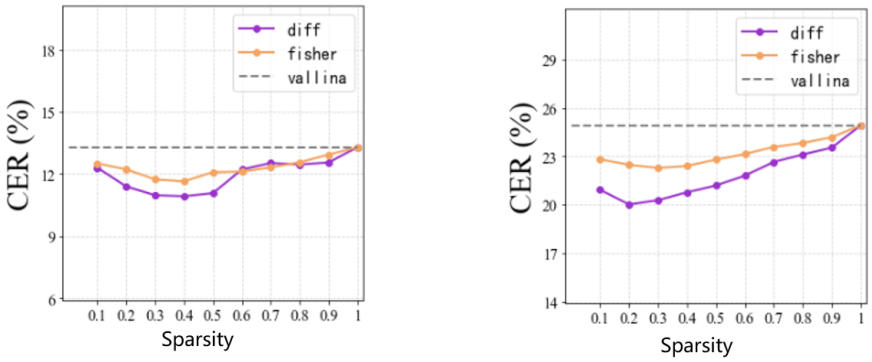

Fig. 3. Performance across two dialects of limited resources, contemplating the range of sparsity from 0.1 to 1. Sparsity denotes the remaining weights compared to the full model.

resource languages when the sparsity ranged from 10% to 30%.

V. Conclusions

Conventional methodologies of transfer learning often suffer from the issue of knowledge forgetting, leading to suboptimal performance in Tibetan dialect transfer learning. In this paper, we propose two sparse fine-tuning techniques based on the lottery ticket hypothesis, which evaluates the importance of each parameter for the target low-resource dialect. By refining the language-specific subnetwork and solidifying the remaining parameters, we mitigate knowledge loss, thereby achieving a more potent transfer of knowledge among Tibetan dialects.

***Abstract*—Automatic music transcription (AMT) is to transcribe music audios into musical symbol representations. Recently, the Transformer-based transcription systems have shown superiority on modeling note-wise sequences. For the frame-wise transcription targets in the AMT, the attention needs to focus more on the neighboring frames instead of notes in context. In this work, we propose a multi-task transcription system with a self-attention mechanism. The designed relative positional self-attention aims to model frame-wise short-term dependencies in audio and transcribe music of variable length. Adding the learnable attention mask on multiple attention head, the network can obtain different multi-scale attention distances for each subtask. Experiments on the MAESTRO dataset show the proposed system with the local relative time attention mechanism achieves state-of-the-art transcription performance on both frame and note metrics (frame F1 93.40%, note with offset F1 88.50%).**

I. Introduction

As one of the key technologies in music information retrieval (MIR), automatic music transcription (AMT) aims to process music audio signals to music symbols [1]. A large number of tasks can benefit from AMT, such as automatic music generation [2], music education [3], and musicology research [4].

Specifically, the purpose of the piano transcription is to transform piano music to note events with pitch, onset, offset and other music symbols. Some early piano transcription methods were based on the discriminative models such as support vector machines (SVM) [5], [6] and hidden Markov models (HMM) [7]. Non-negative matrix factorization (NMF) and probabilistic latent component analysis (PLCA) were also proposed to decompose polyphony piano music spectra into note spectrum templates and activations [8], [9]. Due to the harmonic overlap of concurrent notes in the frequency domain, it is a challenging task for traditional hand-crafted transcription method.

With the development of deep learning, the neural networks (NNs) have been widely used in AMT systems. The multi-task framework achieved superior performance in transcription, such as the onsets and frames (OAF) model [10], [11]. Recently, the Transformer showed great success in the sequence-to-sequence transcription methods [12], [13]. These Transformers modeled note-wise sequence context information with absolute position embedding method. The Transformer's potential was also explored on the multi-task AMT system [14]. By modeling the correlation of note-wise velocity sequence, the Transformer achieved an improvement on velocity estimation subtask. Due to the global absolute position embedding, the self-attention mechanism in these Transformers connected all the frames on time steps. In this scenario, not only the transcription flexibility on variable audio length is limited by the absolute position embedding, but the global self-attention also causes confusion in the network by mixing up on several note event features.

In this work, we implement a multi-task piano transcription system with local relative time self-attention. The self-attention mechanism is improved using the local relative position embedding to model frame-wise short-term dependencies on different subtasks. In addition, a learnable attention mask is adopted to obtain the proper attention distance for each head. To aggregate the inter-head information across the multi-scale self-attention heads in the transcription subtasks, a head-wise gating mechanism is utilized to emphasize the informative features among these multi-scale attention heads. The experiments show that the proposed system achieves state-of-the-art performance on MAESTRO dataset [11] compared to previous transcription systems.

II. Related work

Multi-task automatic piano transcription systems have been deeply developed recently. These transcription systems consist of multiple subtasks, such as onset and offset detection, pitch and velocity estimation. Hawthorne et al. [10] proposed the OAF transcription system to extract the pitch features of notes attack stage, which could model the frame-level targets and the note-level targets at the same time. Kelz et al. [15] proposed a multi-task framework with an extra note offset detection subtask and decomposed a note to attack, decay, sustain and release (ADSR) phases. Kim et al. [16] improved the OAF system with adversarial learning method and Kong et al. [17] designed the high-resolution note targets for the multi-task transcription system. Wei et al. [18] used harmonic dilated convolution to capture the harmonic structures and frequency grouped recurrent neural network to model the pitch-invariance over time. With multiple modifications, the multi-task framework has became a typical piano transcription method.

Attention mechanism [19] was also introduced into the piano AMT tasks to explore the temporal relationship of the audio frames [20]. Further, the generic Transformer was directly utilized to accomplish the end-to-end piano transcription [12],

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

[13]. In these previous studies, a standard absolute position embedding method was utilized to represent the positional relationship of each audio frame in the attention mechanism. The embedded position vectors were summed to frame spectra before all the encoders and decoders. These researches indicated that the attention mechanism was promising in the the piano transcription tasks.

III. Method

A. System architecture

The architecture of the proposed piano transcription system is shown in Fig. 1(a), which we term as Local Relative Time Attention (LRTA) transcription system. There are two acoustic models and three FG-LSTMs [18] to model three transcription subtasks, which include onset detection, pitch estimation and offset detection. We use a joint binary cross entropy (BCE) loss of all subtasks for model optimization. Specifically, the loss functions are:

$$l_{\text{BCE}}(y,p) = -wy\log p - (1-y)\log(1-p) \tag{1}$$

$$l_{\text{onset}} = \sum_{k=1}^{K}\sum_{t=1}^{T} l_{\text{BCE}}(I_{\text{onset}}(t,k), P_{\text{onset}}(t,k)) \tag{2}$$

$$l_{\text{frame}} = \sum_{k=1}^{K}\sum_{t=1}^{T} l_{\text{BCE}}(I_{\text{frame}}(t,k), P_{\text{frame}}(t,k)) \tag{3}$$

$$l_{\text{offset}} = \sum_{k=1}^{K}\sum_{t=1}^{T} l_{\text{BCE}}(I_{\text{offset}}(t,k), P_{\text{offset}}(t,k)) \tag{4}$$

where all the losses are computed on frame aligned frame-wise piano-roll-liked ground truth I and model output P, K refers to all the pitches and T is the number of frames in each sample, w in (1) is a positive weight. $w = 2$ only in onset loss and $w = 1$ in other subtasks. The joint BCE loss is given as the following function:

$$l_{\text{note}} = l_{\text{onset}} + l_{\text{frame}} + l_{\text{offset}} \tag{5}$$

The acoustic model consists of stacked standard convolution layers and temporal attention blocks. Firstly, the local features are captured by the input standard convolutions. Then we use the temporal dynamic convolution (TDY-Conv) [21] and local relative time attention with residuals to extract notes local time-variant attributes from the former hidden features, which these attributes can be benefit from more on neighboring frames. Here, the local relative time attention is devised to extract short-term correlations among the frame-wise features. After the acoustic model, for each transcription subtask, FG-LSTMs are adopted to model the temporal relationship on individual pitches.

B. Local relative time attention

Inspired by Music Transformer [2], we propose the self-attention with a local relative position embedding method to extend the transcription length flexibility of the attention mechanism. Different from absolute position embedding method, the relative position embedding method focuses more on the relative distance between the elements in sequence. At each tap of the multi-head self-attention calculation, where the head dimension is d_h, there is:

$$\text{RelativeAttention} = \text{softmax}(\frac{QK^T + S}{\sqrt{d_h}})V \tag{6}$$

where Q, K, V represent query, key, and value vectors mapped from input, S is the relative position weights. For a sequence of length L, the shape of S is (L, L). Equation (6) was firstly proposed in [22]. Then the implementation of relative attention was improved by reducing its intermediate memory requirement in [2] and [23]. We further modify the relative position embedding to local situation, where each frame in the audio sequence interacts with the forward and backward terms in a limited scope. In this case, the length of the audio being transcribed can be arbitrary, as long as it is larger than the maximum attention range.

During the evolution of a piano note, the energy has a rapid increase at onset. For the onset branch, each frame is more relevant to neighboring frames in the audio sequence. Therefore, the attention distance N in different subtasks on each head may be different. To get the proper N, the adaptive attention mask [24] is simplified and adopted in the bi-directional relative position embedding method:

$$m_z(x) = \text{min}[\text{max}(z - |x|, 0), 1] \tag{7}$$

where $m_z(x)$ is the attention mask add on each S and $m_z(x) \in [0, 1]$. $x \in [-L + 1, L - 1]$ represents the directed relative distance in sequence L. $z \in [0, L - 1]$ is the learnable parameter controlling relative attention distance N. Here, the N is represented as $N = 2z + 1$. Specifically, we apply attention masks on multi-heads in different branches, which enables the network to model multi-scale temporal dependencies in different subtasks.

We use the Squeeze-and-Excitation (SE) [25] network to help the LRTA extract useful ones across these multi-scale attention heads. The SE network applied on multi-head self-attention can be regarded as a superior attention mechanism of the basic attention across different attention scales. It allows the network to aggregate the inter-head information and boost temporal feature discriminability.

As illustrated in Fig. 2, the h-heads relative position weights S in different branches are masked by the designed multi-scale attention masks. After the relative positions are skewed to the corresponding absolute positions, the multi-scale head-wise information are aggregated through the SE network.

IV. Experiments

A. Dataset and metrics

The experiments are conducted on the MAESTRO V3.0.0 dataset [11], which contains 200 hours of high-quality realistic recordings. We use the provided train, validation, and test splits in the MAESTRO.

We use the frame-level [26] and the note-level evaluation metrics in the *mir_eval* [27] library to get the precision, recall and F1 score. Following the tolerance range settings in previous researches [10], [17], we use $\pm$50ms as the onset tolerance and use offset tolerance of $\pm$50ms or 20% of the total note duration. The velocity estimation includes a tolerance within 0.1 of the prediction and ground truth after scaling the velocity values to $[0, 1]$.

B. Preprocessing

We use the *librosa* [28] library to preprocess the audio in the MAESTRO dataset. The raw audio is downsampled to 16kHz mono soundtrack. The frame length is set to 128ms, and the hop length is 20ms. Then the log amplitude CQT [29] spectrum of each sample is calculated with a Hanning window of 2048 with minimum frequency of 27.5Hz (A0) and bins per octave of 48, which the total frequency bins number is 352. At last, the dynamic range of the spectrum is rescaled to $[-40\text{dB}, +40\text{dB}]$. Each training sample contains 600 frames, which is corresponding to 12 seconds of the raw piano audio. During the evaluation, the length of each test sample is 19200 frames, which contains 384 seconds of the piano audio.

For the label preprocessing, when a note is played and the sustain pedal value is no less than 64, the note will be extend until the key is re-pressed or the sustain pedal is off [10].

C. Model configuration

As Fig. 1(a) shown, the proposed AMT system consists of acoustic models and FG-LSTMs. The acoustic model, as Fig. 1(b) shown, are composed of a input batch normalization [31], stacked standard CNNs, a linear layer and temporal attention blocks. The input standard CNNs are composed of three convolution blocks, and each contains a convolution kernel with a size of 7×7, a GELU layer, a instance-norm

layer, and channel expansion from 1 to 16 and $C = 64$. After that, a linear layer is applied to map the frequency bins from 352 to 88.

For the temporal attention block, the TDY-Conv layer is consisted of 4 temporal dynamic convolution kernels, which each kernel has larger reception filed along the time axis and has the shape of 7×3. The reduction factor in the convolution channels squeeze is set to 8. The local relative time attention is consisted of 64 heads, which each head is corresponded to each channel in the previous TDY-Conv layer. We use 8 learnable attention mask parameter z to adjust every 8 heads' attention range. We set $z = 49$ as the maximum attention range, where the maximum relative distance $N = 99$. In addition, the inter-head information are aggregated by the SE network with the reduction factor of 8.

For the FG-LSTM, we follow the configuration proposed in [18]. There are 64 units in each direction of a one layer bidirectional LSTM. At last, the outputs of all the subtasks are $T \times 88$ piano rolls, where T refers to the frame number of the audio sample and 88 indicates the number of piano keys. All the outputs are rescaled by a sigmoid layer.

We use an extra acoustic and FG-LSTM for note velocity estimation branch. The velocity branch has the same configuration as described above, except for the local relative time attention, which we found that replacing the attention layer with a linear layer resulted in better performance. The onset hidden feature is also concatenated to the velocity branch before the FG-LSTM. The velocity estimation module is optimized with the multi-task transcription model, and its mean square error loss is only computed at onset valid points.

The entire model contains 3.2M trainable parameters. We set batch size of 8 for training, and use the Adam [32] optimizer with learning rate of 0.0005, and reduce the learning rate to 98% after every 5 epochs. The complete model is trained on two GeForce RTX 3090 for about 70 hours, with a total of 35 epochs of 210K steps.

In post-processing, we use 0.4 and 0.4 as the onset and the frame output posterior probabilities binarization thresholds. Notice that the offset is only used in training. To get complete note events, we start each note with its velocity at onset valid point, and end the note at frame invalid point or re-onset point.

V. RESULTS

A. Final system

We compare the proposed LRTA system with other state-of-the-art systems in Table I. Among the existing AMT systems, the HPPNet [18] is the best model in the frame F1 score and the note F1 score, the Semi-CRFs [30] used Semi-Markov Conditional Random Fields to directly predict note events and is the best model in the note with offset and velocity F1 scores.

The LRTA model achieves state-of-the-art in both frame F1 score and note with offset F1 score in the MAESTRO V3.0.0 dataset, which improves 0.25% and 0.08%, reaching 93.40% and 88.50% respectively. We also evaluate our LRTA transcription model on the test splits of MAESTRO V1.0.0 and V2.0.0. Most of the performances in different versions of the MAESTRO datasets are the same. While there are additional performances in v2 and v3 comparing with v1, and several erroneously included recordings were removed in v3. It is remarkable that the LRTA model outperforms all other models in the frame F1 scores, which indicates the superior performance of its designed local relative time attention on frame-wise targets. With a total of 3.2M parameters, the LRTA model's effectiveness makes it an ideal transcription model for various tasks.

B. Ablation study

To demonstrate the contribution of the local relative time attention, we conduct an ablation study on the MAESTRO dataset. We replace the self-attention layer with a single linear layer, which the linear layer has the 88 input and output features. The results are shown in Table II. These results indicate that the the local relative time attention layer is crucial in all transcription tasks, where all the F1 scores decrease after the self-attention layer is ablated.

VI. CONCLUSIONS

In this paper, we propose a multi-task automatic piano transcription system, which utilizes the adaptive local relative position embedding self-attention to model frame-wise transcription targets. The relative position embedding makes it possible to transcribe arbitrary length of piano music. The local self-attention mechanism helps the network to focus more on the temporal features across adjacent audio frames. We also apply learnable attention masks and a head-wise gate mechanism to improve and aggregate multi-scale attention ranges. The experimental results show that the designed local relative time attention is effective on modeling frame-wise short-term denpendencies, and the proposed system achieves state-of-the-art performance both in frame and note transcriptions. For the future work, it is worth exploring a reasonable self-attention method for the velocity estimation subtask.

***Abstract*—Speech enhancement and de-reverberation are the key points of speech signal front-end processing. Direct mapping of speech spectrum is a standard method in speech enhancement and de-reverberation. In previous studies, the real and imaginary parts of the spectrum are estimated separately, which would make the error of direct estimation more significant. This paper proposes a real and imaginary parts interactive network (RIINet) in which the branches of real and imaginary parts interact through a linear complex attention mechanism. In addition, this paper proposes a time-frequency analysis module to improve the performance of local time-frequency feature extraction effectively. RIINet achieved state-of-the-art performance in the Deep Noise Suppression Challenge using minimal model parameters. Excellent performance has also been achieved in the noise-reverberation speech enhancement test set.**

I. Introduction

In natural environments, the presence of noise and reverberation can significantly disrupt the clarity of speech. While traditional speech enhancement methods [1], [2] have been developed over many years, they primarily address stationary noise and may struggle to handle non-stationary noise effectively. However, numerous highly effective speech enhancement methods have been proposed with the emergence of deep neural networks (DNN). Because of the nonlinear mapping capabilities of DNNs, DNN-based methods mitigate non-stationary noise compared to traditional methods. DNN-based speech enhancement methods can be broadly categorized into two groups: time-frequency domain speech enhancement methods and time-domain speech enhancement methods.

In the time domain, DNN-based speech enhancement methods such as CleanUNet [3] and DenseCNN [4] often utilize end-to-end waveform recovery. In these methods, the input consists of the noisy waveform and the enhanced waveform is directly predicted, encompassing the enhancement of both magnitude and phase during this process. Time-domain enhancement offers the advantage of circumventing the need for signal conversion from the time domain to the frequency domain. It also enables the utilization of smaller frame lengths and frameshifts, thereby reducing the model's real-time processing delay. However, it is essential to note that when the frame length is set to a minimal value, additional calculations are required to ensure the model's performance remains uncompromised.

In the time-frequency domain, the primary training targets in DNN-based speech enhancement methods involve spectral mapping methods and spectral masking methods. Owning to the powerful nonlinear mapping capability of deep neural networks, the spectrum mapping method can directly estimate the clean speech spectrum. There are magnitude spectral mapping methods [5] and complex spectral mapping methods [6]. Furthermore, spectral mapping methods encompass magnitude spectral masking methods such as ideal binary masking (IBM) [7], [8] and ideal ratio masking (IRM) [9], [10], as well as complex spectral masking methods like complex ideal ratio mask (cIRM) [11], [12].

In previous spectral mapping speech enhancement methods [6], the real and imaginary parts of the spectrum are estimated by independent branches. In complex operations, the real and imaginary parts are closely related. Estimating the real and imaginary parts separately may lead to large errors. This paper proposes a real and imaginary part interactive network (RIINet) for speech enhancement and de-reverberation. In this paper, we propose that the time-frequency analysis module can capture local time-frequency information and specific long-term context dependence. We propose a linearly complex attention module for the interaction of real and imaginary parts. RIINet outperforms state-of-the-art models on the blind test set of the Deep Noise Suppression Challenge [13]. Excellent denoising and de-reverberation performance are demonstrated on the noisy-reverberant verification set.

II. Real and imaginary part interaction network

The overall structure of RIINet is shown in Figure1. k ,d, s denote kernel size, dilation rate, and stride, respectively. The model adopts the classical convolutional recurrent neural network (CRN), which has been proven to be a very effective speech enhancement structure. Different from CRN, we use two branch decoders to estimate the real and imaginary parts of the complex spectrum, respectively. The detailed structure of each module is described in the following subsections.

A. Gated feature downsampling and upsampling

Convolutional recurrent neural network [6], [14] is a classical network structure in speech enhancement tasks. Convolution and deconvolution can change the spectral feature dimension to enhance the ability of the model to extract embedding. Context dependencies in speech are captured by recurrent neural networks (RNN). In this paper, Gated feature downsampling and upsampling are used. We use gated 2-D convolution for feature downsampling to reduce the feature dimensionality. The gated 2-D convolution consists of two 2-D

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

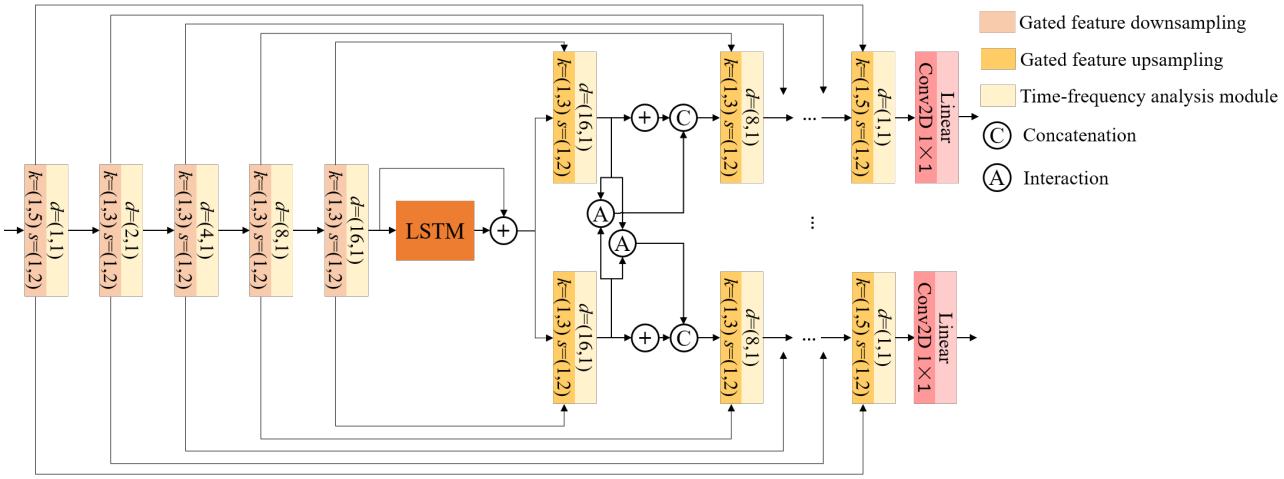

Fig. 1: Illustration of the proposed RIINet.

convolutions with the same structure, where the output of one is multiplied by the output of the other after a sigmoid activation function to generate the final output. The stride of the 2-D convolution is (1, 2) to achieve the feature dimension halving. Instance normalization and PReLU are used after gated 2-D convolution. The structure of feature upsampling is similar to feature downsampling, except that 2-D deconvolutions replace 2-D convolutions.

B. Time-frequency analysis module

To further analyze the spectral features of noisy speech, each encoder and decoder use a time-frequency analysis module (TFAM) to extract local features. The structure of TFAM is shown in Fig.2. Instance normalization and PReLU activation functions are used after pointwise convolution. After causal padding, a depthwise 2-D convolution [15] with a kernel size of (5,5) and a dilation rate of d is applied to extract local features. Instance normalization, PReLU activation function, and pointwise convolution are applied to the extracted features. The output of TFAM is generated by adding the output of the pointwise convolution with the original input.

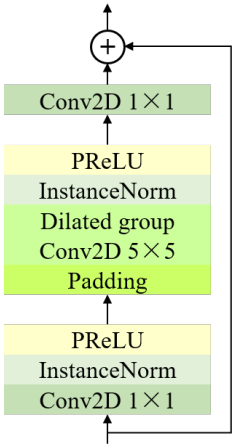

Fig. 2: Illustration of the time-frequency analysis module.

C. Real and imaginary part interaction module

To avoid the distortion of the reconstructed speech due to the separate decoding of the real and imaginary part, we add a real and imaginary part interaction module (RIIM) between the two branches. In classical attention algorithms [16], the Softmax activation function and the multiplication of matrices make attention inevitably introduce quadratic complexity. The squared complexity causes the computational cost to increase significantly as the speech duration grows. We extend Flowformer [17] to propose multi-channel flow attention for RIIM.

According to the flow network theory, the information flow in the attention mechanism can be expressed as converging from the sources (V) to the sinks (R) based on the learned flow capacity (corresponding attention weights calculated from Q and K), as shown in Fig.3. The amount of inflow information to the i-th sink I_i and outflow information from the j-th

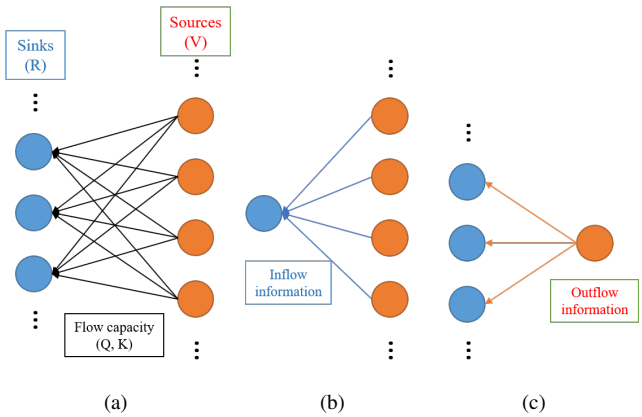

Fig. 3: (a)Sources-Sinks information flow. (b)Inflow information of each sink. (c)Outflow information of each source.

source O_j can be calculated as Eq.1. To keep the flow capacity positive, non-negative functions $\phi(\cdot)$ are used.

$$I_i = \phi(Q_i)\sum_{j=1}^{m}\phi(K_j)^T, O_j = \phi(K_j)\sum_{i=1}^{n}\phi(Q_i)^T \quad (1)$$

To utilize the conservation property of the flow network theory, the conservation of sources outflow and sink inflow are used through normalization.

$$\hat{I} = \phi(Q)\sum_{j=1}^{m}\frac{\phi(K_j)^T}{O_j}, \widehat{O} = \phi(K)\sum_{i=1}^{n}\frac{\phi(Q_i)^T}{I_i} \quad (2)$$

where $\hat{I} \in R^{n\times 1}$ indicates the amount of information obtained by each sink after the competition when the amount of source outflow information is fixed. $\widehat{O} \in R^{m\times 1}$ indicates the amount of the information supplied by each source when the amount of inflow information is fixed. Finally, the attention mechanism based on flow network theory can be expressed as the Eq.3:

$$\begin{aligned} \text{Competition}: \widehat{V} &= \text{Softmax}(\widehat{\text{O}}) \odot V \\ \text{Aggregation}: A &= \frac{\phi(Q)}{I}\left(\phi(K)^T\hat{V}\right) \\ \text{Allocation}: R &= \text{Sigmoid}(\hat{I}) \odot A \end{aligned} \quad (3)$$

where $\odot$ indicates the element-wise multiplication. $\hat{V} \in R^{m\times d}$ represents the source after the competition, which is reweighted according to the inflow conservation. $\hat{A} \in R^{m\times d}$ is the aggregated information source, which is calculated by the associativity of matrix multiplication to reduce the computational complexity. $\hat{R} \in R^{n\times d}$ represents the results of this new attention mechanism. The whole process of the SDCAN based on flow network theory is shown in Fig.4.

In calculating the real part to imaginary part attention, the real part is used as Q, and the imaginary part is used as K and V, and vice versa. By this method, we achieve to compute the attention value between real part to imaginary part with linear complexity.

D. Loss function

We use a combined mean error loss function because both magnitude and phase enhancement are essential for speech quality improvement. Research [18] shows that the complex compressed spectrum is closer to subjective human hearing than the complex spectrum. The combined mean square error loss function is demonstrated in Eq.4

$$\mathcal{L}_{cMSE} = (1-\beta)\cdot\|\hat{S}_{cRI} - S_{cRI}\|^2 + \beta\cdot\|\hat{S}_{cMag} - S_{cMag}\|^2 \quad (4)$$

where $\hat{S}_{cRI}$ and $\hat{S}_{cMag}$ denote the enhanced complex compression spectrum and the enhanced magnitude compression spectrum, respectively. In this paper, β takes 0.7.

III. Experiments and Discussions

A. Experiment setup

We have created two training datasets for the purpose of comparing advanced models and conducting the ablation study. To construct the first dataset, we have extracted clean speech and noise samples from the 1st Deep Noise Suppression Challenge [13]. This dataset comprises 1000 hours of training data, which we use to evaluate the speech enhancement performance in comparison to other state-of-the-art (SOTA) models. The noisy speech in this dataset has a signal-to-noise ratio (SNR) ranging from -5 dB to 15 dB, with approximately 75% of the samples mixed with reverberation. The reverberation time (RT60) varies between 0.3 seconds and 1.3 seconds.

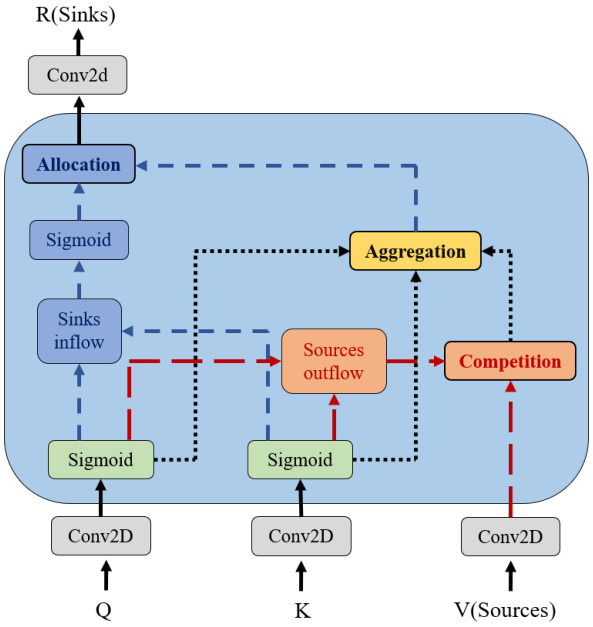

Fig. 4: Illustration of the real and imaginary part interaction module.

For the ablation study and comparison of noisy-reverberant speech enhancement performance, we also utilize the clean speech and noise samples from the 1st Deep Noise Suppression Challenge. However, this dataset has a duration of 500 hours, and the SNR of the noisy speech ranges from -5 dB to 20 dB. All speech samples in this dataset are mixed with simulated room impulse responses, where the RT60 values span from 0.3 seconds to 1.3 seconds.

The duration of each frame is set to 20 ms, with a frameshift of 50%. Prior to the Short-Time Fourier Transform (STFT), Hamming windows are applied. Moreover, all model hyper-parameters are initialized randomly and optimized using the AdamW optimizer [24]. The initial learning rate is set to 1×10^{-3}, and it exponentially decays by 0.98 as the training epoch progresses. If the loss no longer decreases, we reduce the learning rate by half. The training process continues until the learning rate reaches 1×10^{-4}.

For assessing the speech enhancement performance against state-of-the-art (SOTA) models, we employ the following evaluation metrics: Wideband Perceptual Evaluation of Speech Quality (WB-PESQ) [25], Narrowband PESQ (NB-PESQ) [26], Short-Time Objective Intelligibility (STOI) [27], and Scale-Invariant Signal-to-Distortion Ratio (SI-SDR) [28]. Ad-

-TFAM	2.87	2.04	86.94	8.97	2.73	2.93	**0.390**	11.10

ditionally, when comparing denoising and de-reverberation performance, we incorporate the following evaluation metrics: Deep Noise Suppression Mean Opinion Score (DNSMOS) [29], Composite Distortion (CD) [30], Log-Likelihood Ratio (LLR) [30], and Signal-to-Noise Ratio with Frequency Weights (SNR_{fw}) [30].

B. Speech enhancement performance comparison with SOTA models

The results of the blind test set for the Deep Noise Suppression Challenge are presented in Table I. The evaluation includes reverberation to assess the models' robustness, although reverberation is not the primary target for suppression. The terms '#Para.' and 'Caus.' indicate the model parameters and whether the model operates causally, respectively. Our proposed RIINet exhibits significant performance enhancements compared to state-of-the-art (SOTA) models in terms of the WB-PSEQ evaluation metric, both with and without reverberation. Furthermore, RIINet performs competitively with FS-CANet regarding the NB-PESQ, STOI and SI-SDR evaluation metrics. It is worth noting that RIINet achieves these advanced performance levels while utilizing minimal model parameters.

C. Speech enhancement and de-reverberation performance comparison

In this subsection, we evaluate the denoising and de-reverberation capabilities of RIINet, and the corresponding results are presented in Table II. The performance of RIINet surpasses that of Uformer, with RIINet's model parameters being only 32% of Uformer's.

We have conducted experiments to assess the impact of our proposed modules on model performance by removing the RIIM and TFAM modules from RIINet, which serves as the backbone network. The RIIM, despite utilizing only an additional 0.02M hyperparameters, demonstrates a significant influence on model performance. This module validates the effectiveness of the proposed interaction between the real and imaginary parts and provides a cost-effective solution with low computational requirements. On the other hand, the TFAM module exhibits strong performance at the expense of approximately 0.24M hyperparameters. After removing TFAM, there is a decrease of 0.07 in average PESQ, a 0.99% decrease in STOI, a 0.45 decrease in SI-SDR, and a 0.06 decrease in DNSMOS. These findings highlight the importance of the TFAM module.

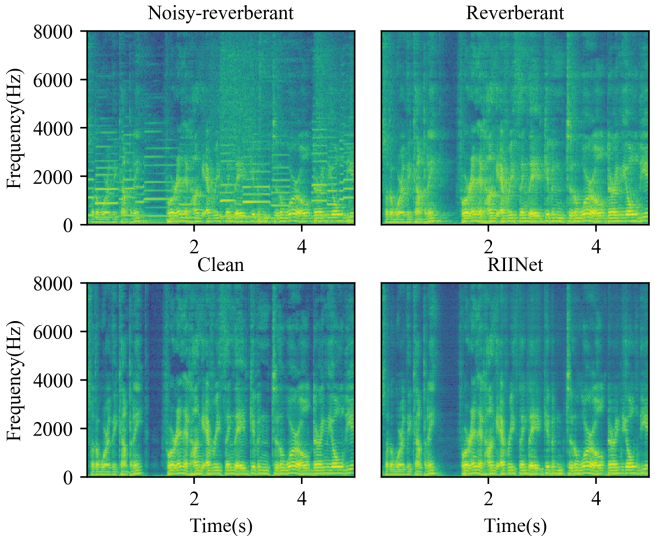

Fig. 5: Noisy-reverberat, reverberat, clean and enhanced speech spectrums

IV. Conclusions

In this study, we introduce a novel single-channel speech enhancement network architecture known as the Real and Imaginary Part Interactive Network (RIINet). Our network incorporates a two-branch interaction module with small parameters and low computational requirements, facilitating effective interaction between the real and imaginary partial branches. Furthermore, we incorporate a time-frequency analysis module that efficiently extracts local time-frequency feature information and captures long-term dependencies. The experimental results demonstrate that RIINet outperforms other state-of-the-art models in denoising and de-reverberation performance, showcasing its excellent capabilities in speech enhancement.

***Abstract*—Self-supervised learning has shown great potential in improving automatic speech recognition (ASR) systems. However, further improvements in recognition performance could be achieved if models focus on audio content information learning. In this paper, we propose a progressive multi-scale self-supervised learning method that reinforces the learning process from easy to difficult. Our progressive strategy utilizes fine-grained target sets to compute self-supervised learning loss at the top layer while using coarse-grained target sets at intermediate layers. Additionally, to match the difficulty of the learning process, we introduce a multi-scale structure into the multi-head self-attention module. We evaluate our method on the Librispeech dataset and demonstrate its effectiveness. Our proposed method achieves a relative word error rate (WER) reduction of 13.7% and 12.7% on the test_other evaluation subsets, respectively, when fine-tuned on 10-hour and 100-hour subsets, outperforming HuBERT.**

I. Introduction

In recent years, deep neural networks have become the backbone of automatic speech recognition (ASR) systems [1], [2], yielding impressive advances in reliability and practicality. However, the reliance of these models on large amounts of supervised speech data poses a fundamental limitation to their widespread application. Therefore, exploring methods to leverage unlabeled data for ASR model training has become a significant research topic, with the potential to further enhance performance. Self-supervised learning, which uses unsupervised objectives to learn representations from raw audio, has shown promising results in other domains and has recently emerged as a promising approach for improving ASR performance without requiring human-labeled data.

In recent years, self-supervised learning (SSL) has emerged as a promising approach to learn general data representations from unlabeled speech examples. Several speech SSL methods have demonstrated impressive results for downstream tasks [3]–[9], such as speaker identification, emotion recognition, and automatic speech recognition (ASR). However, for the ASR task, it is essential to improve the generalization ability of semantic content. While some SSL methods have been successful in learning representations that correlate with phonetic units, not all layers have such high correlations. For instance, the intermediate layers in the HuBERT model have been found to have lower mutual information scores with force-aligned phonetic transcripts in [6]. To address this limitation, some recent SSL approaches, such as [10], have computed SSL loss on both intermediate and top layers using the same target labels.

As the number of layers in a self-supervised learning model increases, the hidden representations gradually adjust to the final constrained objective. We hypothesize that these hidden representations at different layers respond to different levels of information granularity. Specifically, the higher layers may focus on high-level linguistic information that is correlated with fine-grained phonetic units, while the lower layers may capture coarse-grained phonetic information. By following a learning process that progresses from simple to complex and from rough to subtle, self-supervised learning can reinforce the practicality and applicability of the learned representations for ASR tasks.

Based on the insights gained from previous research, we propose a novel approach in this paper to further enhance the self-supervised learning (SSL) of ASR models. Our method, called Progressive Multi-Scale SSL (PMS-SSL), is designed to enable the learning process to reinforce itself from easy to difficult, with a focus on the audio content information level. We adopt the two-iteration pretraining process with masked prediction loss in HuBERT as the basis for our method. The main contributions of this paper are as follows:

1) In the second iteration, we perform multiple k-means clustering on the learned representations to generate the final target sets with different granularity. The fine-grained target sets have large cluster numbers, while the coarse-grained target sets have small cluster numbers. We then compute the SSL loss on both intermediate layers and the top layer using multi-task learning, with fine-grained target sets used at the top layer and coarse-grained target sets used at intermediate layers.
2) We introduce a multi-scale structure into the self-attention module to match the target granularity. This is achieved by restricting the attention area of the self-attention module at each layer to a different scope, which is more suited for the progressive learning strategy. This approach is closely related to the diversity and discrimination of local and global contexts, which in turn affects the information granularity.

Our proposed PMS-SSL method has been evaluated on the Librispeech dataset. Following standard HuBERT, 960 hours of

audio are used for pre-training and two subsets with different size are used for fine-tuning. When progressive target sets and multi-scale self-attention are both introduced into pre-training, the model fine-tuned with 10 hours and 100 hours subsets can achieve 13.7% adn 12.7% word error rate reduction respectively on test_other subset compared with HuBERT. The progressive multi-scale self-supervised learning method follows the principle from easy to difficult and makes speech representation more suitable for ASR task at the audio content information level.

II. RELATED WORK

The basic idea of SSL is to learn the superior universal representations effectively based on unlabeled data by reconstructing or predicting itself with the context information. As a representative SSL model, HuBERT follows the wav2vec 2.0 architecture [5], consisting of a convolutional waveform encoder, a BERT encoder [11], a projection layer and a code embedding layer.

During pre-training, $p\%$ of the timesteps are randomly selected as start indices, and spans of l timesteps are masked. Let $\tilde{X} = [\tilde{x}_1, \tilde{x}_2, \cdots \tilde{x}_T]$ denote the corrupted sequence of T frames. The Transformer encoder module consumes $\tilde{X}$ and outputs a hidden state sequence $O = [o_1, o_2, \cdots o_T]$. The distribution over codewords is parameterized with:

$$p_f(c \mid \tilde{X}, t) = \frac{\exp\left(\mathrm{sim}\left(Ao_t, e_c\right)/\tau\right)}{\sum_{c'=1}^{C} \exp\left(\mathrm{sim}\left(Ao_t, e_{c'}\right)/\tau\right)} \tag{1}$$

where A is the projection matrix, $e_c$is the embedding for codeword c, $sim()$ computes the cosine similarity between two vectors, and τ scales the logit. And an important factor in the implementation of HuBERT is the design of objective function, which applys the prediction loss over the masked regions only. Realizing the mixture learning of acoustic and linguistic representation is very important to obtain different aspects of the speech content. We denote the cross-entropy loss computed over masked timesteps as L_m, which is defined as:

$$L_m = \sum_{t \in M} \log p_f(c \mid \tilde{X}, t) \tag{2}$$

where M denotes the set of timestep indices to be masked.

Following the idea that iterative refinement target labels can generate better pseudo-labels for the next iteration of training [12], [13], HuBERT conducts two iterations of pre-training. During the first iteration, HuBERT runs k-means clustering on MFCCs to generate targets for speech features. Then HuBERT re-clusters the learned latent representations and re-train the model with the newly discovered units for second iteration.

HuBERT is able to learn the speech representations which are highly correlated with phonetic units. However, not all layers have such a high correlation with phonetic units. In order to force more layers to learn more content information,[10] simultaneously computes the SSL loss on both the intermediate layers and the top layer. Therefore, the total loss can be formulated as:

$$L = \sum_{l \in K} L_m^l \tag{3}$$

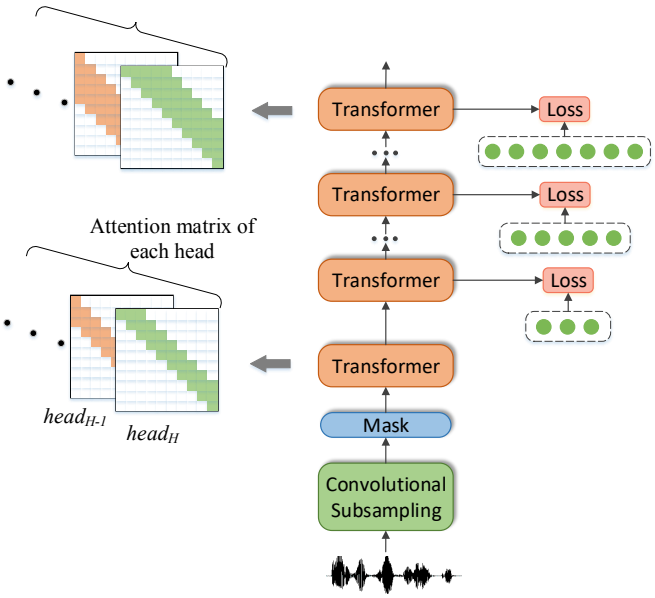

Fig. 1. Model architecture

where K denotes the set of selected layers for computing SSL loss. L_m^l denotes the predictive loss at l-th layer, which is calculated by Eq.(2).

III. PROPOSED METHOD

To improve the suitability of self-supervised learning representations for the ASR task, it is essential to prioritize context learning following the principle of progressing from easy to difficult. In this section, we present the Progressive Multi-Scale Self-Supervised Learning (PMS-SSL) method, which assigns different-granularity target sets for various layers and incorporates multi-scale structures into multi-head self-attention. The architecture of our model is shown in Fig. 1.

A. Progressive target sets

As previously discussed, prior work such as [10] has used the same target sets for both intermediate and top layers when computing the SSL loss. However, the receptive fields and learning difficulties of different layers may correspond to phonetic units of different granularities. Using the same target labels for all layers may result in overlooking the learning pattern of the different layers, and therefore, we propose a different approach.

In order to effectively guide the model to learn from easy to difficult levels, we propose the Progressive Multi-Scale Self-Supervised Learning (PMS-SSL) method, which assigns different-granularity target sets to different layers. We use the same clustering and pre-training process as HuBERT for the first iteration, given the uncertainty of target sets from MFCC features. During the second iteration, the learned representations can achieve better matching precision for different target labels. To generate multiple target sets, we perform multiple k-means clustering on the learned representations with different

cluster numbers. Coarse-grained target sets are considered to be easier to learn compared to fine-grained target sets. We then select a set of layers K as the supervised layers set to match the different-granularity target sets. Specifically, the larger target sets are used at the top layer and the smaller target sets are used at the intermediate layers. The size of different target sets is closely tied to the degree of difficulty in model learning. By assigning different-granularity target sets to different layers, our proposed PMS-SSL method reinforces the learning process from easy to difficult and helps the model learn more effectively. Therefore, the distribution defined in Eq.(1) can be refined as:

$$p_f^l(c \mid \tilde{X}, t) = \frac{\exp\left(\mathrm{sim}\left(Ao_t, e_c^l\right)/\tau\right)}{\sum_{c'=1}^{c^l} \exp\left(\mathrm{sim}\left(Ao_t, e_{c'}^l\right)/\tau\right)} \tag{4}$$

Where e_c^l is the embedding of c-th label used on the l-th layer.

We adopt the predictive loss in HuBERT which only computes SSL loss over masked regions as the object, therefore p_f in Eq.(2) is replaced by p_f^l and the total loss of all the supervised layers is also computed by Eq.(3).

B. Multi-scale multi-head self-attention

In order to improve the suitability of self-supervised learning representations for the ASR task, we propose a progressive learning strategy that leverages multi-scale structures in multi-head self-attention (MSA) [14] to emphasize the diversity of information and determine the classification target. With this approach, we bundle and deploy the receptive field of different layers as part of the progressive model.

By restricting the working area of each layer into various scopes through multi-scale attention, we enable higher layers to have larger attention areas, while lower layers have smaller attention areas. As the layer number increases, the gap in the receptive field widens. Compared to regular self-attention, which has a fixed scale of sequence length, multi-scale self-attention enables models to capture patterns at different scales and extract more robust features[15], [16].

Given a sequence of features $X \in R^{N\times D}$, where N is the length of sequence and D is the dimension of features, regular MSA first projects X into three matrices: the query $\boldsymbol{Q}$, the key $\boldsymbol{K}$ and the value $\boldsymbol{V}$, and then decompose the three matrices into H sub-spaces which corresponds to H heads. MSA computes the scaled dot-product attention in each head and integrates the results of all heads, which can be formulated as:

$$\begin{aligned} \mathrm{head}_i &= \mathrm{softmax}\left(\frac{Q_i K_i^T}{\sqrt{d}}\right) V_i \\ \boldsymbol{O} &= [\ \mathrm{head}_{\ 1},\ \mathrm{head}_{\ 2}, \cdots \mathrm{head}_{\ H}]\, W^o \end{aligned} \tag{5}$$

where i indicates i-th head, d indicates the dimension of each head, and W^o are parameter matrices.

To incorporate both local and global context information into our model, we adopt multi-scale multi-head self-attention. Specifically, we restrict the attention area of only two heads, while the other heads retain the original global attention scale. This design allows the model to learn representations that capture both fine-grained and coarse-grained information, enabling it to extract robust features from speech data. A restricted attention head can be computed as:

$$\mathrm{head}(X, w)_{i,j} = \mathrm{softmax}\left(\frac{Q_{i,j} C_{i,j}(K, w)^T}{\sqrt{d}} C_{i,j}(V, w)\right) \tag{6}$$

where j indicates j-th position, $C()$ is the function to restrict the attention area with a context window of length w . Specially, one of the two restricted heads is used to learn history context information, thus $C()$ is defined as:

$$C_{i,j}(K, w) = [K_{i,j-w}, \cdots, K_{i,j}] \tag{7}$$

Another restricted heads is used to learn future context information, in which case $C()$ is formulated as:

$$C_{i,j}(K, w) = [K_{i,j}, \cdots, K_{i,j+w}] \tag{8}$$

The history window size and future window size at each layer are the same, while the size of window grows up progressively from bottom layer to top layer. After pre-training, We use the connectionist temporal classification (CTC) loss [17] for ASR fine-tuning. Whole model weights except the convolutional audio encoder remains frozen and the projection layer is removed and replaced with a randomly initialized softmax layer.

IV. EXPERIMENTAL DETAILS

A. Data

We evaluated the performance of the PMS-SSL nethod on LibriSpeech task [18] . To keep the tasks comparable with the base HuBERT model, the full 960 hours of LibriSpeech audio are used for pre-training. For fine-tuning stage, we consider two different partitions: 10 hours and 100 hours. Each model is tested on the standard LibriSpeech test_other sets and test_clean sets respectively.

B. Experiment Setup

We followed the pre-training process and model configuration used in HuBERT to train our model. To generate the target labels for pre-training stage, we ran k-means clustering with 100 clusters on 39-dimensional MFCC features over the full 960 hours of training audio sets for the first iteration. For the second iteration, we ran multiple k-means clustering with different cluster numbers $\{50, 100, 300, 500\}$ on the latent features extracted from the 6th transformer layer of the pre-trained model to obtain different granularity target sets. The SSL loss was computed on both the top layers and intermediate layers with different target sets. Since the extracted feature dimension was much higher than the MFCC features, we randomly sampled 10% of the extracted features for clustering to reduce memory costs. The model was trained on 32 GPUs, with a batch size of 87.5 seconds of audio per GPU. The first iteration was trained for 250k steps, while the second iteration was trained for 400k steps.

As for the masking configurations, $p = 8\%$ of the waveform encoder output frames were randomly selected as mask start

and the mask span is set as $l = 10$. We also used Adam optimizer with $\beta = (0.9, 0.98)$ to train the model, and the learning rate ramped up linearly from 0 to the peak learning rate for the first 8% of the training steps, and then decayed linearly back to zero. The peak learning rate was $5e^{-4}$.

During the supervised fine-tuning, the model was fine-tuned on 8 GPUs with a batch size of 200 seconds of audio per GPU. In addition, the parameters of the waveform encoder were fixed, and only the new softmax matrix was trained. We used Adam optimizer with tri-stage schedule to fine-tune the model and adopted the word error rate (WER) on the dev-other subset as the criterion for model selection.

Finally, we used wav2letter++ [19] beam search decoder with beam size 1500 for 4-gram language model fused decoding, which optimizes:

$$\log p_{CTC}(\boldsymbol{y} \mid \boldsymbol{x}) + w_1 \log p_{LM}(\boldsymbol{y}) + w_2|\boldsymbol{y}| \tag{9}$$

where the hyperparameter settings are the same as those used in HuBERT method.

C. Results and analysis

Table 1 and Table 2 presents the performances of different pre-trained models in the w/o language model setting , all of which are pre-trained on 960h subset and fine-tuned on 10-hour and 100-hour subsets. We compare the proposed PMS-SSL method with several competitive self-supervised approaches in the literature, including wav2vec 2.0 [5], HuBERT[6] and ILS-SSL [10].It should be noted especially that ILS-SSL adds a bucket relative position embedding to the model, which further improves the performance. For comparison with ILS-SSL, we select same supervised layer set $\{4, 12\}$ and target set $\{500, 500\}$ to pre-trained models without bucket relative position embedding. As for PMS-SSL, we set the supervised layer set K as $\{6, 12\}$, and the target sets with size $\{300, 500\}$ are used for computing self-supervised learning loss. What's more, we set w (attention context window size) at layers 1-6 as 80 and set w at layers 7-12 as 160 respectively.

The results shown both in Table 1 and Table 2 suggest that the proposed mthhod are practical strategies that work, whether including 4-gram language model or not. In order to prove the practicability and generalization of the proposed pre-trained model, the results on different self-supervised approaches with 4-gram language model are taken as the main reference as described in Table 2.

In the ultra-low resource setup with 10 hours of labeled data, PMS-SSL method obtained the WERs of 4.11% / 8.27% on test_clean / test_other set respectively, which achieves a relative word error rate reduction of 4.6% / 13.7% compared with standard HuBERT, and 3.9% / 5.8% compared with ISL-SSL mthod. By further increasing the amount of labeled data from 10 hours to 100 hours, PMS-SSL method can also get stable improvement, with a relative word error rate reduction of 5.9% / 12.7% compared with HuBERT, and 3.3% / 5.3% compared with ISL-SSL. Overall, progressive learning paradigm makes self-supervised approaches obtain more competitive advantage.

D. Ablation Studies

To explore how the selected supervised layer set K and the target sets influence the performance of pre-trained models, we perform some ablation experiments without multi-scale self-attention. We select different sizes of target sets for the selected supervised layer. And all ablation models are finetuned with 10-hour subset and the results evaluated on test_other set are listed in Table 3, where target_layer denotes K and target_label denotes the size of selected target sets. As shown in Table 3, supervised layer set $\{6, 12\}$ paired with target set $\{300, 500\}$ achieves the best performance for two target layers. What's more, both the two sets: $\{4, 12\}$,$\{6, 12\}$ outperform the set $\{8, 12\}$, which indicates that small-size target sets are more suitable for lower layers.

In addition, more supervised layers such as $\{3, 6, 12\}$ is introduced to prove the motivation. Compared with the super-

TABLE III
RESULTS OF THE MODELS WITH DIFFERENT SUPERVISED LAYER.

Target_layer	Target_label	Test_other
4,12	300,500	8.76
6,12	300,500	**8.55**
8,12	300,500	9.04
3, 6, 12	100, 300, 500	8.71
3, 6, 12	50, 300, 500	**8.51**

TABLE IV
RESULTS OF THE MODELS WITH DIFFERENT ATTENTION SCALE.

layer	Window_size	Test_other
base		8.55
1-12	80	8.38
1-6,7-12	80,160	8.27

vised layer set $\{3, 6, 12\}$ paired with target set $\{100, 300, 500\}$, target set $\{50, 300, 500\}$ achieved better performance because learning difficulty has such a high correlation with different target granularity. Meanwhile, supervised layer set $\{3, 6, 12\}$ paired with target set $\{50, 300, 500\}$ can also guarantee better performance than the supervised layer set$\{6, 12\}$.

Furthermore, we build some ablation models with different attention window size w to explore the effect of different attention scales. As mentioned in section 3.2, the receptive field of different layers has a correlation with the progressive target numbers. The attention areas of only two heads are restricted. Based on the model with supervised layer set $\{6, 12\}$, we restrict the attention area of each layer into variable scopes. The results of different attention scale are listed in Table 4. The setting at second line restricts the attention area of each layer into an 80-timestep context window, which achieves 2.0% WER reduction on test_other. The setting at third line enables the attentions of layer 1-6 work on an 80-timestep scope and enables the attentions of layers 7-12 work on a 160-timestep scope, which obtains 3.4% WER reduction.

V. Conclusion

In this paper, we proposed a novel approach to self-supervised learning for speech recognition, called Progressive Multi-Scale Self-Supervised Learning (PMS-SSL). Our method introduces a progressive learning strategy by assigning different granularity target sets for different layers, with the target set size increasing progressively from the bottom to the top supervised layer. In addition, we incorporated a multi-scale structure into the multi-head self-attention mechanism to restrict the attention area into a small scope at lower layers and a larger scope at higher layers. Experimental results demonstrate that PMS-SSL outperforms the base HuBERT model, indicating the effectiveness of our proposed approach.

***Abstract*—Speech pre-training method has shown great success in learning useful and general latent representations from large-scale unlabeled data. In order to further improve the performance of self-supervised learning method for specific downstream tasks, an improved approach based on data2vec framework with soft supervised hidden unit is proposed. To take full advantage of the labeled data from downstream task, a supervised model is firstly trained to extract supervised hidden unit. And then based on data2vec, an extra Bert-like prediction task with soft cluster distance is introduced to match the downstream task and avoid unnecessary information loss. The proposed method can form a virtuous circulating utilization pattern for the downstream labeld data. Experiments on the small open-source Mandarin speech corpus AISHELL-2 and large private-source Mandarin speech corpus TRANS-L tasks show that our method can achieve relative character error rate reductions of 13.2% and 5.2% respectively when pre-trained on AISHELL-2 and TRANS-L corpus compared with data2vec framework.**

I. Introduction

With the rapid development of deep learning, intelligent speech technology has been applied in a wide range of fields. However, automatic speech recognition (ASR) system is still significantly dependent on labeled data, which may limit its application and popularization in low resource scenarios.

In order to better use the unlabeled speech data, self-training and self-supervised learning (SSL) methods have been adopted to improve the recognition performance. Self-training method, which applies the pseudo-labels on unsupervised speech data to augment training effect, may depend a great deal on the quality of pseudo-labels [1]–[5]. Self-supervised learning for speech data aims to learn better representations by predicting targets that are derived from the input speech data itself [6]–[10]. These typical methods include prediction of the future frames on past frames or reconstruction of the masked input frames, and so on.

As one of the representative self-supervised learning method for speech filed, HuBERT carries out the clustering operation to obtain the target labels for a BERT-like prediction loss [8]. Compared with HuBERT, data2vec provides a more general paradigm by predicting the contextualized latent representations of the full input data [10]. Unlike the limitation on the number of target units for HuBERT, there are little or no constraints for data2vec. However, similar to other self-supervised learning method, HuBERT and data2vec tend to generate a more universal speech representation which may be suitable for multiple downstream tasks. Obviously, using ensemble techniques to combine multiple variations of self-supervised learning method can achieve even higher performance [11].

So as to better grasp the subdivision scenarios and improve the interpretability of the hidden layer representation, specific downstream tasks can be closely bound up with the self-supervised learning method. In [12], an end-to-end joint unsupervised and supervised training method is proposed to select a pre-trained checkpoint which is better suited to the downstream ASR task. In [13], embeddings trained both under supervised and unsupervised settings are explored to improve robustness to accents. However, the existing methods do not fully exploit the advantages of downstream tasks, especially the labeled data which contain abundant information. In terms of ASR task, we argue that the performance could be further improved if the self-supervised network focus on learning content information from downstream implementation tasks. Meanwhile, multiple iteration pattern such as HuBERT may affect the generalization performance. Obviously, better initial target labels from supervised model can accelerate convergence and improve the representation while most methods do not fully exploit these advantages in low resource application tasks.

Motivated by the above, an improved self-supervised multi-task learning method which is more suited for the downstream task is proposed. Take ASR task for example, the labeled data are not only used to optimize the final model during the fine-tuning stage in the usual manner, but also to guide the generation of target labels for pre-training stage. The two training stages including pre-training and fine-tuning can form a virtuous cycle. Firstly, a supervised ASR model is trained with a certain amount of labeled speech data from downstream task. Then all unlabeled audio are fed into the supervised model to extract the latent features, and a quantization procedure similar to HuBERT is applied on these feature to get the target labels for self-supervised stage. Based on the data2vec self-supervised framework, an extra BERT-like prediction task is introduced to match the downstream task. In order to avoid unnecessary information loss, the BERT-like prediction task use soft cluster distance. To evaluate the effectiveness of the proposed method, we conducted experiments on both the small open-source Mandarin speech corpus AISHELL-2 and large private-source Mandarin speech corpus TRANS-L.

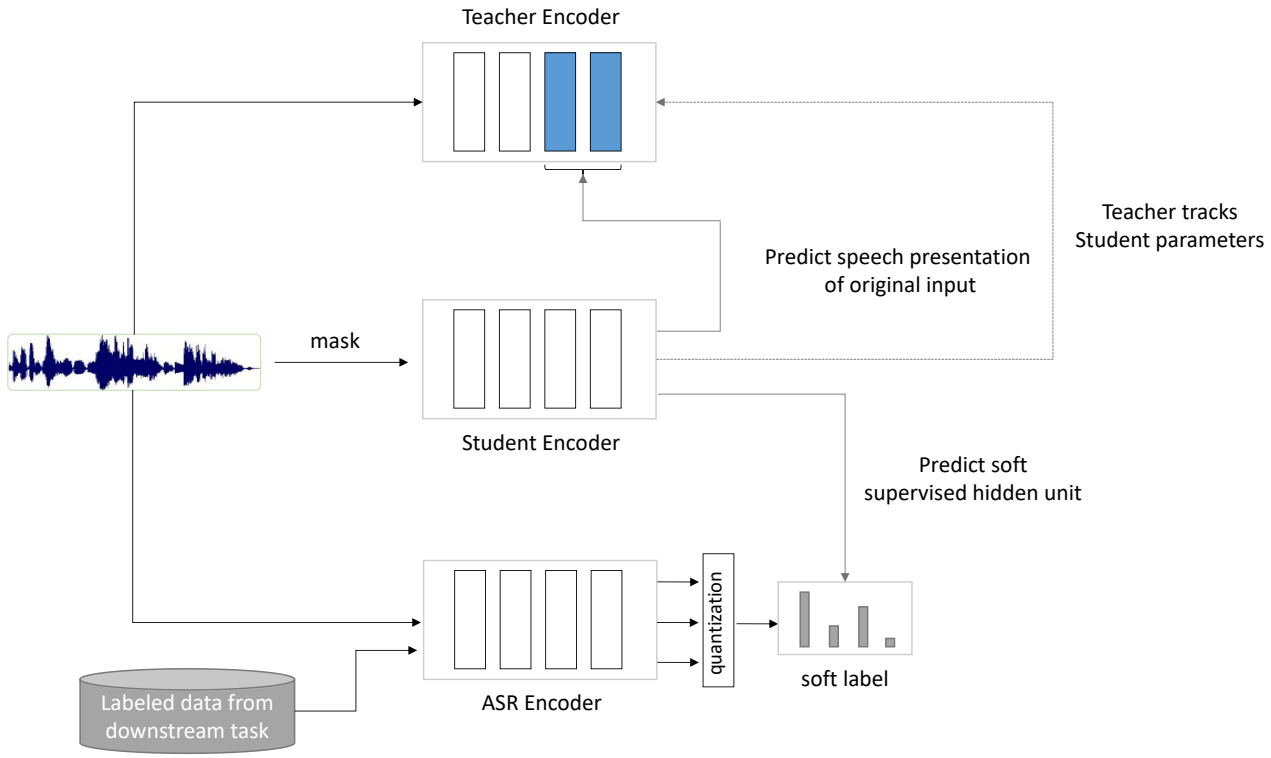

Fig. 1. The framework of proposed data2vec with soft supervised hidden units.

Compared with the baseline data2vec, our approach fintuned on AISHELL-2 achieved relative CER reductions of 13.2% and 5.2% respectively when pre-trained on AISHELL-2 and TRANS-L corpus.

II. RELATED WORK

As the mainstream theory, self-supervised pre-training paradigm has develop various types of method. Both HuBERT and data2vec have been proved to be effective for downstream task. In HuBERT, an offline clustering step is utilized to generate aligned target labels for a BERT-like pre-training [8], [10], [14]. Different from wav2vec 2.0, HuBERT benefits from the offline clustering step due to the consistency of the targets [7], not just their correctness. What is more, the prediction loss is only applied over the masked regions, forcing the model to learn a combined acoustic and language model over the continuous inputs. HuBERT pre-training adopts an iterative re-clustering and re-training process. As a more general pre-training paradigm, data2cvec predicts latent representations of the full input data based on a masked view of the input in a self-distillation setup using a standard Transformer architecture.

Multi-task learning in self-supervised pre-training method aims to introduce some extra task to improve the representation of unlabeled data or better match downstream tasks. Some research work has focused on applying multi self-supervised method [15], [16] while others has combined self-supervised learning and supervised learning to improve downstream task performance [17].

III. PROPOSED METHOD

In order to take advantage of different self-supervised pre-training method and combine more guidance information from downstream task, an improved self-supervised learning method based on data2vec with soft supervised hidden unit is proposed. The architecture of the proposed method is illustrated as figure 1. A supervised ASR model with a certain amount of labeled speech data from the downstream tasks is firstly trained to extracted latent feature. And then simple discrete latent variable models such as k-means are used to generate target units with the deep representations. Finally the data2vec framework is trained alongside with the soft supervised instruction loss which is more suitable for the downstream task. The two training stages including pre-training and fine-tuning forms a mutually reinforcing mechanism.

A. Extraction of supervised latent feature

For most self-supervised paradigm, the labeled information from downstream task is insufficiently exploited. In order to combine some guidance information to Data2vec framework, an offline clustering step to provide aligned target labels for a BERT-like prediction loss is introduced into the framework.

To obtain better supervised representation, the first step of the proposed method is using the labeled data from the specific downstream task to train a supervised instructive

model. Compared with standard HuBERT pre-training process, the discrete targets are assigned by clustering on the supervised model instead of MFCC features to strengthen the content presentation and reduce the training cost.

To simplify the training procedure, the model architecture used in supervised training is same as data2vec pre-training. A classification layer and a CTC loss is added to the baseline architecture, and the model is trained until converges. After supervised training, the supervised latent feature can be extract from last transformer layer, denoted as $H = [h_1, h_2, ..., h_t]$.

B. Quantization of supervised feature

After supervised training, the extracted latent feature is expected to instruct the audio pre-training. Motivated by HuBERT, the latent feature is quantized to build the supervised hidden unit. Feature quantization can improve the consistency of training target, where all frames are clustered into limited classes. In addition, by using different codebook size, the granularity of target labels can be more easily controlled.

A mini batch K-Means algorithm implemented in scikit-learn is used to trained the k-means model [18]. The cluster centers C can be denoted as $C = [c_1, c_2, ..., c_i]$, where c_i represents i-th cluster center. The assigned center of each frame represents supervised hidden unit, which can be used as training target like HuBERT. The training object can be wrote as follow:

$$\mathcal{L}_{Sup} = -\sum_{i} logP_f(i) \tag{1}$$

where P_f is the parameterized distribution over codebooks:

$$P_f(i) = \frac{exp(sim(Ao_t, e_i)/\tau)}{\sum_j exp(sim(Ao_t, e_j)/\tau)} \tag{2}$$

where $O = [o_1, o_2, ..., o_t]$ is the masked version of feature, A is the project matrix, e_i is the embedding of cluster center i, and τ is a logit scalar set to 0.1.

C. Soft supervised instruction loss

However, the progress of the quantization step will also cause information loss, because different frames may have different distances to codebooks even though they are assigned to the same one. On the other hand, the distance itself also contains the information of acoustic property. To tackle the information loss caused by quantization, we define $P_t(i)$ as the negative softmax of t-th frame to measure the distances to center i:

$$P_t(i) = \frac{exp(-||h_t - c_i||^2)}{\sum_j exp(-||h_t - c_j||^2)} \tag{3}$$

On this basis, the training objective can be rewrote by intorducing the distances to codebooks as:

$$\mathcal{L}_{Sup} = -\sum_{i} logP_f(i)P_t(i) \tag{4}$$

D. Model pre-training and fine-tuning

The pre-training and fine-tuning details follow the scheme of data2vec. The masked version of waveform can be fed into the main framework, followed by a feature extractor composed by convolution layers, and transformer layers are used on extracting high-level feature. The teacher network is fed with unmasked waveform, and updated by exponential mean average. The training target is about mean square error, which can be computed between student and teacher:

$$\mathcal{L}_{MSE} = (y_t - f_t(x))^2 \tag{5}$$

where y_t is the output of teacher network, $f(x)$ is the prediction of student network.

The total training objective can be defined as follow:

$$\mathcal{L} = \mathcal{L}_{MSE} + \lambda\mathcal{L}_{Sup} \tag{6}$$

where λ is used as a hyper-parameter to balance the two tasks.

During pre-training, the model is joint optimized by $\mathcal{L}_{MSE}$ and $\mathcal{L}_{Sup}$. While in fine-tuning procedure, a linear layer and a CTC loss is added on the model, and the model is trained with labeled data for specific downstream task.

IV. Experimental Evaluation

A. Data

We evaluated the performance of our proposed approach on both the small open-source speech corpus AISHELL-2 and the sizeable private-source speech corpus TRANS-L; the details of the two speech recognition corpus are illustrated as follows.

AISHELL-2 dataset: The AISHELL-2 task is a benchmark for large-Mandarin-vocabulary continuous speech recognition, so we choose it as the main task. As an elaborately prepared public datase, AISHELL-2 contains 1000 hours speech data. The dev-other subset is used to select the final model. For pre-training stage, all 1000 hours speech data are used to conduct self-supervised learning. In addition, 100 hours and 1000 hours speech data are used as different experimental configuration both on first supervised training stage and downstream fine-tuning stage respectively.

TRANS-L dataset: TRANS-M is a private-source Mandarin dataset with 50K hours speech data which combines multiple data styles, including lessons, conferences, interviews, and television programs. Unlike AISHELL-2, TRANS-L turns to a more colloquial and dialogic linguistic style. We use TRANS-L dataset during the pre-training stage, while all AISHELL-2 are used on first supervised training stage and downstream fine-tuning stage.

B. Model configuration

For AISHELL-2 dataset, the model configuration is same as data2vec. The architecture of the model is composed of 12-layer transformer blocks with 1024 hidden dimension. For TRANS-L dataset, the feature extractor is removed and the waveform input is replaced by 40-dimensional filterbank. These modifications are mainly used to improve the training efficiency.

TABLE I
CER (%) RESULTS OF DIFFERENT AMOUNT OF TRAINING DATA ON AISHELL-2.

Model	data for first supervised training(h)	data for pre-traing (h)	data for downstream task(h)	dev	test
data2vec	-	1000	100	9.6	9.8
our method	100	1000	100	9.1	9.6
data2vec	-	1000	1000	7.2	7.6
our method	100	1000	1000	6.6	7.1
our method	1000	1000	1000	6.2	6.6

C. training configuration

The AISHELL-2 audios are fed into the main framework with 16KHZ waveform. For AISHELL-2 pre-training stage, we decrease the updates to 20K while keep other configurations the same as wav2vec 2.0. For AISHELL-2 fine-tuning stage, the updates of 100 hours is increased to 120K, while the configuration of 1000 hours keeps the same as standard configurations. The configurations of supervised training is similar as fine-tuning stage. The only difference is that the updates is increased into 350K and 500K for 100 hours and 1000 hours labeled data respectively. The standard data2vec result was reproduced with fairseq tool [19]. For TRANS-L dataset, the training configurations are same as AISHELL-2.

D. Results on AISHELL-2 dataset

The results with different amount of training data are listed in Table I. The training data were used both in the first supervised training stage and downstream fintuning stage. Compared with standard data2vec, the proposed method can get significant recognition performance improvement on different amount of training data. Especially as the amount of training data increases into 1000 hours, the CER of development set dropped from 7.2% to 6.2% while test set dropped from 7.6% to 6.6%, which indicated that the proposed method achieve a considerable improvement of over 13%. Obviously, the quality of the first supervised model affects the effectiveness of the target units used for pre-training stage. That is to say, with a well-trained supervised model suited for downstream task, the pretraining stage can achieve better performance.

E. Results on TRANS-L dataset

The results on TRANS-L dataset are shown in table II. After replacing the feature extractor and training with more unlabeled data, the CER on AISHELL-2 test set is also significantly improved because of the better representation learning. The 5% relative increase demonstrates that our proposed method is still effective on large-scale industrial audio dataset. Unintentionally, the increase in data size and the mismatch between pre-training and downstream task data to some extent reduced the improvement of our method.

F. Ablation studies

To evaluate the effectiveness of the proposed soft supervised instruction label, we replace the soft label with hard label. The experiment is conducted on AISHELL-2 while 1000 hours data can be used for first supervised training stage, pre-training stage and downstream fine-tuning stage.

TABLE II
CER (%) RESULTS OF DIFFERENT PRE-TRAINING METHOD WHICH FINTUNED ON ALL AISHELL2 DATA.

Model	data for pre-traing(h)	test
data2vec	50k	5.8
our method	50k	5.5

TABLE III
CER (%) RESULTS OF DIFFERENT LABELS USED IN OUR METHOD.

Model	dev	test
Hard lables	6.4	6.9
Soft lables	6.2	6.6

The results in Table III shows that the CER rises from 6.2% to 6.4% on AISHELL-2 development set, and rises from 6.6% to 6.9% on AISHELL-2 test set. The results further proves the involving of distance information leads to better pre-training effectiveness. To further illustrate the information loss of hard label, we choose some frames from latent feature of supervised model and depict their $P_t(i)$ in figure 2. Some frames are in unimodal distribution while the other are in multimodal distribution. For the multimodal distribution, applying hard target will result in information loss.

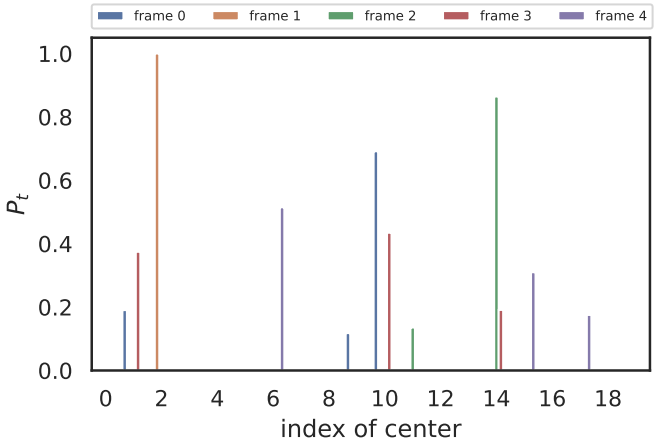

Fig. 2. P_f of extracted supervised latent features, and the frames are distinguished by color.

V. Conclusion

In this work, an improved self-supervised learning method based on data2vec with soft supervised hidden unit is proposed, which is more suited for downstream task. The experiments on both AISHELL-2 and TRANS-L achieve better performance compared with the baseline data2vec. We believe that this approach has great potential for improving the performance of downstream task which can form a virtous circulatin utilization pattern for the labeled data.

***Abstract*—Traditional deep learning based speech emotion recognition (SER) methods are restricted to the lack of emotional speeches. Recently, the self-supervised learning (SSL) speech representation model is emerging and has become the state-of-the-art method for SER because of its ability to learn a more generalized emotion representation. Some SSL models adopt a similar network architecture, but utilize various training strategies or pre-trained speech data to learn speech representations from different perspectives, thus containing complementary information for the SER task. In this paper, we conduct an investigation of ensemble learning with six SSL models for SER using three kinds of ensemble methods: decision ensemble, late feature ensemble, and early feature ensemble. The six SSL models adopted in this paper are Wav2vec 2.0 Base, HuBERT Base, WavLM Base, WavLM Base+, UniSpeech-SAT Base, and UniSpeech-SAT Base+. Our experimental results on three datasets show that: 1) all three kinds of ensemble learning methods can significantly improve the SER performance, demonstrating that there may exist a large amount of complementary information between different SSL models; 2) in terms of the decision ensemble methods, the evidence theory (ET) based fusion performs better than the average-based fusion because of its ability to deal with the uncertainty of different models; 3) the ET-based decision ensemble is the best in comparative ensemble methods because of its superior performance and lower computational cost.**

I. Introduction

Speech emotion recognition (SER) is the task of identifying the emotional state of the speaker from speech, which plays a critical role in the field of human-computer interaction. Since it may be difficult for humans to perceive others' emotions in some scenarios, understanding humans' emotions is a more challenging task for computers. Considerable efforts have been devoted to improving the performance of SER in the research community. Traditional machine learning (ML) approaches rely on handcrafted features (e.g. OpenSmile [1]) or feature engineering techniques, resulting in low generalization on various datasets. With the rapid development of deep learning (DL), the DL-based SER approaches [2]–[4] become popular and achieve superior performance than ML-based methods. However, the improvement of DL-based algorithms is restricted to the small size of the SER dataset. Compared with the large-scaled datasets on other speech-related tasks (e.g., LibriSpeech [5] for speech recognition and VoxCeleb [6], [7] for speaker recognition), the commonly used SER datasets (e.g. IEMOCAP [8], Emo-DB [9] and RAVDESS [10]) are not enough for DL models to learn a generalized representation.

Recently, several self-supervised learning (SSL) speech representation models [11]–[17] are emerging and perform well on various speech-related downstream tasks. Those SSL models are pre-trained to learn a generalized and useful representation with a large number of unlabeled speeches. Fine-tuning the SSL model becomes the state-of-the-art SER method and shows higher accuracy on many SER datasets [18]–[20]. Ref. [21] evaluates nineteen SSL models on five SER datasets and we observe that four kinds of SSL models, i.e., Wav2vec 2.0 [12], HuBERT [13], WavLM [14] and UniSpeech-SAT [15], perform significantly better than other models. The four SSL works adopt a similar network architecture but utilize different training strategies and objective functions to learn speech representations from different perspectives. In addition, these models use various kinds of speech data during the pre-training and learn various knowledge. Based on above observations, we argue that these SSL models contain complementary information for SER tasks, which inspires us to exploit ensemble learning methods of SSL models.

In this paper, we conduct an investigation about ensemble learning of SSL models for SER using three kinds of ensemble methods: decision ensemble, late feature ensemble, and early feature ensemble. The decision ensemble method fuses the probabilities produced from each fine-tuned SSL model via the average-based fusion or the evidence theory (ET) based fusion. The late feature ensemble approach trains a simple classification model with two fully-connected (FC) layers to combine the features from fine-tuned SSL models. The early feature ensemble method trains a well-performed backend model called ECAPA-TDNN [22] based on several kinds of pre-trained SSL features. Six SSL models are utilized for the ensemble including Wav2vec 2.0 Base, HuBERT Base, WavLM Base, WavLM Base+, UniSpeech-SAT Base, and UniSpeech-SAT Base+.

Our experiments are conducted on three commonly used SER datasets, IEMOCAP [8], RAVDESS [10] and MSP-IMPROV [23]. The experimental results show that: 1) all three kinds of ensemble learning methods can significantly improve the SER performance, demonstrating that there may exist a large amount of complementary information between different SSL models; 2) in terms of the decision ensemble methods, the ET-based fusion performs better than the average-based fusion because of its ability to deal with the uncertainty of

TABLE I
A SUMMARY OF THE SIX SSL MODELS USED IN THIS PAPER.

Model	Size	Pre-trained dataset	Key Techniques
Wav2vec 2.0	Base	960 hrs LibriSpeech	Masking latent representations; solving a contrastive task over quantized speech representations.
HuBERT	Base	960 hrs LibriSpeech	Generating aligned target labels with a K-Means cluster approach; applying the prediction loss over masked regions.
WavLM	Base	960 hrs LibriSpeech	Employing Gated relative position bias; Jointly Learning masked speech prediction and denoising.
	Base+	60k hrs Libri-Light & 10k hrs GigaSpeech & 24k hrs VoxPopuli	
UniSpeech-SAT	Base	960hrs LibriSpeech	Integrating utterance-wise contrastive loss; presenting an utterance mixing strategy for data augmentation.
	Base+	60k hrs Libri-Light & 10k hrs GigaSpeech & 24k hrs VoxPopuli	

different models; 3) the ET-based decision ensemble is the best in comparative ensemble methods because of its superior performance and lower computational cost. We hope that our observations can provide the research community with a new perspective to improve the effectiveness of SSL models on the SER task.

II. Related Work

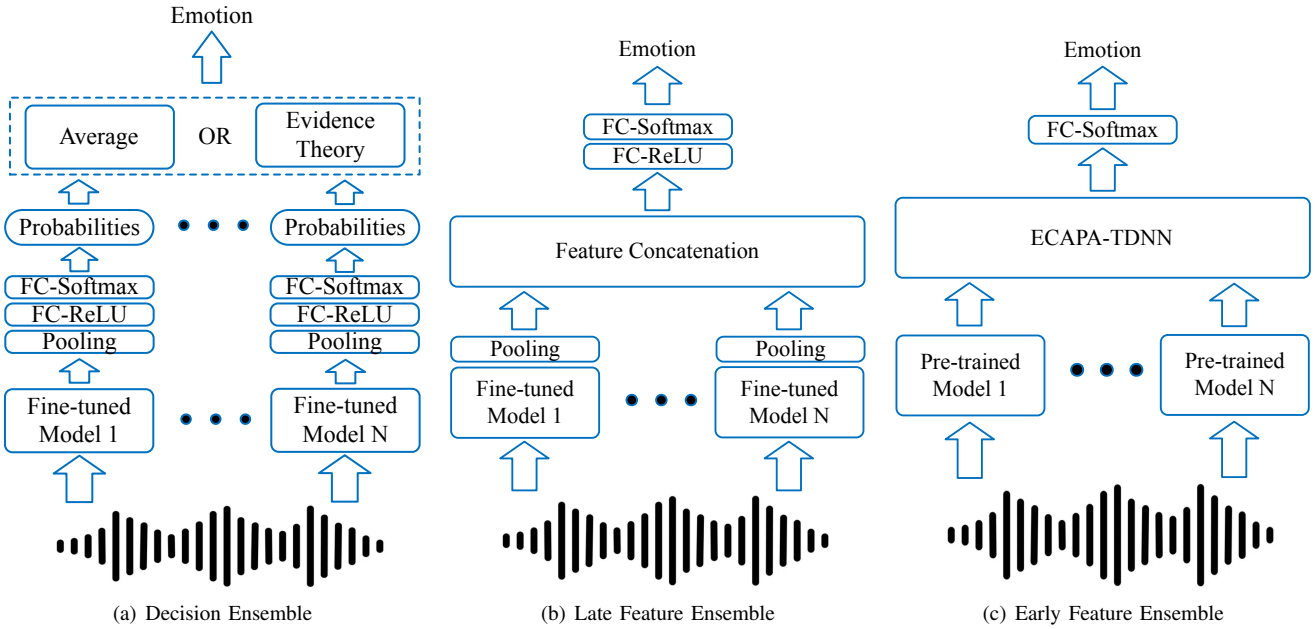
A. Self-supervised speech representation learning

Self-supervised speech representation learning provides a single universal model which can benefit a wide variety of speech-related tasks [24]. With the help of the release of more and more large-scale speech databases, many SSL models have emerged in recent years. Among them, Wav2vec 2.0 [12], HuBERT [13], WavLM [14] and UniSpeech-SAT [15] are four widely used models. They adopt similar network architectures which consist of a CNN-based feature extractor module, a feature projection module, and a Transformer-based [25] feature encoder module. The main differences between them are the employed training approaches and the amount of training data. Table I gives a summary of the six SSL models used in this paper. The four kinds of SSL works utilize various training objectives and data augmentation techniques. In addition, WavLM and UniSpeech-SAT provide the Base+ model which extends the training data with the GigaSpeech [26] and the VoxPopuli [27] dataset. Thanks to the diversity of training objectives and pre-trained speech data, the six SSL models can generate speech representations from different aspects with the same model size. Hence, we select the six SSL models as the baseline model to evaluate all ensemble methods in this paper.

B. Fine-tuning SSL models for SER

Fine-tuning SSL models has become the state-of-the-art method for many downstream tasks. Ref. [28] applied the Wav2vec 2.0 framework to speaker recognition and achieved a comparable EER of 1.88% on the VoxCeleb dataset. Ref. [20] presented a simple framework, namely SUPERB, to benchmark the capability of SSL models on downstream speech processing tasks. Ref. [29] explored fine-tuning on Wav2vec 2.0 and HuBERT for three speech tasks.

In terms of the SER task, due to the insufficiency of large-scale well-labeled emotional data, it is hard for current DL architectures to learn a generalized and robust emotion representation. Since performing well with a small amount of fine-tuned data is a main advantage of SSL models, many researchers utilize fine-tuned SSL models or pre-trained SSL features for SER. Ref. [19] combined the different layers in Wav2vec 2.0 model and then extracted pre-trained features for SER. Ref. [18] developed a novel method for fine-tuning Wav2vec 2.0 and yielded better performance on the IEMOCAP dataset. Ref. [21] evaluated the SER performance of nineteen SSL models on five datasets. However, there is a main limitation in [21] that cross-validation is not performed. Ref. [30] conducted a comprehensive analysis of fine-tuning Wav2vec 2.0 and HuBERT for SER. The main difference between our work and prior works is that we mainly focus on the ensemble learning of the SSL models and conduct extensive experiments on six SSL models to demonstrate the effectiveness of the adopted methods.



C. Ensemble learning

Ensemble learning aims to exploit multiple classifiers or models to yield better performance than any single one, which is widely applied in speech-related tasks. Ref. [31] proposed an ensemble of seven different models to predict the mean opinion score. Ref. [32] proposed to utilize an ensemble of many SSL representations and models for the speech recognition task. Ref. [33] proposed an ensemble of various pre-trained SSL speech models to train a perceptual loss for speech denoising. In this paper, we adopt three kinds of ensemble methods to combine six different SSL models for SER. To the best of our knowledge, our work is the first to apply an ensemble of SSL models to the SER task.

III. Approach

A. Fine-tuning SSL models

Fig. 1 shows the three kinds of used ensemble methods in this paper: decision ensemble, late feature ensemble, and early feature ensemble. Both the decision ensemble method and late feature ensemble method need fine-tuned SSL models. Hence, the first step is fine-tuning six SSL models in Table I with emotion labels, respectively. The detailed architecture is shown in 1(a). The output of the last layer in the feature encoder module is extracted. Then the average pooling operation is

(a) Decision Ensemble (b) Late Feature Ensemble (c) Early Feature Ensemble

Fig. 1. Three kinds of ensemble methods of the SSL models. The "Fine-tuned Model" represents the model fine-tuned with emotion labels, and the "Pre-trained Model" means it is the pre-trained version without fine-tuning.

performed to acquire a 768-dimensional embedding. Finally, the embedding is fed into two FC layers to generate the predicted emotions. We exploit the weighted cross-entropy loss to train all models. In the fine-tuning step, only the feature encoder module is trained, while the parameters of the feature extractor module and the feature projection module are frozen. A modified version of SpecAugment [34] is exploited for SSL models to obtain better generalization.

B. Decision ensemble

The decision ensemble method fuses the probabilities from each fine-tuned SSL model, as shown in Fig. 1(a). Since the average and the evidence theory are both sample-level fusion methods, we take a sample as an example. Assuming that the probability produced by the SSL model n for this sample is

$$P_n = [p_1^n, p_2^n, ..., p_M^n], \forall n \in \{1, 2, ..., N\}, \tag{1}$$

where M is the number of the emotion class and N is the number of SSL models.

1) Average: The first approach is a simple average fusion, which averages the probabilities of each class:

$$P_{Avg} = \frac{\sum_{n=1}^{N} P_n}{N}. \tag{2}$$

2) Evidence theory: The evidence theory approach [35]–[38] is a reasoning theory that deals with uncertainty. The ensemble decision based on evidence theory is the fusion of the decision beliefs produced by several SSL models through Dempster's combination rule [35] and can be presented as:

$$P_{ET} = \underbrace{P_1 \oplus P_2 \oplus \cdots \oplus P_N}_{N-1 \text{ times}} \tag{3}$$

where $\oplus$ represents the Dempster's rule of combination. Taking the emotion recognition result produced by certain SSL model P_n as one piece of "evidence" in evidence theory, two pieces of evidence P_1 and P_2 can be combined with Dempster's fusion rule as follows:

$$P(A) = \frac{\sum_{B \cap C = A} P_1(B) P_2(C)}{1 - K} \tag{4}$$

where

$$K = \sum_{B \cap C = \emptyset} P_1(B) P_2(C) \tag{5}$$

where A, B and C represent the emotion classes of the SSL models.

C. Late feature ensemble

The late feature ensemble method takes all features extracted from fine-tuned SSL models as input and trains another network including two FC layers, as shown in Fig. 1(b). The emotion embeddings from all fine-tuned SSL models are combined by a feature concatenation operation. Note that all parameters of fine-tuned models are frozen and only the parameters of top FC layers are optimized in this training step. This method is inspired by the findings in [39], which shows that the two-step training can greatly improve SER performance. On the other hand, it is difficult to jointly fine-tune the parameters of several SSL models because of their large model sizes. The late feature ensemble method can be regarded as an alternative method.

D. Early feature ensemble

The early feature ensemble method utilizes the pre-trained speech representations from multiple SSL models and trains a small network as an emotion classifier. Note that the SSL

TABLE II
THE LABEL DISTRIBUTION OF THE DATASETS USED IN THIS PAPER.

Dataset	Angry	Happy	Neutral	Sad	Calm	Surprised	Fear	Disgust	Total
IEMOCAP	1,103	1,636	1,708	1,084	-	-	-	-	5,531
RAVDESS	192	192	96	192	192	192	192	192	1,440
MSP-IMPROV	792	2,644	3,477	885	-	-	-	-	7,798

models in this approach are not fine-tuned with emotion labels. In this paper, we choose the ECAPA-TDNN [22] as the backbone network. ECAPA-TDNN is the state-of-the-art network in the speaker recognition tasks and also performs well on SER [17]. The architecture of ECAPA-TDNN is composed of two one-dimensional convolutional layers, three SE-Res2Blocks, an attentive statistics pooling layer, and an FC layer. The input of ECAPA-TDNN in the original paper is 80-dimensional MFCCs. In our implementation, we concatenate the output of SSL models on feature dimension. The output of ECAPA-TDNN is a 192-dimensional vector, followed by an FC layer to predict the emotion class. Like the late feature ensemble approach, the parameters of pre-trained SSL models are also frozen during the training.

IV. EXPERIMENT

A. Datasets

	Scheduler	polynomial decay		

[a] Early stopping with the patience of 50 epochs.

All experiments are conducted on three public datasets, IEMOCAP, RAVDESS, and MSP-IMPROV. The label distribution of the datasets used in this paper is listed in Table II.

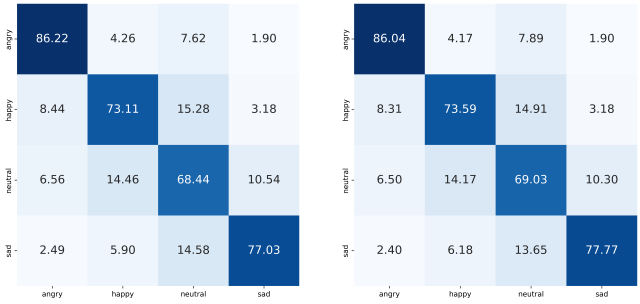
a) IEMOCAP: The Interactive Emotional Dyadic Motion Capture (IEMOCAP) database [8] contains approximately twelve hours of data labeled with nine different emotions. Each utterance includes three kinds of modalities: audio, video, and text. Following the conventional evaluation protocol, we only adopt four categories of utterances: *angry*, *happy*, *neutral* and *sad*, and merge the *excited* label into the *happy* label. As a result, there are a total of 5,531 utterances. We conduct five-fold leave-one-session-out cross-validation to evaluate all models.

b) RAVDESS: The Ryerson Audio-Visual Database of Emotional Speech and Song (RAVDESS) database [10] is an audio-visual database consisting of emotional speech and song acted by 24 professional actors. We select the speech recordings partition of the RAVDESS, which contains 1,440 utterances labeled with eight emotions: *angry*, *calm*, *surprised*, *fear*, *happy*, *sad*, *neutral* and *disgust*. We perform six-fold leave-four-speakers-out cross-validation. The number of male and female speakers in the training set and test set is equal for a fair comparison.

c) MSP-IMPROV: The MSP-IMPROV [23] is a multimodal emotional database containing 8,438 improvised, read, and natural emotional utterances. We select a subset of 7,798 utterances with four emotion labels: *angry*, *happy*, *neutral*, and *sad*. The MSP-IMPROV dataset is divided into six sessions, so we perform six-fold leave-one-session-out cross-validation.

B. Implementation details

The experiments are conducted using six pre-trained SSL models on the Huggingface website: Wav2vec 2.0 Base[1], HuBERT Base[2], WavLM Base[3], WavLM Base+[4], UniSpeech-SAT Base[5], UniSpeech-SAT Base+[6]. Our implementation is based on an existing Pytorch framework [18]. Table III lists the settings of hyper-parameters used in the experiments. Considering that the average duration of utterances in the three datasets is quite different, the max sequence length is set to 8s for IEMOCAP and MSP-IMPROV, and 5s for RAVDESS. If the utterance is shorter than the max length, we pad it to the max length and exploit a mask to let the network ignore the padding part. We find that the learning rate and the scheduler play a critical role in the fine-tuning of SSL models. In our experiments, the learning rate is set to 1e-4 for all three datasets. We employ a linear decay scheduler after a warm-up period in the first 10 epochs. All experiments are carried out on an NVIDIA Tesla V100 32GB GPU.



C. Experimental results

Table IV lists the SER results of the fine-tuned SSL models as well as four ensemble methods on three datasets. The unweighted accuracy (UA) and the weighted accuracy (WA) are reported as evaluation metrics.

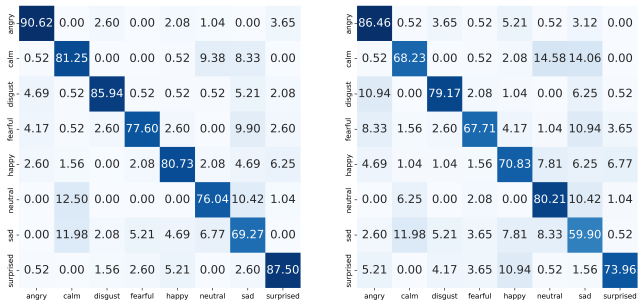
(a) Average (b) Evidence Theory



(c) Late Feature Ensemble (d) Early Feature Ensemble

Fig. 3. The confusion matrix of four evaluated ensemble methods for the RAVDESS dataset.

We first compare the performance of the single SSL models. It can be observed that the best model is different in various datasets. For the IEMOCAP dataset, the WavLM Base obtains the best UA while the WavLM Base+ achieves the best WA. WavLM Base achieves the highest UA and WA on the RAVDESS dataset, and the WavLM Base+ yields the highest UA and WA on the MSP-IMPROV dataset. In terms of the four Base models, the WavLM Base performs best and others obtain similar performance, which is different from [21]. A possible reason is that we utilize the SpecAugment technique and the cross-validation which [21] does not use. In addition, compared with the Base models, the Base+ models of the WavLM and the UniSpeech-SAT perform better on the IEMOCAP and MSP-IMPROV, but perform worse on the RAVDESS.

We then evaluate the performance of four ensemble methods. It can be seen that the average, the evidence theory, and the late feature ensemble method can significantly improve the UA and WA on three datasets compared to the single SSL model, demonstrating that the ensemble of various SSL models is effective on the SER task. The early feature ensemble method is worse than the fine-tuned SSL model because it only employs six kinds of pre-trained SSL features without fine-tuning. However, it outperforms the "Fixed HuBERT + ECAPA-TDNN" model which only uses the pre-trained HuBERT features and the ECAPA-TDNN model, suggesting that the ensemble of pre-trained SSL features can also improve the SER performance. Overall, all four ensemble methods

(a) Average (b) Evidence Theory

(c) Late Feature Ensemble (d) Early Feature Ensemble

Fig. 4. The confusion matrix of four evaluated ensemble methods for the MSP-IMPROV dataset.

can notably improve the performance on three SER datasets compared to the single fine-tuned or pre-trained SSL model. This suggests that there may exist a large of complementary information between different SSL models and combining multiple SSL models or SSL features is an effective method to improve the performance of SER.

In terms of the decision ensemble method, it can be observed from Table IV that the ET-based fusion method performs better than the average-based fusion method on all three datasets. The reason may be that the evidence theory has the ability to deal with the uncertainty of different SSL models, thus can make full use of multi-source information to improve the reliability and accuracy of the decision ensemble. The experimental result suggests that the ET-based fusion is a better method for the decision ensemble in the SER task.

In addition, it can be seen from Table IV that the ET-based decision ensemble method obtains higher UA and WA on all three datasets, compared with the late feature ensemble method. The average-based decision ensemble method also yields competitive performance. A possible reason is that the late feature ensemble method only integrates the output feature of the last layer in the SSL models. The late feature ensemble and the decision ensemble are both in top level of the model, and thus yield similar performance. However, the late feature ensemble method needs additional training with much computational cost, while the decision ensemble methods only need to fuse the probabilities produced from multiple SSL models. Hence, it can be concluded that the ET-based decision ensemble method is the best in four comparative ensemble methods to ensemble various SSL models for SER because of its superior performance and lower computational cost.

[a] We only report the highest of UA or WA as the accuracy in all comparative works.

To verify the performance of ensemble methods on each emotion class, we report their prediction confusion matrix for each dataset, which is shown in Fig. 2, Fig. 3 and Fig. 4, respectively. It can be seen from Fig. 2 that the *angry* emotion is the best-performing class. The *neutral* class and *happy* class are hard to distinguish in the IEMOCAP. In the RAVDESS dataset, the best-performing class is also *angry*, while the worst-performing class is *sad*. The two classes that are hardest to distinguish for models are *neutral* and *calm*. In the MSP-IMPROV, the *sad* class is the worst performing class, while the *happy* class and *neutral* class are easily recognized. The reason is that the MSP-IMPROV is an unbalanced dataset where the samples of the *happy* and *neutral* are obviously more, making it difficult for models to recognize other emotions.

To verify the effectiveness of our work, we further compare our systems with recent state-of-the-art works. Since these works usually take the IEMOCAP as the dataset, we list the experimental results of different works on the IEMOCAP, as shown in Table V. Our implemented WavLM Base model achieves the highest accuracy of 74.38% in all comparative works, and the ET-based decision ensemble method using six SSL models further improves the accuracy to 76.74%. The results indicate the effectiveness of our introduced ensemble methods.

V. CONCLUSIONS

In this paper, we conduct an investigation of ensemble learning of SSL models for SER. We utilize three kinds of ensemble methods (i.e., decision ensemble, late feature ensemble, and early feature ensemble) to combine six SSL models (i.e., Wav2vec 2.0 Base, HuBERT Base, WavLM Base, WavLM Base+, UniSpeech-SAT Base, and UniSpeech-SAT Base+). The experiments are conducted on three datasets, IEMOCAP, RAVDESS and MSP-IMPROV. The results demonstrate the effectiveness of the ensemble method of multiple SSL models on the SER task. We also observe that the ET-based decision ensemble method performs best in all comparative ensemble methods. In the future, we plan to study the multi-view SER based on multiple pre-trained SSL features.

***Abstract*— Estimating the direction of arrival (DOA) is an important topic in the array signal processing. This paper addresses the issue of multisource localization in a closed environment. We propose a single source zone (SSZ) detection method based on first-order relative harmonic coefficient (RHC), and designs a dynamic SSZ detection rule. Finally, 2-D kernel density estimation (KDE) and peak search are used to achieve multisource DOA estimation. The proposed method is evaluated by simulation experiment and compared with the reference methods, and the effectiveness of the proposed method is verified.**

I. INTRODUCTION

The purpose of multi-source localization is to estimate the Direction of Arrival (DOA) of each sound source. DOA estimation is widely used in various application scenarios, such as sound event detection [1], fault detection, sound source target tracking [2], speech separation [3], and human-computer interaction [4].

In the early days, the main DOA estimation methods were based on the time difference of arrival (TDOA) [5]. The cross-correlation was adopted in these methods to estimate the relative delay of sources to different microphones [6]. And the estimated relative delay is combined with microphone array geometry to obtain the DOA information. Some improved methods have been proposed to by changing the array structure and enhancing the reliability of geometric mapping. However, the TDOA method is mainly used in single sound source scenarios. Another type of method is multiple signal classification (MUSIC) [7], which uses the orthogonality of signal and noise subspace to obtain the spatial spectrum, and then estimates the direction information of sources through spectral peak search [8]. However, the priori known number of sources is necessary in these methods. Beamforming technology is also an important approach to estimate the multi-source DOAs. The principle is to realize DOA estimation by minimum variance distortionless response beamformer [9]. Recently, deep learning has been introduced into DOA estimation [10]. The mapping between the extracted feature of recording signal and the direction information of sources is constructed to complete DOA estimation of the sound source. Nevertheless, if the number of sources increases, the number of categories of network output increases significantly.

Due to the sparsity of speech signal in the time-frequency (TF) domain, sparse component analysis (SCA) based multi-source DOA estimation methods are proposed using the W-Disjoint Orthogonality (WDO) [11]. The WDO reveals the phenomenon that most of the components of different sources are disjoint in the TF domain. In a word, only one source dominates for most TF points. These points are considered as single-source points (SSPs). Multi-source localization can be transformed into multiple single-source localization by using SSPs [12]. Several SSP detection methods have been proposed for different microphone arrays, such as spherical array [13] and B-format array [14,15]. Hu et al. proposed a new feature named relative harmonic coefficient (RHC) in [16-18], which is used to detect SSPs to achieve multi-source localization. The localization performance of SSP-based methods usually depends on the accuracy and number of detected SSPs. Nevertheless, it is difficult to detect a sufficient number of SSPs for localization as the recording environment deteriorates.

In order to obtain more TF points which are conducive to localization, some DOA estimation methods were proposed by detecting the single source dominant components at TF zone level. If most of the TF components in a TF zone (consist of contiguous and adjacent TF points) belong to the same source, this zone is called a single source zone (SSZ) [19]. The

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

correlation between different channel have been introduce for SSZ detection. Several correlation-based SSZ detection methods have been designed for different arrays, such as circular array [20], linear array [21], acoustic vector sensor [22,23].

In addition, a SSZ detection method was proposed based on the angle distribution of TF points. However, in these SSZ detection methods, the setting of the TF zone is fixed. In fact, single source dominant components are randomly distributed. Therefore, the existing SSZ detection methods cannot detect these components as much as possible. In order to solve this issue, this paper designs a dynamic SSZ detection method. Meanwhile, a SSZ detection method is proposed based on the first-order RHC.

The reminder of the paper is organized as follows: the spherical harmonic decomposition of sound pressure and RHC are introduced in Section II. Next, the proposed DOA estimation method is presents in Section III. Then, the performance evaluation through various experiments is given in Section IV. Finally, some conclusion are discuss in Section V.

II. PRELIMINARY KNOWLEDGE

This section introduces some preparatory knowledge about spherical harmonic decomposition and gives the definition of RHC to prepare for the proposed method.

A. Spherical Harmonic Decomposition of Sound Pressure

Assume there are Q simultaneous active sound sources in a closed room with reverberation, and a spherical microphone array consists of J sensors is used to pick up the sound pressure, the sound pressure measured by the j-th microphone in the TF domain is given as,

$$X_j(l,k) = \sum_{q=1}^{Q} S_q(l,k) H_{q,j}(l,k) + V_j(l,k), \quad (1)$$

where l and k denote the indices of frame and frequency, respectively. $S_q(l,k)$, $H_{q,j}(l,k)$ and $V_j(l,k)$ denote the STFT coefficients of the q-th source, acoustic transfer function from the q-th source to the j-th microphone and white Gaussian noise attached to the j-th microphone, respectively. In remainder of this paper, the frame index l will be omitted for simplicity unless otherwise specified. Further, the sound pressure can be decomposed by a complete set of orthogonal spherical harmonic basis functions [16],

$$X_j(k) = \sum_{n=0}^{N} \sum_{m=-n}^{n} \alpha_{nm}(k) \beta_n(\bar{k}r) Y_{nm}(\vartheta_j, \varphi_j), \quad (2)$$

where $N = \lceil \bar{k}r \rceil$ denotes the spherical harmonic order of truncation, $\bar{k} = 2\pi f / c$ is the wave number, where f and c are the frequency and the speed of sound, respectively, r is the array radius. n and m are the spherical harmonic expansion order and mode, respectively. $Y_{nm}(\vartheta_j, \varphi_j)$ is the spherical harmonic function,

$$Y_{nm}(\vartheta_j, \varphi_j) = \sqrt{\frac{(2n+1)}{4\pi} \frac{(n-m)!}{(n+m)!}} P_{nm}(cos\vartheta_j) e^{im\varphi_j}, \quad (3)$$

where ϑ_j and φ_j are the elevation and azimuth, respectively, of the j-th microphone. $\alpha_{nm}(k)$ in (2) is the spherical harmonic coefficient of sound field，which can be obtained using the weighted sum of the sound pressure measured by each microphone,

$$\alpha_{nm}(k) = \frac{1}{\beta_n(\bar{k}r)} \sum_{j=1}^{J} w_j X_j(k) Y_{nm}^*(\vartheta_j, \varphi_j), \quad (4)$$

where w_j is the weight of the corresponding microphone on the array. $\beta_n(\bar{k}r)$is a function related to array configuration and wave number, whose definition is,

$$\beta_n(\bar{k}r) = \begin{cases} j_n(\bar{k}r), & \text{open array} \\ j_n(\bar{k}r) - \dfrac{j_n'(\bar{k}r)}{h_n'(\bar{k}r)} h_n(\bar{k}r), & \text{rigid array} \end{cases} \quad (5)$$

where $j_n'(\cdot)$ and $h_n'(\cdot)$ are the first partial derivative of the first kind of n-order spherical Bessel and Hanke functions, respectively.

B. RHC Definition

In the far-field hypothesis, the recording received by the microphone follows the plane wave propagation model. According to the Green's function, hence, the spherical harmonic coefficient $\alpha_{nm}(k)$ for the TF point dominated by the q-th source is [17],

$$\alpha_{nm}(k) = S_q(k) 4\pi i^n Y_{nm}^*(\vartheta_q, \varphi_q), \quad (6)$$

where $(\cdot)^*$ denotes the conjugate operation, ϑ_q and φ_q are the elevation and azimuth of the q-th source, respectively. The definition of RHC is the ratio between $\alpha_{nm}(k)$ and $\alpha_{00}(k)$, i.e.,

$$\lambda_{nm}(k) = \frac{\alpha_{nm}(k)}{\alpha_{00}(k)} = 2\sqrt{\pi} i^n Y_{nm}^*(\vartheta_q, \varphi_q). \quad (7)$$

Therefore, a first-order RHC vector is given as,

$$\boldsymbol{\lambda}(k) = \left[\lambda_{1,-1}(k), \lambda_{1,0}(k), \lambda_{1,1}(k)\right]^T, \tag{8}$$

where each element is frequency independent and only related to the azimuth and elevation of the source. Further, $\boldsymbol{\lambda}(k)$ can be rewritten according to the expression of spherical harmonic function,

$$\boldsymbol{\lambda}(k) = \left[\sqrt{\frac{3}{2}}\sin(\vartheta_q)\, e^{i\left(\varphi_q+\frac{\pi}{2}\right)}, \sqrt{3}\cos(\vartheta_q) e^{i\frac{\pi}{2}}, \sqrt{\frac{3}{2}}\sin(\vartheta_q)\, e^{-i\left(\varphi_q+\frac{\pi}{2}\right)}\right]. \tag{9}$$

III. THE PROPOSED METHOD

In this section, we propose an SSZ detection method based on first-order RHC. Then, the DOA estimates of TF points are obtained using the relationship between the elements of first-order RHC vector. Finally, 2D kernel density estimation (KDE) and peak search are used to achieve multi-source localization.

A. SSZ Detection

For a single source TF point, we can find that the magnitude of $\lambda_{1,-1}(k)$ is the same as that of $\lambda_{1,1}(k)$ from (9). Assume that there are M TF points in the g-th zone of certain time frame, the construction of this zone is defined as,

$$\boldsymbol{\mathcal{H}}_g = \{k_g, k_g+1, \cdots, k_g+M-1\}, \tag{10}$$

where k_g denotes the first frequency point in the g-th TF zone. Thus, we can construct two magnitude vectors of this zone about $\lambda_{1,-1}(k)$ and $\lambda_{1,1}(k)$,

$$\boldsymbol{\mathcal{H}}_g^{\mathrm{N}} = \left[\left|\lambda_{1,-1}(k_g)\right|, \left|\lambda_{1,-1}(k_g+1)\right|, \cdots, \left|\lambda_{1,-1}(k_g+M-1)\right|\right]^T, \tag{11}$$

$$\boldsymbol{\mathcal{H}}_g^{\mathrm{P}} = \left[\left|\lambda_{1,1}(k_g)\right|, \left|\lambda_{1,1}(k_g+1)\right|, \cdots, \left|\lambda_{1,1}(k_g+M-1)\right|\right]^T. \tag{12}$$

Assume the zone $\boldsymbol{\mathcal{H}}_g$ is an ideal SSZ, where all TF points are SSPs, there is,

$$\left|\lambda_{1,-1}(k)\right| = \left|\lambda_{1,1}(k)\right|. \forall k \in \boldsymbol{\mathcal{H}}_g. \tag{13}$$

Hence, these two vectors are the same under interference-free condition, i.e.,

$$\boldsymbol{\mathcal{H}}_g^{\mathrm{N}} = \boldsymbol{\mathcal{H}}_g^{\mathrm{P}}. \tag{14}$$

Considering that the actual recording environment is usually affected by reverberation, noise and intersource interference, the corresponding elements of $\boldsymbol{\mathcal{H}}_g^{\mathrm{N}}$ and $\boldsymbol{\mathcal{H}}_g^{\mathrm{P}}$ are approximately equal rather than absolute. So, there will be a strong correlation between $\boldsymbol{\mathcal{H}}_g^{\mathrm{N}}$ and $\boldsymbol{\mathcal{H}}_g^{\mathrm{P}}$ when the zone $\boldsymbol{\mathcal{H}}_g$ is an SSZ.

However, for TF zones dominated by multi-source mixed components and/or significantly interfered by reverberation components, $|\lambda_{1,-1}(k)|$ and $|\lambda_{1,1}(k)|$ are usually quite different. Consequently, the correlation between $\boldsymbol{\mathcal{H}}_g^{\mathrm{N}}$ and $\boldsymbol{\mathcal{H}}_g^{\mathrm{P}}$ is weak.

According to the above analysis, we propose to use normalized cross-correlation function to judge the similarity between these two vectors, i.e.,

$$r_{\mathrm{NP}}(g) = \frac{C_{\mathrm{NP}}(g)}{\sqrt{C_{\mathrm{NN}}(g) \cdot C_{\mathrm{PP}}(g)}}, \tag{15}$$

where $C_{\mathrm{NP}}(g)$ denotes the cross-correlation coefficient, it is defined as,

$$C_{\mathrm{NP}}(g) = \left(\boldsymbol{\mathcal{H}}_g^{\mathrm{N}}\right)^T \cdot \boldsymbol{\mathcal{H}}_g^{\mathrm{P}}. \tag{16}$$

Therefore, if TF zone $\boldsymbol{\mathcal{H}}_g$ satisfies,

$$r_{\mathrm{NP}}(g) > 1-\xi, \tag{17}$$

it will be identified as an SSZ, where ξ is a pre-defined SSZ detection threshold, a small ξ indicates that the stronger the correlation between the two vectors and this zone is an SSZ with high probability.

Traditional SSZ detection methods usually divide the frequency-band into several zones of fixed length, and then detect whether these zones are SSZ in turn. We know that when most of the points in a TF zone are SSPs, this zone can be regarded as an SSZ. In fact, SSPs are randomly distributed in the TF domain. The fixed length of zone may lead to the partition of some continuously distributed SSPs into two adjacent TF zones. In this way, these two zones are identified as non-SSZs because of the small number of SSPs. Therefore, many SSZs will not be identified by traditional SSZ detection methods, which results in the loss of localization accuracy. Aiming at this problem, we propose to detect SSZs dynamically. To be specific, if the TF zone $\boldsymbol{\mathcal{H}}_g$ do not satisfy the SSZ detection rule, the traditional detection algorithm commands that the first frequency point of the next zone to be detected is k_g+M, while the proposed detection rule requires moving frequency point by frequency point until a zone satisfying the detection rules is identified. That is, the first frequency point of the next zone to be detected is k_g+1. The detail is shown in **Algorithm 1**. Note that the cost of improving localization accuracy is the increase of computational complexity.

B. DOA Estimation

Benefited from the first-order RHC containing the azimuth and elevation information of source, [17] proposes a direction

vector to achieve single source localization. The definition of direction vector equation is given as,

$$\begin{cases} \mathcal{T}_1(k) = \sqrt{\frac{1}{6}} Im\{\gamma_{1,-1}(k) - \gamma_{1,1}(k)\} = sin(\vartheta)\, cos(\varphi) \\ \mathcal{T}_2(k) = -\sqrt{\frac{1}{6}} Re\{\gamma_{1,-1}(k) - \gamma_{1,1}(k)\} = sin(\vartheta)\, sin(\varphi) \\ \mathcal{T}_3(k) = \sqrt{\frac{1}{3}} Im\{\gamma_{1,0}(k)\} = cos(\vartheta) \end{cases}, \quad (18)$$

where $Re\{\cdot\}$ and $Im\{\cdot\}$ denote the real and imaginary parts of a complex number, respectively. Thus, we can estimate the azimuth and elevation from above relation, respectively,

$$\varphi(k) = arctan\left(\frac{\mathcal{T}_2(k)}{\mathcal{T}_1(k)}\right), \quad (19)$$

$$\vartheta(k) = arctan\left(\frac{\sqrt{\mathcal{T}_1{}^2(k) + \mathcal{T}_2{}^2(k)}}{\mathcal{T}_3(k)}\right). \quad (20)$$

For a detected TF point DOA set, the 2-D angle histogram of can be obtained. Some existing probability density estimation methods such as Gaussian Mixture Model (GMM) or KDE can be used to smooth the histogram. In this paper, we employ 2-D KDE as a post-processing tool. Therefore, the estimated probability density function is given as,

$$\mathcal{F}(\varphi, \vartheta) = \frac{1}{\mathcal{C}} \sum_{k \in \boldsymbol{\mathcal{H}}_{\mathrm{SSZ}}} \frac{1}{\rho_\varphi \rho_\vartheta} \mathcal{K}\left(\frac{\varphi - \tilde{\varphi}(k)}{\rho_\varphi}, \frac{\vartheta - \tilde{\vartheta}(k)}{\rho_\vartheta}\right), \quad (21)$$

where C denotes the number of elements in $\boldsymbol{\mathcal{H}}_{SSZ}$, and $\mathcal{K}(\cdot)$ is a kernel function. Gaussian kernel function is selected in this work,

$$\mathcal{K}\left(\frac{\varphi - \tilde{\varphi}(k)}{\rho_\varphi}, \frac{\vartheta - \tilde{\vartheta}(k)}{\rho_\vartheta}\right) = \frac{1}{2\pi} e^{-\frac{1}{2}\left[\frac{\left(\varphi - \tilde{\varphi}(k)\right)^2}{\rho_\varphi{}^2} + \frac{\left(\vartheta - \tilde{\vartheta}(k)\right)^2}{\rho_\vartheta{}^2}\right]}, \quad (22)$$

where ρ_φ and ρ_ϑ are the corresponding bandwidth parameter. Subsequently, the peak search algorithm is chosen to estimate the DOAs of sources. The proposed DOA estimation method is presented in **Algorithm1**.

Algorithm 1: The proposed DOA estimation method

Input: $X_j(l,k), j = 1,2,\cdots J$ // the sound pressure

Output: $\{\vartheta_q, \varphi_q\}_{q=1}^{Q}$ // the estimated DOAs

// TF points set of the detected SSZs
// l_g denotes the number of the detected SSZs in the l-th frame
$\{\vartheta_q, \varphi_q\}_{q=1}^{Q}$ are estimated by 2-D KDE and peak search

IV. Experimental Evaluation

This section used several simulated experimental data to evaluate the performance of the proposed method. Room impulse response (RIR) is generated using a famous mirror sound source model [24]. The experiment was conducted in a closed room with size of $[6m, 4m, 3m]$, where an open spherical microphone array is simulated and is placed in the center, with a distance of $1m$ between the sound source and the array. Note that the array consists of only four omnidirectional microphones located on non-adjacent vertices of a cube. The speech source is taken from the Nippon Telegraph and Telephone (NTT) database, and the sampling frequency is 16kHz. When the time domain signal is converted into the TF domain, 2048-point discrete Fourier transform (DFT) is done for the sample points with a window length of 0.032s, where the overlap rate between adjacent frames is 50%. Besides, frequency points in the frequency range of [800Hz, 3200Hz] in each frame are selected. The length of the detected TF zone was set to 10 and the SSZ detection threshold was set to $\xi = 0.04$. We use the mean absolute estimated error (MAEE) to evaluate the localization performance,

$$\mathrm{MAEE} = \frac{1}{T} \sum_{t=1}^{T} \left(\frac{1}{2Q} \sum_{q=1}^{Q} \left| \tilde{\varphi}_{t,q} - \varphi_{t,q} \right| + \left| \tilde{\vartheta}_{t,q} - \vartheta_{t,q} \right| \right), \quad (23)$$

where t and q denote the indices of the t-th experiment and the q-th source, T denotes the number of experiments performed.

Fig.1 demonstrates the MAEE results of the proposed methods and the other two reference methods under different reverberation times {0.2 s, 0.3 s, 0.4 s, 0.5 s} with SNR = 25 dB, where (a) and (b) denote the two- and three-source scenarios, respectively and source separation is set to 60°. The method without any process (TF points in the frequency band of the selected frequency range are used) is labeled as "Baseline" and single source confidence measure-based method is represented using the abbreviation "SSCM" [21]. The method based on the proposed SSZ detection rule with fix length of TF zone is represented using the abbreviation "Proposed SSZ detection non-dynamically". And the method based on the proposed dynamic SSZ detection is represented as "Proposed SSZ detection dynamically". It is obvious that these four methods can all exhibit excellent localization performance under low reverberation environment. In comparison with two-source scenario, the DOA estimation accuracy is lower in the three-source scenario. Besides, with the increase of reverberation time, their localization accuracy deteriorates significantly due to the directional interference from early reverberation components and contamination from late reverberation components. Generally, the MAEE result of the DOA estimation method based on the proposed dynamic SSZ detection achieves lower error compared with the other three methods, which also verifies the effectiveness of the proposed method.

It is well-known that the angular separation between sources also influence the localization accuracy, which is similar to the principle of reverberation interfere localization performance, a smaller separation usually increases the risk of contamination of SSPs. Fig. 2 compares the MAEEs of these four methods at different angular separations with reverberation time of 0.4 s and SNR = 25 dB. When the angular separation is 90° and 120°, the localization accuracy of these methods is high. While the angular separation is set as 60° and 40°, the performance of the reference methods gradually increases, but the DOA estimation method based on the proposed dynamic SSZ detection can achieve a good localization performance.

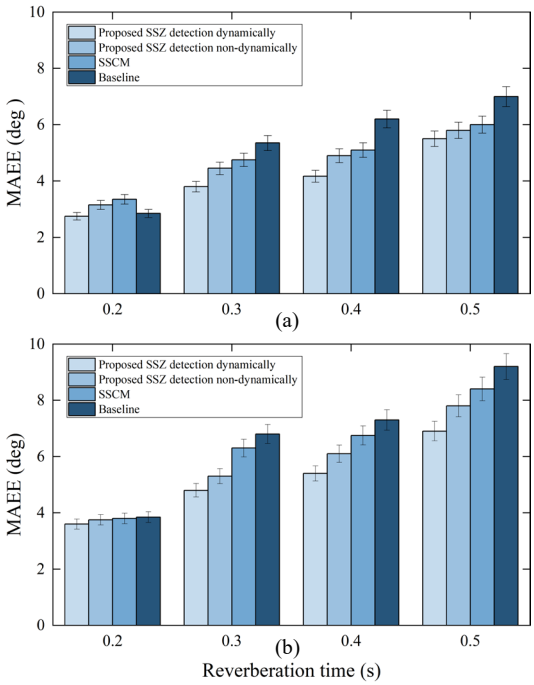

Fig. 1. MAEE results with different reverberation times in (a) two- and (b) three-source scenario.

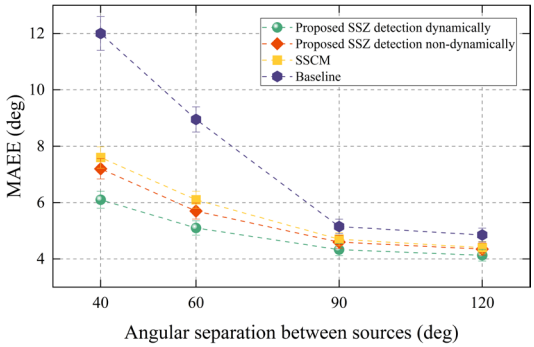

Fig. 2. MAEE results with different angular separation between sources in two-source scenario.

V. CONCLUSION

This paper proposed a multisource localization method based on SSZ detection in spherical harmonic domain. We use the consistency between the magnitude of elements with mode -1 and 1 in first-order RHC to identify TF zones where only one source dominants. In addition, different from the traditional SSZ detection rule, we propose to detect the SSZs dynamically, which can improve the localization accuracy. Then, 2-D KDE and peak search are used as post-processing to realize the multisource localization task. In the future, we focus on analyzing SSP or SSZ characteristics in more complex scenario to achieve multisource localization with high precision and robustness and apply this feature to deep learning.

***Abstract*—Speech emotion recognition (SER) is essential for the machine to understand human intentions. Various deep neural network (DNN) based models are proposed but still suffer from overfitting on small training dataset, especially the identical distribution assumption is usually violated in practical datasets. Data augmentation with normalization for single instances is a common approach to train models more stably, where the moments (a.k.a. mean and variance) of the augmented data representation are removed as noise. To further improve the robustness, a label-perturbing data augmentation method Moment Exchange (MoEx) is introduced in this paper, forcing DNN models to pay attention to the difference in moments extracted from individual instances of each emotion class. Experiments on several classical model structures demonstrate the promising performance improvement with an extremely simple but effective implementation of MoEx.**

I. Introduction

Emotions are an important factor in enabling machines to understand human intentions during human-computer interaction. Speech is one of the most natural ways for humans to express emotions in real life [1]. Nowadays, machines have become proficient at processing speech signals, and have achieved high performance in areas such as automatic speech recognition (ASR) and speaker recognition. Speech emotion recognition (SER) has also recently gained attention, as it can make human-computer interactions more humane and harmonious.

A typical SER system extracts emotion features from the original speech signals and then classifies them with machine learning models into specific emotion categories [2].Prosodic features like energy, pitch, and duration are proved to be useful in emotion prediction tasks. Researchers also use Teager Energy Operator (TEO) features [3] and some hand-crafted features [4] to recognize emotions. Recently, spectral features have been widely used and performed relatively better in SER task [5].

With the rapid development of deep learning, deep neural network (DNN) has brought a lot of breakthroughs in many fields, which includes the SER task. A convolutional neural network (CNN) was firstly proposed to learn local feature information in spectrograms [5], which outperforms traditional machine learning methods on multiple metrics. Recurrent neural networks (RNN) are also used to learn timing information in speech signals [6]. CNN and Long Short-term Memory (LSTM) are fused into one model [7], in which CNN can process spectrogram features, and then LSTM can predict emotions from timing CNN outputs. More models based on CNN+RNN are proposed because of its excellent performance. The RNN model is replaced by the Bi-RNN model in [8], which is proved better in audio tasks [9] because it is able to take the longer bidirectional features of input vectors into account. A new SER model based on non-linear Radial Basis Function Network (RBFN) [10] is proposed with CNN and deep BiLSTM [11], in which ResNet [12] was further applied in the CNN model. Transformer model [13], a multi-head attention mechanism, allows for parallelization and jointly attends to the feature information. It has also been widely used in SER [14] recently. Conformer model [15] is proposed to combine convolutional layers and a transformer model for speech recognition. Conformer blocks are also used in SER task to learn local information from extracted emotional features [16], which is the state-of-the-art work.

However, one of the challenges that the SER task is facing now is that the existing datasets are relatively small, while the robustness of emotional representations extracted from speech signals is particularly limited to the training dataset [17]. The performance of complex deep networks usually plummets under the situation where the data distribution between the training dataset and the testing dataset is not identical in practice [18]. A piece of evidence is that categories can be separated on the training set while still being mixed together on the testing set. Commonly, data augmentation is used to solve the above problems [19], and it has been proved useful in image [20] and text [21] tasks, which can be divided into two categories: label-preserving or label-perturbing. Compared with label-preserving methods, label-perturbing methods process the labels of augmented data more smoothly and achieve better performance. For example, the corresponding labels of two inputs are linearly interpolated in MixUp [22].

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Normalization operations including LayerNorm (LN) [23], InstanceNorm (IN) [24] or PositionalNorm (PONO) [25] on the label-perturbing augmented single instances are usually needed to make sure that training is stable. Among these methods, the first moment (a.k.a. mean) and the second moment (a.k.a. variance/standard deviation) are removed in intra-sample normalization, which means, simply subtracting the mean and dividing by the variance. After normalization, an underlying representation of single instances with more robustness is captured. Instead of simply removing the moments, Moment Exchange (MoEx) [26] is further proposed to improve the stability of training by randomly exchanging the feature moments across samples.

In this paper, we apply MoEx to the previously mentioned classical model structures of SER task and achieve a significant improvement in performance with extremely simple implementation. More specifically, the mean and variance of representation from a certain selected layer of every sample are computed and then re-injected into target representation from the same layer of other randomly-selected samples among one batch during training, which is figuratively called a Moment Exchange operation. Meanwhile, the corresponding labels involved in each exchange are interpolated by a hyper-parameter when calculating the loss. The experiments show that the classification performance and robustness of the previously mentioned classical model structures are improved by MoEx because the representation from the selected layer has more discriminative power by forcing each model to pay special attention to the variation of moments extracted from different intra-samples. Among these structures, Conformer with MoEx is verified to get the best performance. The sensitivity of parameters is also fully verified.

II. Methods

The framework of the proposed model is depicted in Figure 1, which includes the structure of the SER model and the structure of Moment Exchange.

SER works generally first extract speech features, and then use a series of deep learning networks to learn these features in the hidden layers. However, there are enormous challenges in the robustness of current SER works, for which we introduce Moment Exchange into the common SER models. Moment Exchange is applied to the hidden layers' output to learn normalized features of the original label and moment information. The last linear and softmax layers are used for emotion classification.

A. SER Model details

We extract the Mel-spectrogram features F of the speech signal as input. We set $F \in \mathbf{R}^{T \times M}$, where T is variable based on the length of the audio and M is the number of Mel bands.

In the field of speech emotion recognition (SER), several deep learning architectures have been developed to learn speech features. Common deep learning model structures such as CNN, RNN,and Transformer are used as hidden layers respectively. Additionally, we use the mask to compress the variable length of the inputs to a fixed-length output vector, resulting from T.

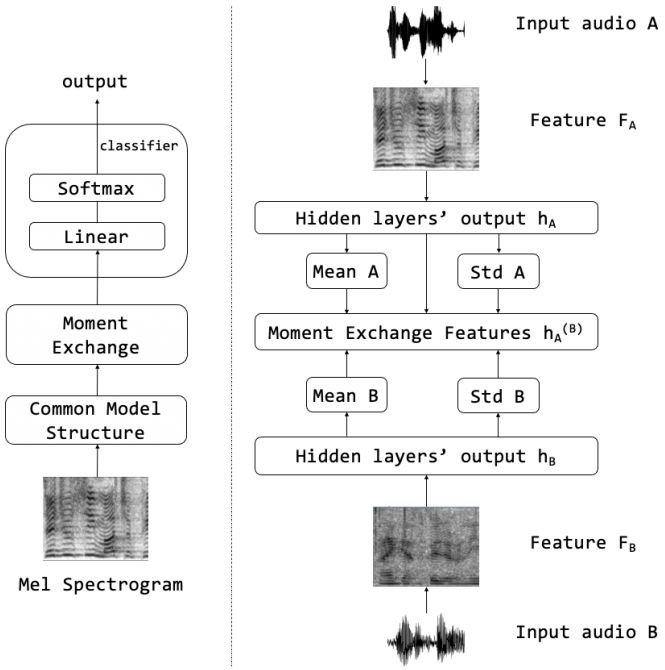

Fig. 1. Framework of the proposed model. The SER model (left) takes mel spectrograms as input and learns discriminative features using deep learning and Moment Exchange. The Moment Exchange (right) injects the moments of hidden layers' output from randomly chosen audio B to audio A.

Representative deep learning models employed in the SER domain often encounter problems with unstable training and overfitting, likely due to small datasets and complex feature dimensions. To counter these issues and improve overall model robustness and classification performance, data augmentation is a widely used technique. While more complex methods, such as collecting noisy data and utilizing adversarial attacks have been employed [27], we propose using Moment Exchange directly within the model as a simple and effective data augmentation method.

The Moment Exchange is performed within each batch for the final hidden output h of the deep learning model and does not change the dimensions, which will be elaborated on in Section 2.2. After that is an emotion classifier, which contains a linear layer and a softmax layer. The output of the linear layer indicates the expected posterior probabilities for the relevant emotion categories and is used for calculating softmax cross-entropy loss. For convenience, we define the function of the classifier here as $c(h_i)$ and softmax cross-entropy loss is $l\big(c(h_i), y_i\big)$, where h_i is hidden layers' output and y_i is the ground truth label of the i-th input F_i.

B. Moment Exchange

Moment Exchange is applied to audio A and audio B as shown in Figure 1, where A and B are two randomly chosen samples. Specifically speaking, a random full permutation

array p is generated according to the length b of the batch and then $B = p[A]$.

PONO [25] is used to compute the first moment (mean) μ_i and the second moment (variance) σ_i of hidden features h_i:

$$\mu_i = \frac{1}{H}\sum_{j=0}^{H-1} h_i[j] \tag{1}$$

$$\sigma_i = \sqrt{\frac{1}{H}\sum_{j=0}^{H-1}(h_i[j] - \mu_i)^2} \tag{2}$$

H in formula (1)(2) is the size of the hidden layers' output. To motivate the model to make use of the moments information, the moments of hidden layers' output from audio B are injected into the normalized features of audio A:

$$h_A^{(B)} = \sigma_B \frac{h_A - \mu_A}{\sigma_A} + \mu_B \tag{3}$$

The new Moment Exchange features $h_A^{(B)}$ contain both the normalized features of audio A and the moments of audio B. Therefore, we need to modify the loss function to let the model notice the label information of y_A and also y_B at the same time. Here we directly introduce a new hyper-parameter λ to propose a straight-forward combination function:

$$\mathcal{L} = \lambda * l(c(h_A^{(B)}), y_A) + (1-\lambda) * l(c(h_A^{(B)}), y_B) \tag{4}$$

The hyper-parameter λ and $1-\lambda$ is the target interpolation weight of label y_A and y_B. And l represents the loss function of the emotion classifier mentioned above.

III. Experiments

A. Dataset and Feature extraction

We evaluated the effectiveness of introducing Moment Exchange into different model structures on the Interactive Emotional Dyadic Motion Capture (IEMOCAP) [28] dataset. This dataset is widely used for studying English speech emotions in the SER task and was collected by the University of Southern California (USC) Speech Analysis and Interpretation Laboratory (SAIL). The dataset contains approximately 12 hours of audio data of ten speakers expressing different emotions in specific scenarios. The original dataset includes nine different emotions, but to better stimulate emotional responses, it makes more sense to group certain similar emotions together. We combined similar emotions to create four categories: happiness, anger, neutral, and sadness (as shown in Table I).

TABLE I
THE DISTRIBUTION OF EMOTIONS IN IEMOCAP

Emotion	Utterance	Participation(%)
Happiness	1636	29.6
Anger	1103	19.9
Neutral	1708	30.9
Sadness	1084	19.6

Log scale Mel-spectrogram is used as the emotion feature. To generate this, we resample the original audio at 16kHz and only use the middle 14 seconds based on statistics of the audio duration. Spectrograms are calculated with a DFT length of 2048, 128 Mel bands, and a Hamming window with a window shift of 10 milliseconds and window size of 40 milliseconds.

B. Experiment setup

We implement our model on the Pytorch deep learning library using Python. Training is done on a machine equipped with a GeForce RTX 2080Ti using Adam optimizer. A learning rate of 0.001 and a drop rate of 0.05 are set during training.

To evaluate our model, we utilize a 5-fold cross-validation (CV) and report the average results. During each fold, 20% of the data are used for testing, while the remaining 80% is randomly split into 80% for training and 20% for validation. Additionally, to account for category imbalance in the IEMOCAP dataset, we use both unweighted accuracy (UA) and weighted accuracy (WA) to compare model performance in our experiments.

To demonstrate the effectiveness of the Moment Exchange operation, we introduce it into five classical model structures. We then compare the performances of the original models and the models with Moment Exchange. The five model structures include the representative DNN baseline models of CNN [29], CNN+unidirectional RNN [7], CNN+bidirectional RNN [30], LSTM+Transformer [14] and Conformer [15]. The performance of Moment Exchange is verified in experiment 1. In experiment 2, we test the sensitivity of the parameters to further evaluate the stability and effectiveness of Moment Exchange.

C. Experimental Results

Main experiment For this experiment, we uniformly set λ to 0.95 and used a mini-batch size of 56. The experimental results of the five deep learning models, with and without Moment Exchange, are presented in Table II. The results show that the Conformer model with Moment Exchange outperformed the other baseline models by achieving 71.6% and 70.5% on the UA and WA metrics, respectively. Furthermore, after implementing Moment Exchange to all five models, both UA and WA values increase in different levels.

TABLE II
THE UA AND WA ON DIFFERENT MODELS WITH AND WITHOUT MOMENT EXCHANGE

Model	UA(%)	WA(%)
CNN	53.3	53.3
+Moment Exchange	54.7	54.6
CNN+RNN	57.9	57.9
+Moment Exchange	60.9	59.9
CNN+Bi-RNN	61.8	60.4
+Moment Exchange	65.5	64.8
LSTM+Transformer	67.2	66.2
+Moment Exchange	70.1	69.5
Conformer	68.4	67.1
+Moment Exchange	**71.6**	**70.5**

Compared to CNN and RNN models, Transformer-based models offer better global information learning and model

expression capabilities, for which they can achieve higher performance. The Conformer model enhances the transformer structure by incorporating a convolution module to learn local features from mel spectrograms. This approach combines both global and local information, resulting in optimal performance. In addition, Moment Exchange helps the model to further learn the robust expression of speech features, so Conformer model with Moment Exchange achieves the highest metrics among all the models in our experiments.

Confusion matrix The confusion matrix of the Conformer model with and without Moment Exchange are shown in Table 3. The results indicate that the accuracy of all classes has been improved to some extent following the introduction of Moment Exchange. This outcome serves as evidence of the capability of the Moment Exchange technique to enhance model classification ability by exchanging information between different samples and categories. Furthermore, Moment Exchange can be widely applied to various deep learning models and is effective across all emotional categories. These results underscore the role of Moment Exchange in improving the robustness of the original model's representation.

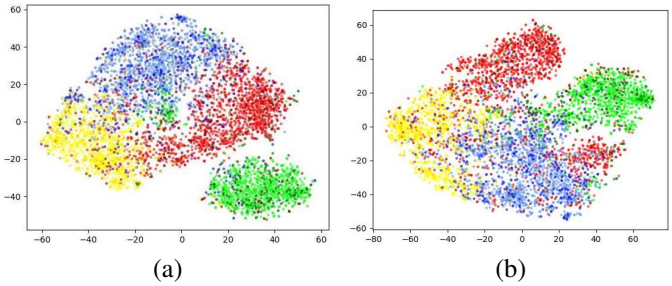

TABLE III
CONFUSION MATRIX (%) WITH AND WITHOUT MOMENT EXCHANGE

with/without	hap	ang	neu	sad
hap	**65.0**/58.9	8.8/10.4	17.2/20.6	9.0/10.1

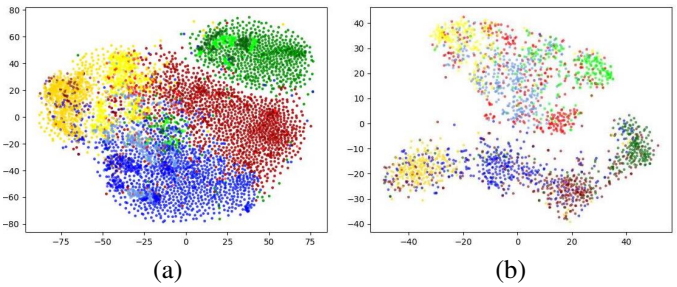
Robustness representaion To demonstrate the impact of Moment Exchange, we utilize Principal Component Analysis (PCA) to embed learned features before softmax layer in both the Conformer model with and without Moment Exchange. For visual analysis, we use the same fold of cross-validation.

Figure 2 presents the characteristics of the train set and the test set on a graph, with (Figure 2-(a)) and without (Figure 2-(b)) Moment Exchange. Different colors represent distinct types, while dark colors within the same color refer to features in the training set. As shown in the figure, we find that the different feature categories are more clearly distinguished and less confused in the model with Moment Exchange. To clarify, let's utilize green dots to demonstrate the emotion of **anger** in this passage. Green dots are more off-center and more clustered internally in the (Figure 2-(a)) than that in Figure 2-(b)), which has a significant impact on the model's classification. In the confusion matrix, we can alse see that the accuracy of anger emotion with Moment Exchange is 70.7%, higher than that without Moment Exchange at 64.3%, which confirms the analysis brought by the visual results. Similar conclusions can be drawn from the visualization results and the numerical results of the confusion matrix on other categories.

Figure 3 presents the characteristics of the model with and without Moment Exchange on the train set (Figure 3-(a)) and the test set (Figure 3-(b)). Similar to the previous figure, different colors represent different types, and dark colors of



(a) (b)

Fig. 2. PCA embedding of features including train and test set from (a) with Moment Exchange and (b) without Moment Exchange. Dark colors represent the train set. **The model with Moment Exchange can separate various emotions more clearly.**

the same color represent features from the model with Moment Exchange. We observe that with Moment Exchange, the dark points tend to move further outward, indicating better distinction between different categories during training. Furthermore, in the test set, dark points with Moment Exchange exhibit clearer distinction, implying better classification performance. As an example, let's also consider the emotion of anger. The dark green dots are located further out in the training set and are more concentrated and distant from the other emotions in the test set. Despite the unequal distribution of green points within the two sets, model with Moment Exchange is proficient in classifying them effectively based on their distinct regions.

Consequently, we can conclude that Moment Exchange enables the original model to amplify the differences between each category in the process of information exchange, so that can better distinguish between different classes when learning speech features during training. Simultaneously, Moment Exchange enhances the model's ability to discriminate during the final test. Moment Exchange enables a model to exchange information, improving the features of a specific class, like the anger class. This strengthens internal features of green points and differentiates them from other color points. Therefore, this method is an effective way to augment data.

(a) (b)

Fig. 3. PCA embedding of features including with/without Moment Exchange from (a) train set and (b) test set. Dark colors represent the model with Moment Exchange. **The darker dots are more scattered around the periphery in (a); The division of dark points is more obvious in (b). Moment Exchange enables the model to enhance the classification ability at different stages**

D. Parameter sensitivity

In order to investigate the stability of Moment Exchange, we test the Conformer and CNN+Bi-RNN model on different hyper-parameters.

TABLE IV
COMPARISON AMONG DIFFERENT λ

	Conformer		CNN+Bi-RNN	
λ	UA(%)	WA(%)	UA(%)	WA(%)
0.3	64.2	64.8	57.8	55.8
0.5	67.9	67.5	61.0	59.2
0.7	68.9	68.1	63.6	62.2
0.9	69.2	68.4	63.5	63.2
0.95	**71.6**	**70.5**	**65.5**	**64.8**
0.97	69.1	68.3	63.1	62.1
0.99	68.5	68.1	62.1	60.8

The weights λ and $1-\lambda$ are used to interpolate between labels y_A and y_B. To demonstrate how λ impacts model performance, we trained our model on the IEMOCAP dataset using values of λ ranging from 0.3 to 0.99. Our results, shown in Table IV, indicate that both UA and WA are maximized when $\lambda = 0.95$. We found that higher values of λ generally lead to increased UA and WA, likely because the normalized features of the original label contain more critical information than the moments, as noted in [26]. However, performance begins to decrease once λ exceeds 0.95, possibly due to the fact that the moments must also contribute to the final result and that λ has a marginal utility.

IV. CONCLUSIONS

This paper presents an approach to enhance DNN training stability and improve classification accuracy and robustness for SER using Moment Exchange. Results indicate that Moment Exchange with appropriate hyper-parameters can improve the model's SER performance, as demonstrated by both experimental numerical comparison and visual analysis. In future work, we plan to explore more robust normalization methods and moment injection techniques. We also aim to conduct experiments on different layers of various DNN models to enhance the model's discrimination power and further improve SER performance.

***Abstract*—Cross-corpus speech emotion recognition (SER) is important for building robust and practical SER systems that can adapt to various real-world scenarios and acoustic conditions. Cross-corpus SER faces the problem of low accuracy partly due to the scarcity and inconsistency of labeled data in the target corpus, in which situation prior knowledge about the relationship between emotion categories may be helpful. Previous studies have suggested that discrete emotion categories and continuous emotion space can complement each other in describing emotions. In this paper, we propose to use the distance between emotion categories derived from their distribution in the continuous emotion space as prior knowledge for cross-corpus speech emotion recognition. We hypothesize that this prior knowledge can help the SER system to learn more meaningful and generalizable representations of emotions that are consistent across domains. Experiment results show that the proposed few-shot learning method based on metric learning leveraging the prior knowledge of emotion distance achieves good performance.**

I. Introduction

Cross-corpus speech emotion recognition (SER) is useful for building robust and practical SER systems and can be adapted to many potential applications in human-computer interaction, health care, education, entertainment, security, etc [1][2].

There have been many studies on cross-corpus SER, and most of them focused on the mismatch and gap between the source and target datasets [3][4][5]. However, the relationship between speech emotion categories was ignored.

Two main types of emotion classification systems have been widely used in emotion research and applications, namely discrete emotion categories and continuous emotion. Discrete emotion theories propose that there are a number of emotion categories, such as anger, fear, happiness, sadness, disgust and surprise, that are biologically based and universally recognizable by facial expressions and physiological responses [6][7][8]. These emotion categories are thought to be triggered by specific appraisals of stimuli or events that have implications for one's goals or survival. Dimensional models of emotion suggest that emotions can be described along a few continuous dimensions, such as valence (positive-negative), arousal (high-low) and dominance (active-passive) [9][10][11]. These dimensions are assumed to reflect underlying neurophysiological processes that modulate emotional states. Dimensional models can account for the gradation and mixture of emotions, as well as the similarities and differences among them. In recent years, there have been articles verifying that discrete emotion labeling and continuous emotion labeling can complement each other, and better emotion recognition performance can be achieved through multi-task learning[12][13][14][15]. The logic behind these articles is that both discrete and continuous emotion annotation information can provide a basic emotion feature extraction capability for emotion recognition models, and the information provided by the two is complementary. Especially, continuous emotion annotations can provide useful information for discrete emotion recognition.

Another problem with traditional cross-corpus SER methods is their weak ability in speech representation because they use traditional speech features mostly coming from openSMILE toolkit or low-level speech descriptor instead of state-of-the-art unsupervised pre-trained speech features. [3] considered deep feature extracted by ResNet50 from the Mel spectrograms, but the speech representation ability of this deep feature still needs to be improved compared with the features obtained by unsupervised pre-training, such as Wav2vec 2.0 [16][17][18], Hubert [19][20], etc.

Inspired by the above series of studies on discrete versus continuous emotions, this paper quantifies the distance between emotion categories through their distribution in continuous emotion space, and uses this as prior knowledge in discrete emotion category learning. The coarse-grained distribution of emotions is shown in Figure 1, where the location relationship of the class centers of the four basic emotional categories in the continuous emotional space is presented. For instance, the Euclidean distance between the two emotions of happy and sad is the farthest, because they are relatively far apart in the two dimensions of valence and arousal. According to the distribution, one can divide the distance between pairs of emotion categories into several levels.

In this paper, we propose to use the distance between emotion categories derived from their distribution in the continuous emotion space as prior knowledge for cross-corpus SER. The emotion distance guides the metric loss construction in few-shot learning to learn more meaningful and generalizable representations of emotions that are consistent across domains. The contributions of this paper are as follows: 1) This paper introduces emotion distance for the first time to the cross-corpus SER task. 2) This paper adopts a self-supervised speech feature extractor instead of traditional features for cross-corpus SER. 3) The proposed few-shot learning guided by emotion distance method achieves good cross-corpus SER performance.

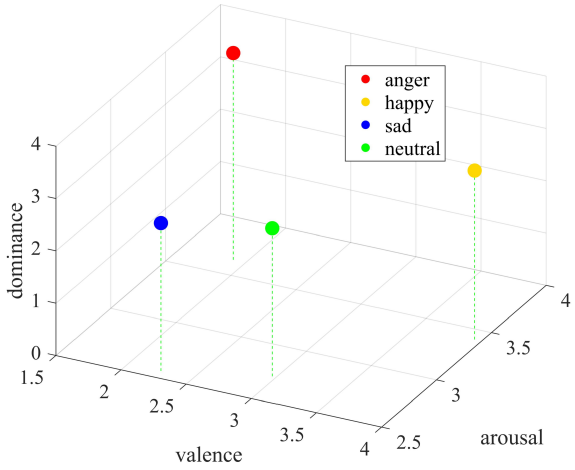

Fig. 1. Emotion distribution in valence-arousal-domination axes

II. Method

In this section, we introduce the baseline transfer learning based on few-shot learning and our proposed method, i.e., few-shot learning guided by emotion distance.

Figure 2 shows the fine-tuning and testing stage of the baseline and emotion distance-guided few-shot learning, from which one can also see how the emotional distance knowledge is used in the construction of the metric loss.

Some general notation assumptions of this paper are as follows. $\mathbf{x}$ represents a speech sample and $\mathbf{F}$ represents the speech emotion feature extractor. $\mathbf{F}(\mathbf{x})$ is the emotion embedding of sample $\mathbf{x}$, and $\mathbf{cen}$ represents the shot average embedding of a certain emotion in the support set. The parameters of the SER model can be represented as $\mathbf{W}$ and the loss function is $L(\mathbf{W})$.

A. Baseline transfer learning based on few-shot learning

A common approach to address cross-corpus speech emotion recognition is to use transfer learning, which leverages the knowledge learned from a source corpus to improve the performance on a target corpus. Besides, few-shot learning that aims to learn from a small number of labeled examples has been proven to be effective in cross-corpus transfer learning.

The baseline method consists of three steps: 1) Training a feature extractor on a large source corpus using a self-supervised contrastive learning objective. 2) Fine-tuning a classifier on a few labeled examples from the target corpus using the extracted features. 3) Testing the SER model on the target corpus. During the fine-tuning stage on the target corpus, the training loss of basic transfer learning (BTL) only contains the CE loss related to emotion labels, while the few-shot learning based transfer learning (FSTL) also takes into account the relationship between categories, as shown in the 'metric loss' in Figure 2.

We employ the framework of the siamese neural network (SNN) for few-shot learning process, which uses the same weights while working on a pair of input vectors to compute comparable output vectors. The SNN is trained by creating positive and negative pairs of inputs, where positive pairs belong to the same class and negative pairs belong to different classes. The network uses a contrastive loss to minimize the distance between similar inputs and maximize the distance between dissimilar inputs:

$$L_{FSTL}(\mathbf{W}) = \sum_{c} \sum_{\mathbf{x_i},\mathbf{x_j} \in \mathcal{X}'_c} d\left(\mathbf{F}\left(\mathbf{x_i}\right), \mathbf{F}\left(\mathbf{x_j}\right)\right) - \kappa \sum_{c \neq c'} \sum_{\substack{\mathbf{x_i} \in \mathcal{X}_c \\ \mathbf{x_j} \in \mathcal{X}_{c'}}} d\left(\mathbf{F}\left(\mathbf{x_i}\right), \mathbf{F}\left(\mathbf{x_j}\right)\right) \tag{1}$$

where $\mathcal{X}_c$ is the set of data belonging to class c, $\mathcal{X}_{c'}$ is the set of data belonging to class c' different than c, d is the Euclidean distance between sample pair embeddings and κ determines the trade-off between penalizing dissimilarity between samples belonging to the same class against similarity between samples belonging to different classes.

B. Few-shot learning guided by emotion distance

Few-shot learning-based transfer learning in cross-corpus SER makes good use of the limited data in the target corpus and the relationship between different emotional categories, but this relationship is only a coarse-grained distinction. Inspired by the distribution of emotion categories in the valence-arousal continuous emotion space, this study proposes few-shot learning based on a fine-grained emotion relationship metric.

As shown in Figure 1, in the continuous emotion space, the {happy, sad} sample pair has the farthest Euclidean distance. In addition, in the learning of speech emotion representation, the representation ability of emotion representation in the arousal dimension is stronger than that of the valence dimension, so when we consider the distance between emotion categories, the distance in the valence dimension is compressed, which leads to the emotion distance between {anger, sadness} sample pair being as far as that between {happy, sad} sample pair. These two types of emotion sample pairs are considered to be pure negative (PN) pairs. For pairs of samples with the same emotion category, we believe that the distance between them should be as close as possible and they are pure positive (PP) pairs. For other emotion sample pairs, such as {happy, neutral} and {happy, angry}, we consider the distance between them to be at an intermediate level, not as far away as PN pairs, and we call them medium negative (MN) sample pairs.

Following the above discussion of emotion distance, we construct a fine-grained metric loss function for few-shot learning guided by emotion distance (EMOFSL):

$$\begin{aligned} L_{EMOFSL}(\mathbf{W}) = & \sum_{c} \sum_{\{\mathbf{x_i},\mathbf{x_j}\} \in \mathbf{PP}} d\left(\mathbf{F}\left(\mathbf{x_i}\right), \mathbf{F}\left(\mathbf{x_j}\right)\right) + \\ & \kappa_1 \sum_{c \neq c'} \sum_{\{\mathbf{x_i},\mathbf{x_j}\} \in \mathbf{PN}} max(\alpha - d\left(\mathbf{F}\left(\mathbf{x_i}\right), \mathbf{F}\left(\mathbf{x_j}\right)\right), 0) + \\ & \kappa_2 \sum_{c \neq c'} \sum_{\{\mathbf{x_i},\mathbf{x_j}\} \in \mathbf{MN}} max(\beta - d\left(\mathbf{F}\left(\mathbf{x_i}\right), \mathbf{F}\left(\mathbf{x_j}\right)\right), 0) \end{aligned} \tag{2}$$

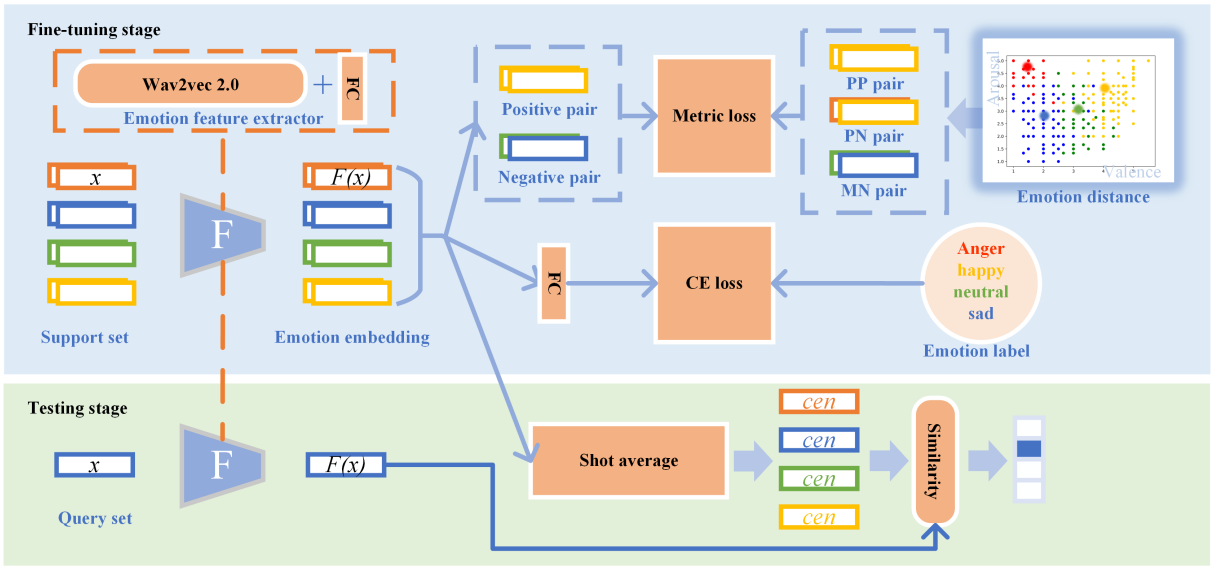

Fig. 2. The fine-tuning and testing stage of the basic and emotion distance-guided few-shot learning

where $\alpha > \beta$ and represent the restricted distance margin of the PN pairs and the MN pairs, respectively, and κ_1 and κ_2 determine the trade-off among different parts of the loss.

III. Experimental Results and Discussions

A. Experimental setup

In this section, we evaluate the proposed framework for cross-corpus SER. Three most common emotion corpora containing English speech, including IEMOCAP (I) [21], RAVDESS (R) [22], and MSP-IMPROV (M) [23], are employed in our experiments. Two of the above corpora are randomly selected as the source and target corpora respectively, and six groups of cross-corpus SER tasks (source corpus-target corpus) I-R, I-M, R-M, R-I, M-I, M-R, are conducted. We select four common emotional categories, i.e., anger, neutral, happy, and sad, in our experiments.

In the transfer learning process, cross-validation (CV) was conducted with different settings for each target corpus to ensure the reliability of the experimental results. For IEMOCAP, we split the dataset by leaving one session out as the test set, and the remaining four sessions were used for training. For RAVDESS, we split the dataset into six equal subsets according to the speaker ID, and chose one subset as test set while the rest subsets as training data. For MSP, 6-fold leave-one-speaker-out CV was conducted according to the session division.

For few-shot learning based transfer learning, 5 random fixed samples of each emotion in the training set of the target corpus are selected for fine-tuning, and all of the samples in the testing set are used for testing. The training set and the testing set are obtained from the cross-validation settings.

We compared the proposed few-shot learning method guided by emotion distance (EMOFSL) with basic transfer learning (BTL) and few-shot learning based transfer learning (FSTL) in terms of unweighted accuracy assessing the SER performance.

For emotional features extraction, we adopt the Wav2Vec 2.0 model that extracts unsupervised speech features by a multi-layer convolutional neural network taking raw speech signals as the input. The output embedding dimension of Wav2vec 2.0 is 768. Then follows a fully connected layer whose input and output dimensions are 768 and 256 respectively.

The common experimental hyperparameters in the finetuning stage are listed in Table I. Note that the finetuning used an exponentially decaying learning rate, which can be calculated as follows:

$$lr = lr_{init} * (r_{\text{decay}})^{\frac{Step_{\text{curr}}}{Step_{\text{decay}}}},$$

where lr_{init} denotes the initial learning rate, $Step_{\text{curr}}$ is the current number of training steps, and $Step_{\text{decay}}$ is the decay period.

TABLE I
Common Hyperparameters in the Finetuning Stage

Hyperparameters	Value
initial learning rate	0.0001
decay rate of learning rate	0.98
max speech length	10 (s)
max epochs	10
precision	32
optimizer	Adam
α	1
β	0.6
κ	1
κ_1	0.6
κ_2	0.3

B. Results and discussions

Table II shows the cross-corpus SER performance of the compared methods, in which 5 samples from each of the 4

Fig. 3. Confusion matrices of the proposed EMOFSL method in six cross-corpus tasks. (R: RAVDESS, M: MSP-IMPROV, I: IEMOCAP) The horizontal axis represents the true labels, and the vertical axis represents the predicted labels.

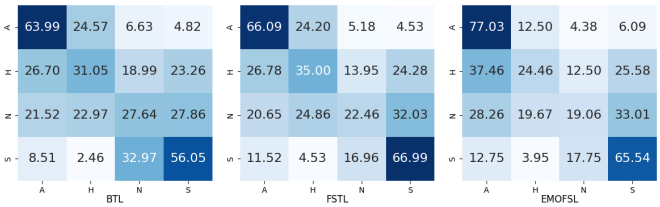

Fig. 4. Confusion matrices of the compared methods in the cross-corpus task when the source and target corpora are RAVDESS and IEMOCAP, respectively. The horizontal axis represents the true labels, and the vertical axis represents the predicted labels.

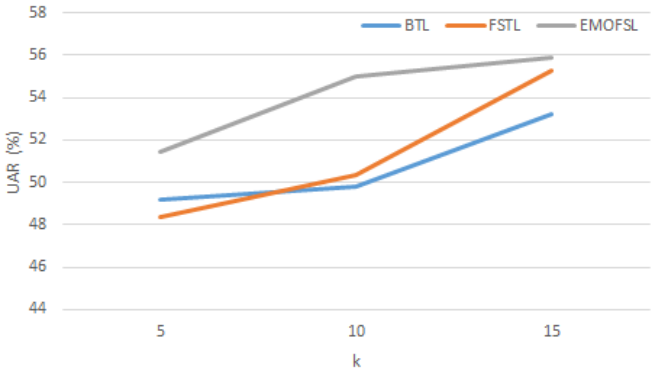

Fig. 5. Performance comparison of BTL, FSTL, and EMOFSL when the size of support set k is 5, 10, and 15, respectively. The source corpus of the cross-corpus task is RAVDESS, and the target corpus is IEMOCAP.

emotions are selected to form the support set in the fine-tuning process. Few-shot learning method guided by emotion distance (EMOFSL) is compared with basic transfer learning (BTL) and few-shot learning based transfer learning (FSTL) in terms of unweighted accuracy rate (UAR).

It can be observed that our proposed EMOFSL performs better than the other two baseline methods, which proves the effectiveness of emotion category distance prior knowledge for cross-corpus SER task. It can be also observed that in most cross-corpus tasks, the few-shot learning-based transfer learning performs better than the basic transfer learning, which verifies that metric loss obtained from the positive and negative sample pairs helps the learning of speech emotion on the target corpus.

Figure 3 presents the confusion matrices of the proposed EMOFSL method for six cross-corpus tasks. One can observe that the recognition results of anger and sad in all tasks are generally better than other emotions, indicating that these two emotions in speech are easier to be recognized, which is partly related to the prior knowledge of the emotional distance we added to the metric loss.

Figure 4 shows the confusion matrix comparison between the proposed method and the baseline methods. We can see that with metric loss representing the distance relationship of different emotion categories, FSTL and EMOFSL achieve better recognition on anger and sad.

Figure 3 and 4 also indicate that happy is often misidentified as anger and neutral is often misidentified as sad, which is consistent with our previous understanding in the continuous emotion space that arousal is easier to distinguish than valence in speech emotion expression.

Figure 5 shows the performance comparison of BTL, FSTL, and EMOFSL when the size of support set k is 5, 10, and 15, respectively. The source corpus of the cross-corpus task is RAVDESS, and the target corpus is IEMOCAP. One can observe that: 1) As the number of training samples in the support set increases, the SER performance of the three methods improves accordingly. 2) In the case of different support set sizes, the performance of EMOFSL is better than the other comparison methods. 3) The performance of FSTL is better than that of BTL in most cases.

There have been several papers on the cross-corpus SER, but most of them are not suitable for comparison because of different configurations for the databases and the utilization of the target domain data for validation. Among the approaches, [5] reached a 43.8% UAR when the source and target corpora are IEMOCAP and MSP-IMPROV, respectively. Our proposed EMOFSL method achieves a higher UAR of 48.48% using fewer shots. The two main reasons for the better performance of the proposed EMOFSL are: 1) A more advanced speech

feature extractor is used. 2) The prior knowledge of emotion distance is introduced as a guide in the cross-corpus speech emotion representation learning.

IV. Conclusion

Cross-corpus speech emotion recognition faces the problem of sparse target set data. To solve this problem, this study introduces the prior knowledge of emotion distance to guide the few-shot learning process of cross-corpus emotion recognition, thereby alleviating the problem of insufficient emotional information to a certain extent. Experimental results show that the proposed method performs better than traditional few-shot learning verifying the efficiency of the emotion distance prior knowledge. In addition, this paper introduces a self-supervised pre-training model with stronger speech representation ability than traditional features as a feature extractor, which also improves the performance of cross-corpus speech emotion recognition.

***Abstract* — In this study, we investigated speech emotion recognition using both linguistic and acoustic features contained in emotional speech. Speech recognition is necessary to extract linguistic features in this system. In this case, speech recognition accuracy affects emotion recognition accuracy; therefore, it is important to improve the accuracy. In particular, we use a language model adapted to a large amount of Twitter data to model colloquial expressions that frequently appear in emotional speech. Consequently, a word recognition accuracy of 82.2% was obtained. Finally, we obtained 51.5% of emotion recognition accuracy from linguistic features, 77.25% from acoustic features, and 82.25% from the fusion of both. Furthermore, according to the analysis of the recognition results, the error tendency of linguistic and acoustic features differed, and we found that complementary effects could be obtained when fusing both features. In this corpus, a human was reported to have an emotion recognition rate of 75.5%; we surpassed that performance. This demonstrated the effectiveness of the proposed method for speech emotion recognition.**

I. INTRODUCTION

As with human interaction, the use of nonverbal information, such as emotions, as a means of communication plays an important role in the smoothness of spoken dialogue systems. Therefore, the importance of emotion recognition has recently increased.

Considerable research has been conducted using acoustic features in this field. Linguistic features obtained from speech can also be used for emotion recognition. Therefore, methods using both linguistic and acoustic features have been studied [1-3]. Speech recognition for emotional speech (emotion speech recognition) is challenging and is necessary for linguistic features extraction. Previously, speech recognition performance was considered insufficient [3].

One reason for the difficulty in emotion speech recognition is the large variation in acoustic features. Furthermore, it is difficult to construct a language model for emotion speech. Colloquial expressions are frequently observed in emotional speech. However, few language corpora include colloquial expressions. For this reason, many studies have used only acoustic features [4-6], even when linguistic features are used, transcripts are often used instead of speech recognition results [1,2,7]. Some studies have attempted to use speech recognition but with poor results [3].

Therefore, we first attempted to improve the speech recognition performance for emotional speech. Consequently, it has been shown that a language model for emotional speech recognition can be effectively created using a large amount of tweet data [8], where the combination of acoustic and language model adaptations improved the recognition rate from 63.9% to 82.2%.

In this paper, we extract linguistic features using the above speech recognition results, and try to recognize emotions using both linguistic and acoustic features. In particular, we compare the recognition results of linguistic and acoustic features and clarify the effect that can be obtained in emotion recognition when they are used together.

In recent years, many open-source frameworks, such as end-to-end models, have been released, and by using them, it has become possible to test speech recognition easily. In particular, methods using model structures, such as wav2vec [21] and huBERT [22], can yield highly accurate recognition results [9-11]. However, when these models are used, the recognition process becomes a black box. Therefore, when linguistic and acoustic features are combined, the role each plays is unclear. In addition, there are reports on the effect of ASR on emotion recognition in [19] and [20], however, the influence of each emotion on linguistic features and acoustic features is not clear.

In our system, emotion speech recognition is performed using

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

uttered speech and linguistic features are extracted from the speech recognition results to perform emotion recognition. In addition, acoustic information is extracted from speech and used for emotion recognition based on acoustic features. Subsequently, the emotion recognition results of the linguistic and acoustic features are fused to obtain the final emotion recognition results. Owing to this procedure, it is possible to clarify why fusion is effective by comparing the recognition results for each feature.

In [12], linguistic information was obtained through speech recognition, and a method for emotion recognition using both acoustic and linguistic information was proposed. In this study, emotion recognition was performed by late fusion using the weighted addition of three types of recognition outputs: linguistic features, acoustic feature statistics from whole utterances, and acoustic features by low-level-descriptor (LLD). However, fusing by the weights had a practical problem that it required data to be recognized for determining the weights, because those were task dependent. In addition, the recognition performance using linguistic features was insufficient.

In this study, the following methods are used to improve the performance. We use BERT [13] for emotion recognition of linguistic features and a deep learning model for late fusion. We demonstrate that a recognition performance equal to or higher than that of humans can be obtained using the above methods.

II. Emotion Recognition by Late Fusion

Conventionally, the LLD is extracted as a time series representing emotional features, and various acoustic statistics representing the features of an entire utterance are calculated. However, because these features represent the characteristics of the entire utterance, it is not possible to extract local emotional fluctuations. Therefore, in the proposed method, emotion recognition based on acoustic features uses both the recognition result from LLD, which is a time-series feature, and the recognition result from the statistics of the entire utterance [12].

Recognition based on time-series features uses bidirectional LSTM (BiLSTM) and bidirectional GRU (BiGRU) as classifiers, whereas recognition based on statistics uses a DNN as a classifier. In emotion recognition based on linguistic features, speech recognition is first performed using acoustic and linguistic models, and emotion is estimated by BERT using the speech recognition results. Finally, emotion recognition was performed by fusion of the recognition results of acoustic features and language features using DNN, and four emotions, "anger (ang)," "joy (joy)," "sadness (sad)," and "neutral (neu)," were recognized. Figure 1 shows a schematic diagram of the proposed emotion recognition system. The left side of the figure shows the recognition unit based on linguistic features, and the right side shows the recognition unit based on acoustic features.

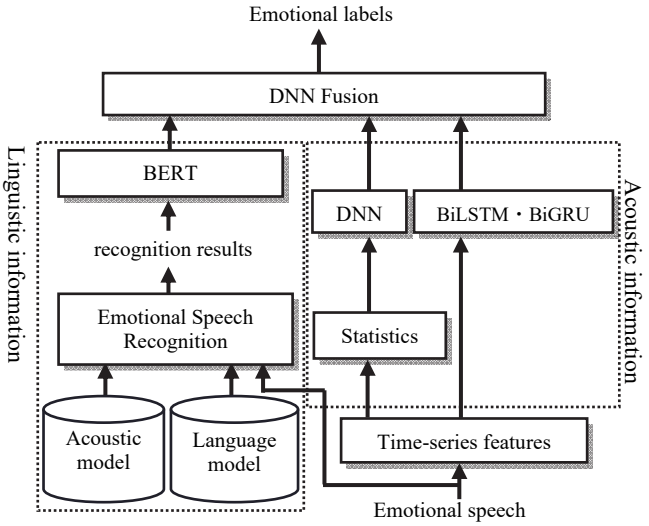

Fig. 1 Block diagram of the proposed system

III. Emotion Recognition Method

A. Emotion recognition using linguistic features

Speech recognition was first performed for emotion recognition based on linguistic features. The speech recognition method presented in [8] was used. A two-pass decoder was used for decoding. In the first pass, word graphs are generated from beam searches using triphones and bigrams, and in the second pass, recognition results are obtained by the trigram rescores of the generated word graphs. The DMM-HMM was used as the acoustic model. In this recognition system, we first generate a baseline acoustic model (AM) and a language model (LM) for emotional speech using a Corpus of Spoken Japanese as training data. Subsequently, model adaptations of AM and LM were performed. In AM adaptation, emotional speech data are used as adaptation data, and adaptation is performed using the back-propagation method. The number of epochs was automatically determined by dividing the adaptation data into a 9:1 ratio and using early stopping by cross-validation using the frame recognition rate. The weighted mixture method was used for the LM adaptation [14]. For LM adaptation, a large amount of tweet data of 25.86 million words collected from Twitter was used as the adaptation data, and the mixed n-gram method was used [14]. In this approach, we generated

the mixed n-gram by combining the n-gram count derived from the adaptation data (n_i^{adapt}) and that derived from baseline data (n_i^{base}). N^{adapt} and N^{base} denote the total n-gram counts of the adaptation and baseline data, respectively. We estimated the occurrence probability of word w_i in the adapted LM by the following formula:

$$P(w_i) = \frac{w \cdot n_i^{adapt} + n_i^{base}}{w \cdot N^{adapt} + N^{base}} \quad (1)$$

where w represents a weighting factor designed to address the imbalance between adaptation and baseline data. The baseline word recognition accuracy was 63.9%, but the recognition accuracy after AM and LM adaptation was 82.2%.

Using these speech recognition results, we performed emotion recognition based on linguistic features. In this study, we used BERT as the discriminator. A pretrained model trained with a large amount of unlabeled data and a fine-tuning method using a small amount of labeled data for the target task were used. For the pretrained model, we used a model trained using Japanese Wikipedia texts [15]. Using this pretrained model, fine-tuning was performed using emotion-labeled data to train an emotion classifier for the four emotions. A total of 1,963 sentences from the Japanese Twitter-based emotional speech (JTES) were used for fine-tuning, 10% of which were used as validation data.

B. Emotion recognition using acoustic features

As the acoustic features for emotion recognition, the LLD was extracted as a time series representing emotional features, and various statistics representing the features of the entire utterance were calculated from the LLD. First, the input speech was divided into frames using a window function, and LLD, such as the fundamental frequency and MFCCs, were extracted. Here, the large openSMILE emotion feature set [16] was used as the LLD, and 168-dimensional feature vectors were used per frame (10 ms). Next, 39 types of statistics were calculated from the 168-dimensional LLD, and 6,552-dimensional features ($= 39 \times 168$) were input into the DNN for statistical features. The structure of the DNN consists of three hidden layers of 2,048 units. The emotion recognition rate was only 69.25% using the feature parameters by the statistics mentioned above.

For the LLD, which is a time-series feature, it is possible to use a model suitable for changes over time. Therefore, in this study, we used an LSTM model as the discriminator. Table I presents the emotion recognition results obtained by examining the combinations of LSTMs, GRUs, bidirectional LSTMs, and bidirectional GRUs. Based on the results, we used a combination of bidirectional LSTM and bidirectional GRU, which achieved the highest accuracy (75.75%).

The network structure in this model consists of one BiLSTM layer, one BiGRU layer, and three fully connected layers (fc1–fc3) from the input side. The BiLSTM and BiGRU had 100 hidden layers. The fully connected layers fc1, fc2, and fc3 contained 512, 256, and 64 units, respectively. The learning rate was set to 5.0×10^{-4}. Adam was used as the optimization method, and cross-entropy was used as a loss function.

Table I

Emotion recognition results by LLD (%)

Conditions	Accuracy
LSTM×2 layers	72.50
BiLSTM×2 layers	73.00
GRU×2 layers	74.25
BiGRU×2 layers	74.50
BiLSTM+BiGRU	75.75

C. Late fusion

Next, late-stage fusion was performed using a DNN-based fusion method for the linguistic and acoustic features. The final result is determined using the fusion method of the DNN using the recognition output of linguistic features based on emotional speech recognition results, statistics for the whole utterance, and time-series features of acoustic characteristics. Using this method, it is possible to automatically estimate emotions without using manually determined weights. The network structure of the DNN consists of 128, 32, and 32 units in the fully connected layers fc1, fc2, and fc3, respectively. The learning rate was 4.0×10^{-5}, the optimization method was Adam, and the loss function was cross-entropy.

For comparison with the DNN fusion, late-stage fusion was performed using the weighted fusion method for linguistic and acoustic features according to the following formula:

$$emo = \alpha Le + (1-\alpha)Ae \quad (2)$$

where emo referred to the final emotion score, Le is the emotion likelihood of a linguistic feature, and Ae is the emotion likelihood of acoustic features. α is a coefficient

with the weight that takes values from 0 to 1. Furthermore, we combined LLD and statistics by the same method.

IV. Emotional Speech Corpus

In this study, we used the JTES database as the speech corpus [17]. In this corpus, colloquial sentences containing emotional expressions were selected from tweets on *Twitter*, considering the balance of phonemes and prosody. A total of 20,000 utterances were prepared for 100 speakers (50 males and 50 females) and 50 sentences for each of the four emotions, ``anger,'' ``joy,'' ``sadness,'' and ``neutral.'' The speaker was instructed to ``convey the intended emotion to the robot (machine)". Anger is divided into ``hot anger" and ``cold anger." They are instructed to be conscious of ``hot anger" in some cases.

V. Emotion Recognition Experiment

A. Experimental conditions

A total of 14,400 utterances (40 sentences × 4 emotions × (45 male speakers + 45 female speakers)) in JTES were used as training data, and 400 utterances (10 sentences × 4 emotions × (5 male speakers + 5 female speakers)) were used as evaluation data. In the late fusion of the weighted fusion method and the fusion method using the DNN described in Section III-C. A total of 12 dimensions of the 4-dimensional LLD, 4-dimensional statistics, and 4-dimensional BERT output were used as the input of the late fusion. We compared the following three types of emotion recognition with different linguistic features extraction methods.

Baseline ASR we use the automatic speech recognizer (ASR) result of 63.9% word recognition rate before adaptation.

Adapted ASR we use the ASR result of 82.2% word recognition rate after adaptation.

Oracle we used the correct text assuming a word recognition rate of 100% for comparison.

In the late fusion of linguistic and acoustic features using the weighted fusion method, the weight α in Eq. (1) was experimentally set to 0.35 for the baseline ASR, 0.25 for adapted ASR, and 0.35 for oracle.

B. Experimental results

For emotion recognition in acoustic features, the recognition rate of late fusion between LLD and statistics using the weighted fusion method was 77.25%. For emotion recognition in linguistic features, the recognition results were 45.5% for baseline ASR, 51.5% for adapted ASR, and 62.5% for Oracle. Figure 2 shows the results of the late fusion of the acoustic and language features using the weighted fusion method.

The emotion recognition rate under optimal conditions was 80.50% with α of 0.35 in baseline ASR, 80.25% with α of 0.25 in adapted ASR, and 83.00% with α of 0.35 in Oracle. Compared with the emotion recognition rate of 77.25% based on acoustic features only, the recognition performance of various linguistic features is low; however, the performance improves when the fusion method is used.

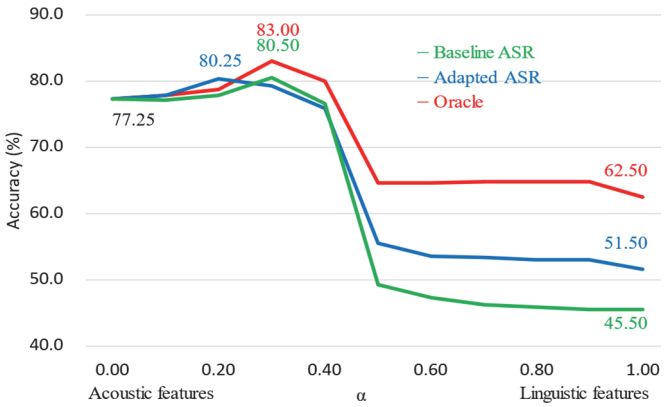

Fig.2 Relationship between weight and emotion recognition accuracy in weighted late fusion

Next, late fusion of linguistic and acoustic features by the fusion method using a DNN was performed. Table II summarizes the emotion recognition results for each fusion condition. In the comparison between the three kinds of linguistic features, Oracle showed the highest recognition rate, but the difference with the other two was not large. Thus, even if recognition accuracy based on linguistic features is somewhat low, it is useful for improving the performance of emotion recognition. In addition, the DNN fusion method achieved a higher performance than the weighted fusion method, as shown in Figure 2.

Next, we present a confusion matrix for the recognition results. Table III shows the results of the acoustic features using the weighted fusion method, Table IV shows the results of the two types of linguistic features only, and Table V shows the results of DNN fusion. In these tables, the vertical axis represents the correct answer, and the horizontal axis represents the predicted result.

The confusion between ‘ang’ and ‘joy’ in the case of acoustic features only in Table III is considered to be due to acoustic similarities such as the strength of the utterance and the fluctuation of the fundamental frequency being larger than that of other emotions.

Table II

Speech recognition and emotion recognition results for each fusion condition (%)

Types＼Conditions	Baseline ASR	Adapted ASR	Oracle
Word recognition rate	63.9	82.2	100
Emotion recognition rate by linguistic features	45.5	51.5	62.5
Emotion recognition rate by acoustic features		77.25	
Emotion recognition rate by DNN fusion	82.00	82.25	85.50

Table III

Confusion matrix for acoustic features only (%). (average recognition rate: 77.25%)

	ang	joy	neu	sad
ang	85	14	1	0
joy	38	57	2	3
neu	1	6	85	8
sad	1	2	15	82

Table IV

Confusion matrix for linguistic features only (%).

	Baseline ASR (average: 45.5%)				Adapted ASR (average: 51.5%)			
	ang	joy	neu	sad	ang	joy	neu	sad
ang	41	11	28	20	52	4	20	24
joy	33	36	3	28	12	55	6	27
neu	15	7	58	20	10	23	46	21
sad	22	11	20	47	20	25	2	53

Table V

Confusion matrix for acoustic and linguistic features (%).

	Baseline ASR (average: 82.0%)				Adapted ASR (average: 82.5%)			
	ang	joy	neu	sad	ang	joy	neu	sad
ang	86	10	4	0	86	8	6	0
joy	16	78	2	4	23	72	2	3
neu	1	5	87	7	2	3	90	5
sad	3	3	17	77	1	4	14	81

When only linguistic features were used (Table IV), there was a tendency to confuse ‘neu’ with ‘joy’ or ‘sad’, and ‘sad’ with ‘ang’ or ‘joy’. These results indicate that it is difficult to discriminate between the emotions ‘neu’ and ‘sad’ using only linguistic features.

Looking at the results of the late fusion of acoustic and language features shown in Table V, it can be confirmed that these recognition errors are greatly reduced, and the accuracy of emotion recognition is improved. Thus, it was shown that the proposed method is effective because it obtains the complementary effects of acoustic and linguistic features.

VI. Conclusions

In this paper, we proposed a speech emotion recognition method based on late fusion using a DNN fusion method for linguistic and acoustic features. The results of the experiments confirmed that highly accurate recognition is possible by compensating for each part of the low recognition rate through the fusion of acoustic and linguistic features. Furthermore, it was confirmed that acoustic and linguistic features could complement each other without being affected by the superiority or inferiority of the emotional speech recognition results when the DNN fusion method was used. In addition, the effectiveness of this system was demonstrated by obtaining a recognition accuracy that surpassed that of the weighted fusion method.

It has been reported that the accuracy of human emotion recognition in the JTES corpus is 75.5% (however, this evaluation focused only on acoustic features) [18]. Because we have obtained the recognition performance sufficient for practical use in the closed task using this corpus, we want to consider methods that target open tasks in the future. In addition, we would like to compare the proposed method with other methods such as wav2vec and HuBERT as ASR.

E-mail: b-atmaja@aist.go.jp, a-sasou@aist.go.jp

***Abstract*—Research on speech emotion recognition has been actively conducted; most are in monolingual settings. Considering that emotion expressed in speech is universal, it is noteworthy to conduct multilingual emotion recognition across different cultures. This paper contributes to evaluating multilingual, cross-lingual, and monolingual automatic speech emotion recognition (SER) on the same EmoFilm dataset. We first evaluated these three scenarios on a fixed training/test split. For multilingual emotion recognition, we then expanded the evaluation with cross-validation. The results show that the multilingual SER gained the highest performance with 74.86% of balanced accuracy for five categorical emotions, followed by 72.17% and 58.03% for monolingual and cross-lingual evaluations. We reduced the number of training samples to observe its impact and found that the monolingual setting is superior among others on the same number of samples. The results of this study could suggest the potential use of multilingual SER over cross-lingual and monolingual SER in future speech technologies.**

***Index Terms*—speech emotion recognition, pre-trained model, multilingual emotion recognition, EmoFilm**

I. Introduction

There is some universality in emotion perception by humans, particularly from vocal cues. A study by Scherer et al. [1] reported that the accuracy of vocal expression across cultures was 66%. The study was conducted in nine countries in Europe, the United States, and Asia. The vocal emotion is acted in the voices of anger, sadness, fear, joy, and neutrality. Another study [2], a meta-analysis study by Elfenbein and Ambaday, revealed that emotions were universally recognized at better-than-chance levels. The study also examined studies that included both a majority and minority group in the design. Majority group members were poorer at judging minority group members than the reverse.

Scherer's study [1] suggested that language differences between encoders (speakers) and decoders (listeners) may play a major role in recognizing emotion through voices. The difference is significant for Germany and Indonesia but marginally different for the German and Indo-European languages. In Elfenbein and Ambady [2], the accuracy of emotion recognition was higher when emotions were both expressed and recognized by members of the same national, ethnic, or regional group. This result suggests an in-group advantage; members in the same culture have higher recognition than members from different cultures. Both studies suggest that although emotion recognition among humans is universal, there are differences between cultures.

The commonness and differences in human perceptual emotion recognition have been studied (in [3], Figs. 6-7) for building automatic emotion recognition by computers. As in human perception of emotion through voice, computers should be able to distinguish human emotion regardless of the culture. The authors found that the direction of neutral speech to other emotional states is similar for Japanese and Chinese. The difference includes the neutral position, which is slightly different among Japanese, Chinese, and German by Japanese, Chinese, and Vietnamese listeners. Since there is commonness in the perception of emotion from speech, it is possible to build a system that can recognize emotion from speech multiculturally or cross-culturally, operationalized by different countries through languages.

The first study for building a cross-cultural automatic emotion recognition dataset for machines perhaps is the work of Scherer in 2000 [4]. He claimed to build the first large-scale dataset to obtain empirical data on cross-cultural emotion recognition from voices in nine countries on three different continents. The results, still evaluated by human listeners, showed recognition rates that were much better than chance accuracy. Scherer also found that in affective speech, voices other than vocal bursts, segmental and suprasegmental aspects of language affect the encoding and decoding of emotion.

The research of cross-cultural and multicultural emotion then grew with its debates. Other researchers [5] claimed that six basic (facial expressions) emotions are not universal. The claim is based on the study among Westeners and Easteners on Ekman's six basic emotions (happy, surprise, fear, disgust, anger, and sad). The Westeners show a unique pattern of facial movement for each basic emotion, while the Easteners do not (but show unique eye movement). On the other hand, Narimatsu et al. [6] have found some commonalities and differences between English and Japanese visual art labels by neural speakers. It can be argued that aside from emotions being expressed differently among cultures, the perceiver across cultures still could recognize the emotion with some cultural differences.

This paper contributes to the evaluation of multilingual, cross-lingual, and monolingual automatic speech emotion recognition (SER) on the same dataset, i.e., EmoFilm Dataset [7]. To the best of our knowledge, this is the first study to evaluate multilingual, cross-lingual, and monolingual SER simultaneously on this dataset. Given the argument that emo-

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

tional speech is universal with cultural differences, the performance of all three evaluations (multilingual, cross-lingual, and monolingual) should be comparable under the same test set. The results of this study could suggest the readability of which SER technologies, from these three evaluations, have the potential to be used in future speech technologies.

II. Previous studies

In the previous section, we introduced the classical approach to multilingual emotion recognition. This section discusses recent research on cross-lingual and multilingual speech emotion recognition in chronological order.

Cross-lingual SER

Elbarougy and Akagi [8] in 2013 investigate whether emotions can be estimated cross-lingually. The study proposed three-layer models with semantic primitives in between categorical emotional and acoustic features. To experiment with that proposal, the authors evaluated the Japanese dataset (Fujitsu database) and the German dataset (EmoDB). The results, based on a system with a fuzzy inference system, show small errors in cross-lingual emotion recognition. Both Japanese and German datasets are small and clean (140 and 200 samples); whether the results can be generalized to other languages is questionable.

Neuman and Vu [9] in 2018 conducted experiments with monolingual, cross-lingual, and multilingual SER in English (IEMOCAP dataset) and French (Recola dataset). The best score for French was achieved using a cross-lingual scenario with finetuning on arousal detection. Other dimensions are obtained their best with monolingual (IEMOCAP-valence and Recola-valence) and multilingual (IEMOCAP-arousal). This study is the closest to our work with different datasets and approaches.

Latif et al. [10] in 2019 proposed unsupervised adversarial domain adaptation for cross-lingual SER. The method was evaluated on four datasets: EmoDB, SAVEE (English), EMOVO (Italian), and URDU. They used EmoDB, SAVEE, and EMOVO as source domains and URDU as the target domain and vice versa. The former achieved 65% of UA while the latter achieved 61% of UA (URDU $\rightarrow$ EmoDB). As a comparison, using a multilingual approach achieved 67.3% on URDU and 65.2% on EmoDB (German).

Cai et al. [11] in 2021 proposed a domain adversarial neural network for cross-lingual SER on IEMOCAP and Recola datasets (IEMOCAP $\rightarrow$ Recola and Recola $\rightarrow$ IEMOCAP). Their method outperformed the baseline method but not the monolingual method. The main advantage of their method is no requirement for the target data. No evaluation of multilingual SER is reported, which may obtain better results than the cross-lingual SER.

Multilingual SER

Li and Akagi [12] in 2016 expanded the previous cross-lingual study [8] with a Chinese dataset for multilingual SER. With an SVM as a classifier, the authors evaluated similar three-layer models with the same semantic primitives and acoustic features. The results show that there are small degradations in classification rates from monolingual to multilingual emotion recognition. As in the previous research, the new Casia dataset is also small and clean (198 selected samples), which makes it difficult to draw robust conclusions from the results. The authors then improved their results in 2019 [13] for Japanese and German by 3-4% of UA by combining several acoustic features. The new result, instead, decreases the performance in the Chinese dataset.

Lee [14] in 2019 evaluated two architectures of multitask learning optimized for emotion recognition, three softmax layers and one softmax layer. The first architecture is to predict gender, emotion, and language. The second architecture is to predict language and emotion. The results revealed a better generalization of the second architecture to predict emotion categories with common normalization. The common normalization was performed by normalized features by variances and means from two databases of two languages (English and Japanese).

Zang et al. [15] in 2021 mixed datasets of IEMOCAP, TESS (English), EMA (English), EmoDB, and EMOVO (Italian) and created their training/set partitions based on the newly merged data. The ratio of training:test is set to 4:1. Using wav2vec 2.0 XLSR version (cross-lingual speech representations) with hierarchical grained and feature model (HGFM) for multilingual SER outperformed the baseline with wav2vec 2.0 and HGFM.

Wang et al. [16] in 2022 proposed a multi-gating mechanism with neural architecture search on English (IEMOCAP), German (EmoDB), and French (Cafe) databases. Their proposed methods outperformed the baseline methods for German and French on monolingual evaluations. The result for multilingual evaluations is very similar to the monolingual methods, highlighting the effectiveness of their proposed gating mechanism across different language corpus.

There are several other papers that include "multilingual" terms, but the definition is for the evaluation of several mono languages (e.g., [17], [18]), not a mixed language, nor a multilingual SER model evaluated on mono languages. We exclude these paper since it does not fall in our scope. Furthermore, we provided a fixed split and cross-validation setting in our project repository that other researchers can benchmark in the future.

III. EmoFilm dataset and its partition

The EmoFilm dataset [7] is the focus of this study on evaluating a multilingual speech emotion recognition system, along with its comparison to cross-lingual and monolingual analyses. The emotional speech corpus consists of 1115 samples from English (EN), Italian (IT), and Spanish (SP), extracted from 43 films and 207 speakers. The Italian and Spanish are the dubbed versions of English. The distribution of samples for each language can be seen in Fig. 1, in which Italian has the most portion, followed by English and Spanish.

The dataset includes five categorical emotions: fear, contempt, happiness, anger, and sadness (chance level of 20%).

The average utterance per emotion is 34.3, 41.3, and 35.9 for English, Italian, and Spanish. The distribution of each emotion category is not balanced since the same sentence in the original English is not always considered as emotional as in Italian and Spanish. Table I shows the distribution of each emotion category for each language. Note that the number (including the number in Fig. 1) might be different from the original paper [7]. The counting is based on the latest version (v3) of the EmoFilm dataset available at https://zenodo.org/record/7665999 (accessed on 29 March 2023).

We performed two evaluations for partitioning the dataset into training and test split. Both evaluations are speaker-independent. First, we create a near-balanced fixed split for training and test partition. We evaluated multilingual, cross-lingual, and monolingual emotion recognition with this first evaluation. Second, we evaluated multilingual-only emotion recognition using five-fold cross-validation. The number of samples for each fold is 223 samples (I), which makes it impossible to create a language-balanced partition for each fold due to the nature of the dataset. For the multilingual with the first fixed split, we evaluated the multilingual model on both multilingual samples (a mixed language, 181 samples in the test set) and three monolingual samples (50, 65, and 66 samples in the test set for English, Italian, and Spanish, respectively). The former represents a multilingual model for multilingual samples, while the latter refers to a multilingual model for monolingual samples.

Finally, we downsampled the original samples with 48 kHz to 16 kHz WAV files. This downsampling is needed since the wav2vec2-based model ([19], [20]) to extract acoustic embedding requires 16 kHz WAV files. We provided a Python file to downsample the dataset's files using SoX in the project repository. The repository also contains a CSV file listing files allocated for fixed training/test split and the code to evaluate the cross-validation.

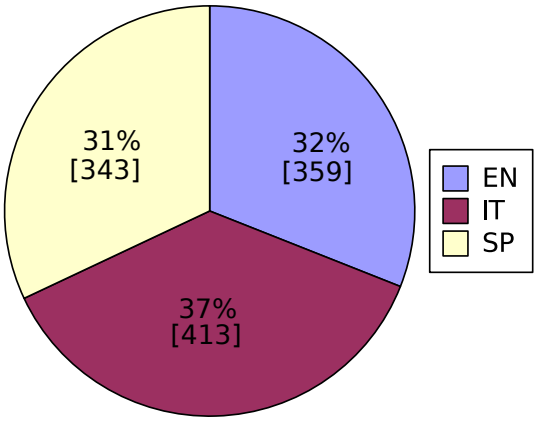

Fig. 1. Percentage [number of samples] of language distribution in EmoFilm dataset; EN: English; IT: Italian; SP: Spanish.

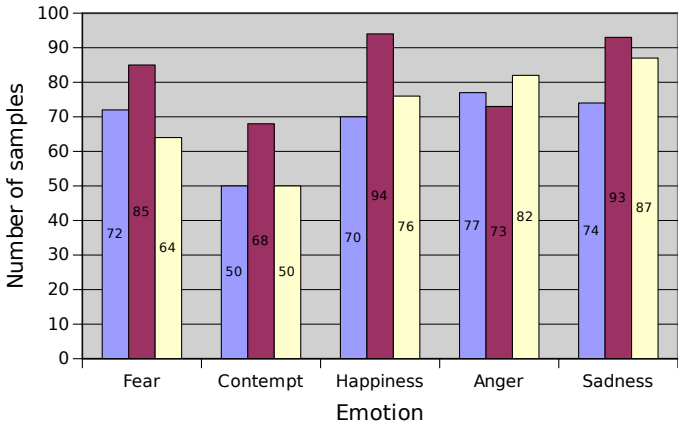

Fig. 2. Distribuion of samples on each emotion category; see Fig. 1 for color code.

TABLE I
DISTRIBUTION OF SAMPLES IN EMOFILM DATASET IN FIXED (TRAIN/TEST) SPLIT AND CROSS-VALIDATION (CV) SPLIT.

Partition	EN	IT	SP	Total
Fixed split				
Train	293	347	294	934
Test	50	66	65	181
Cross-validation				
Fold 1	49	122	52	223
Fold 2	100	86	37	223
Fold 3	64	75	84	223
Fold 4	83	72	68	223
Fold 5	47	58	118	223

IV. MULTILINGUAL, CROSS-LINGUAL, AND MONOLINGUAL SER

In this section, we defined the terms multilingual, cross-lingual, and monolingual emotion recognition as shown in Fig. 3. Multilingual emotion recognition is the process of recognizing emotions in multiple languages (e.g., languages A+B+C), either in a set of mixed languages (language A+B) or sets of several mono languages (Fig. 3 left). In this study, we mixed English, Italian, and Spanish to train the speech-emotion recognition (SER) system and tested the system in a set containing sentences from these languages (both in a mixed language or three mono languages). Cross-lingual emotion recognition is the process of recognizing emotions in different languages (language A+B $\rightarrow$ language C or language B $\rightarrow$ language C). Monolingual emotion recognition is the process of recognizing emotions in a single language (e.g., language B $\rightarrow$ language B). The term multicultural and cross-cultural emotion recognition may be better to replace multilingual and cross-lingual since emotion is more related to culture than language. Since different countries with their specific languages operationalize the cultures, we use the term multilingual and cross-lingual in this study following the previous studies.

V. ACOUSTIC FEATURE AND CLASSIFIER

Recent self-supervised learning models have shown promising results in speech emotion recognition [21], [22], [23],

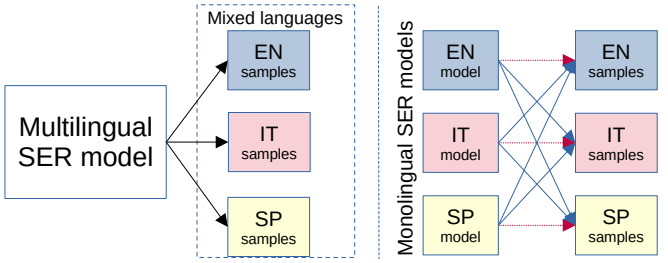

Fig. 3. The difference between multilingual (left), cross-lingual (right: solid blue line), and monolingual SER (right: magenta dot line) in experiments; the models are built using an SVM classifier.

[24]. Following this trend, we evaluated a pre-trained model finetuned on an affective speech dataset [20], [19], which is based on wav2vec2-large-robust model [25] trained on MSP-Podcasts dataset [26]. Models based on wav2vec 2.0 are known to be effective for SER and vocal bursts [27]. The speech embedding is the hidden state of the last layer before the output layer (1024-dim).

We evaluated the support vector machine (SVM) for classification (hence, support vector classification or SVC) for all experiments. This choice is based on the effectiveness of SVM in the previous research on small data [28], [29]. We optimized the C parameter in SVC with a loop in a range [0, 100] with step 0.1. The kernel is RBF with gamma "scale". Other parameters are left as default. The SVC is implemented in scikit-learn [30] with version `1.0.2`.

The evaluations are evaluated by both unbalanced accuracy (overall accuracy or weighted accuracy, WA) and balanced accuracy (unweighted average recall or unweighted accuracy, UA). WA is suitable for balanced datasets, and UA is suitable for unbalanced datasets. UA is perhaps more suitable in this study since the data is not balanced (both in categorical emotions and languages).

All information to reproduce the experiments is available in the project repository: [https://https://github.com/aistairc/emofilm-mser]. The Python codes are light and can be run on a notebook PC. We used the Iiyama laptop model L140MU (i7-1165G7, 24 GB RAM) with Ubuntu 20.04 OS for experiments. The experiments run for about three minutes for extracting acoustic embedding and within a minute for the classification result. We replicate the methods on the other two PCs to check the consistency.

VI. Results and Discussion

We present our results in two parts. The first part is the multilingual SER evaluation on both a multilingual model for multilingual/mixed data and a multilingual model for monolingual data. The second part is evaluations of cross-lingual SER and monolingual SER.

A. Multilingual results

Table II shows the result of WA and UA of a multilingual model on multilingual data or mixed languages (multi2multi). The first row refers to the fixed training/test split, while the rest are cross-validation results. The results of WA in both cases are generally higher than UA. In this unbalanced data, the UA scores are more reliable since they are the average score of each emotion category. The highest score from cross-validation was achieved on Fold 1 as test data, in which the Italian samples occupy the majority of that test data (Table I). In both cases, the cross-validation attained a lower score (average of five folds) and should be considered as the more reliable score since the data is shifted five times.

TABLE II
Results of Multilingual SER model on Mixed Languages

Split	% WA	% UA
Fixed split	78.45	75.77
Cross-validation		
Fold 1	79.37	78.89
Fold 2	68.61	68.27
Fold 3	69.06	66.04
Fold 4	77.13	77.13
Fold 5	77.13	77.13
Average	72.11	71.91

Table III exhibits the results of a multilingual model on monolingual data (multi2mono). This is similar to Table II but with a different test set for each language. In Table II, we mixed all samples from three languages; in Table III, we separated samples for each language. This evaluation used a fixed-split partition. This result is comparable to Table II, highlighting the robustness of the model. Italian samples attained the highest score in WA. Surprisingly, the highest score for UA was obtained in the Spanish language. A possible assumption for this finding is given as follows. Spanish may be more similar to English than Italian (perhaps because English has borrowed many words from it), and the pre-trained model is trained in English. Although the model for extracting acoustic embedding was trained in English, the portion of English samples in the training set is the lowest among the three languages. These explanations lead to Spanish being the highest score. However, the assumption is rejected since Spanish obtained the lowest scores on language-balanced evaluations (Table V), remaining unclear explanations on why Spanish is gaining the highest score in this multilingual to monolingual evaluation. Nevertheless, the differences in recognition rate occur mainly due to differences in the number of samples for each language. Future research could investigate this phenomenon, particularly by comparing the effect of languages in strict conditions (e.g., same number of samples, same speakers, same emotions, etc.).

TABLE III
Results of Multilingual SER model on Mono Languages (Fixed Split)

Language	% WA	% UA
EN	78.00	74.52
IT	81.81	72.34
SP	76.92	77.73
Average	78.91	74.86

B. Cross-lingual and monolingual results

Table IV depicts the results of cross-lingual and monolingual speech emotion recognition. Notice that monolingual evaluation can be seen as a special case of cross-lingual evaluation where the source and target are the same language. Hence, the configuration for both is the same. We combined both cases in one table for a better comparison. The diagonal cells are the monolingual SER results. The cross-lingual SER results are in the other cells. The results are in the form of WA / UA. The partition of data follows the fixed split evaluation. If we look at the score of UA, the preferred metric over WA, almost all scores showed low-performance scores ($< 70\%$) for cross-lingual emotion recognition. Only the Italian model tested on the Spanish model gained 70.52% of UA, perhaps due to the similarity between both languages. Monolingual evaluations scored higher than cross-lingual evaluations, particularly on the UA scores. The only exception for this case (monolingual vs. cross-lingual) is the score of WA for the Spanish model, in which the score of WA for Italian data (70.52%) is higher than its own Spanish data (69.15%). Among the three languages in monolingual evaluations, Italian scored the highest (78.41%), perhaps because of the number of samples (on both training and test) and the expressiveness of the Italian language. Although cross-lingual emotion recognition is more challenging than monolingual emotion recognition, one can merge multilingual data to build a multilingual model, which previously performed better than cross-lingual emotion recognition.

TABLE IV
RESULTS (% WA / % UA) OF CROSS-LINGUAL (ALL ROWS EXCEPT THE DIAGONAL MAGENTA) AND MONOLINGUAL (DIAGONAL MAGENTA) SER MODELS; PARTITION: FIXED SPLIT

Language	EN	IT	SP
EN	72.00 / 68.96	62.12 / 52.52	50.76 / 54.86
IT	62.00 / 61.14	77.27 / 78.41	67.69 / 70.52
SP	62.00 / 53.41	77.27 / 65.05	70.76 / 69.15

C. Discussion

The evaluations of multilingual, cross-lingual, and monolingual emotion recognition show the potential benefit of multilingual emotion recognition systems. First, it achieved comparable results to monolingual emotion recognition. The score of average UA was 71.91% in cross-validation multilingual SER (mixed languages) compared to 72.17% in monolingual SER (average of three languages). For a multilingual model to mono languages, the UA was higher, i.e., 74.86%, which is an average score for a multilingual model on three languages. The multilingual model to mono language evaluations may gain this higher score due to more samples in the training data. Cross-lingual SER performed worst since it is the most challenging task. Given the higher score of a multilingual model on mono languages, we found no benefit in using the monolingual model for SER in this study, evidenced by the scores evaluated on the same test set (fixed split). In this fair comparison, multilingual SER gained an average UA of 74.86%, followed by monolingual (average UA 72.21%) and cross-lingual (average UA 58.03%, still higher than chance level 20%). This result is in line with the previous study, in which multilingual SER outperformed cross-lingual and monolingual SER [9] but within different dataset evaluations.

To check that the high score of multilingual SER is due to the number of data, we reduced the number of training samples from the previous 934 samples to 420 samples (160 samples per language), 360 samples (120 samples per language), and 300 samples (100 samples per language). The last number of samples is to match the least sample number (EN 293 samples). Table V shows the result. It can be shown that by reducing the number of samples, the performance of both WA and UA decreased. Interestingly, using only 360 language-balanced samples, we achieved comparable results with 934 language-unbalanced samples. Furthermore, using 420 balanced samples, less than half of the original training samples, we achieved a new higher score of multilingual SER to monolingual samples (multi2mono) with a UA of 75.52%. Another interesting finding in Table V is that Italian SER still obtained the highest scores under language-balanced evaluations. Again, it highlights the expressiveness of Italian culture among English and Spanish.

Table V also shows the inconsistency ranking of languages in the multilingual model to monolingual evaluations. In 420 samples and 360 samples, the best-performing language is English, followed by Italian and Spanish. In this case, the benefit of pre-training wav2vec2 on the English dataset (MSP-Podcasts) as an acoustic feature extractor may be the cause. In the smallest number of samples setting, with 300 samples, Italian gained the highest score, followed by Spanish and English. In this small number of samples, the effect of the classifier may be more dominant than the acoustic feature extractor (perhaps due to the expressiveness of the Italian languages than others).

TABLE V
EFFECT OF REDUCING THE NUMBER OF TRAINING SAMPLES ON MULTILINGUAL SER (OVERLINES SHOW MEAN SCORES)

# Samples	Multi2mono				Multi2multi	
	WA	UA	$\overline{WA}$	$\overline{UA}$	WA	UA
420 samples						
EN	78.00	80.08				
IT	80.30	77.76	74.82	**75.52**	74.59	73.13
SP	66.15	68.71				
360 samples						
EN	74.00	77.39				
IT	78.79	76.33	72.98	74.24	72.83	72.51
SP	66.15	69.00				
300 samples						
EN	66.00	66.52				
IT	75.76	72.37	68.79	68.85	69.06	67.47
SP	64.62	67.67				

There is a tendency that the more samples for a language in the test set, the higher the score. An example is the Italian language which has the most samples in the Fold 1 cross-validation (mixed languages, Table II) and in the fixed split mono language evaluations (Table III). In both cases,

the performances were the highest among others. These also can be caused by Italian data having the largest samples in the training set. Future research could be directed to build a language-balanced multilingual speech emotion dataset for observing the effect of language and samples in multilingual SER.

As an extension of this study, we expand our experiments to find insights into the usefulness of the extracted acoustic embedding. We plot the t-SNE visualization in Fig. 4 to show the groups of features according to their labels. As shown in that figure, there is a strong separation between anger and sadness; however, there is confusion between contempt and fear. Happiness is located in between since its features occupy both a specific location (left-top) and other locations (spread). We checked the t-SNE for each language, and the results were similar to the mixed language. This result supports the universality of emotional information from speech.

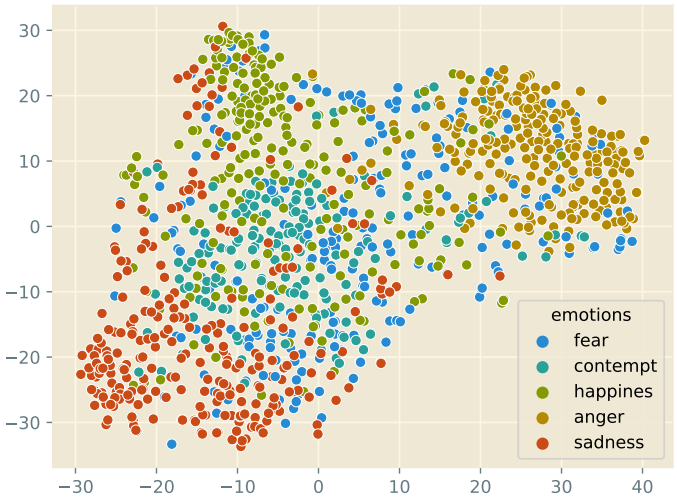

Fig. 4. t-SNE visualization of acoustic embedding from all samples (mixed languages)

VII. Conclusions

The research on multilingual speech emotion recognition has progressively evolved; this study evaluated different cases of speech emotion recognition in speaker-independent multilingual scenarios. It is believed that emotion, including those expressed in speech, is universal across cultures (operated by languages). We support this belief by showing the results of cross-lingual SER, which is higher than the chance level. Multilingual SER achieved better than cross-lingual and monolingual emotion recognition on the same test set. We achieved a score of 74.86% in the multilingual SER model on mono languages and 71.91% in the cross-validation multilingual SER model. The former score is higher than monolingual and cross-lingual evaluations in the same test set (but not on the same number of training sets). The high score of multilingual emotion recognition may be due to its natural benefit from merging all samples from all languages. We experimented with reduced numbers of training samples to prove this hypothesis. We also found a new high score using 420 language-balanced samples for the multilingual model to the monolingual with 75.52% balanced accuracy. However, the fair comparison using a similar number of training samples shows the superiority of monolingual SER among multilingual and cross-lingual.

Nevertheless, the previous scores (multilingual $>$ monolingual $>$ cross-lingual) may also show a fair comparison since all evaluations are done in the same test set. An ideal performance (unbalanced accuracy) would be over 90% for application in real-world scenarios. Hence, a direct implementation of multilingual speech emotion recognition into technology is far from being reliable. The results of this study are promising, but there is still a long way to go before we can achieve a reliable speech emotion recognition system. One way to mitigate this issue is by reducing the number of emotion categories to those that show strong correlations with the extracted acoustic feature/embedding. In this multilingual speech emotion recognition study, we showed that anger and happiness are separable from each other in t-SNE visualization.

Future research could also be directed to investigate the effectiveness of a large number of multilingual SER data by combining several datasets. It also discovered the possibility of training a model simultaneously to predict transcription, Language, age, gender, and emotion from speech [31], [22], [32]. This multitask learning may also help multilingual SER in the future. In this research, we showed that a monolingual setting is still the best-performing configuration under a similar number of training samples. Given the benefit of multilingual data that is available abundantly by nature, it is worth investigating the effectiveness of multilingual over monolingual SER on specific levels (e.g., benchmarking multilingual models to a monolingual dataset which have a large number of samples like English by tracking the performance improvements with the increase of training samples in the multilingual model).

Acknowledgment

This paper is partly based on results obtained from a project, JPNP20006, commissioned by the New Energy and Industrial Technology Development Organization (NEDO), Japan. The authors would like to thank the authors of the EmoFilm dataset [7] for sharing their data and Prof. Akagi of JAIST for the valuable discussion.

Ethical Impact Statement

This study explored the feasibility of multilingual speech emotion recognition (language A+B+C $\rightarrow$ language A+B+C) compared to cross-lingual (language A $\rightarrow$ language B) and monolingual (language A $\rightarrow$ language A) speech emotion recognition. One of the evaluations was performed on the same test set (a fixed train/test split) to compare the three evaluations fairly. The study shows the potential benefit of multilingual speech emotion recognition over monolingual and cross-lingual emotion recognition. The results support the previous finding of similar evaluations on the different datasets (English and French) [9]. This study's results are limited to the EmoFilm dataset (English, Italian, and Spanish) and should not

be generalized (to other datasets). Instead, it could be used as a reference for future studies. A CSV file for splitting samples into training/test sets will be given in the open repository to enable future benchmarking, along with cross-validation and other settings. The model generated by this study should not be used in real-case scenarios.

E-mail: b-atmaja@aist.go.jp, a-sasou@aist.go.jp

***Abstract*—Speech emotion recognition has evolved from research to practical applications. Previous studies of emotion recognition from speech have focused on developing models on certain datasets like IEMOCAP. The lack of data in the domain of emotion modeling emerges as a challenge to evaluate models in the other dataset, as well as to evaluate speech emotion recognition models that work in a multilingual setting. This paper proposes an ensemble learning to fuse results of pre-trained models for emotion share recognition from speech. The models were chosen to accommodate multilingual data from English and Spanish. The results show that ensemble learning can improve the performance of the baseline model with a single model and the previous best model from the late fusion. The performance is measured using the Spearman rank correlation coefficient since the task is a regression problem with ranking values. A Spearman rank correlation coefficient of 0.537 is reported for the test set, while for the development set, the score is 0.524. These scores are higher than the previous study of a fusion method from monolingual data, which achieved scores of 0.476 for the test and 0.470 for the development.**

***Index Terms*—speech emotion recognition, ensemble learning, multilingual speech processing, pre-trained model, emotion share**

I. Introduction

Research on speech emotion recognition (SER) has been focused mainly on recognizing categorial emotions like happy, angry, sad, or neutral. There are attempts to predict dimensional emotions like valence, arousal, and dominance; however, their application is still limited. The reason is that the dimensional emotion is not as straightforward as the categorical emotion. Nevertheless, the previous studies on categorial emotion recognition are designed to choose a single class of emotions in multiclass settings. In contrast to categorial emotions, the emotions, particularly conveyed by vocal bursts, are bridged by smooth gradients (instead of clear separation between discreet emotions) with continuously varying meanings [1]. In that study, the authors found 24 categorial emotions, which may not have been limited to vocal bursts only but also to general emotion perception or speech perception (since vocal bursts are commonly found within speech).

An attempt to analyze emotion fine-grained emotion (i.e., as a regression task) instead of coarse-grained emotion (i.e., by classification task) has been conducted from a linguistic point of view [2]. The authors mapped the degrees of valence and arousal given the sentence into six basic categorical emotions via several lexicons and corpus. The top model (using WKB lexicon) obtained correlation scores of 0.65 for dimensional emotions (valence, arousal, dominance) and 0.416 for categorial emotions. Besides only using linguistic information, the evaluation was conducted on English data only.

Recently, the multilingual approach to tackle the limitation of speech technology has been proposed in the parent tasks of speech processing, automatic speech recognition, speech synthesis, and speech translation. Models like Whisper [3] and MMS [4] can precisely recognize speech in multiple languages. Stirred by this direction, research on speech emotion recognition has been directed to tackle its limitation under multilingual settings. Assuming that emotion is a universal language (i.e., the pattern of angry speech is the same across languages or cultures), the multilingual approach is expected to work also on speech-emotion recognition with diverse language samples.

Multilingual SER attempts to recognize emotion regardless of the language. One can build a single model (including a model trained on multilingual data) for each language with language detection as pre-processing; another can build a single model for all languages. This study is aimed at the latter approach. The previous studies utilized transfer learning for cross-lingual SER [5], distribution adaption [6], and implicit distribution alignment [7]. The last two studies were developed for cross-corpus SER with different languages.

The use of multiple models for SER has shown to be effective for monolingual data. The technique of ensemble was usually adopted to fuse several models from different modalities and/or features. Examples are acoustic and linguistic for dimensional SER [8], [9], acoustic and facial expression [10], and multi-feature fusion [11]. In the previous study [12], ensemble learning was also utilized to tackle the limitation of skewed training data in monolingual SER by maximizing, averaging, and log averaging of the output probabilities of the component classifiers.

This paper contributes to the evaluation of ensemble learning, combining several models via late fusion methods for predicting emotion share from speech in multilingual settings. The fusion was performed by averaging predictions of different

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

models. We evaluated eight multilingual pre-trained models since the dataset contains multilingual data from English and Spanish. The pre-trained models are chosen from those languages. We showed that by combining the models via ensemble learning with the late fusion method, we could improve the performance of the baseline model with a single model. The performance is measured using the Spearman rank correlation coefficient since the task is a regression problem with ranking values.

II. Dataset and Task

The dataset used in this study is obtained from the dataset for The ACM Multimedia 2023 Computational Paralinguistic Challenge (ComParE) Emotion Request Sub-Challange [13], which is provided by Hume AI [14]. There are nine categorical emotions in the dataset: 'Anger', 'Boredom', 'Calmness', 'Concentration', 'Determination', 'Excitement', 'Interest', 'Sadness', and 'Tiredness'. The choice of these nine emotions is based on their more balanced distribution in the valence-arousal space. The basis for the dataset itself is more than 5,000 'seed' samples.

Seeds consist of various emotional expressions, which were gathered from openly available datasets, including MELD [15] and VENEC [16]. The seed samples were mimicked by speakers recruited via Amazon Mechanical Turk by the provider of the dataset [14]. The dataset consists of 51,881 'mimic' samples (total of 41:48:55 h of data, mean 2.9 s, range 1.2 - 7.98 s) from 1,004 speakers aged from 20 to 66 years old. The data were collected from 3 countries with broadly differing cultures: the United States (English/EN), South Africa (English/EN), and Venezuela (Spanish/SP). Each seed sample was rated by the individual who imitated it using a 'select-all-that-apply' method. Seeds were assigned a mean of 2.03 emotions per rater (max: 7.11, min: 1.00), with a standard deviation of 1.33 emotions. The proportion of times a given seed sample was rated with each emotion was then applied to all mimics of that seed sample. This method results in the share per emotion assigned by the speakers. The label then is normalized by dividing all (floating point) scores with their highest score per sample; hence, each sample has a maximum score of 1.0 for one emotion category and other scores less than 1.0 for other emotion categories. The baseline results for this dataset is a Spearman score of 0.500 for the development set and 0.514 for the test set (using wav2vec finetuned of affective speech dataset with SVM method). The labels of the test set are not open to the public; hence, only performance on the development/validation data can be calculated directly.

Table I shows the characteristics of the dataset. The ratio for training/test split follows the practical machine/deep learning practice, i.e., 80/20. About 18.3% of the samples are allocated for the test (without labels), while the rest are for training (including validation/development). The ratio of female/male is about 63.5/36.5, with the number of female samples being higher than male. The splitting of training/test follows speaker-independent criteria with a total of 1004 speakers; 20% of them is allocated for the test set while the rest is for training and development.

TABLE I
Summary of the dataset for Emotion Share Recognition, derived from [13]

	Train	Dev	Test	Σ
Sample no.	30,133	12,241	9,507	51,881

III. Pre-Trained Models

We evaluated nine pre-trained models as acoustic embedding feature extractors and fused the results of these models for ensemble learning. Ensemble learning leverages the advantages of multiple models to achieve a better performance score. In this study, we evaluated a single late fusion method by averaging the emotion share predictions of different models. The baseline model is the robust version of on wav2vec 2.0 [17] finetuned the affective dataset [18]. For multilingual pre-trained models, we employed XLS-R 53 [19] and its variants, XLSR variants [20] (XLSR-300M, XLSR-1B, and XLSR-2B). For the XLS-R 53 and XLSR-1B, we also evaluated the finetuned version of this model on the English (EN) and Spanish (SP) datasets. Finetuning for these languages is not available on other XLSR variants. The complete pre-trained models are listed in Table II.

IV. Classifier and Hyperparameter Search Space

We employed a support vector machine (SVM) classifier for regression (SVR, support vector regression). The type of kernel for SVR is linear (LinearSVR in the scikit-learn toolkit). The optimal parameters for this SVR were searched using the Grid Search algorithm, i.e., the regularization parameter C and the algorithm to solve either the 'dual' or 'primal' optimization problem. Other parameters like scoring were also searched. The scoring is either using negative mean absolute error (NMAE) or negative mean squared error (NMSE). The maximum iteration is fixed at 5000. The value range for these parameters is shown in Table III.

For the fusion of all nine models, we employed the average of the predicted values (arithmetic mean). The predicted values are the continuous values in either development or test for each of the nine emotion categories. The ordinal values are then

TABLE III
VALUE RANGE FOR HYPERPARAMETER GRID SEARCH IN LINEARSVR

Hyperparameter	Value range
Scoring	[NMAE, NMSE]
Scaler	[StandardScaler, MinMaxScaler]
C	$[10^{-2} - 10^{-6}]$
dual	[True, False]
max_iter	[50000]

used to calculate performance metrics. The final score is an average of nine emotional categories.

The performance for evaluating the models is measured as the Spearman correlation coefficient (ρ) [21]. This Spearman's ρ metric is similar to the Pearson correlation coefficient but for ranked data. This metric is chosen since the annotation of the dataset is ordinal (based on rank) and for consistency with the baseline model [13]. Spearman correlation coefficient is calculated as follows:

$$\rho = \frac{\text{cov}(\text{R}(X), \text{R}(Y))}{\sigma_{\text{R}(X)}\sigma_{\text{R}(Y)}}, \quad (1)$$

where $\text{cov}(\text{R}(X), \text{R}(Y))$ denotes the covariance of the ranked data $\text{R}(X)$ and $\text{R}(Y)$, and $\sigma_{\text{R}(X)}$ and $\sigma_{\text{R}(Y)}$ denote the standard deviation of the ranked data $\text{R}(X)$ and $\text{R}(Y)$, respectively.

A repository is created to ensure the reproducibility of the experiments [1]. The repository contains the experiment settings, including the hyperparameter search space, and the results of the experiments. The requirements to run the experiments are also provided in the repository with the exact version of the libraries used at the time of the experiment.

V. EXPERIMENT RESULTS AND DISCUSSIONS

We divided our results into validation or development (Table IV) and test results (Table V). In the development stage, we ensure that the result of ensemble learning (Fusion all in Table IV) is higher than baseline results, either from a single model or late fusion. We submitted our prediction of the test result to the provider of the dataset [13] to obtain the performance on the test set.

Table IV shows our result in the development stage using nine pre-trained models and a fusion of all these models. On a single model evaluation, it is shown that using pre-trained models (such as XLS-R 53 and XLSR variants) achieves higher accuracies than conventional acoustic feature extractors like auDeep and ComParE. For instance, XLS-R 53 (the smallest multilingual model) gained a Spearman score of 0.4328, while ComParE achieved 0.359. For the fusion models, our fusion of all nine pre-trained models also overcomes the previous late fusion of wav2vec2, auDeep, DeepSpectrum, and ComParE.

Having good results in the development stage, we evaluated the same model on the test set. Table V shows the result of the test set. The result shows that the fusion of all models achieves the highest Spearman score of 0.537 (compared to the 0.476 of the late fusion from the previous study [13]).

TABLE IV
SPEARMAN CORRELATION COEFFICIENT (ρ) ON THE DEVELOPMENT SET OF THE EVALUATED PRE-TRAINED MODELS

No.	SSL model	NMSE	NMAE
1	wav2vec 2.0	0.5022	0.5001
2	XLS-R 53	0.4328	0.4341
3	XLS-R 53 EN	0.4732	0.4739
4	XLS-R 53 SP	0.4687	0.4691
5	XLSR-300M	0.4555	0.4561
6	XLSR-1B	0.4694	0.4679
7	XLSR-1B EN	0.4559	0.4533
8	XLSR-1B SP	0.4451	0.4440
9	XLSR-2B	0.4813	0.4835
	Fusion all (of 9)	**0.5236**	**0.5266**

TABLE V
COMPARISON OF SPEARMAN CORRELATION COEFFICIENT (ρ) ON THE DEV(EVELOPMENT) AND TEST SETS OF THE BASELINES (FIRST FIVE ROWS) AND THE PROPOSED FUSION METHOD (THE LAST ROW)

No.	Model	Dev	Test
1	wav2vec2 [18]	0.500	0.514
2	auDeep [22]	0.347	0.357
3	DeepSpectrum [23]	0.335	0.331
4	ComParE [24], [25]	0.359	0.365
	Late Fusion (of 4) [13]	0.470	0.476
	Fusion all (of 9)	**0.524**	**0.537**

This result is also higher than the previous best result of 0.500 from wav2vec2 [18]. We assume ensemble learning works by leveraging information across different languages and pooling maximum information for multilingual SER.

Similar trends between test and development sets are observed where the performance of the test set is slightly higher than the development set. An exception only applies to the DeepSpectrum result where the test result is 0.004 lower than the development set. This trend indicates the generalization of the evaluated method (including the baseline methods that use a similar SVM classifier) to unseen data and shows that, perhaps, the distribution of the test set is similar to the development set.

Finally, Table VI breaks down the average Spearman's ρ in the test set ($\rho = 0.537$) into each emotion category. The result is from 'Fusion all' of nine pre-trained models on the test set. The result shows that the model performs best in the 'Calmness' emotion category (0.6061) and worst in the 'Interest' emotion category (0.4238). The result is similar to the previous study [13] where the 'Calmness' emotion category is the highest (0.559), and the 'Anger' emotion category is the lowest (0.428). The previous study's result was achieved with wav2vec 2.0 but with a different setup from this study (particularly on the scoring method).

VI. CONCLUSIONS

In this study, we evaluated nine pre-trained speech models and a fusion of all these nine models for emotion share recognition from speech. The idea was to collect multilingual models from different languages and apply the fusion of these models to multilingual SER data. A dataset from three countries with English and Spanish languages was selected. First, the fusion

TABLE VI
SPEARMAN CORRELATION COEFFICIENT (ρ) ON EACH EMOTION CATEGORIES FOR THE TEST SET

Emotion	Spearman's ρ
Anger	0.4894
Boredom	0.6032
Calmness	0.6061
Concentration	0.5855
Determination	0.5589
Excitement	0.4669
Interest	0.4238
Sadness	0.5123
Tiredness	0.5867

of nine pre-trained models defeats the previously reported best result of a single model (in which the performance of this single model is higher than the late fusion of four methods). Second, the results of any single model in this study generally are also higher than the single models/methods in the previous study. Third, there is a trend in which the performance of the test set is slightly higher than the development set. Future studies could be directed to explore more about the dataset and improve the performance using more advanced methods with more recent speech embeddings.

ACKNOWLEDGMENT

This paper is partly based on results obtained from a project, JPNP20006, commissioned by the New Energy and Industrial Technology Development Organization (NEDO), Japan.

***Abstract*—Emotional speech synthesis has gained attention for enhancing the naturalness and expressiveness of synthesized speech. However, developing emotional speech synthesis presents challenges due to the lack of high-quality emotional speech datasets, especially for low-resource languages. This paper proposes an automated process for building datasets of emotional speech that reduces dataset generation time by 92%. The pipeline combines trained models and leverages publicly available data. The effectiveness of the proposed pipeline is examined and demonstrated using a Vietnamese case study.**

I. Introduction

In recent years, Text-to-Speech (TTS) technology has achieved widespread popularity for its time-saving and accessibility benefits in communication [1], [2]. One promising area of this research is emotional speech synthesis, which aims to generate speech that effectively conveys emotional nuances through the modulation of prosody and other vocal cues. By making human-computer interaction more natural and human-like, emotional speech synthesis has the potential to become a revolutionary technology.

However, the development of emotional speech synthesis comes with several technical challenges. One significant problem is the requirement for the quantity of training data [3]. Achieving human-like and emotional speech requires a large amount of data, and the process of collecting and classifying that data can be both time-consuming and expensive. Most publicly available emotional speech datasets are in popular languages, such as IEMOCAP [4], SAVEE [5], RAVDESS [6] for English; EMODB [7] for German; MES [7], CHEAVD [8] for Chinese, while efforts in other languages are less common [9]. To solve this problem, some papers mention generating data in specific language. Most emotional speech datasets are built by recording data from prepared scripts and specified emotion labels, such as [10]–[13]. With collected speech data like podcasts, the data are classified based on votes [14], [15]. Agreement voting is used to resolve disagreements among annotators. The three annotators rely on a majority vote when there is disagreement. The utterance is deleted if there is still no consensus among the annotators. However, these approaches lack uniformity, pose challenges when applied to different languages, and often rely on manual processes, which results in expenses for both money and labor.

In a low-resource language like Vietnamese, there has been some progress in the development of expressive speech synthesis, although it remains in the early stages. One of the primary challenges faced by researchers in Vietnam is the lack of high-quality speech datasets, which hampers the training of authentic emotion speech synthesis models. In an effort to address this, studies such as [16], [17] have constructed a 90-minute audio-visual expressive speech corpus for Vietnamese through recording methods, while [18] proposes a method to generate synthetic emotional speech using data from text-to-speech tools. Despite these constraints, there is still room for improvement in this domain, emphasizing the need to obtain a large number of datasets specifically designed for studying emotional speech synthesis.

To meet this demand, an automatic pipeline for quickly building an emotional speech dataset using available resources is presented. We collect data from the Internet and automatically process the steps of audio separation for target speakers, text transcription, emotion labeling, and audio enhancement. This method saves 92% of data construction time compared to the manual method. Additionally, to prove the effectiveness of the proposed pipeline, a Vietnamese emotional speech dataset was built, has been released, and is freely downloadable at https://github.com/ngocanh2162/Vietnamese_emotional_dataset.

The rest of the paper is organized as follows: Section II presents the design, followed by the description of the dataset and analysis of results in Section III. Finally, the conclusions are drawn in Section IV.

II. The automatic emotional speech corpus design

This work proposes a pipeline with data collection, four automatic processing steps, and manual verification (optional). The resulting dataset will contain speech sounds, corresponding text, and emotion labels.

A. Data Collection

The first step in creating a corpus is to collect audio data. This can be obtained from various sources, such as recorded speeches, phone conversations, or other audio files. The quality of the audio data is an important factor that affects the quality of the TTS model.

In general, there are three methods for creating an emotional speech dataset, depending on their intended application: acted (simulated), elicited (evoked, induced), and natural speech (spontaneous) [9]. The majority of the databases record forced (simulated) emotional speech using professional artists, drama students, or voice talents [12]. In this work, the natural speech

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

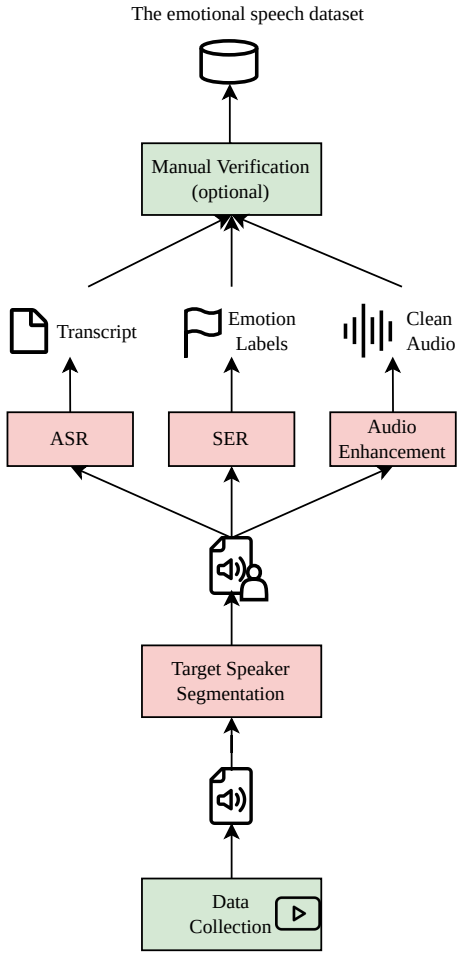

Figure 1. Automatic pipeline for building emotional speech dataset.

approach is preferred for creating a low-resource emotional speech dataset due to its benefits. It allows for the retention of natural emotions, and the necessary data is easily accessible and immediately available while helping to save time and reduce human costs.

To design a speech corpus for speech synthesis, specific criteria must be defined. The corpus will be used to study prosody and pronunciation and build expressive speech synthesis models. The following requirements have been determined:

- Large quantity of data from one speaker.
- Good sound quality.
- Varied discourse styles and literary genres.
- The emotion conveyed in speech.
- Consistent timbre and speed.

With the above criteria, many data sources can be selected, such as movies, talk shows, and audiobooks. In the Vietnamese case study, one female drama actress was chosen. All her speech data on the Internet was collected from 2008 to 2013. This ensures consistent data without too many variations in speech changes that could affect analysis and interpretation.

Data crawling collects the highest-quality video clips available. The audio is then extracted to a WAV file using the "SoX" package[1]. Due to the diversity of the sources from which the data is collected, there are numerous variations in acoustic conditions. Therefore, all audio is reduced to a sampling rate of 22,050 Hz and 16 bits. The next step is to preprocess the acquired data.

B. Target Speaker Segmentation

Once audio with multiple speakers, silence, and background noise has been collected, the audio must be extracted into segments containing only the speech of the target speaker.

Normally, to get an audio clip containing only the target speaker, the listener would have to watch the whole video and manually select it, adjusting the timestamp to avoid clipping into the audio containing the voice or other speakers. For this work, audio segments of the target speaker are obtained using Speaker Diarization and Speaker Verification. First, Speaker Diarization divides a conversation with multiple speakers into segments spoken by the same speaker. Then, Speaker Verification verifies a speaker's identity based on their speech characteristics.

The first step in the pipeline involves segmenting the 5-45 minute-long audio file into smaller, more manageable 1-15 second-long utterances. This is achieved through the use of a pre-trained Speaker Diarization model, which is capable of isolating human speech from other background noises. The resulting audio clips contain only the human speech that is of interest for further processing.

In the second step, these audio clips are passed through a pre-trained Speaker Verification model, which is used to identify the target speaker's audio segments. This is achieved by manually extracting 10- to 120-second audio segments containing only the target speaker's speech, which are then passed through the Speaker Verification model. This model is trained to recognize the unique characteristics of the target speaker's speech and can identify their speech segments with a high degree of accuracy.

In this step, depending on the confidence threshold set, the model can select more segments with lower accuracy or fewer segments with higher accuracy. A high confidence threshold to limit errors in the data obtained. If crawl data is a small quantity, a lower threshold can be selected to capture as much positive data as possible.

In our study case, a Vietnamese pre-trained model [19] was used for this step, but any language pre-trained model can be used because it is language-independent.

Then, the audio segments containing the target speaker's speech were obtained. To ensure data quality, files containing the speech of another speaker are manually found and excluded from further processing.

C. Text Transcribing

In this step, with the advanced development of Automatic Speech Recognition (ASR) in languages, a same-language ASR model is used to convert spoken language into a text

[1]https://sox.sourceforge.net/

transcript instead of using the labeler to listen to the audio and then write down the text. For Vietnamese, a state-of-the-art pre-trained ASR model [20] with 4.17% Syllable-Error-Rate (SyER) has been decided to be used.

After completing this step, the text file will contain transcripts for each audio file created. The text file may have recognition mistakes due to noise, distortion, accents, and out-of-vocabulary (OOV) words.

The text in the dataset, extracted from the ASR model, does not require segmentation or normalization, only occasional correction of OOV words or inconsistencies caused by ASR errors. Our experiments showed many long periods of silence in audio without any corresponding prosodic punctuation, negatively impacting TTS performance. To address this issue, punctuation was inserted into the transcript at the positions of corresponding silences. Using the aligned time stamps provided by the ASR system, the duration of internal silence is calculated, and prosodic punctuation is inserted into the transcript at the corresponding silence positions. The silence duration threshold for inserting punctuation is set to 0.35 seconds.

D. Emotional Labeling

The first thing to determine is which emotion labels will be included in the dataset. The basic emotions in emotional speech research include neutral, anger, disgust, fear, happiness, sadness, surprise, and others [21]. These are also prevalent in the majority of the world's datasets. In the Vietnamese case, the emotions chosen are neutral, happy, sad, and angry. By choosing these emotions, the classification process can be simplified, and the dataset can be representative of the most common emotions.

Manual labeling of emotional speech data is a time-consuming and expensive task that requires human annotators to listen to and label each utterance based on the expressed emotion. With manual labeling, it requires a large number of annotators, which is time- and labor-intensive, not to mention the disagreement in label voting.

However, in recent years, there has been significant progress in developing automatic methods for labeling emotional speech data. These methods can significantly reduce the cost and time required for labeling. Most of the research on Speech Emotion Recognition (SER) has been conducted in English, with state-of-the-art (SOTA) results reaching 75-80% [22]. However, this limits the applicability of SER in low-resource languages such as Vietnamese. The dataset was inferred for emotion labeling with some pre-trained models [23]–[25] that were available to the public. However, only 35% of the predicted labels matched the manual labels. In our experience, this result can be attributed to (1) the differences in emotional expression between languages and (2) the overfitting of the models to the training dataset.

To overcome these challenges, techniques such as transfer learning, data augmentation, and unsupervised learning have been developed. In this work, transfer learning was used to build emotion labels. An SER model [26] was trained using corpora that included several other emotional speech datasets, such as IEMOCAP, CremaD, RAVDESS, TESS, ShEMO, EmoDB, EmoVo, SAVEE, and then fine-tuned with one Vietnamese emotional speech dataset, which we manually created.

Although there has been significant progress in automatically labeling emotional speech data, there are still some challenges and limitations. One of the main challenges is the lack of a standardized emotional speech dataset. The emotional speech datasets that are currently available are often small and not diverse enough to cover all emotional states.

Table I
COMPARE MANUAL PIPELINE AND PROPOSED PIPELINE PROCESSING TIME

Step	Data Duration (hours)	Proposed Processing (hours)	Manually Processing (hours)
Speaker Segmentation	32.5	-	65
Text Transcribing	4.8	-	15
Emotional Labeling	4.8	-	21
Error checking	4.8	8	-
Processing Time	**3.9**	**8**	**101**

E. Audio Enhancement

To process the audio data, silence trims were performed initially. For this, a simple script was created to trim the audio based on the threshold of sound amplitude.

The dataset consists of spontaneous data captured in many environments at varying volumes. As a result, the data contains a lot of noise and non-valuable signals. Using a pre-trained Speech Enhancement model [27], the signal was enhanced and the noise was removed to improve the data quality. This process involved eliminating background music and enhancing the audio waveform's clarity.

To handle volume differences between distinct utterances, the peak amplitude of all audio clips was normalized. The silence portions at the start and finish of utterances were adjusted to 0.2 seconds.

After the aforementioned four steps, the dataset contains corresponding audio files, text transcripts, and emotion labels. However, to be used effectively in speech research, the data must undergo further processing to achieve optimal quality.

III. RESULT

A. Analysis of Pipeline Errors

An experiment was conducted to compare the manual data processing times using the traditional approach with those using the recommended pipeline.

According to the data presented in Table I, when employing manual processing techniques, a total of 32.5 hours of collected data needs 65 hours of processing time to obtain 4.8 hours of target speaker audio. Additionally, it takes an additional 15 hours to convert this audio into text using a single labeler. The subsequent step of labeling the emotions of each labeler requires at least 7 hours. When considering a scenario with

Table II
PIPELINE ERRORS IN THE DATASET

Error Types	%
Segmentation	5.17
Another speakers	9.13
Mispronounced words	8.69
Wrong emotion label	14.15
Total	**19.26**

*Some utterances may have multiple errors.

the number of labelers set to 3, this step takes a total of 21 hours.

In contrast, the proposed pipeline demonstrates significantly improved efficiency compared to manual processing methods. Without error checking, the pipeline achieves a processing time of zero. If adding the correction and error removal steps, the processing of 4.8 hours of data requires approximately 8 hours to produce 3.9 hours of data. This remarkable reduction of 92.08% in processing time surpasses the manual data processing duration, which amounts to 101 hours with three reviewers.

Overall, the proposed pipeline significantly enhances processing efficiency, leading to substantial time savings when compared to the traditional manual approach.

To evaluate the utility of the proposed automated data build pipeline, the error statistics of the dataset were analyzed. The results are shown in Table II. These errors can be seen as corresponding errors in the data processing steps: segmentation error and another speaker corresponding to the target speaker segmentation step; mispronounced words with the text transcribing step; and wrong emotion label with the emotional labeling step. The emotion labeling step has a high error rate across all types of errors. By applying this pipeline in the future, it becomes possible to generate more datasets, contributing to enhanced accuracy in SER and reducing this error.

As a result, the proposed pipeline can be utilized to quickly produce an emotional speech dataset with an error rate of approximately 20%, or to perform an additional step of error correction while still saving approximately 76% of the processing time to produce datasets with the same quality as human data production.

B. Released Dataset

The Vietnamese emotional speech dataset has been standardized with good quality to synthesize artificial speech. All audio recordings were saved in WAV format at 22,050 Hz sampling rate and stored at 16 bits per sample. All transcripts are stored as TXT files in UTF-8 encoding. The audio and the corresponding transcript filenames are identical except for the extension. The released dataset has removed the errors found. Creating an error-free speech dataset is not an easy task. Even after manual checks and data validation, some mistakes may remain. According to my knowledge, our work is the first study to publish a Vietnamese emotional speech dataset.

Table III
DATASET SUMMARY

Dataset	Duration (hours)	# Utterances	# Words
Neutral	2.98	7,204	48,558
Happy	0.23	625	3,463
Sad	0.22	521	3,368
Angry	0.45	1,255	7,583
Total	3.88	9,605	62,088

Table IV
THE MOS SCORE

Emotion	Ground truth speech	Synthetic speech
Neutral	4.463 ± 0.736	4.167 ± 0.741
Happy	4.458 ± 0.632	3.458 ± 0.785
Sad	4.250 ± 0.833	4.000 ± 0.667
Angry	4.528 ± 0.656	3.944 ± 0.846

Table III provides statistics for the dataset. The public dataset contains approximately 3.88 hours of audio with 9,605 utterances. The neutral label accounts for 75% of the dataset, followed by angry, while happy and sad labels have equal proportions.

One of the goals of building the emotional speech dataset is to create good-quality synthetic voices. Hence, the quality of the synthetic speech produced from emotional speech data is also assessed. In order to evaluate the data quality without being biased by the model, a fine-tuning approach [28] is employed: The acoustic model is first trained with a neutral sub-dataset of the target speaker to establish a base architecture. Then, for each remaining emotion (happy, sad, and angry), fine-tuning is done with the corresponding emotional sub-dataset. In this case, the acoustic model is FastSpeech2 [29] and the vocoder is HifiGAN [30] V1. To evaluate the naturalness of the synthesized speech, a group of 25 listeners was assigned mean opinion scores (MOS) on a scale of 1 to 5. This evaluation process aims to create good-quality synthetic speeches and ensure the overall fluency and authenticity of the generated speech.

As shown in Table IV, the MOS scores of the synthesized speech generally convey emotions well, although slightly lower than the ground truth score. It shows that the speech effectively expresses emotions, demonstrating its capability to generate speech that is emotionally expressive and understandable. There is room for improvement, but these scores indicate its potential in various emotional contexts.

IV. CONCLUSIONS

An automatic pipeline was proposed to efficiently generate a low-language emotional speech dataset, and the emotional speech dataset was released to facilitate research on speech emotion recognition and speech synthesis. In our pipeline, it is possible to annotate speeches at half-time without suffering a loss in quality.

Analysis of Emotions in Speech using AESDD

S. Uthiraa and Hemant Patil
Speech Research Lab, DA-IICT, Gandhinagar Gujarat
E-mail: {uthiraa_s, hemant_patil}@daiict.ac.in

***Abstract*—Speech Emotion Recognition (SER) has been in focus for some time now. With increasing technological advancements in Artificial Intelligence (AI), machines are becoming an integral part of human life, thus expanding the scope and motivation for emotion recognition. In this paper, we use a relatively new (2018) dataset, namely, Acted Emotional Speech for Dynamic Database (AESDD) for Greek language, for acoustic analysis of emotions in speech, as this dataset has not been explored much in the literature. We focus on some prosodic features, such as energy, loudness, pauses/ silences, and narrowband spectrograms, to analyze five emotions, namely, anger, fear, disgust, happiness, and sadness. This is done by studying the narrowband spectrograms and squared energy function (i.e., l^2 norm of a signal). Further, as hearing is the process of detecting energy, a non-linear energy tracking operator, namely, Teager Energy Operator (TEO) profile of the audio sample, is taken. Results showed some distinguishing parameters among emotions and also between male *vs.* female speakers uttering the same sentence. The effect of cognition on emotions is briefly discussed to strengthen the results obtained.**

***Index Terms*—Speech Emotion Recognition, AESDD, Narrowband Spectrogram, Teager Energy Operator, Cognition.**

I. Introduction

Emotion, a word so common in day-to-day life, yet we still have not found scientific consensus on its exact definition. Emotion is " a strong feeling, such as love or anger, or feelings in general". Further, " emotions are mental states brought on by neurophysiological changes, variously associated with thoughts, feelings, behavioral responses, and a degree of pleasure or displeasure". It is also a "complex experience of consciousness, bodily sensation, and behavior that reflects the personal significance of a thing, an event, or a state of affairs". Emotion is the most significant attribute that distinguishes us (humans) from robots. In this era, where Artificial Intelligence (AI) and other technologies are advancing, we are more and more dependent on machines, and for them to understand us in a meaningful way, emotion recognition is essential. Researchers after analyzing emotion, its source and effects have classified it in a ***4***-D model, where each dimension is independent from one another, namely, duration, quality, intensity, and pleasure [1].

The literal meaning of emotion recognition would be to identify the emotions. It is known that the production of speech is not just because of the vocal tract system, larynx, and lungs, however, it is the cognitive processes that are going from mind to mouth, i.e., transforming a non-linguistic concept with communicative intent to linguistically well formed utterance, which involves linguistic as well as physiological level of speech communication between speakers and the listeners [2], [3], in particular, transmission of electric signals from the brain via motor nerves to activate the muscles of larynx and vocal tract system. This implies that if the speech, which carries the emotion has cognitive characteristics, the emotion recognition refers to the attributes of emotional states based on the observation of ***visual*** and ***auditory*** non-verbal cues. Eventhough emotion recognition can be done using speech and facial expressions, this paper is solely focused on the analysis of emotions using speech.

As it is already stated that there is a huge gap between man and machine-based processing of audio and visual stimuli, i.e., a machine is unable to identify the emotional state of a speaker. This problem has opened a new research field called Speech Emotion Recognition (SER) [4]. Applications of emotion recognition are vast, some of which include - man-machine interaction, drivers safety, mobile communications, military applications, educational software [4], [5], and incorporating emotions in Text-To-Speech (TTS) voice. Emotion recognition also plays a vital role in recognizing the emotions of people with disabilities, such as Cerebral Palsy, Parkinson's Disease, and Autism Spectrum Disorder; which would enable us to bring them into the mainstream (i.e., blend well) with society [6]. However, to develop a good emotion recognition model, it is very important to understand the acoustics of various emotions. In particular, humans have a remarkable ability to convey and perceive emotions in speech using various prosodic cues, such as loudness (amplitude), pitch, duration of speech sound units, intonation (i.e., derivative of F_0 (fundamental frequency) contour), and energy of speech wave.

In this paper, we analyze five emotions from the dataset, namely, anger, fear, disgust, happiness, and sadness using narrowband spectrograms, their energies, and their Teager Energy Operator (TEO) profile. Observations prove that both speech features and cognition are important to analyze emotions.

The organization of the rest of the paper is as follows: Section II discusses the proposed work in detail. Section III gives the details of the experimental setup used for this study and discusses the results and inferences made during the analysis. Section IV concludes the paper along with potential future research directions.

II. Proposed Work

For designing any system capable of emotion recognition, selection of suitable features and classifiers is essential. In

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

this paper, we will only focus on features. The local and global features of Speech Emotion Recognition (SER) are analyzed in the following categories [7] - 1. Prosodic Features 2. Spectral Features 3. Voice Quality Features 4. Teager Energy Operator (TEO)-based features. In prosodic features, the 4 levels of computing prosody are - (a) linguistic intention-level, (b) articulatory-level, (c) acoustic realization-level, and (d) perceptual-level [4]. They include accent, stress, rhythm, tone, pitch, intonation, and loudness. Therefore, in this paper, we use prosodic features, in particular, loudness, energy, and pauses to analyse emotions. So far, for AESDD corpus not much work is done in analysing the features of audio samples. Mostly, this database has been used for comparative analysis. To that effect, in this paper, we performed energy-based analysis w.r.t. three techniques, namely, narrowband spectrogram analysis, energy (via $\boldsymbol{l}^2$ norm) of audio data, and TEO.

A. *Spectrographic Analysis*

Spectrogram is a visual representation of an acoustic signal, which gives time (X- axis), frequency (Y-axis), and amplitude (brightness) measure all in one graph. Energy distribution and pauses are also measured from this plot depending on the size of analysis window (a function used for Fourier-based spectral analysis), different levels of frequency/time resolution is achieved, i.e., a long window (atleast 2-3 pitch periods: 10-30 ms) gives good frequency resolution as harmonic lines (seen as horizontal striations in time-frequency domain) are resolved, this is also known as ***narrowband*** spectrogram. Similarly, a short window (duration less than a single pitch period: 4 ms) shows the formants of the vocal tract system with individual pitch periods appearing as vertical lines (striations), called ***wideband*** spectrogram. In this paper, we obtained the narrowband spectrograms for male and female speakers in 5 emotions using *wavesurfer tool*. Fig.1 and Fig.2 depicts the spectrograms obtained for a sentence uttered by a male and a female speaker, respectively. Narrowband spectrograms are employed rather than their wideband counterparts as they represent pitch source harmonics clearly in the form of horizontal striations. Moreover, as discussed in Section I, the pitch and its harmonics (along with its dynamic implementation) are important correlates of speech prosody to convey a particular emotion in speech. Pauses or silences between the words, energy content, and gaps between the horizontal striations are studied to identify the difference between each emotion. Another observation from Fig.1 and Fig.2 is that the gap between pitch source harmonics is higher in Fig.2 than in Fig.1 as females have higher F_0 (fundamental frequency) than males.

B. *Energy of Emotions*

The energy measurements are obtained using the standard discrete-time energy formula. In particular, for a discrete-time signal $x(n)$, energy is computed as E= $\sum_{n=\infty}^{-\infty} |x(n)|^2$. It should be noted that this energy, E is conserved in frequency domain (i.e., Parseval's energy equivalence) and also in the Short Time Fourier Transform (STFT) framework (proof given in Appendix A1, for the continuous-time version of STFT).

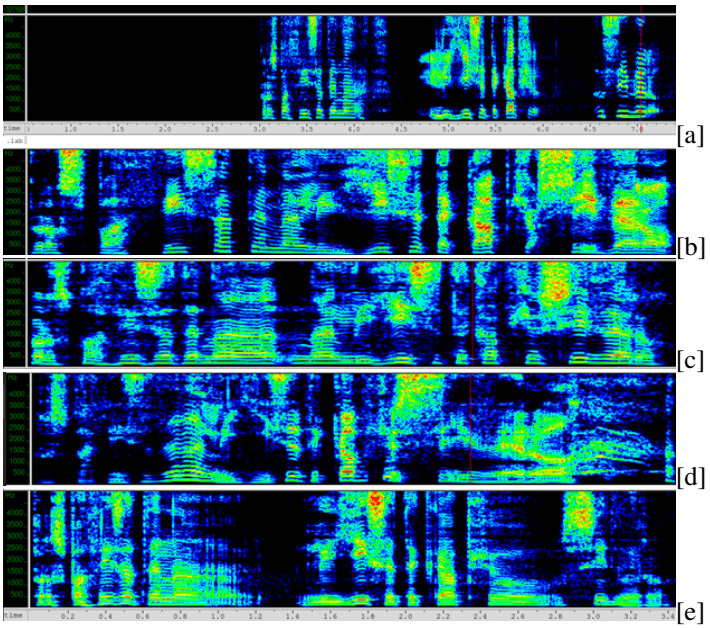

Fig. 1. Narrowband spectrograms of 5 emotions of a male speaker: (a) disgust, (b) anger, (c) fear, (d) happiness, and (e) sadness.

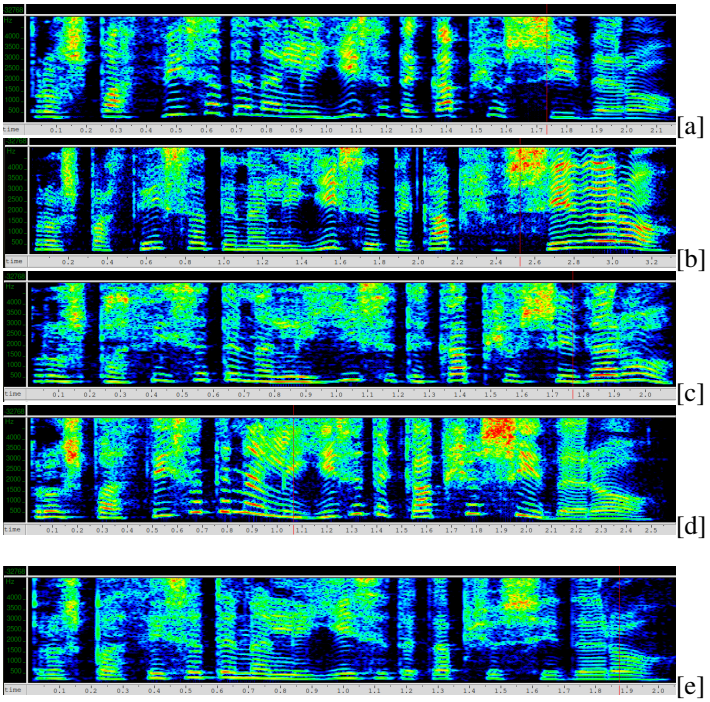

Fig. 2. Narrowband spectrogram of 5 emotions of a female speaker: (a) anger, (b) disgust, (c) fear, (d) happiness, and (e) sadness.

The sampling rate of the audio files is 44100 Hz. The audio sample is then frame-blocked and windowed (Hann window), so that the acoustic events in the speech sample can be represented as a compact set of speech parameters. Hop size is taken to be 10ms and Fast Fourier Transform (FFT) size is 2048 samples. Observations on how energy changes for different emotions and between gender is analysed. Fig 3-7 shows the plots of 5 speakers (3 females and 2 males) uttering the same sentence in 5 emotions, namely, anger, disgust, happiness, fear, and sadness, respectively. Energy is then represented in the

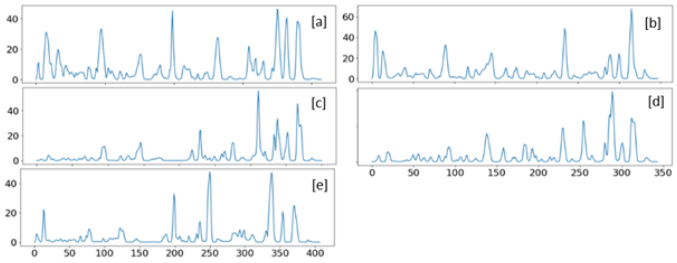

Fig. 3. l^2 Energy of ***anger*** by 5 speakers uttering the same sentence ((a) female1, (b) female2, (c) male1, (d) male2, and (e) female3).

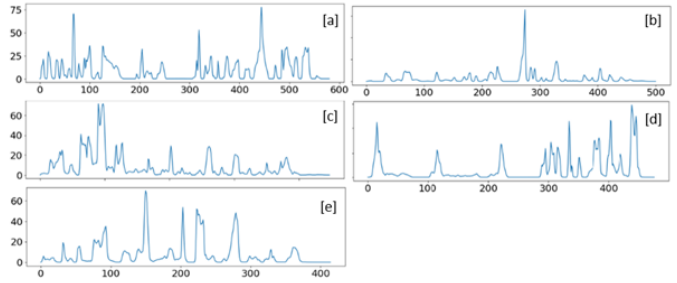

Fig. 4. l^2 Energy of ***disgust*** by 5 speakers uttering the same sentence ((a) female1, (b) female2, (c) male1, (d) male2, and (e) female3).

form of boxplot. Fig.8[a] describes how a male speaker (1 male speaker chosen of 2 male speakers) utters a sentence in 5 emotions (disgust, anger, fear, happiness, and sadness, respectively) and Fig.8[b], provides the same information for a female speaker (plot of 1 female speaker chosen from 3 female speakers). Boxplot provides a visual summary of data thereby enabling us to identify the average score, skewness, dispersion, and outliers in the dataset. Historgram is plotted for a male and female speaker (Fig.9[a] and Fig.9[b], respectively) to find the quantitative distribution of energy.

C. TEO for Analysis of Emotions

This non-linear feature or operator was introduced in 1990s by Teager and Kaiser [8]. Speech is produced by non-linear, vortex-airflow interaction in the vocal tract system. Stressful situation affects the muscle tension of the speaker that results in an alteration of the airflow during the production of the sound [9]. This is captured ***via*** TEO, in particular, Ψx(n)=

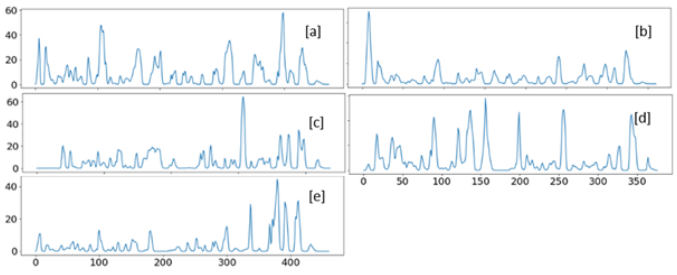

Fig. 5. l^2 Energy of ***happines*** by 5 speakers uttering the same sentence ((a) female1, (b) female2, (c) female3, (d) male1, (e) male2).

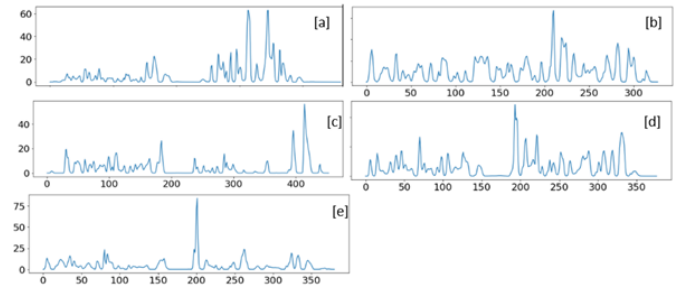

Fig. 6. l^2 Energy of ***fear*** by 5 speakers uttering the same sentence ((a) male1, (b) female2, (c) female3, (d) male2, and (e) female1).

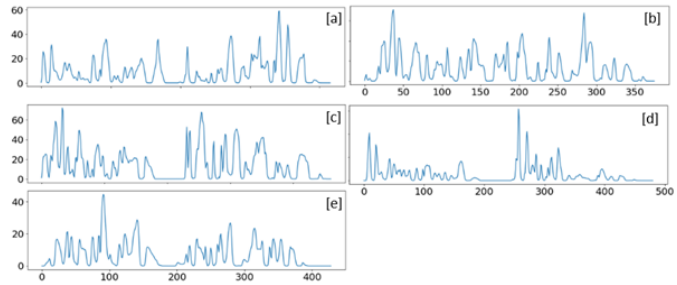

Fig. 7. l^2 Energy of ***sadness*** by 5 speakers uttering the same sentence ((a) female1, (b) female2, (c) female3, (d) male2, and (e) male1).

$x^2(n) - x(n+1)x(n-1)$, where Ψ is the Teager Energy Operator and $x(n)$ is the discrete time signal.

In Fig.10 and Fig.11, x-axis representing the frames and y-axis the amplitude, are the TEO plots obtained for a male speaker speaking a sentence in 5 emotions and a female speaker uttering the same sentence (as male) in 5 emotions respectively. The energy distribution, silence or pauses were observed to distinguish between the emotions.

III. Results and Inferences

A. Experimental Setup: Dataset Used

For this study, we have used AESDD corpus, developed in 2018, a publicly available greek dataset for SER [10]. This dataset contains utterances of ***acted*** emotional speech in Greek language [11]. The dataset contains 500 utterances of emotional speech for 5 actors (3 females and 2 males) X 5 emotions (anger, fear, disgust, happiness, and sadness) X 20 utterances [12]. This dataset is chosen as it is a relatively newer dataset with not much work reported using it. Another important reason for selecting this dataset is that each speaker has spoken the same sentence (total of 20 sentences) in different emotions and thus, providing a common base for analysis. In addition, analysis of emotions in male ***vs.*** female is also possible.

The results analyzed here takes atleast 5 sentences of each emotion and only some of them are plotted in this paper. The spectrographic analyzed from Fig.1 and Fig.2 had some distinct differences for each emotion, as shown in Fig.12. We also noted that in sadness, there is relatively least distance

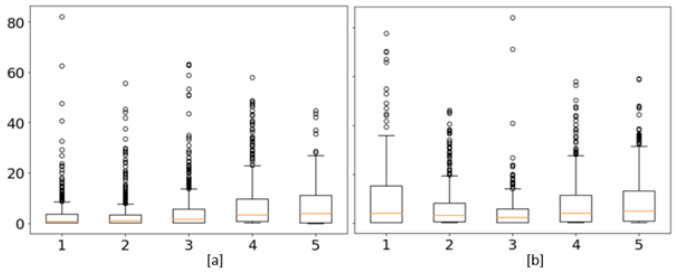

Fig. 8. l^2 Energy boxplot of [a] showing male-1 speaker, and [b] showing female-1 speaking the same sentence in 5 emotions- (1) disgust, (2) anger, (3) fear, (4) happy, and (5) sadness.

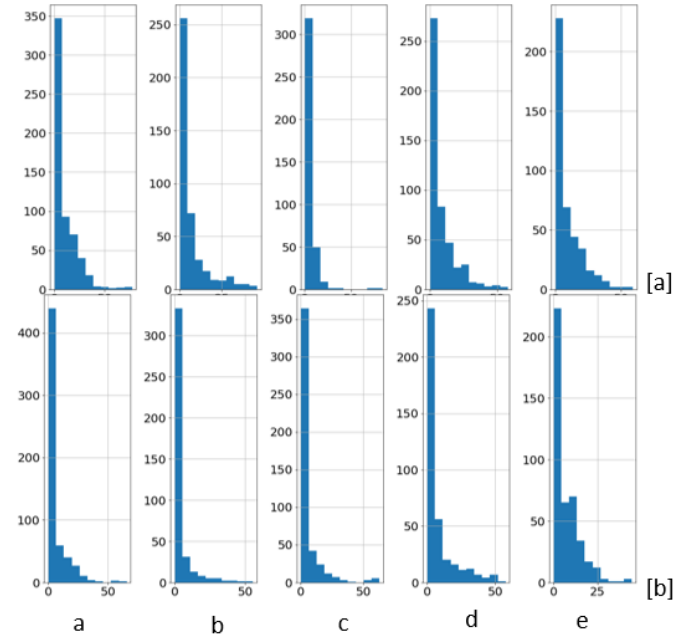

Fig. 9. l^2 Energy histogram of [a] showing male-1 speaker, and [b] showing female-1 speaking the same sentence in 5 emotions- (a) disgust, (b) anger, (c) fear, (d) happy, and (e) sadness.

between the harmonic striations, i.e., pitch source harmonics in both male and female. Hence, from Fig.12, it can be inferred that the highest energy content is available in anger and least in sadness. It should be noted that short pauses are highest in anger. This result is linked to the fact that when one gets angry, breathing is released in shorter and quicker puffs and the force with which air is released from the lungs to vocal tract system is also high and thus, showing these characteristics.

Energy plots in Fig.(3 to 7) providing the amplitude of audio signal is shown in Table II. It should be noted that apart from

TABLE I
SUMMARY OF SPEECH CORPORA USED IN THE EXPERIMENTS
(F - FEMALE, M - MALE)

Database	Speakers	Emotions
AESDD	5 (3F, 2M)	5 (anger, happy, disgust, fear, sadness)

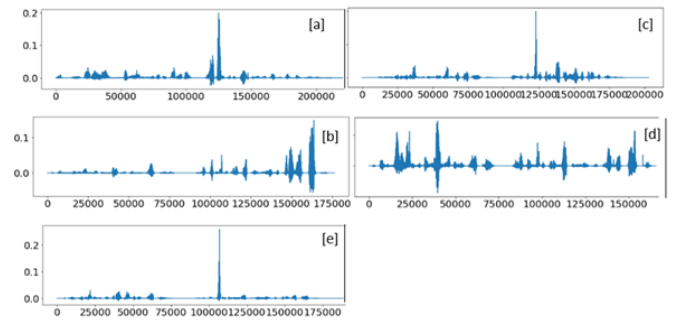

Fig. 10. TEO profile of male 1 uttering same sentence in 5 emotions- (a) disgust, (b) anger, (c) fear, (d) happy, and (e) sad.

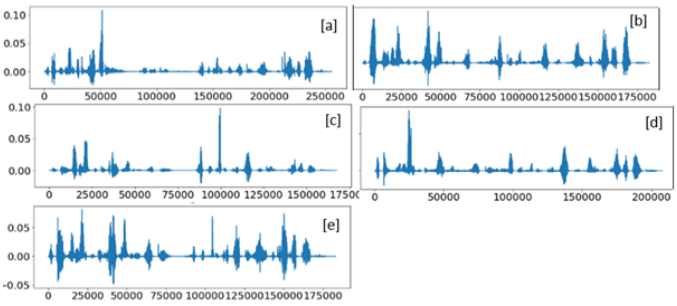

Fig. 11. TEO profile of female 1 uttering same sentence in 5 emotions- (a) disgust, (b) anger, (c) fear, (d) happy, and (e) sad.

the disgust emotion, females have higher amplitude peaks. This states that in females, loudness is seen more than males, while expressing emotions. We also see that fear and disgust have the highest amplitude in females and males, respectively. Surprisingly, we observed that anger has the least amplitude of all and we believe that this needs a further investigation. Boxplots of energy is shown in Fig.8(a) and Fig.8(b) for male and female, respectively. It can be observed that the median is lowest for disgust and highest for sadness in males,

Features	Anger	Disgust	Fear	Happy	Sadness
Pauses	Females: Highest (Short and Multiple)	Females: Lesser than anger	Females: Lesser than anger, but more than disgust	Females: Very less	Females: Clearly distinct
	Males: Highest (short and multiple)	Males: 2 huge gaps observed	Males: Least pauses found among males	Males: Very less	Males: High
Energy Concentration	Females: High throughout the sentence	Females: High concentration only at high frequencies	Females: Lesser compared to anger and disgust	Females: High but reduces towards end of the sentence	Females: Very less
	Males: High, particularly at higher frequencies	Males: High towards the end of the sentence	Males: High energy concentration at higher frequencies	Males: High throughout the sentence	Males: Very less

Fig. 12. Spectrographic analysis of emotions.

TABLE II
HIGHEST AMPLITUDES REACHED FOR EACH EMOTION BY MALE AND FEMALE SPEAKERS

Amplitude	Anger	Disgust	Fear	Happy	Sad
Females	60 dB	75 dB	80 dB	70 dB	65 dB
Males	55 dB	80 dB	60 dB	60 dB	60 dB

whereas, in females, fear has the lowest median with the other emotions having similar median values. All the emotions are positively skewed, implying most values are towards the lower bound. Sadness emotion has the most even spread among all the emotions and thus, having the least outliers. Spread/ dispersion is least in fear for females and anger for males. These findings of ours are in agreement with the original study reported in [13]. This implies, sadness and happiness has greater variability in speaking than the other emotions.

Histogram in Fig.9, is a right skewed distribution, i.e., data values fall at the lower range (as seen in the boxplots). Most of the values occur within the interval of 0-10 dB for all the emotions, and fear has the least range of 0-20 dB, within which almost all its values are covered, proving why fear has the least median in females.

TEO plots in (Fig.10 and Fig.11) shows that for male speaker 1, happiness followed by anger has the greatest energy profiles, and sadness has the lowest. However, for female speaker 1, the results obtained were surprisingly different from the other analysis, as sadness and anger has the greatest energy profiles and fear has the lowest energy profile. This result may be because of cognitive psychology [14]. Studies prove that emotions are not always instantaneous rather, it is a build up of feelings that are acquired over the period of time [14], [15]. This makes sense, as sometimes, a small trigger is enough to make a person emotional and thus, giving extreme reactions. Also, the dataset (AESDD) has its own errors [12]. All these cognitive factors affect the results obtained and we believe it requires much deeper investigations and remains as an open research problem.

IV. SUMMARY AND CONCLUSIONS

This study investigated the analysis of five emotions: anger, fear, disgust, happiness, and sadness. This is carried out by using prosodic features of speech, in particular, loudness (amplitude measure), energy and pauses or silences, and narrowband spectrograms. We also use the novel TEO on AESDD dataset to get energy profiles. It is found that anger and happiness show similar spectrographic characteristics, however, it can be distinguished by plotting their energy spectrum. Sadness has the most spread and balanced data values among the other emotions. Characteristics of disgust seemed very similar to anger. Distinct differences between male and female emotions can also be seen (boxplot- Fig.8) by acquiring their energy values. Along with speech features, the impact of cognition are equally important for recognizing a particular emotion. Future work can explore these features in pattern classifiers, developing a feature set that can distinguish anger and happiness better and extending this work to recognize emotions for disabled people. The investigations presented in this study are based on our current humble understanding of speech prosody in the literature, in particular, we believe that loudness, pitch, energy, intonation, speech spectrum dynamics, etc, all contribute ***implicitly*** to speech prosody. Since the definition of speech prosody is evolving everyday and authors believe that definition of speech emotion also continues to evolve (as it is a function of prosody), which may open interesting future research directions.

APPENDIX

A.1. Energy Conservation in STFT

The energy conservation in Short Time Fourier Transform (STFT) $f(t) \in L^2(R)$ is expressed as [16] :

$$\int_{-\infty}^{+\infty} |f(t)|^2 dt = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} |Sf(u,\zeta)|^2 d\zeta du, \quad (1)$$

Here, u and ζ shows the time-frequency indices that vary across R and hence, covers the entire time-frequency plane. The reconstruction of the signal is given by

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} Sf(u,\zeta) g(t-u) e^{i\zeta t} d\zeta du. \quad (2)$$

Applying Parseval's formula to eq. (2) w.r.t. to the integration in u, we get

$$Sf(u,\zeta) = e^{-iu\zeta} f * g_\zeta(u), \quad (3)$$

Here, $g_\zeta(t) = g(t)e^{i\zeta t}$. Hence, Fourier transform of $Sf(u,\zeta)$ is $\hat{f}(\omega_\zeta)\hat{g}(\omega)$. Furthermore, after applying the Plancherel's formula to eq. (1) gives

$$\frac{1}{2\pi} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} |Sf(u,\zeta)|^2 du d\zeta =$$

$$\frac{1}{2\pi} \int_{-\infty}^{+\infty} \frac{1}{2\pi} \int_{-\infty}^{+\infty} |\hat{f}(\omega+\zeta)\hat{g}(\omega)|^2 d\omega d\zeta. \quad (4)$$

Finally, the Plancheral formula and the Fubini theorem result in $\frac{1}{2\pi}\int_{-\infty}^{+\infty} |\hat{f}(\omega+\zeta)|^2 d\zeta = ||f||^2$, which validates STFT's energy conservation as demonstrated in eq. (1). It explains why the overall signal energy is the same as the time-frequency sum of the STFT.

Modified Parametric Multichannel Wiener Filter for Low-latency Enhancement of Speech Mixtures with Unknown Number of Speakers

***Abstract*—This paper introduces a novel low-latency online beamforming (BF) algorithm called the Modified Parametric Multichannel Wiener Filter (Mod-PMWF), which enhances speech mixtures with unknown and varying number of speakers. Although such conventional BFs as Linearly Constrained Minimum Variance BFs (LCMV BFs) can enhance a speech mixture, they typically require such speech mixture attributes as the number of speakers and the acoustic transfer functions (ATFs) from the speakers to the microphones. When mixture attributes are unavailable, estimating them by low-latency processing is challenging, hindering the application of BFs to the problem. In this paper, we overcome this problem by modifying a conventional Parametric Multichannel Wiener Filter (PMWF). The proposed Mod-PMWF can adaptively form a directivity pattern that enhances all the speakers in the mixture without explicitly estimating these attributes. Our experiments show the proposed BF's effectiveness in interference reduction ratios and subjective listening tests.**

I. Introduction

Microphone array processing has grown in importance due to the increased need for remote communication. Speech signals captured by microphones often suffer from degradation caused by background noise and reverberation. Microphone array processing improves the quality of speech signals by reducing noise and reverberation, thus enhancing speech perception and the performance of applications such as automatic speech recognition (ASR).

Researchers have successfully applied adaptive beamformers (BFs) [1]–[3] to enhance a single speech signal in a captured signal by low-latency processing. The speech's direction-of-arrival (DOA) is typically used to estimate the acoustic transfer function (ATF) from the speaker to the microphones (the steering vector) based on a plane-wave assumption, and the estimated ATF is used to optimize the BF [3], [4]. A method based on generalized eigenvalue decomposition (GEV) was developed to accurately estimate the ATF in reverberation (i.e., multipath environments) using the spatial covariance matrices (SCMs) of the signals [5], [6]. Next, a Parametric Multichannel Wiener Filter (PMWF) was proposed that allows the direct optimization of a BF from the SCMs without estimating the ATF [7], [8]. Furthermore, a PMWF can flexibly control the speech distortion and the noise reduction tradeoff.

In contrast, enhancing a mixture of speech signals, such as a conversation, with low-latency beamforming remains challenging. This is because the mixture may contain an unknown and varying number of speakers whose ATFs are unknown in general, and two or more speakers may talk simultaneously. In such a scenario, a BF needs to quickly and accurately adapt its directivity pattern to the unknown and varying number of speaker locations. If the number of speakers and the ATFs are given, a Linearly Constrained Minimum Variance (LCMV) BF can form a directivity pattern that enhances all the speakers in a mixture [1], [6], [9]–[11]. Similarly, a blind source separation (BSS) technique, e.g., Independent Vector Extraction (IVE) [12]–[14], can enhance a mixture by first extracting all the speakers and remixing them when the number is known. However, the requirements by these methods on the number of speakers and their ATFs are not acceptable in the assumed scenario. Alternatively, an Unknown Reference Multichannel Wiener Filter (UR-MWF) [15] can enhance a mixture without knowing the number of speakers or the ATFs. However, our experiments show that its denoising and dereverberation performance is limited.

To enable low-latency speech mixture enhancement, we propose a modified version of a PMWF, Mod-PMWF. A Mod-PMWF is defined by replacing the spatial covariance matrix (SCM) of a single target source in a conventional PMWF with the SCM of the mixture of the desired signals. Our mathematical analysis reveals that a Mod-PMWF has several desirable characteristics for low-latency speech mixture enhancement:

1) A Mod-PMWF achieves a weighted sum of the Minimum-Variance Distortionless Response (MVDR) BFs, each of which enhances each source in the mixture. It quickly adapts the weights of the MVDR BFs to enhance the sources with larger powers at each time-frequency (TF) point. Thus, a Mod-PMWF forms a directivity pattern that enhances the active sources at each TF point in the mixture.
2) We can reliably estimate a Mod-PMWF without knowing the number of sources in the mixture using a practical approximation technique. In addition, similar to a con-

[1]This work was supported by a JSPS summer program fellowship (No. SP21313)

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

ventional PMWF, we do not need to know the individual sources' ATFs for the estimation.

3) In terms of processing latency and computational efficiency, a Mod-PMWF is comparable to such conventional adaptive BFs as a PMWF.

In out experiments, we selected three conventional BFs, a GEV-based MVDR (GEV-MVDR) BF [6], Independent Single Component Extraction (ISCE) [13], and an UR-MWF since we believe that might perform mixture enhancement in certain senses without the number of sources or their ATFs. We also chose Independent Multiple Component Extraction (IMCE) [12] as an approach that can perform mixture enhancement with the prior knowledge of the number of sources. A comparison of our proposed Mod-PMWF with these conventional BFs using noisy reverberant speech mixtures confirms that Mod-PMWF outperformed the other BFs in terms of interference reduction ratios and MUltiple Stimuli with Hidden Reference and Anchor (MUSHRA) subjective listening tests [16].

In the following, we introduce a signal model and present the conventional PMWF in Sections II and III. Section IV presents the proposed Mod-PMWF, and Section V describes other conventional BFs that might be used for mixture enhancement. Section VI provides the experiment setup and results. Conclusions are drawn in Section VII.

II. Signal Model and Enhancement Goal

Suppose N speech signals are captured by M microphones with reverberation and diffuse noise. Let $x_{m,t,f}$ be the captured signal at the mth microphone and a TF point (t, f) in the short-time Fourier transform domain for $1 \leq t \leq T$ and $1 \leq f \leq F$, where T and F are the numbers of time frames and frequency bins, and let $(\cdot)^\top$ denote a non-conjugate transpose. Then the captured signal at all the microphones, $\mathbf{x}_{t,f} = [x_{1,t,f}, \ldots, x_{M,t,f}]^\top \in \mathbb{C}^M$, is modeled:

$$\mathbf{x}_{t,f} = \mathbf{d}_{t,f} + \mathbf{v}_{t,f}, \tag{1}$$

$$\mathbf{d}_{t,f} = \sum_{n=1}^{N} \mathbf{d}_{t,f}^{(n)} = \sum_{n=1}^{N} \mathbf{h}_f^{(n)} s_{t,f}^{(n)}, \tag{2}$$

where $\mathbf{d}_{t,f} \in \mathbb{C}^M$ is a mixture of speech signals $\mathbf{d}_{t,f}^{(n)}$ for all n. We assume that each speech signal, $\mathbf{d}_{t,f}^{(n)}$, which comprises a direct signal plus early reflections of the nth source, can be modeled by a product of a time-invariant ATF $\mathbf{h}_f^{(n)} \in \mathbb{C}^M$ and the nth clean source signal $s_{t,f}^{(n)} \in \mathbb{C}$. $\mathbf{v}_{t,f}$ is the sum of all the other signals, comprising the late reverberation of all the sources and the additive diffuse noise. In this paper, we deal with $\mathbf{d}_{t,f}$ as a desired signal to be obtained and $\mathbf{v}_{t,f}$ as an interference signal to be reduced. In addition, we assume that $\mathbf{d}_{t,f}^{(n)}$ for all n and $\mathbf{v}_{t,f}$ are mutually uncorrelated.

This paper assumes that both the late reverberation and the additive diffuse noise share the same spatial characteristics. We collectively model their sum as interference signal $\mathbf{v}_{t,f}$ that follows a stationary complex Gaussian distribution with mean vector $\mathbf{0}$ and SCM $\Phi_{\mathbf{v},f} \in \mathbb{C}^{M\times M}$:

$$p(\mathbf{v}_{t,f}) = \mathcal{N}(\mathbf{v}; \mathbf{0}, \Phi_{\mathbf{v},f}) \quad \text{where} \quad \Phi_{\mathbf{v},f} = E\{\mathbf{v}_{t,f}\mathbf{v}_{t,f}^{\mathsf{H}}\}, \tag{3}$$

where $E\{\cdot\}$ is an expectation function, and $(\cdot)^{\mathsf{H}}$ is a conjugate transpose.

Our goal in this paper is to estimate BF $\mathbf{W}_{t,f} \in \mathbb{C}^{M\times M}$ at each TF point that does not change speech mixture $\mathbf{d}_{t,f}$ and minimizes $\mathbf{v}_{t,f}$. With the BF, we obtain the following enhanced speech mixture, $\mathbf{y}_{t,f}\ (\approx \mathbf{d}_{t,f}) \in \mathbb{C}^M$:

$$\mathbf{y}_{t,f} = \mathbf{W}_{t,f}^{\mathsf{H}} \mathbf{x}_{t,f}. \tag{4}$$

III. Conventional BF for Single Source Extraction

This section briefly overviews a conventional BF (a PMWF) for single source extraction that we modify in the next section into a Mod-PMWF for mixture enhancement. Hereafter, we omit index f in the symbols since we apply the same processing separately in each frequency.

A. PMWF

When there is just one source in the observed signal (i.e., $N = 1$), PMWF $\mathbf{w}_{m,t} \in \mathbb{C}^M$ [7], which enhances $\mathbf{d}_t^{(1)}$ $(= \mathbf{h}^{(1)} s_t^{(1)})$ in Eq. (2) at the mth microphone, is defined as the one that minimizes the interference while constraining the speech distortion without exceeding allowable level σ:

$$\mathbf{w}_{m,t} = \arg\min_{\mathbf{w}} E\{|\mathbf{w}^{\mathsf{H}}\mathbf{v}_t|^2\} \quad \text{s.t.} \quad E\{|\mathbf{w}^{\mathsf{H}}\mathbf{d}_t^{(1)} - d_{m,t}^{(1)}|^2\} < \sigma.$$

Letting $\Phi_{\mathbf{d},t}^{(1)} = E\{\mathbf{d}_t^{(1)}(\mathbf{d}_t^{(1)})^{\mathsf{H}}\}$ be the SCM of $\mathbf{d}_t^{(1)}$ at t, solution $\mathbf{W}_t = [\mathbf{w}_{1,t}, \ldots, \mathbf{w}_{M,t}]$ is obtained at all the microphones:

$$\mathbf{W}_t = \left(\Phi_{\mathbf{d},t}^{(1)} + \gamma\Phi_{\mathbf{v}}\right)^{-1} \Phi_{\mathbf{d},t}^{(1)}. \tag{5}$$

Here $\gamma\ (\geq 0)$ is a weight that controls the tradeoff between the noise reduction and the speech distortion. This solution is also known as the Speech Distortion-Weighted MWF (SDW-MWF) [17]. Next, considering that $\Phi_{\mathbf{d},t}^{(1)}$ in Eq. (5) is rank-1 because it can be rewritten as $\Phi_{\mathbf{d},t}^{(1)} = E\{|s_t^{(1)}|^2\}\mathbf{h}^{(1)}(\mathbf{h}^{(1)})^{\mathsf{H}}$, we obtain a PMWF [7]:

$$\mathbf{W}_t^{\text{PMWF}} = \frac{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{d},t}^{(1)}}{\gamma + \lambda_{\mathbf{d},t}} \quad \text{where} \quad \lambda_{\mathbf{d},t} = \text{tr}\{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{d},t}^{(1)}\}, \tag{6}$$

and $\text{tr}\{\Phi\}$ is a matrix trace. Here, we can use γ as a parameter that controls the noise reduction level. For example, a PMWF with $\gamma = 0$ becomes an MVDR BF:

$$\mathbf{W}_t^{\text{MVDR}} = \frac{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{d},t}^{(1)}}{\lambda_{\mathbf{d},t}}. \tag{7}$$

A PMWF with $\gamma = 1$ also becomes a MWF.

An important advantage of a PMWF is that we can estimate it without estimating the ATF from the source to the microphones, i.e., $\mathbf{h}^{(1)}$, once we obtain $\Phi_{\mathbf{v}}$ and $\Phi_{\mathbf{d},t}^{(1)}$. Techniques for estimating $\Phi_{\mathbf{v}}$ and $\Phi_{\mathbf{d},t}^{(1)}$ have been proposed using voice activity detection [7] and TF masks estimated by a neural network [8].

IV. Proposed BF for Mixture Enhancement

This section presents a modified version of PMWF (Mod-PMWF) for mixture enhancement. We first define Mod-PMWF and analyze its characteristics focusing on how it performs mixture enhancement. Then we describe its implementation using a practical approximation technique.

A. Definition of Mod-PMWF

We define the Mod-PMWF by replacing the SCM of the target signal of a PMWF, i.e., $\Phi^{(1)}_{\mathbf{d},t}$ in Eq. (6), with the SCM of the desired mixture, i.e., $\Phi_{\mathbf{d},t} = E\{\mathbf{d}_t\mathbf{d}_t^{\mathsf{H}}\}$, at each time frame. The following is the Mod-PMWF formula:

$$\mathbf{W}_t^{\text{Mod-PMWF}} = \frac{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{d},t}}{\gamma + \lambda_{\mathbf{d},t}} \quad \text{where} \quad \lambda_{\mathbf{d},t} \quad = \text{tr}\{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{d},t}\}. \tag{8}$$

This BF is different from a PMWF in that $\Phi_{\mathbf{d},t}$ contains the characteristics not only of a single target source but of all the sources included in the mixture.

Below we explain how a Mod-PMWF can perform mixture enhancement. Then, in Sections IV-B and IV-C, we describe how we can reliably estimate a Mod-PMWF using an approximation technique.

1) Analysis of Mod-PMWF: Based on the assumption that $\mathbf{d}_t^{(n)}$ for all n are mutually uncorrelated, SCM $\Phi_{\mathbf{d},t}$ can be expanded:

$$\Phi_{\mathbf{d},t} = \sum_{n=1}^{N} \Phi^{(n)}_{\mathbf{d},t}, \tag{9}$$

where $\Phi^{(n)}_{\mathbf{d},t} = E\{\mathbf{d}_t^{(n)}(\mathbf{d}_t^{(n)})^{\mathsf{H}}\}$ is an unknown SCM of $\mathbf{d}_t^{(n)}$. Substituting Eq. (9) into Eq. (8) followed by a certain mathematical manipulation yields:

$$\mathbf{W}_t^{\text{Mod-PMWF}} = \sum_{n=1}^{N} \mu_{n,t}\mathbf{W}_t^{\text{MVDR}(n)}. \tag{10}$$

where $\mathbf{W}_t^{\text{MVDR}(n)}$ is an MVDR BF that enhances the nth source $\mathbf{d}_t^{(n)}$ by reducing interference $\mathbf{v}_t$. Each MVDR BF is defined based on a PMWF with $\gamma = 0$ in Eq. (7):

$$\mathbf{W}_t^{\text{MVDR}(n)} = \frac{\Phi_{\mathbf{v}}^{-1}\Phi^{(n)}_{\mathbf{d},t}}{\lambda^{(n)}_{\mathbf{d},t}} \quad \text{where} \quad \lambda^{(n)}_{\mathbf{d},t} = \text{tr}\{\Phi_{\mathbf{v}}^{-1}\Phi^{(n)}_{\mathbf{d},t}\}. \tag{11}$$

$\mu_{n,t}$ in Eq. (10) is a time-varying weight:

$$\mu_{n,t} = \frac{\lambda^{(n)}_{\mathbf{d},t}}{\gamma + \lambda_{\mathbf{d},t}} \quad \text{where} \quad \lambda_{\mathbf{d},t} = \sum_{n=1}^{N} \lambda^{(n)}_{\mathbf{d},t}. \tag{12}$$

According to Eq. (10), a Mod-PMWF is a weighted sum of the MVDR BFs, each of which is designed to enhance each source in the mixture. The weights are determined by $\lambda^{(n)}_{\mathbf{d},t}$ for all n, which are roughly proportional to the power of $\mathbf{d}_t^{(n)}$.

In the following, we look into more details of the BF characteristics for the cases with $\gamma = 0$ and $\gamma > 0$.

2) Behavior with $\gamma = 0$: When $\gamma = 0$, the Mod-PMWF has the following characteristics.

- Since the weights sum to one according to Eqs. (12), Eq. (10) becomes a weighted average of the MVDR BFs. Because all the MVDR BFs reduce $\mathbf{v}_t$, their weighted average, i.e., the Mod-PMWF, should also reduce $\mathbf{v}_t$.
- The MVDR BFs that compose the weighted average cover all the sources in $\mathbf{d}_t$ given $\Phi_{\mathbf{d},t}$, even without explicitly specifying the number of sources.
- Each MVDR BF follows the unknown ATF of each source included in $\mathbf{d}_t$. Thus, it can preserve its corresponding source without distortion.
- Since the weights of the BFs are roughly proportional to the powers of the respective sources, the Mod-PMWF can quickly adapt the weights to focus on active speakers at each TF point, i.e., sources with larger powers.

In summary, each MVDR BF that composes the Mod-PMWF preserves each source in the mixture and reduces the interference. The Mod-PMWF rapidly controls the weights of the MVDR BFs depending on the change in the relative powers of the sources. In this sense, a Mod-PMWF with $\gamma = 0$ can achieve mixture enhancement.

3) Behavior with $\gamma > 0$: With $\gamma > 0$, a Mod-PMWF is equivalent to multiplying a factor η_t to the output of the Mod-PMWF with $\gamma = 0$:

$$\eta_t = \frac{\lambda_{\mathbf{d},t}}{\gamma + \lambda_{\mathbf{d},t}}. \tag{13}$$

Based on analogy from the conventional PMWF, we expect this factor to work as a single channel Wiener filter that will further reduce the remaining interference in the output of the Mod-PMWF with $\gamma = 0$. We also confirmed such behavior of the Mod-PMWF with $\gamma > 0$ based on our preliminary experiments. A more thorough analysis of this behavior will be included in future work.

B. Practical approximation for Mod-PMWF

Although accurate estimation of $\Phi_{\mathbf{d},t}$ is crucial for Mod-PMWF, it is challenging under general recording conditions. To avoid this difficulty, this paper approximates $\Phi_{\mathbf{d},t}$ by the SCM of captured signal $\Phi_{\mathbf{x},t} = E\{\mathbf{x}_t\mathbf{x}_t^H\}$, disregarding $\Phi_{\mathbf{v}}$ in $\Phi_{\mathbf{x},t}$:

$$\Phi_{\mathbf{d},t} \simeq \Phi_{\mathbf{x},t} (= \Phi_{\mathbf{d},t} + \Phi_{\mathbf{v}}). \tag{14}$$

Unlike $\Phi_{\mathbf{d},t}$, $\Phi_{\mathbf{x},t}$ can be obtained easily and accurately from the given $\mathbf{x}_t$. In addition, this approximation does not significantly affect the Mod-PMWF performance, as discussed below.

With this approximation, the Mod-PMWF in Eq. (8) is rewritten:

$$\mathbf{W}_t^{\text{Approx-Mod-PMWF}} = \frac{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{x},t}}{\gamma + \lambda_{\mathbf{x},t}} \quad \text{where} \quad \lambda_{\mathbf{x},t} = \text{tr}\{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{x},t}\}. \tag{15}$$

Similar to Eq. (10), the approximated Mod-PMWF can be expanded using $\Phi_{\mathbf{x},t} = \Phi_{\mathbf{d},t} + \Phi_{\mathbf{v}}$:

$$\mathbf{W}_t^{\text{Approx-Mod-PMWF}} = \mu'_{\mathbf{d},t}\mathbf{W}_t^{\text{Mod-PMWF}} + \mu'_{\mathbf{v},t}\frac{\mathbf{I}_M}{M}, \tag{16}$$

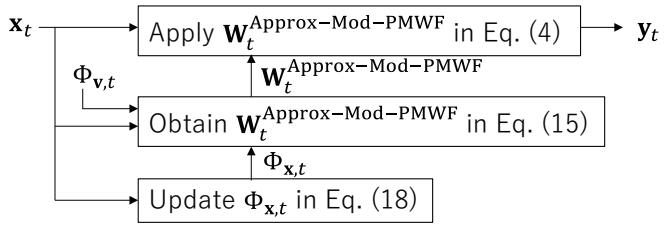

Fig. 1: Processing flow of Mod-PMWF at a time frame t and a frequency. Interference SCM $\Phi_{\mathbf{v},t}$ is assumed to be given in advance or estimated by online processing (Section VI-E).

where $\mathbf{I}_M \in \mathbb{R}^{M\times M}$ is an identity matrix. $\mu'_{\mathbf{d},t}$ and $\mu'_{\mathbf{v},t}$, which are time-varying weights roughly proportional to the power of $\mathbf{d}_t$ and $\mathbf{v}_t$, are defined as

$$\mu'_{\mathbf{d},t} = \frac{\gamma + \lambda_{\mathbf{d},t}}{\gamma + \lambda_{\mathbf{d},t} + \lambda_{\mathbf{v}}} \quad \text{and} \quad \mu'_{\mathbf{v},t} = \frac{\lambda_{\mathbf{v}}}{\gamma + \lambda_{\mathbf{d},t} + \lambda_{\mathbf{v}}}. \quad (17)$$

Here $\lambda_{\mathbf{v}} = M(= \text{tr}\{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{v}}\})$.

Equation (16) is a weighted average of the Mod-PMWF (without approximation) and a filter that reduces the gain of the captured signal by a factor of M. Note that $\mathbf{W}_t^{\text{Mod-PMWF}}$ in Eq. (16) is accurate because it is based on an accurate $\Phi_{\mathbf{d},t}$, which is included in $\Phi_{\mathbf{x},t}$. This means that using the approximated Mod-PMWF in Eq. (15) is equivalent to applying an accurate Mod-PMWF and adding the captured signal with a reduced level. Although this approximation slightly reduces the interference reduction effect of Mod-PMWF, it can precisely preserve the speech mixture. We use this approximation throughout out experiments.

C. Implementation of Mod-PMWF

Figure 1 shows the processing flow of Mod-PMWF. To estimate a Mod-PMWF with the approximation, we only need to estimate $\Phi_{\mathbf{x},t}$ and $\Phi_{\mathbf{v},t}$ and calculate Eq. (15) at each TF point. First, according to the convention of low-latency online adaptive BFs, we can estimate $\Phi_{\mathbf{x},t}$ by online processing as the time average of $\mathbf{x}_t\mathbf{x}_t^{\mathsf{H}}$ using forgetting factor β ($0 < \beta \leq 1$). $\Phi_{\mathbf{x},t}$ can be recursively updated:

$$\Phi_{\mathbf{x},t} = \beta\Phi_{\mathbf{x},t-1} + (1-\beta)\mathbf{x}_t\mathbf{x}_t^{\mathsf{H}}. \quad (18)$$

Note that active sources may differ at different time frames, and sources that are not included in current frame t may be included in previously captured signals in Eq. (18). Their influence remains in $\Phi_{\mathbf{x},t-1}$. Using a small β minimizes such influence.

The interference SCM $\Phi_{\mathbf{v},t}$ can be estimated, e.g., from noise recorded separately in advance or from a captured signal during speech absent periods. We can also use the same techniques proposed for conventional PMWFs [7], [8].

V. Potentially Applicable Conventional BFs to Mixture Enhancement

This section describes several conventional BFs that we believe may be used for mixture enhancement in certain senses. We also compare the computational time complexity and latency of the BFs with our proposed Mod-PMWF. In the next section, we experimentally compare the BFs with our proposed Mod-PMWF.

A. GEV-MVDR BF

The first conventional BF is a GEV-MVDR BF, which we present as a technique for single source enhancement and explain how to use for mixture enhancement.

When the number of sources in the observed signal is one (i.e., $N = 1$), an ATF at each time frame $\mathbf{h}^{(1)}$ for the source can be estimated based on GEV [6]:

$$\mathbf{h}_t^{(1)} = \Phi_{\mathbf{v}}\mathbf{u}_t \quad \text{where} \quad \mathbf{u}_t = \text{MaxEig}\{\Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{x},t}\}, \quad (19)$$

where $\text{MaxEig}\{\Phi\}$ extracts an eigenvector of Φ corresponding to the maximum eigenvalue. Considering $\Phi_{\mathbf{d},t}^{(1)} = E\{|s_t^{(1)}|^2\}\mathbf{h}_t^{(1)}(\mathbf{h}_t^{(1)})^{\mathsf{H}}$ in Eq. (7) and substituting Eq. (19) into Eq. (7), we obtain a GEV-MVDR BF:

$$\mathbf{W}_t^{\text{GEV-MVDR}} = \frac{\mathbf{u}_t\mathbf{u}_t^{\mathsf{H}}\Phi_{\mathbf{v}}}{\text{tr}\{\mathbf{u}_t\mathbf{u}_t^{\mathsf{H}}\Phi_{\mathbf{v}}\}}. \quad (20)$$

For low-latency processing, we can calculate $\Phi_{\mathbf{x},t}$ in Eq. (19) using Eq. (18) and obtain $\mathbf{u}_t$ in Eq. (20) in a computationally efficient way using a power method for calculating $\text{MaxEig}\{\cdot\}$ in Eq. (19) [18], [19]. This iterates the following update after first setting $\mathbf{u}_t = \mathbf{u}_{t-1}$ at each time frame:

$$\mathbf{u}_t \leftarrow \Phi_{\mathbf{v}}^{-1}\Phi_{\mathbf{x},t}\mathbf{u}_t/|\mathbf{u}_t|. \quad (21)$$

In general, the power method converges very quickly, and one iteration was sufficient in our experiments.

1) Application of GEV-MVDR BF to mixture enhancement: As shown in a previous work [20], a GEV-MVDR BF can also be viewed as a realization of a Maximum Signal-to-Noise Ratio (MaxSNR) BF [2], [21], [22], a property that can be used for mixture enhancement.

Regardless whether the captured signal contains a single source or multiple sources, we can define MaxSNR BF $\mathbf{w}_t^{\text{MaxSNR}} \in \mathbb{C}^M$ as one that maximizes the signal's SNR, i.e., the power ratio of desired signal $\mathbf{d}_t$ to interference $\mathbf{v}_t$:

$$\mathbf{w}_t^{\text{MaxSNR}} = \arg\max_{\mathbf{w}} \frac{E\{|\mathbf{w}^{\mathsf{H}}\mathbf{d}_t|^2\}}{E\{|\mathbf{w}^{\mathsf{H}}\mathbf{v}_t|^2\}}, \quad (22)$$

$$= \arg\max_{\mathbf{w}} \frac{E\{|\mathbf{w}^{\mathsf{H}}\mathbf{x}_t|^2\}}{E\{|\mathbf{w}^{\mathsf{H}}\mathbf{v}_t|^2\}}, \quad (23)$$

where we used $E\{|\mathbf{w}^{\mathsf{H}}\mathbf{x}_t|^2\} = E\{|\mathbf{w}^{\mathsf{H}}\mathbf{d}_t|^2\} + E\{|\mathbf{w}^{\mathsf{H}}\mathbf{v}_t|^2\}$ to obtain the above second line. The solution to Eq. (23) is obtained based on GEV: $\mathbf{w}_t^{\text{MaxSNR}} = b^*\mathbf{u}_t$, where b is an indefinite constant, $(\cdot)^*$ is a complex conjugate, and $\mathbf{u}_t$ is from Eq. (19). Let $\mathbf{b} \in \mathbb{C}^M$ be a vector composed of M different realizations of b and let $\mathbf{W}_t = \mathbf{u}_t\mathbf{b}^{\mathsf{H}}$ be a matrix realization of a MaxSNR BF based on $\mathbf{b}$. Then the MaxSNR BF with $\mathbf{b}$ defined below is identical to the GEV-MVDR BF in Eq. (20):

$$\mathbf{W}_t^{\text{MaxSNR}} = \mathbf{u}_t\mathbf{b}^{\mathsf{H}} \quad \text{where} \quad \mathbf{b} = \frac{\Phi_{\mathbf{v}}\mathbf{u}_t}{\text{tr}\{\mathbf{u}_t\mathbf{u}_t^{\mathsf{H}}\Phi_{\mathbf{v}}\}}. \quad (24)$$

The above analysis indicates that the GEV-MVDR BF in Eq. (20) works as a MaxSNR BF even when the observed

signal contains two or more sources. In other words, the GEV-MVDR BF may enhance the mixture of the speech signals, i.e., $\mathbf{d}_t$ in Eq. (1), in the MaxSNR sense regardless of the number of sources.

B. Two versions of Independent Component Extraction (ICE): ISCE and IMCE

Next, we chose Independent Component Extraction (ICE) since it is applicable for mixture enhancement. ICE is a variation of a popular BSS technique, IVE [12]–[14]. Even without prior knowledge of the ATFs of the sources, both IVE and ICE can extract a given number ($N \geq 1$) of sources based on an assumption that they are mutually independent. We here adopt ICE because our preliminary experiments identified its superiority over IVE for mixture enhancement. The difference between ICE and IVE is their source models. Although IVE's model specifies the source's spectral characteristics over all the frequencies, ICE's model separately specifies the characteristics at each frequency. We defined the latter model at each frequency by a complex Gaussian with a mean of 0 and a time-varying variance. The optimization algorithm for an online ICE can be easily obtained from that of an online IVE [14].

We below present two different usages of ICE for mixture enhancement, referred to as ISCE and IMCE, respectively.

1) Application of ISCE to mixture enhancement: When we set the number of sources to be extracted as $N = 1$ for ICE, we call it Independent Single Component Extraction (ISCE), which this paper uses for mixture enhancement by utilizing speech sparseness. With speech sparseness, we assume that the speakers are not simultaneously active at each TF point. With this assumption, which is based on the spectral characteristics of speech and has proven effective for source separation purposes [23]–[25], we can simplify a mixture enhancement task to a single source extraction task at each TF point. Thus, we can use ISCE for mixture enhancement by simply applying it to a mixture with a quick adaptation over time frames.

2) Application of IMCE to mixture enhancement: When we assume that the number of sources is given ($N \geq 2$) and use ICE to extract all of them from a mixture, we call it Independent Multiple Component Extraction (IMCE). By remixing the extracted sources, we can obtain an enhanced mixture. Unlike the other methods, this method requires the prior knowledge of the number of sources; we just use IMCE for reference.

C. UR-MWF

We can also use a version of a conventional MWF called UR-MWF [15] for mixture enhancement. MWF is defined as BF $\mathbf{W}_t^{\text{MWF}}$ that gives the minimum mean square error (MMSE) estimate of desired mixture $\mathbf{d}_t$:

$$\mathbf{W}_t^{\text{MWF}} = \arg\min_{\mathbf{W}} E\{\|\mathbf{d}_t - \mathbf{W}^{\mathsf{H}}\mathbf{x}_t\|_2^2\}. \tag{25}$$

Assuming $\Phi_{\mathbf{x},t} = E\{\mathbf{d}_t\mathbf{d}_t^{\mathsf{H}}\} + \Phi_{\mathbf{v}}$, we obtain UR-MWF:

$$\mathbf{W}_t^{\text{UR-MWF}} = \Phi_{\mathbf{x},t}^{-1}(\Phi_{\mathbf{x},t} - \Phi_{\mathbf{v}}). \tag{26}$$

Based on Eq. (26), UR-MWF can enhance a mixture given $\Phi_{\mathbf{x},t}$ and $\Phi_{\mathbf{v}}$ without the number of sources or their ATFs.

TABLE I: Computational time complexity for adapting and applying a BF to each TF point: Complexity of Mod-PMWF, GEV-MVDR, and UR-MWF is estimated assuming that we recursively update $\Phi_{\mathbf{v}}$ and its inverse, e.g., during speech absent periods, as in a previous work [19].

Mod-PMWF	GEV-MVDR	ISCE	IMCE	UR-MWF
$O(M^2)$	$O(M^2)$	$O(M^2)$	$O(NM^2)$	$O(M^2)$

D. Comparison of computational time complexity and latency

Table I shows the computational time complexity of the BFs and the Mod-PMWF. All the BFs (except for IMCE) have identical complexity $O(M^2)$. The complexity increases to $O(NM^2)$ for IMCE to extract N sources.

All the BFs update their coefficients at each time frame using current and past time frames. Thus, their algorithmic delay (or latency) corresponds to the window length minus the window shift of the overlap-add synthesis.

VI. Experiments

We evaluated our proposed Mod-PMWF in comparisons with other conventional BFs using signal level metrics and a MUSHRA listening test.

A. Dataset

For the evaluation, we prepared a simulated noisy reverberant mixture dataset containing 100 samples of two speakers from ATR digital speech database set B [26]. To reverberate each speaker's utterances, we used room impulse responses (RIRs) measured with a cubic array of eight microphones in a room with a T60 of 380 ms. Each edge of the cubic array was 4 cm, and a microphone was equipped at each vertex of the array. We used 5 of 8 microphones in the experiments. The two speakers were located 1 m from the array on opposite sides. We then mixed two speech signals starting simultaneously with babble noise recorded by the same array in the same room. We created two versions of the dataset by setting the Reverberant speech Mixture to Noise Ratio (RMNR) to 20 dB and 10 dB. The sampling frequency was set at 16 kHz.

B. Analysis condition

Throughout the experiments, we set $\gamma = 0$ for Mod-PMWF to evaluate its MVDR behavior. Forgetting factor β for updating $\Phi_{\mathbf{x},t}$ in Eq. (18) decides how quickly the algorithm adapts to the change in the signals' spatial characteristics. We chose $\beta = 0.99$ for UR-MWF, 0.96 for ISCE and IMCE, and 0.85 for Mod-PMWF and GEV-MVDR based on preliminary experiments. We set the window length and shift at 20 ms and 5 ms.

In Sections VI-C and VI-D, we assume that interference SCMs $\Phi_{\mathbf{v}}$ can be estimated in advance and estimated them from a part of the measured babble noise not used for generating the mixtures. Then we evaluated the Mod-PMWF with no prior knowledge of $\Phi_{\mathbf{v}}$ in Section VI-E, where we estimated $\Phi_{\mathbf{v}}$ by online processing from observed signals [19] using the estimated speech presence probability [27].

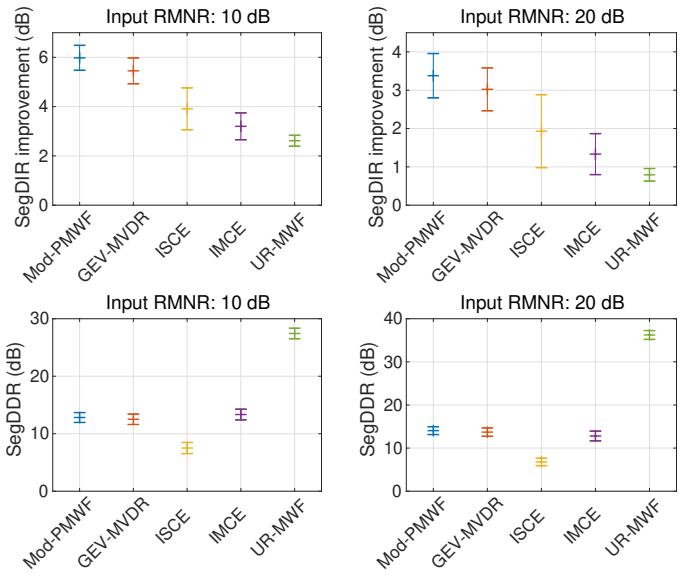

Fig. 2: SegDIR improvements and SegDDRs averaged over 100 samples: Error bars indicate standard deviation. Mod-MPDR, Gev-MVDR, and UR-MWF used interference SCMs separately estimated in advance.

C. Evaluation results using signal level metrics

We defined two signal level metrics for the evaluation [28], [29]: the Segmental Desired to Interference Ratio (SegDIR) and the Segmental Desired to Distortion Ratio (SegDDR). The former measured the degree of interference reduction; the latter measured the degree of signal distortion introduced to the enhanced speech. Let $d_m(i)$ and $v_m(i)$ be the ith samples of the desired mixture and the interference signal in the time domain at the mth microphone, and let $\hat{d}_m(i)$ and $\hat{v}_m(i)$ be samples obtained by applying a BF to $d_m(i)$ and $v_m(i)$. To determine desired signal $d_m(i)$, we set the duration of the early reflections at 50 ms. We defined the metrics:

$$\text{SegDIR} = \frac{10}{|\mathcal{A}|}\sum_{\tau\in\mathcal{A}}\log_{10}\frac{\sum_{m=1}^{M}\sum_{i=\tau\delta+1}^{\tau\delta+\delta}|\hat{d}_m(i)|^2}{\sum_{m=1}^{M}\sum_{i=\tau\delta+1}^{\tau\delta+\delta}|\hat{v}_m(i)|^2},$$

$$\text{SegDDR} = \frac{10}{|\mathcal{A}|}\sum_{\tau\in\mathcal{A}}\log_{10}\frac{\sum_{m=1}^{M}\sum_{i=\tau\delta+1}^{\tau\delta+\delta}|d_m(i)|^2}{\sum_{m=1}^{M}\sum_{i=\tau\delta+1}^{\tau\delta+\delta}|\hat{d}_m(i)-d_m(i)|^2},$$

where $\delta = 800$ samples ($= 50$ ms) is the segment length, τ is a segment index, $\mathcal{A}$ is a set of segments where at least one speech signal is active, and $|\mathcal{A}|$ is the number of segments in $\mathcal{A}$.

Figure 2 shows the evaluation results. We show SegDIR as its relative improvement from the captured signal and SegDDR as its absolute value.

First, when we compare the SegDIRs obtained by the BFs, the proposed Mod-PMWF had the best performance. In particular, Mod-PMWF significantly outperformed ISCE, IMCE, and UR-MWF. When we compare the SegDDRs obtained by the BFs, Mod-PMWF outperformed ISCM and was comparable with GEV-MVDR and IMCE. In contrast, UR-MWF achieved significantly better SegDDR results than all the others, although its SegDIR improvement was minimal.

We draw the following implications from these results.

1) Although Mod-PMWF and GEV-MVDR did not use prior knowledge of the number of sources, they achieved comparable SegDDRs with IMCE, which does use the knowledge of the number of sources. This suggests that Mod-PMWF and GEV-MVDR effectively enhanced the mixture based on their unique mechanisms described in Sections IV-A1 and V-A1.
2) For improving SegDIR, the sparseness assumption used for ISCE was effective, to some extent, in comparison with IMCE, but insufficient in comparison with Mod-PMWF and GEV-MVDR. The assumption also introduced more speech distortion than the other BFs.
3) The inferior SegDIR obtained by IMCE is probably caused by remixing the two separated signals. The remixing combines the interference that remained in each separated signal. In contrast, Mod-PMWF effectively reduced the interference while enhancing the mixture probably because it adaptively controls the BF weights to enhance only the active sources at each TF point.

In contrast, comparing UR-MWF's effectiveness with the other BFs is difficult based only on the above results.

To more reliably compare the proposed BF with the other BFs, including UR-MWF, we conducted a subjective listening test.

D. Evaluation results with MUSHRA listening test

We conducted a MUSHRA listening test [16] to evaluate the perceived speech quality. We selected two speech mixtures composed of either two male or two female speakers and tested them under each RMNR condition. Each sample had seven signals to rate, including the desired mixture as the (hidden) reference and the noisy reverberant observation as the anchor. Ten experienced listeners participated in the test and concentrated on the audio's overall quality including both the noise level and the speech degradation.

Figure 3 shows the result. The two sub-figures show the results under input RMNRs of 20 dB and 10 dB and both exhibit almost the same tendency. First, the participants rated the high-quality reference as 100 points and the test conditions between 40-80 points, confirming our choice of MUSHRA as appropriate based on ITU-R recommendation BS. 1534. In addition, the improvements obtained by all the BFs were statistically significant from the anchor, i.e., the noisy observation received the lowest scores. Thus our anchor indicates how the methods compare to known audio quality levels.

Next, when comparing the results among BFs, the proposed Mod-PMWF significantly outperformed all the other BFs, including GEV-MVDR and UR-MWF. The result was better correlated with SegDIR than with SegDDR. One reason might be that the speech distortion is, to some extent, masked by active speech and noise residual and thus less annoying to the listeners than the noise residual.

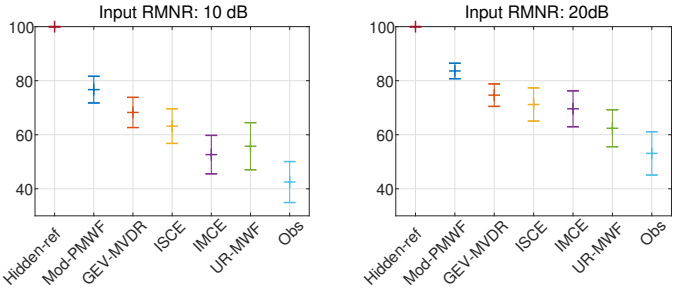

Fig. 3: MUSHRA test results: Error bars indicate 95% confidence based on t-distribution test. Mod-MPDR, GEV-MVDR, and UR-MWF used interference SCMs separately estimated in advance.

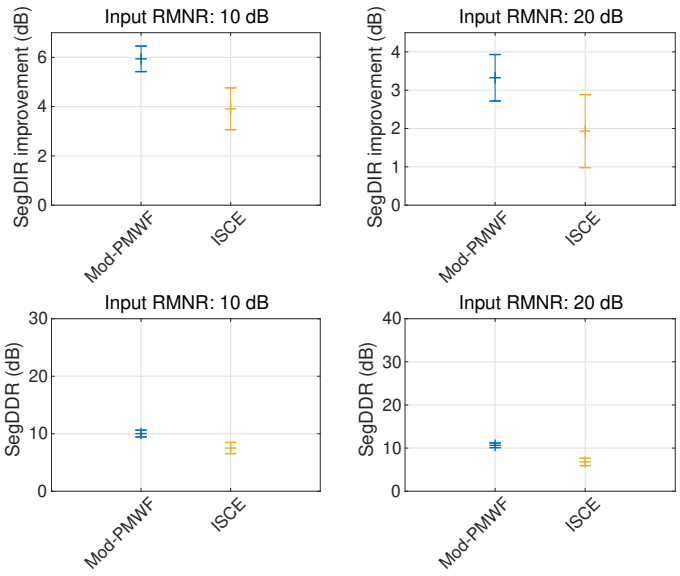
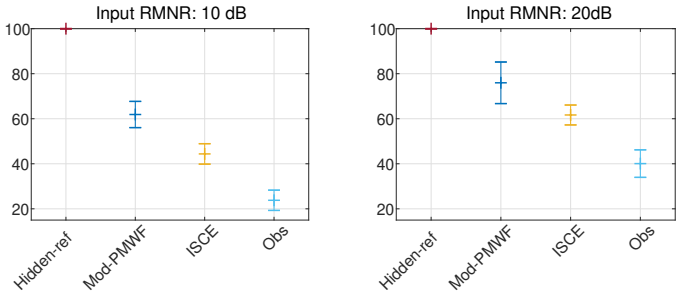
E. Evaluation with no prior knowledge of interference SCM

Finally, we evaluated Mod-PMWF without any prior knowledge of the interference SCM. We recursively updated interference SCM $\Phi_{\mathbf{v},t,f}$ at each TF point:



$$\Phi_{\mathbf{v},t,f} = \alpha' \Phi_{\mathbf{v},t-1,f} + (1-\alpha')\mathbf{x}_{t,f}\mathbf{x}_{t,f}^H, \tag{28}$$

$$\alpha' = \alpha + (1-\alpha)q_{t,f}, \tag{29}$$



where $\alpha = 0.9998$ is a forgetting factor and $q_{t,f}$ is a speech presence probability estimated recursively by maximum likelihood estimation [27].

Figures 4 (a) and (b) show the SegDIR improvements, the SegDDRs, and the MUSHRA test results. We selected two methods, a Mod-PMWF based on online interference SCM estimation and an ISCE based on BSS, mainly to elaborate the reliability of the MUSHRA test. For it, we also added a mixture sample composed of male and female speakers. Totally we had three samples for each RMNR condition. Eight experienced listeners participated in this test.

Mod-PMWF significantly outperformed ISCE in terms of all the metrics. The overall tendency of the results is almost identical to that in Figs. 2 and 3 except that the SegDDRs obtained by Mod-PMWF were slightly lower than Fig. 2. These results show that Mod-PMWF effectively performed mixture enhancement even when no prior knowledge on the interference SCMs was available.

(a) SegDIR improvements and SegDDRs averaged over 100 samples: Error bars indicate standard deviation.

(b) MUSHRA test results: Error bars indicate 95% confidence based on t-distribution test.

Fig. 4: Evaluation without prior knowledge of interference SCM. The interference SCM was estimated by online processing for Mod-PMWF.

VII. Conclusion

We proposed a Mod-PMWF for low-latency online speech mixture enhancement in noisy reverberant environments. We showed mathematically that Mod-PMWF is equivalent to a weighted sum of MVDR BFs, each of which can preserve each source included in the captured signal and the time-varying weights quickly adapt at each time frame to put larger weights on sources with larger powers. We estimated the Mod-PMWF by low-latency online processing without relying on the prior knowledge of the number of sources or the ATFs from the sources to the microphones. We discussed that approximating the SCM of the desired mixture by the captured signal's SCM for Mod-PMWF is advantageous for accurate preservation of the speech mixture although it slightly reduces the interference reduction effect. We verified the effectiveness of the Mod-PMWF for mixture enhancement in terms of the interference reduction ratios and the subjective speech quality tests. The Mod-PMWF outperformed several conventional BFs, including GEV-MVDR BF that performs mixture enhancement in a MaxSNR sense, a BSS technique ISCE that utilizes speech sparseness, another BSS technique IMCE with prior knowledge of the number of sources, and an UR-MWF that gives the MMSE estimates of the desired mixtures.

***Abstract*—Block permutation is a problem that occurs in the separated signals obtained by independent low-rank matrix analysis. To deal with this problem, a new method that induces a low-rank property on the projection of the separated spectrogram to the so-called consistent spectrogram for short-time Fourier transform has recently been proposed. In contrast to conventional methods, which disregard how far the separated spectrogram is from the projected spectrogram, we design a regularization term that induces the separated spectrogram itself to be consistent. For the newly designed optimization problem, we derive the update rule based on the majorization-minimization algorithm and the vectorwise coordinate descent method. We verify the effectiveness of the proposed method experimentally.**

I. Introduction

Blind source separation (BSS) is a technique for estimating original source signals from mixed multichannel signals in situations where the characteristics and spatial arrangements of the sources and microphones are unknown. As a known instance of BSS, frequency-domain independent component analysis (FDICA) has been proposed [1]. FDICA estimates separation filters for each frequency bin under the overdetermined condition (where the number of microphones M is equal to or greater than the number of sources N). In FDICA, there is the well-known problem called the permutation problem: for each frequency bin, the order of the sources in the separated signals is not determined. Many methods to solve this problem have been researched [2]–[7]. This indicates that research on solving the permutation problem is one of the critical themes in BSS.

Among the solutions to the permutation problem, post-processing methods that solve the permutation problem by estimating the source's direction of arrival [2] or the correlation between the frequencies [3] have been proposed. Although these are two-step methods, the methods for estimating the separation filters and dealing with the permutation problem simultaneously by modeling the time-frequency structure of the separated signals have been proposed [4], [5]. Independent vector analysis (IVA) [4] is a method in which a distribution with higher-order correlations between frequency bins is assumed, which results in capturing the synchronicity in the time direction. Independent low-rank matrix analysis (ILRMA) [5] assumes low-rankness in the power spectrogram of the separated signals by introducing a nonnegative matrix factorization (NMF) model [8]. Inducing the time-frequency structure for the source model allows the permutation problem to be solved automatically within the optimization problem. Among these approaches, it has been reported that ILRMA achieves a higher separation performance than do FDICA and IVA [5]. Although ILRMA implicitly solves the permutation problem by capturing the time-frequency structure, the high degree of freedom in the NMF model can cause a block permutation problem, where inconsistencies occur in a neighboring frequency band [9].

In recent years, to deal with permutation and block permutation problems, new approaches based on the spectrogram consistency of complex spectrograms [10]–[13] have been proposed [6], [7]. Here, a spectrogram is said to be *spectrogram-consistent* (or simply *consistent*) if there exists a corresponding time-domain signal through short-time Fourier transformation (STFT) and inverse STFT (ISTFT). Since STFT is a linear transformation that converts time-domain signals to complex spectrograms in the time-frequency domain and the dimension of the spectrogram space is generally larger than that of the time-domain-signal space, consistent spectrograms form a linear subspace in the entire spectrogram space that we call *consistent space*. Some signal-processing methods in the time-frequency domain may cause the consistent spectrogram to deviate from the consistent space. Therefore, when converting such an inconsistent spectrogram to the time domain using ISTFT, unintended changes in the time-frequency structure may occur [10]. As an example, consider performing ISTFT on a separated signal with a block permutation in ILRMA and then applying STFT. In this case, a phenomenon that the frequency band appears to bleed into adjacent bands often occurs near the block-permutated frequency bands in spectrograms before performing ISTFT. This phenomenon causes the collapse of low-rankness and the loss of independence between the sources in the bled-out bands. There is also a method that considers consistency in ILRMA [7]. As described in [7], the spectrogram of the separated time-domain signals, which is projected from possibly inconsistent signals onto consistent space via STFT after ISTFT, is modeled using NMF for low-rankness. By inducing low-rankness in the time-frequency structure of the actual output time-domain signals,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

block permutation is expected to be alleviated. It has been reported that the separation performance of this method is equivalent to or better than that of ILRMA in source separation experiments [7]. Unfortunately, such a projection-based approach is based on heuristics and is not formulated as a strict optimization problem.

The conventional consistency-based approach disregards how far the original separated spectrogram is from the consistent space. In contrast, we are motivated to induce the separated spectrogram itself to be near the consistent space. In this study, we design a regularization term based on the distance between the separated spectrogram and consistent space, and formulate the regularized optimization problem with it. We derive the update rule for this regularized optimization problem on the basis of the majorization-minimization (MM) algorithm [14] and vectorwise coordinate descent (VCD) method [15]. We also confirm the effectiveness of the proposed method through a simulated experiment.

II. Preliminaries

A. MM Algorithm [14]

The MM algorithm is a technique for optimizing iteratively the objective function using an auxiliary function called the upper-bound function. The MM algorithm is often effective when it is difficult to optimize the objective function directly by finding the stationary points and there is an appropriate auxiliary function.

Let $\mathcal{J}(\Theta)$ be the objective function to be minimized with respect to the objective variable Θ. In the MM algorithm, we design an auxiliary function $\mathcal{J}^{+}(\Theta,\Omega)$ that satisfies the following two properties.

$$\mathcal{J}(\Theta) \leq \mathcal{J}^{+}(\Theta,\Omega), \qquad (\forall\Theta,\forall\Omega) \tag{1}$$

$$\mathcal{J}(\Theta) = \min_{\Omega} \mathcal{J}^{+}(\Theta,\Omega), \qquad (\forall\Theta) \tag{2}$$

where Ω is called the auxiliary variable. In the MM algorithm, the optimal solution is obtained by iterating the following steps (i) and (ii).

(i) Update the auxiliary variable from the latest objective variable

$$\tilde{\Omega} \leftarrow \arg\min_{\Omega} \mathcal{J}^{+}(\tilde{\Theta},\Omega). \tag{3}$$

By definition of the auxiliary function, $\tilde{\Omega}$ becomes the value that satisfies the equality in inequality (1).

(ii) Update the objective variable from the new auxiliary variable

$$\Theta \leftarrow \arg\min_{\hat{\Theta}} \mathcal{J}^{+}(\hat{\Theta},\tilde{\Omega}). \tag{4}$$

The update by the MM algorithm guarantees the monotonic nonincreasing property of the objective function.

It is necessary to design an auxiliary function $\mathcal{J}^{+}(\Theta,\Omega)$ for the MM algorithm so that the optimization of $\mathcal{J}^{+}(\Theta,\Omega)$ becomes possible to optimize (4). Furthermore, when the gap between the auxiliary function and the objective function is large, the step size of the update tends to be small, so it is desirable to have an auxiliary function close to the objective function.

B. Representation Matrix of STFT

Consider a real-valued signal of length L, denoted by $\tilde{\boldsymbol{\psi}} \in \mathbb{R}^{L}$. The corresponding vectorized complex-valued spectrogram is represented by $\boldsymbol{\Psi} \in \mathbb{C}^{I_{\mathrm{S}}J}$, where I_{S} and J represent the window length and the number of time frames in STFT, respectively. In this paper, we assume that I_{S} is an even integer for simplicity. Let τ be the shift length of STFT, and $\boldsymbol{h} \in \mathbb{R}^{I_{\mathrm{S}}}$ be the window function. $L^{(\mathrm{pre})}$ and $L^{(\mathrm{post})}$ denote the length of zero-padding at the beginning and end of the time signal, respectively. We denote the length of the signal after zero-padding as $L' = L + L^{(\mathrm{pre})} + L^{(\mathrm{post})}$. Hereafter, we consider the practical case where $I_{\mathrm{S}}J > L$ holds. The $L' \times L$ matrix representing zero-padding is given by $Z = (O_{L\times L^{(\mathrm{pre})}}, E_L, O_{L\times L^{(\mathrm{post})}})^{\mathsf{T}}$, where $O_{q\times q'}$ and E_q denote the $q \times q'$ zero matrix and $q \times q$ identity matrix, respectively. Here, $^{\mathsf{T}}$ represents the transpose operation. Note that $L^{(\mathrm{pre})}$, $L^{(\mathrm{post})}$, and J are defined as $L' = \tau(J-1) + I_{\mathrm{S}}$.

The representation matrix of the normalized discrete Fourier transform (DFT) is denoted by $F \in \mathbb{C}^{I_{\mathrm{S}}\times I_{\mathrm{S}}}$, and the representation matrix of the inverse DFT is given by F^{H}, where $^{\mathsf{H}}$ represents the Hermitian transpose. These matrices are formed by arranging the orthonormal Fourier bases. The $((j-1)I_{\mathrm{S}}+1)$th to jI_{S}th elements of $\boldsymbol{\Psi}$, which correspond to the jth frame of the spectrogram, are obtained by multiplying the $(\tau(j-1)+1)$th to $(\tau(j-1)+I_{\mathrm{S}})$th samples of the zero-padded time signal by the window function and applying DFT. We define $\Upsilon \in \mathbb{C}^{I_{\mathrm{S}}J\times L'}$ as

$$\Upsilon = \begin{pmatrix} F\Delta'_1 \\ \vdots \\ F\Delta'_J \end{pmatrix}, \tag{5}$$

where $\Delta'_j \in \mathbb{R}^{I_{\mathrm{S}}\times L'}$ $(j = 1,\ldots,J)$ is given by

$$\Delta'_j = (O_{I_{\mathrm{S}}\times\tau(j-1)}, \mathrm{diag}(\boldsymbol{h}), O_{I_{\mathrm{S}}\times(L'-\tau(j-1)-I_{\mathrm{S}})}). \tag{6}$$

Here, $\mathrm{diag}(\cdot)$ represents the diagonal matrix whose qth diagonal element is the qth element of the input complex vector. Then, $\Psi = \Upsilon Z\tilde{\boldsymbol{\psi}}$ holds. In the following, the representation matrix of STFT is given by $\mathcal{F} = \Upsilon Z$.

In this paper, we define ISTFT in the least-squares sense, meaning the representation matrix for ISTFT becomes the Moore–Penrose pseudo-inverse matrix corresponding to that for STFT. Therefore, the representation matrix of ISTFT $\mathcal{F}^{\dagger}$ is given by

$$\mathcal{F}^{\dagger} = (\mathcal{F}^{\mathsf{H}}\mathcal{F})^{-1}\mathcal{F}^{\mathsf{H}} = \left(\sum_j \Delta_j^{\mathsf{H}}\Delta_j\right)^{-1}\mathcal{F}^{\mathsf{H}}, \tag{7}$$

where $\Delta_j = \Delta'_j Z$. By definition, $\mathcal{F}^{\dagger}\mathcal{F} = E_L$ holds, and $\mathcal{F}\mathcal{F}^{\dagger}$ becomes an orthogonal projection matrix.

III. Conventional Methods

A. ILRMA [5]

Let $\boldsymbol{s}_{ij} = (s_{ij1}, \ldots, s_{ijN})^{\mathsf{T}}$, $\boldsymbol{x}_{ij} = (x_{ij1}, \ldots, x_{ijM})^{\mathsf{T}}$, and $\boldsymbol{y}_{ij} = (y_{ij1}, \ldots, y_{ijN})^{\mathsf{T}}$ represent the spectrograms of the source signals, separated signals, and observed signals, respectively, where $i = 1, \ldots, I_{\mathrm{N}}$; $j = 1, \ldots, J$; $n = 1, \ldots, N$; and $m = 1, \ldots, M$ denote the indices of frequency bins, time frames, sources, and microphones, respectively. I_{N} is the index of the frequency bin corresponding to the Nyquist frequency. Assuming that each source is a point source and the reverberation time is sufficiently shorter than the length of the STFT window, the mixing system can be approximated as instantaneous mixing in the frequency domain: $\boldsymbol{x}_{ij} = A_i \boldsymbol{s}_{ij}$, where $A_i \in \mathbb{C}^{M \times N}$ is called the mixing matrix. In this study, we assume that $N = M$ and A_i is regular. Under these assumptions, the separated signals are obtained by estimating the inverse matrix of A_i, called the separation matrix, $W_i = (\boldsymbol{w}_{i1}, \ldots, \boldsymbol{w}_{iN})^{\mathsf{H}} \in \mathbb{C}^{N \times M}$, as follows:

$$\boldsymbol{y}_{ij} = W_i \boldsymbol{x}_{ij}. \tag{8}$$

In ILRMA, the separated signals are assumed to follow the following zero-centered univariate complex Gaussian distribution with variance r_{ijn}^2:

$$p(y_{ijn}) = \frac{1}{\pi r_{ijn}^2} \exp\Big(- \frac{|y_{ijn}|^2}{r_{ijn}^2} \Big). \tag{9}$$

Furthermore, to model the low-rank structure of source signals, the $I_{\mathrm{N}} \times J$ matrix whose (i, j)th element is r_{ijn}^2 is modeled by NMF for each n as

$$r_{ijn}^2 = \sum_k t_{ikn} v_{kjn}, \tag{10}$$

where $t_{ikn} \geq 0$ and $v_{kjn} \geq 0$ are elements of the basis matrix and activation matrix of NMF, respectively, and $k = 1, \ldots, K$ denotes the index of the basis. In ILRMA, the following negative log-likelihood is used as the objective function:

$$\begin{aligned}
&\mathcal{J}_{\mathrm{I}}(W_i, \{t_{ikn}\}, \{v_{kjn}\}) \\
&= - \log \prod_{i=1}^{I_{\mathrm{N}}} \prod_{j,n} p(x_{ijn}) && (11) \\
&= - \log \prod_{i=1}^{I_{\mathrm{N}}} \prod_{j,n} p(y_{ijn}) - J \sum_i \log |\det W_i|^2 && (12) \\
&= \sum_{i=1}^{I_{\mathrm{N}}} \sum_{j,n} \left(\frac{|\boldsymbol{w}_{in}^{\mathsf{H}} \boldsymbol{x}_{ij}|^2}{\sum_k t_{ikn} v_{kjn}} + \log \sum_k t_{ikn} v_{kjn} \right) \\
&\quad - J \sum_{i=1}^{I_{\mathrm{N}}} \log |\det W_i|^2 + \mathrm{const.}, && (13)
\end{aligned}$$

where const. represents the terms independent of W_i, $\{t_{ikn}\}$, and $\{v_{kjn}\}$.

We focus (13) on the separation matrix W_i at first because we update W_i, $\{t_{ikn}\}$, and $\{v_{kjn}\}$ alternately. By rearranging (13) with respect to W_i, we obtain

$$\begin{aligned}
\mathcal{J}_{\mathrm{I}}(\{W_i\}) =& J \sum_{i=1}^{I_{\mathrm{N}}} \left[\sum_n \boldsymbol{w}_{in}^{\mathsf{H}} D_{in} \boldsymbol{w}_{in} - \log |\det W_i|^2 \right] \\
&+ \mathrm{const.}, && (14)
\end{aligned}$$

where $D_{in} = \sum_j \boldsymbol{x}_{ij} \boldsymbol{x}_{ij}^{\mathsf{H}} / (J \sum_k t_{ikn} v_{kjn})$ and const. denotes terms independent of $\{W_i\}$. It is possible to minimize (14) by iterative projection (IP) [16], as described in [5]. The update rule for the separation filter $\boldsymbol{w}_{in}$ using IP are

$$\boldsymbol{w}_{in} \leftarrow (W_i D_{in})^{-1} \boldsymbol{e}_n, \tag{15}$$

$$\boldsymbol{w}_{in} \leftarrow \frac{\boldsymbol{w}_{in}}{\sqrt{\boldsymbol{w}_{in}^{\mathsf{H}} D_{in} \boldsymbol{w}_{in}}}, \tag{16}$$

where $\boldsymbol{e}_n \in \mathbb{C}^N$ represents a vector whose nth element is one and others are zero. For the NMF variables $\{t_{ikn}\}$ and $\{v_{kjn}\}$, the following update rules have been derived on the basis of the MM algorithm (see details in [5]):

$$t_{ikn} \leftarrow t_{ikn} \sqrt{\frac{\sum_j |y_{ijn}|^2 v_{kjn} (\sum_{k'} t_{ik'n} v_{k'jn})^{-2}}{\sum_j v_{kjn} (\sum_{k'} t_{ik'n} v_{k'jn})^{-1}}}, \tag{17}$$

$$v_{kjn} \leftarrow v_{kjn} \sqrt{\frac{\sum_i |y_{ijn}|^2 t_{ikn} (\sum_{k'} t_{ik'n} v_{k'jn})^{-2}}{\sum_i t_{ikn} (\sum_{k'} t_{ik'n} v_{k'jn})^{-1}}}. \tag{18}$$

The output of ILRMA involves uncertainty at the scale of the separated signals. Therefore, the separated signals are converted into signals at the microphone positions by back-projection [17] as follows:

$$y_{ijn} \leftarrow \boldsymbol{e}_{m_{\mathrm{ref}}}^{\mathsf{H}} W_i^{-1} \boldsymbol{e}_n y_{ijn}, \tag{19}$$

where m_{ref} represents the index of the reference channel. To modify the variables in ILRMA while ensuring that the separated signal becomes (19) and the objective function (13) remains unchanged, we update $\boldsymbol{w}_{in}$ and t_{ikn} as follows:

$$\boldsymbol{w}_{in} \leftarrow \boldsymbol{w}_{in} \lambda_{inm_{\mathrm{ref}}}, \tag{20}$$

$$t_{ikn} \leftarrow t_{ikn} |\lambda_{inm_{\mathrm{ref}}}|^2, \tag{21}$$

where $\lambda_{inm_{\mathrm{ref}}} = \boldsymbol{e}_{m_{\mathrm{ref}}}^{\mathsf{H}} W_i^{-1} \boldsymbol{e}_n$.

B. ILRMA Based on Projection to Consistent Space [7]

Recently, methods that address spectrogram consistency have been proposed [6], [7]. The spectrogram is said to be consistent if and only if the spectrogram is in the image of STFT. Thus, the consistent space, which is spanned by consistent spectrograms, is denoted as $\{\mathcal{F}\tilde{\psi} | \tilde{\psi} \in \mathbb{R}^L\}$. Since the consistent space is the subspace of the entire spectrogram space under $I_{\mathrm{S}} J > L$, applying a naive signal processing in the time-frequency domain to the consistent spectrogram may result in deviation from the consistent space. To measure this deviation, we define the measure

$$\mathcal{E}(\boldsymbol{\Psi}) = \left\| \mathcal{F}\mathcal{F}^{\dagger} \boldsymbol{\Psi} - \boldsymbol{\Psi} \right\|_2^2 \tag{22}$$

for given $\boldsymbol{\Psi} \in \mathbb{C}^{I_S J}$ because $\mathcal{F}\mathcal{F}^{\dagger}$ is the orthogonal projection onto the consistent space. Here, the spectrogram $\boldsymbol{\Psi}$ is consistent if and only if $\mathcal{E}(\boldsymbol{\Psi}) = 0$ holds.

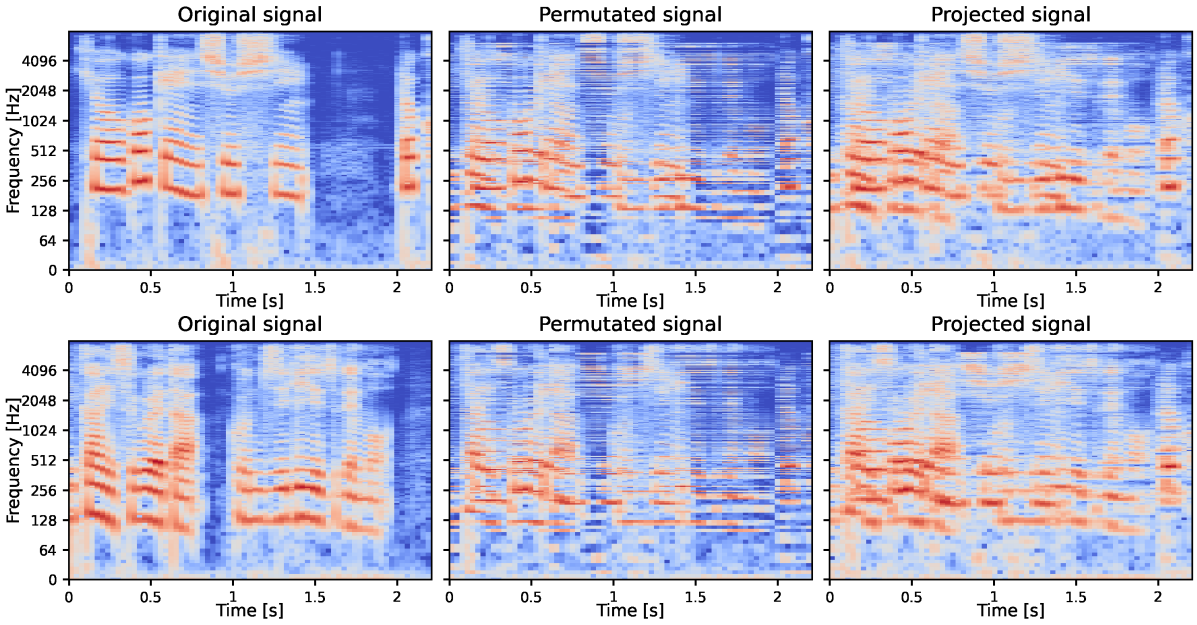

Fig. 1. Spectrograms whose frequency bins are intentionally swapped (middle) from two original spectrograms of speech (left) and projected spectrograms onto spectrogram-consistent space (right).

In ILRMA, it is found that the block permutation may cause a large deviation. When a block permutation occurs in the separated signals obtained by ILRMA, the separated signals projected onto the consistent space may exhibit the phenomenon of bleed-out into adjacent frequency bins in the block-permuted band. As an example, Fig. 1 represents the spectrograms projected onto the consistent space from inconsistent spectrograms obtained by artificially swapping frequency bins for two consistent spectrograms. It is easily seen that the time-frequency structure changes as a result of projection; mutual diffusion occurs in the discontinuous frequency bands. Therefore, independence between sources or low-rank properties of the power spectrograms may be lost upon projecting the block-permuted spectrogram onto the consistent space. To focus on this, in [7], it was hypothesized that block permutation is alleviated by updating parameters to induce low-rankness in the projected separated spectrograms. In detail, this method updates the power spectrogram modeled by NMF so that it becomes close not to Y_n but to $\mathcal{F}\mathcal{F}^{\dagger}Y_n$, where Y_n is the vectorized spectrogram whose $((j-1)I_{\mathrm{S}}+i)$th element is y_{ijn} for each n. The algorithm of ILRMA based on projection to consistent space is outlined in Algorithm 1.

Algorithm 1 Projection-based ILRMA

Initialize $\{W_i\}$, $\{t_{ikn}\}$, and $\{v_{kjn}\}$.
for iter $= 1, \ldots,$ maxIter **do**
  $y_{ij} \leftarrow \boldsymbol{w}_{in}^{\mathsf{H}} \boldsymbol{x}_{ij}$
  $Y_n \leftarrow \mathcal{F}\mathcal{F}^{\dagger}Y_n$
  Update $\{t_{ikn}\}$ and $\{v_{kjn}\}$ using (17) and (18).
  Update $\{W_i\}$ using (15) and (16).
  Execute back-projection (19).
  Update variables using (20) and (21).
end for
return $\{y_{ijn}\}$

IV. Proposed Method

A. Motivation and Approach

The conventional method described in Section III-B is unfortunately a heuristic method that has not been rigorously formulated as an optimization problem. Moreover, since it only discusses the projected separated signals, it does not address how far the original separated signals are from the consistent space.

In this work, we aim to construct an optimization problem that induces the separated signals to be consistent by designing a regularization term based on the deviation from the consistent space. First, we design a regularization term related to the separation filters W_i from the deviation measure $\mathcal{E}(Y_n)$ and take it into account in the optimization problem. We find out that this new optimization problem is difficult to solve using conventional optimization methods. Therefore, on the basis of the MM algorithm, we design an auxiliary function to which VCD [15] can be applied, and derive a new update rule.

B. Designing the Regularization Term for Consistency

In this section, we define a regularization term inducing consistency for W_i, which consists of the separated spectrogram $\boldsymbol{y}_{ij}$ shown by (8).

For the separation filter W_i, we denote $\vec{\boldsymbol{w}}_{nm} = (w_{1nm}^*, \ldots, w_{I_{\mathrm{S}}nm}^*)^{\mathsf{T}}$, $\mathcal{W}_{nm} = \mathrm{diag}(\vec{\boldsymbol{w}}_{nm})$, and let $\tilde{x}_m$ be the time-domain signal of the mth observed signal, where * denotes the complex conjugate. The jth frame of the

separated signal corresponding to the nth source is given by $(y_{1jn},\dots,y_{I_{\mathrm{S}}jn})^{\mathsf{T}} = \sum_m \mathcal{W}_{nm}F\Delta_j\tilde{\boldsymbol{x}}_m$. From (5) and (7), we deform the deviation of the separated spectrogram from the consistent space as

$$\sum_n \mathcal{E}(Y_n) = \sum_{n,j}\Big\| \sum_m (F\Delta_j\Phi_{nm} - \mathcal{W}_{nm}F\Delta_j)\tilde{\boldsymbol{x}}_m \Big\|_2^2, \quad (23)$$

where $\Phi_{nm} = \big(\mathcal{F}^{\mathsf{H}}\mathcal{F}\big)^{-1}\Big(\sum_{j'}\Delta_{j'}^{\mathsf{H}}F^{\mathsf{H}}\mathcal{W}_{nm}F\Delta_{j'}\Big)$.

To induce consistency for arbitrary observed signals, we consider the case where $\tilde{\boldsymbol{x}}_m$ is a white Gaussian signal and the expectation of (23) is calculated as

$$\mathbb{E}\Big[\sum_n \mathcal{E}(Y_n)\Big] = \sum_{n,m,j}\|F\Delta_j\Phi_{nm} - \mathcal{W}_{nm}F\Delta_j\|_{\mathrm{F}}^2. \quad (24)$$

We use this expression as the regularization term $\mathcal{C}(W_i)$ and deform it as follows:

$$\begin{aligned}\mathcal{C}(W_i) =& \sum_{n,m}\Big\|\Big(\sum_j \Delta_j\Delta_j^{\mathsf{H}}\Big)^{\frac{1}{2}}U_{nm}\Big\|_{\mathrm{F}}^2 \\ &- \sum_{n,m}\Big\|\Big(\sum_j \Delta_j^{\mathsf{H}}\Delta_j\Big)^{-\frac{1}{2}}\Big(\sum_j \Delta_j^{\mathsf{H}}U_{nm}\Delta_j\Big)\Big\|_{\mathrm{F}}^2, \quad (25)\end{aligned}$$

where we define $U_{nm} = F^{\mathsf{H}}\mathcal{W}_{nm}F$. Because of the Fourier transform on a diagonal matrix, U_{nm} becomes a circulant Toeplitz matrix, which is formed by cyclically shifting its first column vector $\boldsymbol{u}_{nm}$. Note that there exists the following relationship between $\boldsymbol{u}_{nm}$ and $\vec{\boldsymbol{w}}_{nm}$:

$$\boldsymbol{u}_{nm} = \frac{1}{\sqrt{I_{\mathrm{S}}}}F^{\mathsf{H}}\vec{\boldsymbol{w}}_{nm}. \quad (26)$$

Now, let us define $\breve{U}_{nm} = \mathrm{diag}(\boldsymbol{h})^{\mathsf{H}}U_{nm}\mathrm{diag}(\boldsymbol{h})$, $\mathcal{I}(l) = \big\{j\big|-L^{(\mathrm{pre})} < l-\tau(j-1) \le I_{\mathrm{S}} - L^{(\mathrm{pre})}\big\}$, and $\sigma(l,j) = l - \tau(j-1) + L^{(\mathrm{pre})}$. Then, we have

$$\Big[\sum_j \Delta_j^{\mathsf{H}}\Delta_j\Big]_{ll'} = \begin{cases}\sum_{j\in\mathcal{I}(l)}[\boldsymbol{h}]_{\sigma(l,j)}^2 & \text{if } l=l' \\ 0 & \text{otherwise}\end{cases}, \quad (27)$$

$$\Big[\sum_j \Delta_j^{\mathsf{H}}U_{nm}\Delta_j\Big]_{ll'} = \sum_{j\in\mathcal{I}(l)\cap\mathcal{I}(l')}\Big[\breve{U}_{nm}\Big]_{\sigma(l,j),\sigma(l',j)}, \quad (28)$$

where $[\cdot]_{qq'}$ denotes the (q,q')th component of the matrix. According to (27) and (28), the second term of (25) becomes

$$\begin{aligned}&\sum_{n,m}\Big\|\Big(\sum_j \Delta_j^{\mathsf{H}}\Delta_j\Big)^{-\frac{1}{2}}\Big(\sum_j \Delta_j^{\mathsf{H}}U_{nm}\Delta_j\Big)\Big\|_{\mathrm{F}}^2 \\ &= \sum_{n,m,l,l'}\frac{\Big(\sum_{j\in\mathcal{I}(l)\cap\mathcal{I}(l')}\Big[\breve{U}_{nm}\Big]_{\sigma(l,j),\sigma(l',j)}\Big)^2}{\sum_{j\in\mathcal{I}(l)}[\boldsymbol{h}]_{\sigma(l,j)}^2}. \quad (29)\end{aligned}$$

In accordance with the definition of $\breve{U}_{nm}$, (29) becomes a quadratic form with respect to $\boldsymbol{u}_{nm}$, expressed as $\sum_{n,m}\boldsymbol{u}_{nm}^{\mathsf{H}}\breve{G}\boldsymbol{u}_{nm}$. In this case, the weight matrix $\breve{G}$ is diagonal and independent of n and m. The ith diagonal element of $\breve{G}$ is given by

$$\sum_l \sum_{l'\in\{l-i+1,l+I_{\mathrm{S}}-i+1\}}\frac{\Big(\sum_{j\in\mathcal{I}(l)\cap\mathcal{I}(l')}[\boldsymbol{h}]_{\sigma(l,j)}[\boldsymbol{h}]_{\sigma(l',j)}\Big)^2}{\sum_{j\in\mathcal{I}(l)}[\boldsymbol{h}]_{\sigma(l,j)}^2}. \quad (30)$$

Additionally, in the first term of (25), since $\sum_j \Delta_j\Delta_j^{\mathsf{H}}$ is a diagonal matrix and U_{nm} is the circulant Toeplitz, the following equation holds:

$$\sum_{n,m}\Big\|\Big(\sum_j \Delta_j\Delta_j^{\mathsf{H}}\Big)^{\frac{1}{2}}U_{nm}\Big\|_{\mathrm{F}}^2 = \sum_{n,m,l}\sum_{j\in\mathcal{I}(l)}[\boldsymbol{h}]_{\sigma(l,j)}^2\|\boldsymbol{u}_{nm}\|_2^2. \quad (31)$$

Thus, we obtain

$$\mathcal{C}(W_i) = \sum_{n,m}\boldsymbol{u}_{nm}^{\mathsf{H}}\bar{G}\boldsymbol{u}_{nm}, \quad (32)$$

where $\bar{G} = \Big(\sum_l\sum_{j\in\mathcal{I}(l)}[\boldsymbol{h}]_{\sigma(l,j)}^2\Big)E_{I_{\mathrm{S}}} - \breve{G}$. Consequently, from (26), the consistency regularization term is deformed to be a quadratic form of $\vec{\boldsymbol{w}}_{nm}$:

$$\mathcal{C}(W_i) = \frac{1}{I_{\mathrm{S}}}\sum_{n,m}\vec{\boldsymbol{w}}_{nm}^{\mathsf{H}}\big(F\bar{G}F^{\mathsf{H}}\big)\vec{\boldsymbol{w}}_{nm}. \quad (33)$$

In the following, we use $G = F\bar{G}F^{\mathsf{H}}/I_{\mathrm{S}}$.

C. Formulation of the Optimization Problem and Derivation of the Update Rule

For updating the NMF variables $\{t_{ikn}\},\{v_{kjn}\}$, since the regularization term is independent of the NMF variables, the updates are performed using (17) and (18) in the same manner as in ILRMA. Therefore, we hereafter discuss the optimization problem with respect to W_i. We formulate the objective function in ILRMA with the consistency regularization term (33) as follows:

$$\begin{aligned}\hat{\mathcal{J}}(W_i) =& J\sum_{i=1}^{I_{\mathrm{N}}}\Big[\sum_n \boldsymbol{w}_{in}^{\mathsf{H}}D_{in}\boldsymbol{w}_{in} - \log|\det W_i|^2\Big] \\ &+ \gamma\sum_{n,m}\vec{\boldsymbol{w}}_{nm}^{\mathsf{H}}G\vec{\boldsymbol{w}}_{nm} + \mathrm{const.}, \quad (34)\end{aligned}$$

where $\gamma > 0$ represents the weight of the regularization term and const. is the term independent of $\{W_i\}$. Here, we define $\tilde{i}$ by $I_{\mathrm{S}}+2-i$ for $2 < i < I_{\mathrm{N}}$, which is frequency bin folding by the Nyquist frequency. It is important that w_{inm} and $w_{\tilde{i}nm}$ have a complex conjugate relationship. With this in mind, (34) can be rewritten for $\boldsymbol{w}_{in}$ at a certain frequency i as follows:

$$\begin{aligned}\hat{\mathcal{J}}(W_i) =& J\Big[\sum_n \boldsymbol{w}_{in}^{\mathsf{H}}D_{in}\boldsymbol{w}_{in} - \log|\det W_i|^2\Big] \\ &+ \gamma\sum_{n,m}\Bigg(\begin{pmatrix}w_{inm}\\ w_{inm}^*\end{pmatrix}^{\mathsf{H}}\hat{G}_i\begin{pmatrix}w_{inm}\\ w_{inm}^*\end{pmatrix} \\ &\quad + \begin{pmatrix}w_{inm}\\ w_{inm}^*\end{pmatrix}^{\mathsf{H}}\boldsymbol{b}_{inm} + \boldsymbol{b}_{inm}^{\mathsf{H}}\begin{pmatrix}w_{inm}\\ w_{inm}^*\end{pmatrix}\Bigg) \\ &+ \mathrm{const.}, \quad (35)\end{aligned}$$

where const. is a term that is independent of $\boldsymbol{w}_{in}$ and $\boldsymbol{w}_{\tilde{i}n} = \boldsymbol{w}_{in}^*$, and we define

$$\hat{G}_i = \begin{pmatrix} [G]_{\tilde{i}\tilde{i}} & [G]_{\tilde{i}i} \\ [G]_{i\tilde{i}} & [G]_{ii} \end{pmatrix}, \tag{36}$$

$$\boldsymbol{b}_{inm} = \begin{pmatrix} \sum_{i' \neq i,\tilde{i}} [G]_{i'i} w_{i'nm} \\ \sum_{i' \neq i,\tilde{i}} [G]_{ii'} w_{i'nm}^* \end{pmatrix}. \tag{37}$$

Regarding the quadratic form of the second term in (35), the off-diagonal elements of the coefficient matrix cause w_{inm}^2 and $(w_{inm}^*)^2$ terms to appear, making it difficult to directly apply conventional IP [16] or VCD [15]. If we can bound the second term of (35) by a quadratic function with a diagonal coefficient matrix for the MM algorithm, it becomes possible to apply VCD. To achieve this, we use the following Claim 1 for designing an auxiliary function.

Claim 1: For any $\boldsymbol{w} \in \mathbb{C}^q$ and $\boldsymbol{\alpha} \in \mathbb{C}^q$ and any positive semidefinite Hermitian matrix $\hat{G} \in \mathbb{C}^{q \times q}$, we have

$$\begin{aligned} \boldsymbol{w}^{\mathsf{H}} \hat{G} \boldsymbol{w} \leq & \boldsymbol{w}^{\mathsf{H}} \hat{G}^{+} \boldsymbol{w} - \boldsymbol{\alpha}^{\mathsf{H}} \Big(\hat{G}^{+} - \hat{G} \Big) \boldsymbol{w} - \boldsymbol{w}^{\mathsf{H}} \Big(\hat{G}^{+} - \hat{G} \Big) \boldsymbol{\alpha} \\ & + \boldsymbol{\alpha}^{\mathsf{H}} \Big(\hat{G}^{+} - \hat{G} \Big) \boldsymbol{\alpha}, \end{aligned} \tag{38}$$

where $\hat{G}^{+}$ is a positive semidefinite Hermitian matrix satisfying $\hat{G}^{+} - \hat{G} \succeq O$. Equality holds when $\boldsymbol{\alpha} = \boldsymbol{w}$.

Proof: Since $\hat{G}^{+} - \hat{G} \succeq O$, for any $\boldsymbol{w} \in \mathbb{C}^q$ and $\boldsymbol{\alpha} \in \mathbb{C}^q$,

$$(\boldsymbol{w} - \boldsymbol{\alpha})^{\mathsf{H}} (\hat{G}^{+} - \hat{G})(\boldsymbol{w} - \boldsymbol{\alpha}) \geq 0 \tag{39}$$

always holds. Therefore, by expanding and rearranging (39), we obtain the desired inequality (38). Equality holds in (38) when equality holds in (39), i.e., when $\boldsymbol{\alpha} = \boldsymbol{w}$. ■

In Claim 1, we set $\boldsymbol{w} = (w_{inm}, w_{inm}^*)^{\mathsf{T}}$, $\boldsymbol{\alpha} = (\alpha_{inm}, \alpha_{inm}^*)^{\mathsf{T}}$, $\hat{G} = \hat{G}_i$, and $\hat{G}^{+} = \hat{G}_i^{+}$. To find a weight matrix $\hat{G}_i^{+}$ such that the auxiliary function becomes close to the original function and has a diagonal structure, we consider the following optimization problem for $\hat{G}_i^{+}$:

$$\begin{aligned} \min_{\hat{G}_i^{+}} \quad & \mathrm{tr}\Big(\hat{G}_i^{+} - \hat{G}_i \Big) \\ \text{s.t.} \quad & \hat{G}_i^{+} - \hat{G}_i \succeq O \\ & \hat{G}_i^{+} \text{ is diagonal.} \end{aligned} \tag{40}$$

Solving (40) yields $\hat{G}_i^{+} = \mathrm{diag}((|[G]_{\tilde{i}\tilde{i}}| + |[G]_{\tilde{i}i}|, |[G]_{ii}| + |[G]_{i\tilde{i}}|)^{\mathsf{T}})$.

By applying Claim 1 to (35) using $\hat{G}_i^{+}$, we obtain the auxiliary function of the objective function as

$$\begin{aligned} \hat{\mathcal{J}}^{+}(W_i) = & J \Big[\boldsymbol{w}_{in}^{\mathsf{H}} \mathcal{D}_{in} \boldsymbol{w}_{in} + \boldsymbol{w}_{in}^{\mathsf{H}} \tilde{\boldsymbol{b}}_{in} + \tilde{\boldsymbol{b}}_{in}^{\mathsf{H}} \boldsymbol{w}_{in} - \log |\det W_i|^2 \Big] \\ & + \text{const.}, \end{aligned} \tag{41}$$

where const. is a term independent of $\boldsymbol{w}_{in}$ and

$$\mathcal{D}_{in} = D_{in} + 2\frac{\gamma}{J}(|[G]_{\tilde{i}\tilde{i}}| + |[G]_{\tilde{i}i}|) E_M, \tag{42}$$

$$\Big[\tilde{\boldsymbol{b}}_{in} \Big]_m = 2\frac{\gamma}{J} \Big([\boldsymbol{b}_{inm}]_1 - |[G]_{i\tilde{i}}| \alpha_{inm} + [G]_{\tilde{i}i} \alpha_{inm}^* \Big). \tag{43}$$

Equality holds when $\alpha_{inm} = w_{inm}$.

Algorithm 2 Proposed method

1: Initialize $\{W_i\}$, $\{t_{ikn}\}$, and $\{v_{kjn}\}$
2: **for** iter $= 1, \ldots,$ maxIter **do**
3: Update $\{\sigma_{izn}\}$ and $\{\nu_{zjn}\}$ using (17) and (18)
4: Update the auxiliary variables by $\alpha_{inm} \leftarrow w_{inm}$
5: Update $\{W_i\}$ using (44)-(48)
6: **end for**
7: Perform back-projection using (19)
8: **return** $\{y_{ijn}\}$

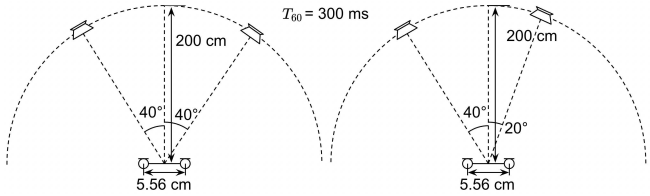

Fig. 2. Recording conditions of impulse response.

In (41), since there is no term related to w_{inm}^2 or $(w_{inm}^*)^2$, VCD can be used to obtain the following update rule:

$$\boldsymbol{\zeta}_{in} \leftarrow (W_i \mathcal{D}_{in})^{-1} \boldsymbol{e}_n, \tag{44}$$

$$\hat{\boldsymbol{\zeta}}_{in} \leftarrow \mathcal{D}_{in}^{-1} \tilde{\boldsymbol{b}}_{in}, \tag{45}$$

$$\chi_{in} \leftarrow \boldsymbol{\zeta}_{in}^{\mathsf{H}} \mathcal{D}_{in} \boldsymbol{\zeta}_{in}, \tag{46}$$

$$\hat{\chi}_{in} \leftarrow \boldsymbol{\zeta}_{in}^{\mathsf{H}} \mathcal{D}_{in} \hat{\boldsymbol{\zeta}}_{in}, \tag{47}$$

$$\boldsymbol{w}_{in} \leftarrow \begin{cases} \frac{\boldsymbol{\zeta}_{in}}{\sqrt{\chi_{in}}} - \hat{\boldsymbol{\zeta}}_{in}, & \text{if } \hat{\chi}_{in} = 0 \\ \frac{\hat{\chi}_{in}}{2\chi_{in}} \Big(1 - \sqrt{1 + \frac{4\chi_{in}}{|\hat{\chi}_{in}|^2}} \Big) \boldsymbol{\zeta}_{in} - \hat{\boldsymbol{\zeta}}_{in}. & \text{otherwise} \end{cases} \tag{48}$$

This update rule guarantees the monotonic nonincrease of the objective function.

The algorithm of the proposed method is outlined in Algorithm 2.

V. Experiment

A. Experimental Conditions

To verify the performance of the proposed method, we conducted a simulated experiment using stereo signals. The dry sources were taken from the JNAS speech corpus [18] and convolved by impulse responses under two recording conditions, as shown in Fig. 2. We used six combinations of mixture: Two mixtures are created for each combination of (male, female), (male, male), and (female, female). The sampling frequency was set to 16 kHz, and we used a 128 ms Hamming window with a 64 ms shift in STFT.

For comparison, we used ILRMA (naive ILRMA) [5], ILRMA based on projection to consistent space (projection-based ILRMA) [7], and the proposed method. In the proposed method, we used $\gamma = 0.01$, 0.1, 1, 10, and 100 as the regularization weights. We set the initial value of the separation matrix W_i in naive ILRMA as Ξ_i^{H}, where we denote $(\rho_{i1}, \ldots, \rho_{iM}) \in \mathbb{R}^M$ and $\Xi_i \in \mathbb{C}^{M \times M}$ as the eigenvalues

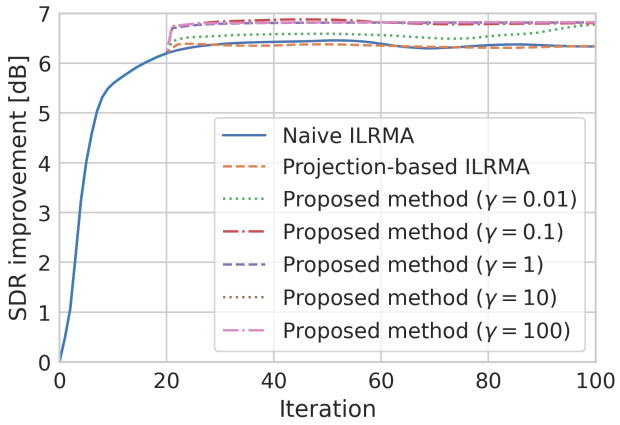

Fig. 3. Behavior of SDR improvement [dB] for each iteration.

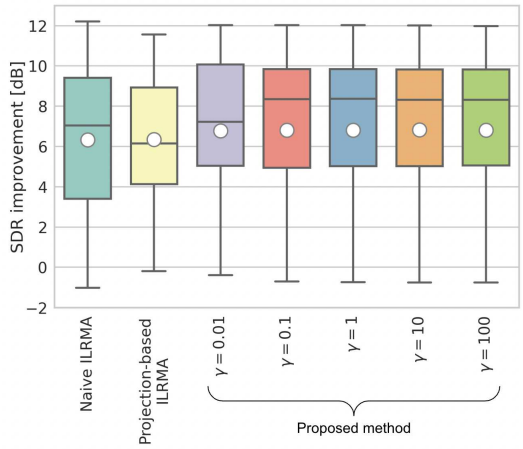

Fig. 4. Box plot of SDR improvement [dB] after 100 iterations for each method. Boxes represent quartiles of SDR improvement's distributions and circles denote averages of SDR improvements.

and the orthonormal matrix composed of the corresponding eigenvectors of the empirical spatial covariance matrix of the observed signals $\sum_j \boldsymbol{x}_{ij}\boldsymbol{x}_{ij}^{\mathsf{H}}/J$, respectively. The initial values of the basis t_{ikn} and the activation v_{kjn} in NMF were uniformly distributed random numbers on the intervals $[0.1 * \rho_{in}, \rho_{in}]$ and $[0.1, 1.0]$, respectively. For ILRMA, ten different random seeds were prepared for each condition. We conducted experiments under $6 \times 2 \times 10 = 120$ conditions. The number of iterations in naive ILRMA was 100. In projection-based ILRMA and the proposed method, the separation matrix and NMF variables were each taken from the 20-iteration point of ILRMA, and an additional 80 iterations were performed.

Throughout this experiment, we used the source-to-distortion ratio (SDR) improvement [19] as the performance metric for source separation.

B. Result

Fig. 3 shows the average SDR improvement for each iteration. In Fig. 3, naive ILRMA and projection-based ILRMA showed similar performances. The proposed method exhibited an improved performance from that of the ILRMA-initialized value with $\gamma = 0.01$ and achieved a 0.5 dB improvement in one iteration when γ was 0.1 or higher. The box plot of the SDR improvement after 100 iterations is shown in Fig. 4. Fig. 4 shows that the proposed method exhibited improved performances in the first and third quartiles compared with naive ILRMA. The median performance of the proposed method when γ was 0.1 or higher remained almost unchanged and was higher than those of naive ILRMA and projection-based ILRMA. Fig. 5 shows the SDR improvements of projection-based ILRMA and the proposed method with $\gamma = 100$ against that of naive ILRMA. In Fig. 5, projection-based ILRMA and the proposed method showed higher performance under most cases in the low-performance region of naive ILRMA, between 0 dB and 1 dB. On the other hand, in regions where the performance of naive ILRMA was 5 dB or higher, there were instances where the performance of projection-based ILRMA was both better and worse than that of naive ILRMA. However, the proposed method stably showed higher performance than that of naive ILRMA. In particular, when the performance of naive ILRMA was 7 dB or higher, the proposed method often achieved performances above 11 dB.

VI. Conclusion

The conventional method has been proposed to focus on spectrogram consistency in the separated spectrogram in order to address the block permutation problem in ILRMA. This method updates its variables so that the power spectrogram modeled by NMF becomes close to the projection of the separated spectrogram onto the consistent space instead of the original separated spectrogram. Unfortunately, the conventional method is not rigorously formulated as an optimization problem. In this study, we aimed to formulate an optimization problem by designing a regularization term that induces consistency in the separated spectrogram itself. On the basis of the MM algorithm, we derived the monotonic nonincreasing update rule of W_i by designing an auxiliary function to which VCD can be applied, because it is difficult to directly optimize the new objective function added to the regularization term by traditional IP or VCD. The effectiveness of the proposed method was confirmed through the simulated experiment.

***Abstract*—In this paper, we propose Multiple Geometrically Constrained Auxiliary function-based Independent Vector Analysis with Iterative Source Steering (MGC-AuxIVA-ISS), an offline geometrically constrained source separation method that removes the moving interference signal. GC-AuxIVA is a method that combines AuxIVA, a Blind Source Separation method, with geometrical constraints so that it achieves high separation performance while obtaining the target speech at the desired output channel. Online processing for GC-AuxIVA has also been proposed and can handle the movement of sound sources. However, it requires the exact positions of the target and interference sound sources for each time frame to make an accurate geometrical constraint. On the other hand, it is relatively easier to obtain a range of the moving speaker. Thus, we propose overdetermined offline-GC-AuxIVA to remove the range of the moving speaker by providing multiple geometrical constraints. We conducted simulation experiments to confirm that the proposed method can remove the interference signal by giving geometrical constraints at equal intervals in the range of the movement.**

I. Introduction

In recent years, speech processing applications have become widespread. However, there is a problem in that the speech quality is decreased by diffuse noises and directional interferences. Therefore, there is a need for techniques that can extract the target speech from the recorded speech mixture. One of the useful techniques to enhance the target speech is Blind Source Separation (BSS), which estimates individual source signals from microphone-observed signals without such prior information as training data [1]. BSS methods for the determined condition (where the number of sound sources is equal to the number of microphones) include Independent Component Analysis (ICA) [2], which estimates a demixing matrix that maximizes the independence between source signals, Independent Vector Analysis (IVA) [3], [4], which solves both the source separation problem and the frequency permutation problem by modeling the entire frequency components as multivariate variables following spherical multivariate distribution, and Auxiliary function-based IVA (AuxIVA) [5], which is more stable and fast update rule using the auxiliary function method. However, they do not uniquely determine the output order of the separated signals, which we call global permutation problem.

Geometrically Constrained ICA (GC-ICA) and its extensions have been proposed to solve the global permutation problem simultaneously and the source separation problem [6], [7], [8], [9], [10], [11]. They can guide the demixing matrix to obtain a signal from a desired direction by exploiting spatial information such as the Direction of Arrival (DOA) of the signals and the microphone positions. Among them, Geometrically Constrained Auxiliary function-based IVA with Iterative Source Steering (GC-AuxIVA-ISS) [11] solves the global permutation problem and achieves better stability and faster update through an update algorithm using Iterative Source Steering (ISS) [12] without requiring inverse matrix operations. Its extension to online processing has also been developed to separate signals in real-time (which we call online-GC-AuxIVA-ISS [13]).

This paper focuses on the problem when applying GC-AuxIVA-ISS to moving source separation. One way to remove the moving interference signal is to estimate a time-variant demixing matrix that removes the interference signals according to the interference sound sources' position. There are several online source separation methods [8], [14], [15], and online-GC-AuxIVA-ISS [13] can estimate time-variant demixing matrix recursively. However, when the interference source moves quickly, it is difficult to remove the interference signal in real time because we obtain less spatial information about the interference signal than when the interference is fixed. Also, in online-GC-AuxIVA-ISS, we require time-variant spatial information for geometric constraints because the position of the interference source is changing. However, it is difficult to know the exact position of the interference source in a real environment. Although previous research has proposed a method that estimates spatial information from the current demixing matrix, preliminary experiments have confirmed that its source separation performance is limited when the sound source moves quickly.

Although it is difficult to obtain the positional information of the moving sound source at each time, it is relatively easy to obtain information on its range. Therefore, we propose a source separation method that removes the signal in the range of the interference source's movement. In concrete, we assume offline processing and an overdetermined condition where the number of microphones is more than the number of sources. Then we add several geometric constraints to guide the demixing matrix to remove the range of the interference source movement. We call this method Multiple GCAuxIVA-ISS (MGC-AuxIVA-ISS) and evaluate its effectiveness using

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

a simulation experiment. As a result, it can be expected to remove the interference signal without giving information on how the interference sound moves at each time.

II. Problem formulation

We consider a determined or an overdetermined situation where J sound source signals are mixed and captured by I ($\geq J$) microphones. The Short-Time Fourier Transform (STFT) coefficients of the j-th estimated source and i-th microphone signals are denoted by

$$\boldsymbol{y}_{fn} = [y_{1fn}, \ldots, y_{Jfn}]^{\mathsf{T}} \in \mathbb{C}^J, \tag{1}$$

$$\boldsymbol{x}_{fn} = [x_{1fn}, \ldots, x_{Ifn}]^{\mathsf{T}} \in \mathbb{C}^I. \tag{2}$$

Here, $f = 1, \ldots, F$ and $n = 1, \ldots, N$ are the indices of the frequency and frame, respectively and $(\cdot)^{\mathsf{T}}$ denotes the transpose.

We consider an instantaneous mixture model in the time-frequency domain where the STFT window length is sufficiently longer than the impulse response between the sound source and microphones. Then, the relationship between the observed signals $\boldsymbol{x}_{fn}$ and estimated sources $\boldsymbol{y}_{fn}$ can be expressed as

$$\boldsymbol{y}_{fn} = \boldsymbol{W}_{fn}\boldsymbol{x}_{fn}, \tag{3}$$

where, $\boldsymbol{W}_{fn} = [\boldsymbol{w}_{1fn}, \ldots, \boldsymbol{w}_{Jfn}]^{\mathsf{H}}$ is a time-variant demixing matrix containing demixing filters $\boldsymbol{w}_{jfn} \in \mathbb{C}^I$, and $(\cdot)^{\mathsf{H}}$ denotes the Hermitian transpose. Our goal is to estimate the source signal $\boldsymbol{y}_{fn} = [y_{1fn}, \ldots, y_{Jfn}]^{\mathsf{T}}$ and solve the global permutation problem.

III. Conventional method

In this section, we introduce two conventional methods: Offline-GC-AuxIVA-ISS and Online-GC-AuxIVA-ISS. Then, we describe the drawback of the conventional methods in Section III-C.

A. Offline-GC-AuxIVA-ISS [11]

Offline-GC-AuxIVA estimates an time-invariant demixing matrix $\boldsymbol{W}_f = [\boldsymbol{w}_{1f}, \ldots, \boldsymbol{w}_{Jf}]^{\mathsf{H}}$. The demixing matrix $\mathcal{W} = \{\boldsymbol{W}_f\}_f$ can be estimated by minimizing the following negative log-likelihood function:

$$\mathcal{L}_{\text{IVA}}(\mathcal{W}) = \sum_{j=1}^{I} \mathbb{E}[G(\boldsymbol{y}_{jn})] - \sum_{f=1}^{F} \log|\det \boldsymbol{W}_f|, \tag{4}$$

where $\mathbb{E}[\cdot]$ denotes the expectation operator and $\boldsymbol{y}_{jn}$ is the vector representation of the estimated sources:

$$\boldsymbol{y}_{jn} = [y_{j1n}, \ldots, y_{jFn}]^{\mathsf{T}} \in \mathbb{C}^F. \tag{5}$$

Here, $G(\boldsymbol{y}_{jn}) = -\log p(\boldsymbol{y}_{jn})$ is the contrast function where $p(\boldsymbol{y}_{jn})$ represents a multivariate probability density function at the j-th source. One typical choice of the contrast function is to use a spherical contract function [3], [4], [5], which is expressed as

$$G(\boldsymbol{y}_{jn}) = G_R(r_{jn}), \tag{6}$$

$$r_{jn} = ||\boldsymbol{y}_{jn}||_2 = \sqrt{\sum_f |y_{jfn}|^2} = \sqrt{\sum_f |\boldsymbol{w}_{jf}^{\mathsf{H}}\boldsymbol{x}_{fn}|^2}. \tag{7}$$

Here, $G_R(r)$ is a function of a real-valued scalar variable r, and $||\cdot||_2$ denotes the L_2 norm of a vector. Adopting the auxiliary function approach [5], the following equation is optimized instead of (4):

$$\begin{aligned}\mathcal{L}_{\text{IVA}}(\mathcal{W}) &\leq \mathcal{L}_{\text{AuxIVA}}(\Sigma, \mathcal{W}) \\ &= \frac{1}{2}\sum_{f=1}^{F}\sum_{j=1}^{J} \boldsymbol{w}_{jf}^{\mathsf{H}}\boldsymbol{\Sigma}_{jf}\boldsymbol{w}_{jf} - \sum_{f=1}^{F}\log|\det \boldsymbol{W}_f|,\end{aligned} \tag{8}$$

where $\Sigma = \{\boldsymbol{\Sigma}_{jf}\}_{jf}$ is the weighted spatial covariance matrix calculated as

$$\boldsymbol{\Sigma}_{jf} = \sum_n \varphi(r_{jn})\boldsymbol{x}_{fn}\boldsymbol{x}_{fn}^{\mathsf{H}}. \tag{9}$$

Here, $\varphi(r_{jn}) = G_R^{'}(r_{jn})/r_{jn}$ and $(\cdot)'$ denotes the derivative operator.

To avoid the global permutation problem, GC-AuxIVA-ISS uses geometric constraints [6] that controls the j-th demixing filter to respond a value $c_{j\theta}$ toward θ direction. The regularization term of the geometric constraint is expressed as

$$\mathcal{L}_{\text{GC}}(\mathcal{W}) = \sum_{f=1}^{F}\sum_{j=1}^{J}\sum_{\theta\in\Theta} \lambda_{j\theta}|\boldsymbol{w}_{jf}^{\mathsf{H}}\boldsymbol{d}_{f\theta} - c_{j\theta}|^2. \tag{10}$$

Here, $\Theta = \{\theta\}$ represents a set including all directions to be considered, $\boldsymbol{d}_{f\theta}$ is a steering vector pointing to the direction θ, $c_{j\theta}$ is a nonnegative value set for all frequency bins as constraints, and $\lambda_{j\theta} \geq 0$ is a parameter that weighs the importance of the constraint. When $c_{j\theta} = 1$, the jth demixing filter $\boldsymbol{w}_{jf}$ is guided to preserve the signals arriving from the θ direction. On the other hand, when the value of $c_{j\theta}$ is close to 0, the jth demixing filter $\boldsymbol{w}_{jf}$ is forced to create a spatial null to the θ direction. Thus, the objective function to be optimized in GC-AuxIVA is given by combining (8) and (10):

$$\mathcal{L}(\Sigma, \mathcal{W}) = \mathcal{L}_{\text{AuxIVA}}(\Sigma, \mathcal{W}) + \mathcal{L}_{\text{GC}}(\mathcal{W}). \tag{11}$$

Because there is no closed update rule to minimize the objective function in (11), GC-AuxIVA-ISS uses update an iterative update algorithm, ISS [11], [12]. In ISS, the demixing matrix is updated using the auxiliary variable $\boldsymbol{v}_{jf} = [v_{1jf}, \ldots, v_{Ijf}]^{\mathsf{T}} \in \mathbb{C}^I$ as follows:

$$\boldsymbol{W}_f \leftarrow \boldsymbol{W}_f - \boldsymbol{v}_{jf}\boldsymbol{w}_{jf}^{\mathsf{H}}. \tag{12}$$

Substituting (12) into the objective function in (11), we have a new objective function to be minimized. Then, we can obtain the update rule of the variable $\boldsymbol{v}_{jf}$ by calculating the partial derivative of the function and equating it to zero. Since the detailed update rule has been discussed in [11] and is not directly related to our main discussion, we skip explaining it.

B. Online-GC-AuxIVA-ISS [13]

Online-GC-AuxIVA-ISS uses time-variant demixing matrices $\boldsymbol{W}_{fn}$ and estimates the matrices in each time frame n.

In offline-GC-AuxIVA-ISS, spatial covariance matrix $\boldsymbol{\Sigma}_{jf}$ is calculated using all time frames of the observed signal. On the other hand in online-GC-AuxIVA-ISS, the spatial covariance matrix is updated in an autoregressive manner:

$$\boldsymbol{\Sigma}_{jfn} = \alpha \boldsymbol{\Sigma}_{jf(n-1)} + (1-\alpha)\varphi(r_{jn})\boldsymbol{x}_{fn}\boldsymbol{x}_{fn}^{\mathsf{H}}. \quad (13)$$

Here, $0 < \alpha < 1$ denotes a forgetting factor. The ISS update can be straightforwardly applied to online-GC-AuxIVA by replacing the update rule of the covariance matrices with (13). The detailed update rule of online-GC-AuxIVA-ISS is also written in [13].

We also need to consider how to model the geometrical constraints in online processing. In this paper, we use the following time-variant GC term for online-GC-AuxIVA-ISS:

$$\mathcal{L}_{\mathrm{GC}}(\boldsymbol{W}_{fn}) = \sum_{f=1}^{F}\sum_{j=1}^{J}\sum_{\theta_n \in \Theta_n} \lambda_{j\theta_n} |\boldsymbol{w}_{jfn}^{\mathsf{H}} \boldsymbol{d}_{f\theta_n} - c_{j\theta_n}|^2. \quad (14)$$

As discussed in the previous research [13], we obtain the steering vector $\boldsymbol{d}_{f\theta_n}$ in each frame n using a DOA estimation method, multiple signal classification (MUSIC) [16]. MUSIC is a subspace-based method that decomposes the spatial covariance matrix of the observed multichannel signals to obtain subspaces of signals and noise that are orthogonal to each other. The operation of MUSIC in this system is described in [13], [17]. We used [18] for implementing the MUSIC method.

C. Drawback of the conventional method in moving source separation

Let us consider a situation of the moving source separation where one interference source is moving as shown in Fig. 1. In this case, offline-GC-AuxIVA-ISS described in Section III-A estimates a time-invariant demixing filter using the signals of all time frames, and thus cannot follow changes in the environment such as the movement of sound source.

On the other hand, online-GC-AuxIVA-ISS estimates a time-variant demixing matrix using only the observed signals up to the present frame. Therefore, it can handle the movement of sound sources. However, when the interference source moves quickly, it is difficult to remove the interference signal in real time because we obtain less spatial information about the interference signal than when the interference is fixed. Moreover, it is not necessarily easy to prepare the accurate direction θ_n in each time frame n to provide geometrical constraints. Although there is a research to estimate the DOAs for online-GC-AuxIVA-ISS, the accuracy of the DOA estimation is limited because the estimation is conducted by using the observed mixture signals up to the present.

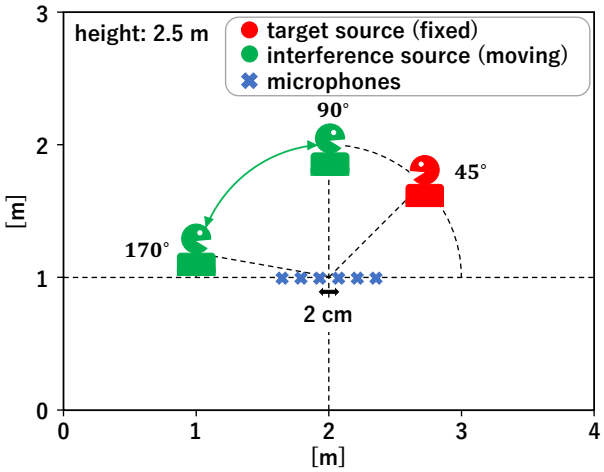

Fig. 1: Layout of a situation of the moving sourece separation. The target speaker is at 45°. The interference speaker moves on an arc from 90° to 170° for the first 10 seconds and from 170° to 90° for the next 10 seconds.

IV. Proposed Method: MGC-AuxIVA-ISS

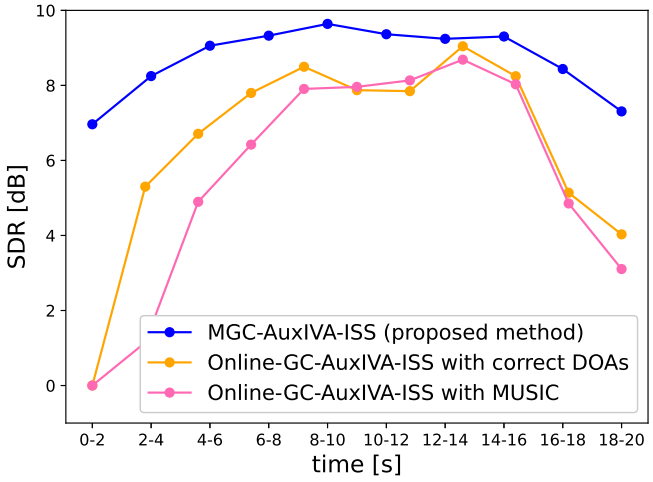
In this section, we propose a method to solve the issues described in Section III-C. Although it is difficult to get the positions of each source at each time, it is easier to obtain the range of the moving sound source. Thus, we propose to remove the range of the moving source by utilizing geometric constraints. In concrete, we extend offline-GC-AuxIVA-ISS to an overdetermined condition and provide null constraints in multiple directions to remove the moving interference signal. We call this proposed method Multiple GC-AuxIVA-ISS (MGC-AuxIVA-ISS). Here, we assume to obtain the range of the moving interference with a range ϕ. For example in Fig. **??**, when the interference source move in the range in 90° to 170° ($\phi = \{\psi \mid 90° \leq \psi \leq 170°\}$) and we have 6 microphones, we set $\Theta = \{90, 110, \ldots, 170\}$, and apply the geometric constraint $c_{1\theta} = 0$ for all $\theta \in \Theta$. Thus, we expect that our MGC-AuxIVA-ISS can remove the entire moving range of the interference signal, regardless of the sound source's movement. This sets up $I - 1$ null constraints equally spaced for ϕ. In this study, we assume the direction range ϕ is known, and let its estimation be a future issue. The cost function for MGC-AuxIVA-ISS is equivalent to that of the Offline-GC-AuxIVA-ISS, and the parameter optimization algorithm is similar.

V. Experimental Evaluation

A. Experimental conditions

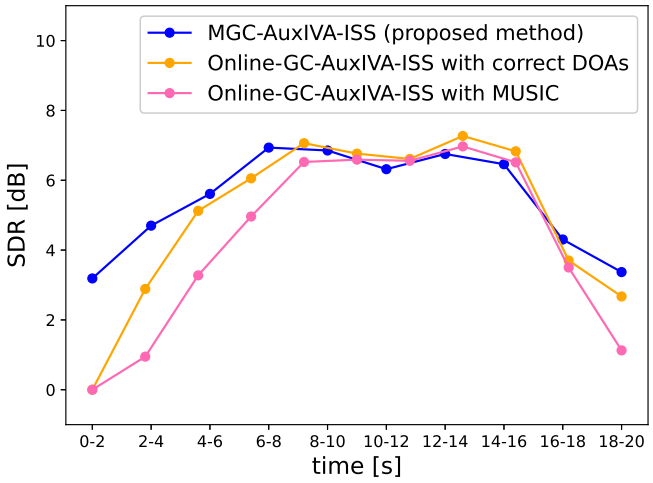
We conducted simulation experiments to evaluate the separation performance of MGC-AuxIVA-ISS in the situation of moving source separation. In this experiment, we used speech signals for 6 speakers (3 male and 3 female) selected randomly from a total of 503 sentences in Set B of the ATR Digital Japanese Speech Database [19]. To generate the

mixture signals, we randomly selected speech signals from two different speakers and created a total of 50 patterns of mixture signals whose length is 20 seconds. We used `signal generator` [20] to create the mixture signals. We show the layout of sound sources and microphones using Fig. 1. The DOA of the target signal was fixed at $45°$ for all 20 seconds and the interference source moved on an arc from $90°$ to $170°$ for the first 10 seconds and moved on an arc from $170°$ to $90°$ for the next 10 seconds. We used 6 microphones and set the distance between adjacent microphones to 2 cm. The distance between sound sources and microphones was set to 1 m. We set the reverberation times (RT_{60}) to 200 ms. We conducted the convolution at a sampling frequency of 48 kHz and then resampled the convoluted signals at 16 kHz to separate the mixtures.



In this experiment, we used the following three methods, MGC-AuxIVA-ISS, online-GC-AuxIVA-ISS with correct DOAs and online-GC-AuxIVA-ISS with MUSIC. We used 6 microphones for MGC-AuxIVA-ISS, and 2 microphones for online-GC-AuxIVA-ISS. We gave information on the moving range of the interference source for MGC-AuxIVA-ISS. On the other hand, we gave the DOA of the interference signal at each time frame to online-GC-AuxIVA-ISS with correct DOAs. Online-GC-AuxIVA-ISS with MUSIC estimated the interference's DOA using MUSIC in each frame and applied the DOA into geometrical constraints. In this experiment, we used null constraints where $c_{j\theta} = 0$ and spatial nulls are formed in the direction of θ. The STFT was computed using a Hanning window, whose length and shift were set at 2048 samples (128 ms) and 1024 samples (64 ms), respectively. The number of iterations is set to 50 for MGC-AuxIVA-ISS and 2 in each frame for online-GC-AuxIVA-ISS. In online-GC-AuxIVA-ISS, the forgetting factor α is set to 0.99, and the spatial covariance matrix $\mathbf{\Sigma}_{jf0}$ is initialized as an identity matrix.

The following two objective metrics were used to evaluate the separation performance: Source-to-Distortions Ratio (SDR) and Source-to-Interferences Ratio (SIR) [21]. Higher values of SDR and SIR indicate better separation performance. The values shown in the experimental results are obtained by tuning the parameter $\lambda_{j\theta}$ so that the accuracy of output signal order is 100% and SDR is the highest value.

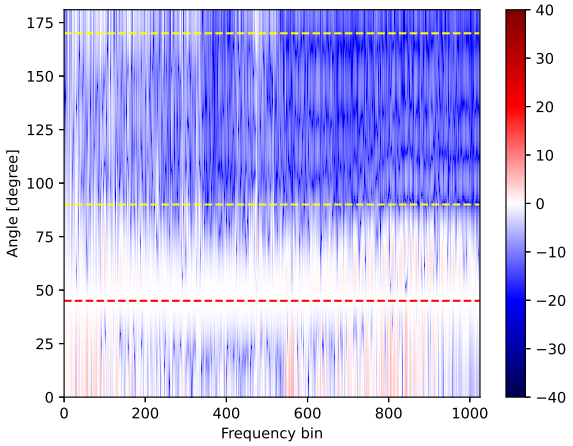


B. Results

We compared the SDR and SIR improvement of MGC-AuxIVA-ISS and the conventional methods using Fig. 2 and Table I. Figure 2 shows the average SDR for the emphasized target signal every 2 seconds obtained by each method. Table I shows the average SDR and SIR of the target signal enhanced by each method in every 2 seconds. To evaluate the SDRs with and without background noise, we conducted two experiments, one without background noise and the other with a noise added by adjusting Source-to-Noise Ratio (SNR) = 25 dB.

We first show the result without background noise. In this experiment, we gave null constraints towards

(a) No background noise



(b) SNR = 25 dB

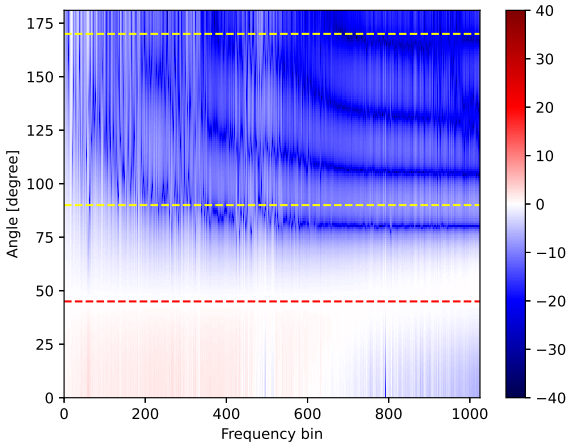


Fig. 2: Average SDR of the target signal enhanced by each method in every 2 s.

$\{90°, 110°, 130°, 150°, 170°\}$ and set $\lambda_{j\theta} = 100$ for MGC-AuxIVA-ISS. We set $\lambda_{j\theta} = 300$ for online-GC-AuxIVA-ISS with correct DOAs, and $\lambda_{j\theta} = 10$ for online-GC-AuxIVA-ISS with MUSIC. From Fig. 2 (a), MGC-AuxIVA-ISS shows the highest SDR overall times. Similarly, Table. I (a) shows that MGC-AuxIVA-ISS achieves the average SDR improvement of 1.64 dB and the average SIR improvement of 5.88 dB compared to online-GC-AuxIVA-ISS with correct DOAs. These results indicate that MGC-AuxIVA-ISS can remove the moving interference signal better than the conventional online-GC-AuxIVA-ISS.

Next, we show the result in a noisy environment. In this experiment, we gave null constraints towards $\{80°, 105°, 130°, 155°, 180°\}$ and set $\lambda_{j\theta} = 3590$ for MGC-AuxIVA-ISS. We set $\lambda_{j\theta} = 30$ for online-GC-AuxIVA-ISS with correct DOAs, and $\lambda_{j\theta} = 20$ for online-GC-AuxIVA-ISS

(a) No background noise

(b) SNR = 25 dB

Fig. 3: Examples of directivity patterns obtained by MGC-AuxIVA-ISS. Red line shows the position of the target source. Yellow lines show the range of the interference source.

with MUSIC. From Fig. 2 (b), MGC-AuxIVA-ISS shows the highest SDR before 4 seconds and after 16 seconds. However, the SDR of MGC-AuxIVA-ISS was close to that of online-GC-AuxIVA-ISS with correct DOAs between 4 to 16 seconds. Table I (b) also shows that MGC-AuxIVA-ISS performs equivalent SDR and higher SIR than online-GC-AuxIVA-ISS with correct DOAs. On the other hand, when compared to online-GC-AuxIVA-ISS with MUSIC, MGC-AuxIVA-ISS achieves the average SDR improvement of 0.77 dB. This result means that when we do not know the correct DOA but know the range of moving interference, using several null constraints toward the moving range is a good way, even in a noisy environment.

Finally, we show the directivity pattern using Fig. 3. The preferred result in Fig. 3 is that the demixing filter removes the steering vector arriving from the moving range of the

TABLE I: Average SDR [dB] and SIR [dB] of the target signal enhanced by each method. In these results, the accuracy of output order was 100%.

(a) No background noise

method	SDR [dB]	SIR [dB]
MGC-AuxIVA-ISS (proposed method)	8.69	16.01
Online-GC-AuxIVA-ISS with correct DOAs	7.05	10.13
Online-GC-AuxIVA-ISS with MUSIC	6.11	10.00

(b) SNR = 25 dB

method	SDR [dB]	SIR [dB]
MGC-AuxIVA-ISS (proposed method)	5.47	10.12
Online-GC-AuxIVA-ISS with correct DOAs	5.50	9.87
Online-GC-AuxIVA-ISS with MUSIC	4.70	9.69

interference source while remaining that from $45°$. So, we normalized the response in each frequency by the response from $45°$. This result shows that MGC-AuxIVA-ISS removes the moving range between $90°$ and $170°$.

VI. Conclusions

In this paper, we proposed MGC-AixIVA-ISS to remove the moving interference speaker. Online-GC-AuxIVA-ISS, which is effective for the movement of the interference source, requires accurate DOAs of the interference signal for each time frame. On the other hand, MGC-AuxIVA-ISS extends offline-GC-AuxIVA-ISS to the overdetermined condition and provides equally spaced null constraints within the moving range of the interference source. To investigate the effectiveness of MGC-AuxIVA-ISS, we conducted speech enhancement experiments to remove the moving interference signal. As a result, we confirmed that the separation performance of MGC-AuxIVA-ISS is more than that of online-GC-AuxIVA-ISS.

***Abstract*—During the pandemic, teleconferencing becomes a necessity to our daily lives. It drives the demand for an integrated system which is not only able to effectively enhance speech sounds, but also to localize the speaker for video enhancement. In this paper, we propose a neural network based composite system which integrates a DoA estimator and a neural beamformer for dual-channel speech enhancement. The proposed system can accomplish two tasks at the same time by using sound signals received from dual microphones. The estimated DoA is converted into a spatial angle related feature, which provides complementary information to boost performance of the neural beamformer. The proposed system is evaluated in simulated far-field conditions with reverberations and noise. Simulation results demonstrate the proposed system outperforms stand-alone baseline systems in either one of the two tasks and achieves comparable results to the best stand-alone models in either one of the two tasks.**

I. Introduction

During the COVID pandemic, online teleconferencing has become a part of people's daily lives. To enhance voice quality, many single-channel and multi-channel speech enhancement methods have been proposed to reduce reverberation and ambient noise. Conventionally, for the multi-microphone scenario, the direction of arrival (DoA) estimation and the beamforming technology were combined to receive the speech signal coming from a specific direction while suppressing interference in other directions. For DoA estimation, the generalized cross correlation with phase transform (GCC-PHAT) [1], the steered-response power with phase transform (SRP-PHAT) [2], and the multiple signal classification (MUSIC) [3] methods are often used. As for beamforming, the delay and sum beamforming (DSB), the minimum variance distortionless response (MVDR) [4], and the linearly constrained minimum variance (LCMV) [5] are popular methods.

In recent years, with the development of deep learning, neural-network (NN) based methods have made substantial progress in both single-channel [6][7][8][9] and multi-channel speech enhancement. In multi-channel speech enhancement, some approaches use NNs to aid traditional beamforming method [10][11][12][13], some use NNs to directly simulate the beamforming mechanism [14][15][16]. For example, [15] directly estimates the weights of a filter-and-sum beamformer using the U-net, whose inputs are those signals received from microphones, and produces the best results in ConferencingSpeech 2021 Challenge [17]. Meanwhile, for robust DoA estimation, [18][19] use NNs to find the time-frequency (TF) bins dominated by the direct sound for calculating weighted GCC-PHAT to estimate DoA. Another type of approach is to directly estimate DoA based on the original spectrograms [20] or the masked spectrograms [21] of microphone signals.

Above mentioned studies treated DoA and beamforming/enhancement separately, i.e., the loss for training was either on DoA or speech enhancement. However, in real world applications, functions of DoA and beamforming are often required at the same time and their performance are intertwined, i.e., a good DoA estimate is beneficial to beamforming while enhanced speech signals help estimate DoA. Intuitively, both tasks can be co-optimized in an iterative fashion. Therefore, in this paper, we propose a unified 3-stage enhancement-DoA-enhancement system using both DoA and speech enhancement loss. The 3-stage system integrates NN-based mask predictors, a NN-based DoA estimator, and a neural beamformer to produce robust performance on both DoA estimation and dual-channel speech enhancement. In the system, the spatial angle related feature is derived from the estimated DoA [22] after single-channel enhancement. The spatial feature is then used as a complementary feature to the neural beamformer for further boosting performance of dual-channel speech enhancement. Not like [12], the proposed system is fully composed of neural networks and all modules can be trained simultaneously. Evaluation results demonstrate the proposed composite system outperforms stand-alone baseline systems in either one of the two tasks. Results also show the proposed system achieves comparable performance to the best stand-alone DoA estimation system and the best stand-alone neural beamformer in either one of the tasks. Under the mild reverberant conditions, the proposed system even slightly outperforms the best stand-alone neural beamformer.

The rest of the paper is organized as follows. In Section 2, we introduce the signal model and the proposed system architecture. In Section 3, the datasets, experimental settings and results are presented and discussed. Finally, we conclude this paper in Section 4.

II. Proposed System

A. Signal model

Fig.1 shows the simulation setup. The distance between the two microphones is 7 cm, and the microphone array is placed 1 meter in height and at least 50 cm from the wall. To simulate a real-world condition, the environment contains diffuse noise,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

directional noise, reverberation, and microphone device noise. The problem formulation is as follows:

$$y_i = s * d_i + s * h_i^{reverb} + n_i^{total} + n_i^{device},\ i = 1,\ 2 \quad (1)$$

where $*$ is the convolution, y_i is the signal received by the i-th microphone, and s is the target source signal. d_i and h_i^{reverb} represent the direct path, and combinations of early and late reflection paths from the target source to the microphone. n_i^{total} is composed of diffuse noise n_i^{dif} and directional noise n_i^{dir} as follows:

$$n_i^{total} = n_i^{dif} + n_i^{dir} \quad (2)$$

$$n_i^{dif} = \sum_{k=1}^{37} n_{dif}^{(k)} * h_{k,i}^{dif},\ i = 1,\ 2 \quad (3)$$

$$n_i^{dir} = n_{dir} * h_i^{dir},\ i = 1,\ 2 \quad (4)$$

The diffuse noise is simulated by placing 37 different segments of a noise signal, $n_{dif}^{(k)}$, at 37 locations in the step of 5° from 0° to 180° on the red semicircle, whose diameter is the length of the room. $h_{k,i}^{dif}$ represents the room impulse response (RIR) from the location k to the i^{th} microphone. The directional noise is used to simulate the outdoor noise leaking through the window. In our experiments, we place the directional noise source at random locations on the three walls in front of the microphone array. h_i^{dir} represents the RIR from the directional noise source to the i-th microphone. Finally, we add device thermal noise n_i^{device} (white noise, SNR = 50 dB) to the two microphone signals. All sound sources are placed on the same horizontal plane as the microphone array.

Above equations are all in the time domain. In simulations, we transformed signals from the time domain to the time-frequency (TF) domain using the short-time Fourier transform (STFT) with the frame length of 512 and the hop size of 256. In this paper, capital letters are used to represent the spectrograms of signals in the TF domain.

B. Proposed system architecture

As shown in Fig.2, the proposed 3-stage system is composed of a magnitude mask predictor, a DoA estimator, and a neural beamformer.

The system is trained in three stages. The first stage is to train the magnitude mask predictor, which gives the DoA estimator and the neural beamformer clues about which TF bins are dominated by the target direct sound. The mask predictor is a monaural system which takes magnitude of the spectrogram as input, and the ideal ratio mask (IRM) between the target direct sound and the received signal as the training target.

In the second stage, we fix the mask predictor and train the DoA estimator with the time difference of arrival (TDOA) as the training target. The DoA estimator takes the summation of masked GCC-PHAT along the frequency axis as the input.

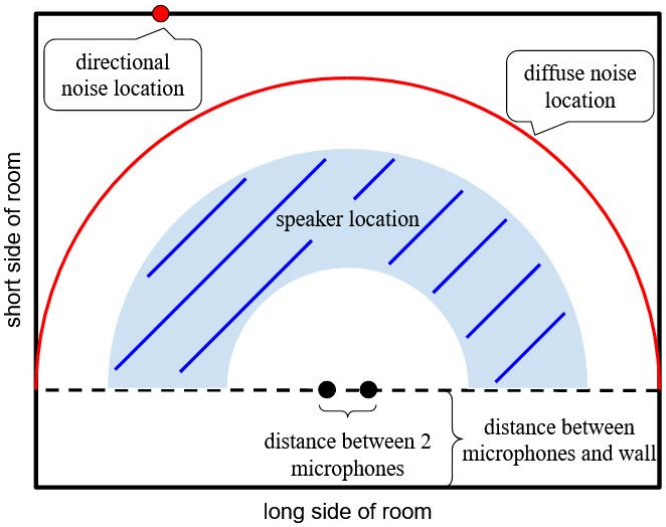

Fig. 1. Schematic diagram of the simulation environment.

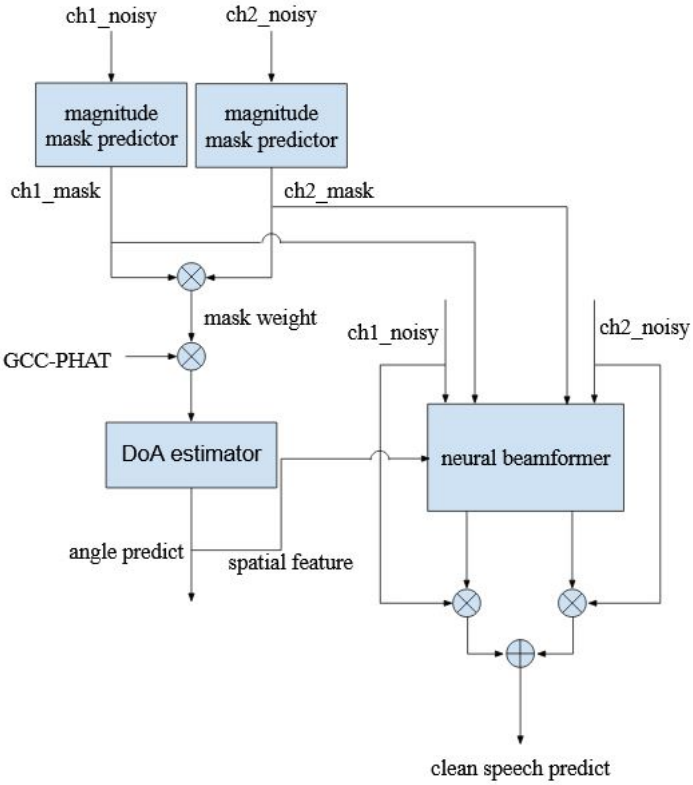

Fig. 2. Architecture of the proposed 3-stage system.

For convenience, the GCC in following equations is the abbreviation of GCC-PHAT:

$$DoA_{input}(\tau,\ t) = \sum_f GCC_{masked}\ (\tau,\ t,\ f) \quad (5)$$

$$GCC_{masked}\ (\tau,\ t,\ f) = \eta(t,\ f) GCC(\tau,\ t,\ f) \quad (6)$$

where $DoA_{input}(\tau,\ t)$ is the input of the DoA estimator and

$GCC_{masked}\ (\tau,\ t,\ f)$ is the TF-weighted version of GCC-PHAT. The weight $\eta(t,\ f)$ is the element-wise multiplication of two predicted masks from the magnitude mask predictor as:

$$\eta(t,\ f) = \hat{M}_1(t,\ f) \times \hat{M}_2(t,\ f) \tag{7}$$

The GCC-PHAT is calculated using received signals of the two microphones and the TDOA parameter τ between two microphones as:

$$\begin{aligned} GCC(\tau,\ t,\ f) &= Real\frac{Y_1(t,\ f)Y_2^H(t,\ f)}{|Y_1(t,\ f)||Y_2^H(t,\ f)|}e^{-j2\pi\frac{f}{N}f_s\tau} \\ &= cos(\angle Y_1(t,\ f) - \angle Y_2(t,\ f) - 2\pi\frac{f}{N}f_s\tau) \end{aligned} \tag{8}$$

where $\angle Y_1(t,\ f)$ and $\angle Y_2(t,\ f)$ represent the phase of the spectrograms of received signals, f_s is the sampling rate in Hz, N is the number of DFT points, f is the frequency bin index, and τ is considered from 37 possible locations (in the step of 5° from 0° to 180°).

Finally, the neural beamformer is added for the third stage training, and the parameters in the magnitude mask predictor and the DoA estimator are fine-tuned simultaneously and optimized during this stage of training. The neural beamformer takes the complex spectrograms of the two microphone signals, two predicted masks, and the estimated spatial angle related feature (SF) as input. The SF is derived as follows:

$$SF(t,\ f) = cos(\angle Y_1(t,\ f) - \angle Y_2(t,\ f) - 2\pi\frac{f}{N}f_s\hat{\tau}) \tag{9}$$

where $\hat{\tau}$ is the estimated TDOA from the DoA estimator.

C. Models and loss functions

The magnitude mask predictor is based on the popular convolutional recurrent neural network (CRN) [23]. It is composed of an encoder, a recurrent module and a decoder. The size of the convolution kernel and stride are respectively set to [5, 2] and [2, 1], and the kernel numbers are set to [16, 32, 64, 128, 256, 256] for the layers in the encoder. Each layer of the decoder mirrors the corresponding layer of the encoder except the transposed convolution layer is used. The middle LSTM recurrent module is constructed with 2 layers of 256 hidden units.

The DoA estimator is constructed with a 3-layer LSTM with 91 hidden units in each layer, followed by a fully connected layer. As for the neural beamformer, each of the input features (two complex spectrograms, two predicted masks, and the estimated spatial angle related feature) is first transformed by a 2-layer fully connected layer, and then concatenated for analysis by a 4-layer LSTM with 512 hidden units in each layer. At the end, the output of the LSTM is connected to four sets of 3-layer FC layer to predict four masks of real and imaginary parts of two complex spectrograms.

In the first stage of training, we use mean absolute error (MAE) as the loss function to calculate the error between the estimated mask and the IRM as in (10). In the second stage of training, MAE is used to calculate the error between the estimated and the true TDOA as in (11). In the third stage of training, we optimize the overall system with the DoA loss and the beamformer loss as in (12) and (13).

$$Loss_{stage1} = \frac{1}{T \times F}\|IRM_i - \hat{M}_i\|_1 \tag{10}$$

$$Loss_{stage2} = \|\tau - \hat{\tau}\|_1 \tag{11}$$

$$Loss_{stage3} = Loss_{stage2} + \alpha \times Loss_{beam} \tag{12}$$

$$\begin{aligned} Loss_{beam} = \frac{1}{T \times F}(&\|Real\{S\} - Real\{\hat{S}\}\|_1 \\ &+\|Imag\{S\} - Imag\{\hat{S}\}\|_1 + \||S| - |\hat{S}|\|_1) \end{aligned} \tag{13}$$

where α is a time-varying parameter to roughly normalize the DoA loss and the beamformer loss epoch by epoch.

III. EXPERIMENTAL RESULTS

A. Dataset preparation and training parameters

We selected the TIMIT database [24] as the source of clean speech. TIMIT contains speech samples of 630 American English speakers from different dialect regions of the United States. We used all 4620 sentences in the TRAIN category for training and randomly selected 48 and 30 sentences in the TEST category for validation and testing. When building the validation and test sets, we excluded the 'sa1' and 'sa2' sentences because these two sentences were spoken by all speakers. Meanwhile, we selected the PNL 100 nonspeech sounds database [25] as the source of noise to make diffuse noise and directional noise in training and validation data. In the test data, we selected 10 stationary noise from Noise92 to make diffuse noise, and other non-stationary noise to make directional noise.

To generate reverberant speech, we used the RIR generator [26] for synthesizing RIRs. Three different room sizes ([10, 7, 3], [15, 12, 3], [20, 17, 3] m) were used in the training set, two different room sizes ([12, 10, 3], [17, 15, 3] m) were used in the validation set, and two different room sizes ([10, 8, 3], [18, 15, 3] m) were used in the test set. The reverberation time T60 of 0.2, 0.4, and 0.6 s were used in the training set, 0.3 and 0.5 s were used in the validation set, and 0.25, 0.35, 0.45, and 0.55 s were used in the test set. SNR values of 0, 5, 10, and 15 dB were used in the training set, and 0, 10, and 20 dB were used in the validation and test sets. Note that our main goal is to solve the teleconferencing problem and the noise level in such venues seldom drops to negative SNR. The distance between the talker and the microphone array was randomly set from 2.5 to 5 meters, and the distance between the microphone array to the back wall was randomly set from 0.5 to 2.5 meters. In the end, about 124 hours of training data, 2.6 hours of validation data, and 13 hours of test data were generated.

In the three training stages, we used Adam optimizer and trained 100 epochs. Batch size was set to 128 in the first training stage and 32 in the second and third stages. Learning rate was set to 0.001 in the first training stage and 0.0001

TABLE I
RESULTS OF DOA ESTIMATION AND SPEECH ENHANCEMENT ON 17280 TEST SENTENCES (SAMPLING RATE = 16 KHZ). SCORES WERE AVERAGED OVER ALL TESTED CONDITIONS.

	DoA	Speech Enhancement			
	avg. error / accuracy	PESQ	CSIG	CBAK	COVL
Noisy	16.41 / 0.41	1.22	2.24	1.37	1.64
(DoA - baseline [19])	4.06 / 0.82	-	-	-	-
(DoA - A)	2.64 / 0.90	-	-	-	-
(beamformer - baseline [15])	-	1.71	2.98	2.25	2.29
(beamformer - A)	-	1.94	3.21	2.42	2.53
(beamformer - B)	-	1.94	**3.25**	2.41	**2.55**
(proposed)	**2.60 / 0.91**	1.92	3.19	2.41	2.51
(proposed-SF)	2.64 / **0.91**	**1.95**	3.23	**2.43**	2.54

in the second and third stages. All of the network weights were initialized by the method described in [27], the default initialization method of Pytorch [28].

B. Results

For evaluations, we compared the following systems:

- Noisy: The neural beamformer is turned off. The DoA estimator finds the $\hat{\tau}$ that maximizes the GCC-PHAT (8) by exhaustive search and outputs the corresponding angle.
- (DoA - baseline [19]): It refers to the subsystem with the fixed magnitude mask predictor and the DoA estimator. It is obtained after the second stage of training.
- (DoA - A): It refers to the subsystem with the adjustable magnitude mask predictor and the DoA estimator. It is obtained from (DoA - baseline) by jointly training the mask predictor and the DoA estimator.
- (beamformer - baseline): It refers to the neural beamformer trained only using microphone signals. It is similar to the system proposed in [15], except it uses LSTM and FC layers rather than U-net.
- (beamformer - A): It refers to the neural beamformer trained using outputs of the fixed magnitude mask predictor and microphone signals.
- (beamformer - B): It refers to the neural beamformer trained using outputs of the adjustable magnitude mask predictor and microphone signals. It is obtained from (beamformer - A) by jointly training the mask predictor and the neural beamformer.
- (proposed): It refers to the proposed 3-stage system. However, the spatial feature SF produced by the DoA estimator is not sent to the neural beamformer. Not like (beamformer - B), the mask predictor is now optimized for both DoA and beamforming tasks.
- (proposed-SF): It is identical to (proposed) except SF now being sent to the neural beamformer.

We used 17280 test sentences to evaluate the proposed system. We used mean absolute error and gross accuracy as criteria for DoA estimation, and four objective metrics, PESQ [29], CSIG, CBAK, and COVL [30], as criteria for dual-channel speech enhancement. In calculating gross accuracy, the case of the absolute error within 5° was considered correct.

The experimental results are shown in Table I. For speech enhancement, by comparing (beamformer - baseline) with (beamformer - A), we observe that adding the mask predictor to the system makes a significant improvement on system performance. The comparison between (beamformer - A) and (beamformer - B) shows that allowing the weights of the mask predictor to be modified during training of the neural beamformer makes a slight improvement on system performance. In contrast, by comparing (DoA - baseline) with (DoA - A), we observe that allowing the weights of the mask predictor to be modified during training of the DoA estimator makes a significant improvement on its estimation performance. These results indicate the joint training in (DoA - A) and (beamformer - B) has the mask predictor produce a more suitable mask for either task.

TABLE II
RESULTS OF PESQ SCORES UNDER DIFFERENT T60. SCORES WERE AVERAGED OVER ALL TESTED CONDITIONS INCLUDING ALL SNRS, RTS AND SPATIAL DISTANCES.

T60 (s)	0.25	0.35	0.45	0.55
Noisy	1.31	1.22	1.18	1.15
(beamformer - B)	2.14	1.98	**1.87**	**1.77**
(proposed-SF)	**2.19**	**1.99**	1.86	1.75

Next, by comparing (proposed) with (beamformer - B), we can see that when the mask predictor is simultaneously optimized for both tasks as in (proposed), it provides less benefit than the stand-alone mask predictor in (beamformer-B). However, when we combine the spatial feature SF from the DoA estimator into the neural beamformer, the proposed (proposed-SF) system gains back lost performance to achieve comparable performance with the stand-alone (beamformer-B) system. We rearrange PESQ scores based on T60 in Table II. It shows that (proposed-SF) system performs slightly better in less reverberant environments while the stand-alone (beamformer-B) system performs slightly better in more reverberant environments.

C. Limitation of the Study

In this study, all RIRs were synthesized using the RIR generator [26]. No real-world RIRs were measured to train the proposed 3-stage model. Hence, the performance of the model will inevitably deteriorate in real-world environments. Using a small amount of real-world data to fine-tune the model is necessary for product development.

IV. Conclusion

In this paper, we propose an integrated 3-stage system containing the magnitude mask predictor, the DoA estimator and the neural beamforemer to simultaneously tackle two common tasks in teleconferencing. Simulation results demonstrate the performance of the neural beamformer is significantly improved when adding the predicted magnitude masks as beamformer's input. In addition, by adding the spatial angle related feature, the neural beamformer achieves comparable results to the best stand-alone beamformer's model. As for DoA estimation, the proposed system also outperforms the best stand-alone DoA model. In the future, we will combine the proposed system with a dual-channel AEC system to constitute a complete system for teleconferencing.

***Abstract*—The performance of sound event classification, including detection or tagging, depends heavily on the number of training samples and the quality of the training data. This paper presents an approach to improving sound event classification performance for events with limited training samples through using a weighted binary cross-entropy loss function. This function aims to constrain the representation space to have lower intra-class variance and higher inter-class differences by mining difficult samples and applying stricter penalties. Experiments demonstrate that the proposed method outperforms the existing ones, and the improvement is particularly significant in scenarios with limited training samples.**

I. Introduction

Sound event classification, including detection and tagging [1], is a process of analyzing audio signals to identify and categorize events present in the audio recordings. It has diverse applications in areas such as security, surveillance, environmental monitoring, and media content analysis, etc. Deep neural network (DNN)-based sound event classifiers can achieve impressive accuracy but typically require a large amount of training data. Due to the high cost of acquiring training data with fine-grained sound event annotations (i.e., specifying the type, onset time, and offset time of every event), many existing datasets, such as AudioSet [2], FSD50K [3], and SONYC-UST-V2 [4], opt for imprecise or coarse-grained labeling, i.e., only specifying the event types without temporal information. The fine-grained and coarse-grained annotations are also, respectively, referred to as strong-labeled and weak-labeled data [5].

Regarding different tasks of sound event classification, tagging focuses on determining the presence or absence of specific events in a given clip, while detection goes further by determining the onset and offset times of the events, typically operating at the frame-level. Consequently, multi-label learning on weakly labeled dataset is a natural choice for training sound event tagging DNN [6]. In contrast, for sound event detection, due to the scarcity of strongly labeled datasets, training models using weakly supervised learning techniques, such as multiple instance learning [1], [7], [8], serves as significant means to alleviate the burden of labeling efforts. In addition, there has also been increasing attention on semi-supervised learning to mitigate the reliance on labeled data [9], [10], [11], as seen in the Task 4 of the DCASE (Detection and Classification of Acoustic Scenes and Events) challenges[1]. While those methods are effective in reducing the burden of labeling efforts, the majority of those operate under the assumption that all training data belongs to events of the current task. Consequently, they encounter difficulties when confronted with few-shot tasks that possess minimal training data, regardless of whether it is labeled or unlabeled. A promising approach to improving performance in this scenario is to transfer knowledge from unrelated datasets. This approach often involves training a pre-trained representation network using techniques such as weakly supervised learning [6] or unsupervised approaches like contrastive learning [12]. Subsequently, the network is fine-tuned using the limited amount of training data available for the target events.

Large-scale weakly labeled datasets, such as Audioset [2], hold promise for training improved representation networks through multi-label classification. However, these datasets also come with challenges, such as label errors and class imbalance. Traditionally, the binary cross-entropy loss function is widely used in both pre-training and fine-tuning stages. Nevertheless, it falls short in addressing the class imbalance issue during pre-training and fails to achieve notable performance improvements during fine-tuning, especially when the available data for fine-tuning is extremely limited. To address this limitation, we propose to learn sound event representations on a hypersphere, and introduce a novel weighted binary cross-entropy loss function based on our previous work [13]. This weighted binary cross-entropy loss function is specifically designed to mitigate the class imbalance problem. Moreover, by incorporating a margin hyper-parameter, it not only promotes a more compact representation but also enhances the fine-tuning results, particularly in scenarios with very few training examples.

II. Preliminaries

Assume that the backbone of a sound event classification DNN is represented by $\hbar_\theta(\cdot)$, and its classification heads consist of a weight matrix $\mathbf{W} = [\mathbf{w}_1 \ \mathbf{w}_2 \ \cdots \ \mathbf{w}_J]$ and a bias vector $\mathbf{b} = [b_1 \ b_2 \ \cdots \ b_J]^T$, where θ represents the parameter of the backbone, J denotes the total number of event types, and the superscript ^{T} is the transpose operator. In the prediction stage, a given nth audio signal $\mathbf{x}_n$ is first embedded into a d-dimensional vector space by $\mathbf{z}_n = \hbar_\theta(\mathbf{x}_n) \in \mathbb{R}^d$ (learned representation). Then, the logits associating to the jth event is calculated as

$$s_{n,j} = \mathbf{w}_j^T \mathbf{z}_n + b_j \tag{1}$$

[1]https://dcase.community/challenge2022/task-sound-event-detection-in-domestic-environments

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

and the posterior probability is given by

$$p_{n,j} = \frac{1}{1 + e^{-s_{n,j}}}. \tag{2}$$

Comparing $p_{n,j}$ with a predefined threshold η, e.g., 0.5, one can predict whether the jth event is presented in the nth signal $\mathbf{x}_n$ or not. Note that the prediction corresponds to clip-level representations (e.g., 10 seconds) for the tagging task and frame-level representations (e.g., 25 milliseconds) for the detection task. This paper focuses on the clip-level representation learning.

In the training stage, let us denote $\mathcal{B} = \{(\mathbf{x}_n, \mathbf{y}_n) | n = 1, 2, \ldots, N\}$ as a min-batch of training representations, where the ground-truth $\mathbf{y}_n \in \{0, 1\}^J$ is

$$\mathbf{y}_n = \begin{bmatrix} y_{n,1} & y_{n,2} & \cdots & y_{n,J} \end{bmatrix}^T, \tag{3}$$

with $y_{n,j} \in \{0, 1\}$ marking the presence or absence of the jth event. The multi-label classification DNN is often trained by the following binary cross-entropy (BCE):

$$\mathcal{L}_{\text{BCE}} = -\frac{1}{NJ} \sum_{n=1}^{N} \mathbf{y}_n^T \ln(\mathbf{p}_n) + (\mathbf{1} - \mathbf{y}_n)^T \ln(\mathbf{1} - \mathbf{p}_n), \tag{4}$$

where $\mathbf{p}_n = \begin{bmatrix} p_{n,1} & p_{n,2} & \cdots & p_{n,J} \end{bmatrix}^T$ consists of the posterior probability of different events presented in the nth signal, which is defined by (2), and $\mathbf{1}$ is a vector of one's.

III. Multi-label weighted binary cross entropy for sound event classification

Due to the number of negative samples ($y_{n,j} = 0$) being significantly larger than that of positive samples ($y_{n,j} = 1$) in the training set, the dominance of the second term in (4) may lead to poor performance. To tackle this challenging issue, this section discusses loss functions that can balance the distribution of positive and negative samples by minimizing category-insensitive partial AUC. Specifically, in Section III-A, we first introduce a weighted BCE loss based on partial AUC optimization for the general binary classification problem. Then, in Sections III-B and III-C, two different loss functions are derived for multi-label classification tasks.

A. Weighted BCE Based on Partial AUC Optimization

Let us first consider the special case of $J = 1$, i.e., we have only one category to detect. Since the dimensions of $\mathbf{y}_n$ and $\mathbf{s}_n$ are both equal to one, we write them as y_n and s_n, respectively, in this subsection. For convenience, we define two index sets of positive and negative samples, $\mathcal{I}^+ = \{n | y_n = 1\}$ and $\mathcal{I}^- = \{n | y_n = 0\}$, respectively, and further define the number of samples in each sets as N^+ and N^-. By definition, we have $N = N^+ + N^-$. Given a threshold η, we can calculate a false positive rate (FPR) of the prediction as

$$f(\eta) = \frac{1}{N^-} \sum_{n \in \mathcal{I}^-} \mathbb{I}(s_n \geq \eta) \tag{5}$$

and a true positive rate (TPR) as

$$t(\eta) = \frac{1}{N^+} \sum_{n \in \mathcal{I}^+} \mathbb{I}(s_n \geq \eta). \tag{6}$$

Then, a ROC curve can be obtained by changing the value of η, where the x-axis represents $f(\eta)$ and the y-axis represents $t(\eta)$. Calculating the partial area under the ROC curve for the range between α and β, we can obtain the partial AUC (pAUC), i.e.,

$$\text{pAUC} = \int_{\alpha}^{\beta} t(\eta) df(\eta). \tag{7}$$

Empirically, this integral form of pAUC can be estimated according to

$$\text{pAUC} \approx \frac{1}{N^+ N^-_{\text{sub}}} \sum_{n \in \mathcal{I}^+} \sum_{m \in \mathcal{I}^-_{\text{sub}}} \left[\mathbb{I}(s_m < s_n) + \frac{1}{2} \mathbb{I}(s_m = s_n) \right], \tag{8}$$

where $\mathcal{I}^-_{\text{sub}}$ is a subset of the index set $\mathcal{I}^-$, and N^-_{sub} denotes the number of samples in $\mathcal{I}^-_{\text{sub}}$. It is calculated by first sorting all logits associated to $\mathcal{I}^-$ in descending order, and then choosing all indices of logits that located between positions $\lfloor \alpha \times N^- \rfloor + 1$ and $\lceil \beta \times N^- \rceil$.

According to [13], the maximization of (8) can be relaxed to minimization of the following weighted binary cross-entropy loss function:

$$\begin{aligned} \mathcal{L}_{\text{pAUC}} = &-\frac{1}{N^+} \sum_{n \in \mathcal{I}^+} \varpi_n \cdot \ln[\varepsilon(s_n)] \\ &-\frac{1}{N^-_{\text{sub}}} \sum_{m \in \mathcal{I}^-_{\text{sub}}} \varpi'_m \cdot \ln[\zeta(s_m)], \end{aligned} \tag{9}$$

where

$$\varepsilon(s_n) = \frac{1}{1 + e^{-s_n + \gamma\delta}}, \tag{10}$$

$$\zeta(s_m) = 1 - \frac{1}{1 + e^{-s_m - (1-\gamma)\delta}}, \tag{11}$$

$$\varpi_n = \frac{1}{N^-_{\text{sub}}} \sum_{m \in \mathcal{I}^-_{\text{sub}}} \mathbb{I}(s_m > s_n - \delta), \tag{12}$$

$$\varpi'_m = \frac{1}{N^+} \sum_{n \in \mathcal{I}^+} \mathbb{I}(s_n < s_m + \delta), \tag{13}$$

with γ being a hyperparameter for balancing the strength of the margin added to positive and negative samples[2], δ being a margin hyparameter introduced in the relaxation process, the positive weight ϖ_n representing the FPR with threshold $s_n - \delta$ for set $\mathcal{I}^-_{\text{sub}}$, and the negative weight ϖ'_m representing the complement of the true positive rate ($1 - \text{TPR}$) with threshold $s_m + \delta$ for set $\mathcal{I}^+$. For simplicity, this paper sets γ to 0.5.

[2]Unlike [13], which only adds the margin to the positive samples, this paper introduces a margin to both the positive and negative samples.

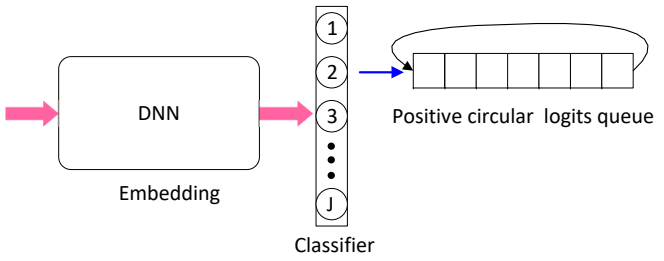

Fig. 1. Illustration of the sound event representation leaning and classification based on $\mathcal{L}_{\text{mpAUC}}$, where the queue is used for cyclically storing positve logits of corresponding sound events of previous iterations, and the computational graphs of these logits are not retained.

B. Sound Event Classification Based on Mean pAUC

As a multi-label sound event classifier can be divided into J binary classifiers, a natural definition of multi-label pAUC is to calculate the mean of the binary pAUC for all the events, i.e.,

$$\text{mpAUC} = \frac{1}{J}\sum_{j=1}^{J}\int_{\alpha_j}^{\beta_j} t_j(\eta)df_j(\eta). \tag{14}$$

where α_j and β_j are hyperparameters of the j-th event. Therefore, the loss function to optimize the multi-label pAUC can be obtained by averaging (9) for all the events.

Traditionally, the logits of a DNN are obtained by computing the inner product between the representations and weights, as shown in (1). Inspired from the results in speaker recognition [13] and face recognition [14], we perform in this work representation learning on a hypersphere with a fixed radius to obtain more effective representation backbone $\hbar_\theta(\cdot)$. Specifically, the logit of a given embedding $\mathbf{z}_n$ in terms of the j-th event is computed as

$$\begin{aligned}\widetilde{s}_{n,j} =& a \times \frac{\mathbf{w}_j^T\mathbf{z}_n}{\|\mathbf{w}_j\|\|\mathbf{z}_n\|} + b_j \\ =& a\cos\vartheta_{n,j} + b_j,\end{aligned} \tag{15}$$

where a is a tunable radius hyperparameter, b_j is a learnable bias corresponding to the jth event, $\vartheta_{n,j}$ is the angle between $\mathbf{z}_n$ and $\mathbf{w}_j$, and $\|\cdot\|$ is the Euclidean norm.

Given a mini-batch training data $\mathcal{B} = \{(\mathbf{x}_n, \mathbf{y}_n)|n = 1, 2, \ldots, N\}$, we have the positive and negative index sets corresponding to the jth event as $\mathcal{I}_j^+ = \{n|y_{n,j} = 1\}$ and $\mathcal{I}_j^- = \{n|y_{n,j} = 0\}$. For convenience, we denote the number of samples in each sets as N_j^+ and N_j^-, and further define a subset of the $\mathcal{I}_j^-$ as $\mathcal{I}_{\text{sub},j}^-$ with $N_{\text{sub},j}^-$ being the number of samples.

In practical situations, the number of sound events J could be comparable to or even larger than the batch size N. In this case, number of the positive samples in each batch is often very small, or even zero, so the approximation in (8) fails. To deal with this issue, as shown in Fig. 1, we first assign a circular logits queue to each kind of sound event to store positive logits from previous iteration. Those stored logits are re-indexed as $\mathcal{I}_{\text{circ},j}^+ = \{N+1, N+2, \cdots, N+L\}$, where L is the length of the queue. When computing the negative weights, we use $\mathcal{I}_j^+$ plus $\mathcal{I}_{\text{circ},j}^+$, i.e.,

$$\hat{\mathcal{I}}_j^+ \leftarrow \mathcal{I}_j^+ \cup \mathcal{I}_{\text{circ},j}^+, \tag{16}$$

to guarantee the number of positive samples in each mini-batch. Taking a subset of negative samples from $\mathcal{I}_j^-$, we form $\mathcal{I}_{\text{sub},j}^-$ for each sound event. The loss function used for optimizing mpAUC can then be expressed as

$$\begin{aligned}\mathcal{L}_{\text{mpAUC}} = -\frac{1}{J}\sum_{j=1}^{J}\Bigg\{&\frac{1}{N_j^+}\sum_{n\in\mathcal{I}_j^+}\varpi_{n,j}\cdot\ln\left[\varepsilon(\widetilde{s}_{n,j})\right] \\ &+\frac{1}{N_{\text{sub},j}^-}\sum_{m\in\mathcal{I}_{\text{sub},j}^-}\varpi'_{m,j}\cdot\ln\left[\zeta(\widetilde{s}_{m,j})\right]\Bigg\},\end{aligned} \tag{17}$$

where

$$\varpi_{n,j} = \frac{1}{N_{\text{sub},j}^-}\sum_{m\in\mathcal{I}_{\text{sub},j}^-}\mathbb{I}(\widetilde{s}_{m,j} > \widetilde{s}_{n,j} - \delta), \tag{18}$$

$$\varpi'_{m,j} = \frac{1}{N_j^+ + L}\sum_{n\in\hat{\mathcal{I}}_j^+}\mathbb{I}(\widetilde{s}_{n,j} < \widetilde{s}_{m,j} + \delta), \tag{19}$$

and the first term within the braces will disappear if $N_j^+ = 0$. Recall that $\vartheta_{n,j}$ is a function of $\mathbf{w}_j$ and $\mathbf{z}_n$, and the representation $\mathbf{z}_n$ is calculated according to $\mathbf{z}_n = \hbar_\theta(\mathbf{x}_n)$. Now, one can use the back-propagation method to learn a proper $\hbar_\theta(\cdot)$, $\mathbf{W}$ and $\mathbf{b}$ by minimizing the loss function $\mathcal{L}_{\text{mpAUC}}$.

C. Sound Event Classification Based on All pAUC

Another way for computing the pAUC of a multi-label sound event classifier is by aggregating all the categories together. We denote this type of multi-label pAUC as opAUC, which is defined as

$$\text{opAUC} = \int_{\alpha}^{\beta}\breve{t}(\eta)d\breve{f}(\eta), \tag{20}$$

where $\breve{t}(\eta)$ and $\breve{f}(\eta)$ are the overall TPR and FPR by considering all the J events. Like what in computing pAUC and mpAUC, we need the positive and negative subsets to compute opAUC. By aggregating the subsets of all the categories, we have $\breve{\mathcal{I}}^+ = \{(n,j)|y_{n,j} = 1\}$ and $\breve{\mathcal{I}}^- = \{(n,j)|y_{n,j} = 0\}$, and further denote the subset of $\breve{\mathcal{I}}^-$ as $\breve{\mathcal{I}}_{\text{sub}}^-$. The number of samples in the three sets are denoted as $\breve{N}^+$, $\breve{N}^-$, and $\breve{N}_{\text{sub}}^-$, respectively. With the introduced variables, we can write the loss function to maximize opAUC as

$$\begin{aligned}\mathcal{L}_{\text{opAUC}} = &-\frac{1}{\breve{N}^+}\sum_{(n,i)\in\breve{\mathcal{I}}^+}\breve{\varpi}_{n,i}\cdot\ln\left[\varepsilon(\widetilde{s}_{n,i})\right] \\ &-\frac{1}{\breve{N}_{\text{sub}}^-}\sum_{(m,j)\in\breve{\mathcal{I}}_{\text{sub}}^-}\breve{\varpi}'_{m,j}\cdot\ln\left[\zeta(\widetilde{s}_{m,j})\right],\end{aligned} \tag{21}$$

TABLE I
CNN STRUCTURE FOR SOUND EVENT REPRESENTATION LEARNING AND CLASSIFICATION [6], WHERE N AND T DENOTE BATCH-SIZE AND NUMBER OF FRAMES, RESPECTIVELY. THE THIRD DIMENSION OF THE OUTPUT SIZE IS AN APPROXIMATION VALUE.

Name	Structure	Output size
Input	—	N clips
Acoustic feature	Log-mel spectrogram (64 mel bins)	$N \times 1 \times T \times 64$

Backbone	$\begin{pmatrix} 3\times 3 & \text{Chan} = 64 \\ \text{BN} & \text{ReLU} \end{pmatrix} \times 2$, Stride=(1,1)	$N \times 64 \times T \times 64$
	Average Pooling 2×2	$N \times 64 \times \frac{T}{2} \times 32$
	$\begin{pmatrix} 3\times 3 & \text{Chan} = 128 \\ \text{BN} & \text{ReLU} \end{pmatrix} \times 2$, Stride=(1,1)	$N \times 128 \times \frac{T}{2} \times 32$
	Average Pooling 2×2	$N \times 128 \times \frac{T}{4} \times 16$
	$\begin{pmatrix} 3\times 3 & \text{Chan} = 256 \\ \text{BN} & \text{ReLU} \end{pmatrix} \times 2$, Stride=(1,1)	$N \times 256 \times \frac{T}{4} \times 16$
	Average Pooling 2×2	$N \times 256 \times \frac{T}{8} \times 8$
	$\begin{pmatrix} 3\times 3 & \text{Chan} = 512 \\ \text{BN} & \text{ReLU} \end{pmatrix} \times 2$, Stride=(1,1)	$N \times 512 \times \frac{T}{8} \times 8$
	Global Pooling 2×2	$N \times 512$
Dense layer	512×512 FC, **ReLU** (With / Without)	$N \times 512$
Classifier	$512 \times J$ Weight matrix and $J \times 1$ Bias vector	$N \times J$

where

$$\breve{\varpi}_{n,i} = \frac{1}{\breve{N}^{-}_{\text{sub}}} \sum_{(m,j)\in\breve{\mathcal{I}}^{-}_{\text{sub}}} \mathbb{I}(\widetilde{s}_{m,j} > \widetilde{s}_{n,i} - \delta), \tag{22}$$

$$\breve{\varpi}'_{m,j} = \frac{1}{\breve{N}^{+}} \sum_{(n,i)\in\breve{\mathcal{I}}^{+}} \mathbb{I}(\widetilde{s}_{n,i} < \widetilde{s}_{m,j} + \delta). \tag{23}$$

In practical situations, the process of computing opAUC is the same as that of computing the classical pAUC once we have the subsets of positive and negative samples, i.e., $\breve{\mathcal{I}}^{+}$ and $\breve{\mathcal{I}}^{-}$.

IV. EXPERIMENTS

A. Experimental Setup

We validate the effectiveness of the proposed loss functions for sound event representation learning and few-shot classification using three datasets: AudioSet [2], ESC [15], and FSD50K [3], where the first dataset is used to train the representation backbone, and the last two are used for the few-shot classification experiment. AudioSet consists of 527 sound classes, with the audio clips taken from YouTube videos. It is divided into three parts, i.e., "unbalanced train," "balanced train," and "evaluation," and we get, respectively, 1934187, 20550, and 18887 audio clips [6]. The duration of every clip is 10 seconds. It should be noted that all these three parts suffer from class imbalance. ESC consists of 2000 audio clips of 50 classes with 40 audio clips for each class. Each clip contains a single event and has a duration of 5 seconds. FSD50K is an open dataset that consist of over 51000 manually labeled audio clips, using 200 classes derived from the AudioSet Ontology.

In our experiments, all audio clips are resampled to a 32-kHz sampling rate. Following the work in [6], we use a DNN architecture as described in Table I. We employ a 64-dimensional log mel spectrogram as the input of the DNN. A batch size of 128 and the Adam optimizer with an initial learning rate of $1e^{-3}$ are used for training. During the representation learning phase, 100000 iterations were performed, and the learning rate is decreased to $1e^{-4}$ and $1e^{-5}$ at the 80000th and 90000th iteration, respectively. For the few-shot classification on ESC, we train 200 epochs, and the learning rate is decreased to $1e^{-4}$ and $1e^{-5}$ at the 100th and 150th epoch, respectively. On FSD50K, we train 150 epochs (for few shot classification) or 60 epochs (using all training data), and learning rate is decreased to $1e^{-4}$ and $1e^{-5}$ at the last 20th and 10th epochs from the end.

The loss function $\mathcal{L}_{\text{mpAUC}}$ in (17) involves six hyperparameters, i.e., the margin δ, the margin balance γ, the buffer length L, the radius a, and the two pAUC constraints α_j and β_j. For simplicity, we empirically set the value of γ to 0.5, the value of α to 0, and the size of the buffer $\mathcal{I}^{+}_{\text{circ},j}$ to 64 and 10 for, respectively, the representation leaning and few-shot fine-tuning experiments. We initialize β_j to 1, and decrease it according to

$$\beta_j^{(k)} = \max(\min(1 - \text{pAUC}_j, \beta_j^{(k-1)}), \beta_{\min}) \tag{24}$$

for every 500 (for representation learning) or 10 (for fine-tuning) iterations, where k is the index of the training iteration, pAUC_j is an exponentially smoothed value with momentum 0.99 (for representation learning) or 0.9 (for fine-tuning), and $\beta_{\min}$ is a tunable hyperparameter. Finally, we have three tunable hyperparameters and perform a grid search based on the following values: $a \in \{10, 20, 30\}$, $\frac{\delta}{a} \in \{0.2, 0.4\}$ and $\beta_{\min} \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$. The loss function $\mathcal{L}_{\text{opAUC}}$ in (21) follows the same process as setting the hyperparameters.

The mean average precision (mAP) and mean area under the ROC curve (mAUC) are used as evaluation metrics for sound event classification [6]. Moreover, the equal error rate (EER) [13] is used to assess the quality of the learned representations.

B. Representation Learning Over AudioSet

To evaluate the quality of the learned representation backbone, we combine the 2000 audio clips of ESC in a pairwise manner, resulting in a total number of 1999000 trials. We then calculate the cosine similarity of their representations and evaluate it using EER. The results of representation learning on AudioSet are presented in Table II. Note that the results in Table II are the averaged results over iterations $\{92000, 94000, 96000, 98000, 100000\}$.

From Table II, one can see that when removing the ReLU activation function after the Dense layer, the proposed loss function yields a significantly lower EER in comparison with the classical BCE, with a relative reduction of more than 20%. It also demonstrates certain advantages in performance on the AudioSet evaluation dataset. Furthermore, comparing the results in the 5th and 6th rows, one can see that $\mathcal{L}_{\text{opAUC}}$ leads to a lower EER though both $\mathcal{L}_{\text{BCE}}$ and $\mathcal{L}_{\text{opAUC}}$ have similar values of mAP on AudioSet-Eval.

	(10, 0.4)	—	—	90.05	98.39	—	—	—	—
	(10, 0.6)	—	—	89.34	97.72	—	—	—	—

With ReLU after the Dense layer, we observe a significant improvement in the performance of BCE, while the proposed loss function shows only a modest improvement. In spite of this, the $\mathcal{L}_{\text{opAUC}}$ still maintains a lower EER. Moreover, if balanced sampling on the training data is not performed, one can see that $\mathcal{L}_{\text{opAUC}}$ achieves a relatively significant performance improvement in comparison with $\mathcal{L}_{\text{BCE}}$, indicating that BCE is more sensitive to the imbalance problem.

Overall, the proposed representation learning loss functions demonstrate significant advantages. Further validation is in progress for other network structures such as those performing better without adding ReLU after the Dense layer.

C. Few-Shot Classification Over ESC and FSD50K

This subsection validates the effectiveness of the proposed loss functions in few-shot classification tasks. Specifically, on the ESC dataset, we randomly chose 10 or 20 clips of each class of sound events as training data, with the rest being used as testing data. For simplicity, we refer to this as 10-shot and 20-shot, respectively. Table III presents the grid search results of hyperparameters on ESC, where the network is trained from scratch under 20-shot condition. From the table, it is observed that the $\beta_{\min}$ parameter has a significant impact on the performance, and the optimal values for a and δ/a are 10 and 0.2, respectively. The $\mathcal{L}_{\text{opAUC}}$ loss yields a better performance than $\mathcal{L}_{\text{mpAUC}}$.

Table IV presents the comparison between the performance of the proposed loss functions and that of the traditional BCE for few-shot classification. The experiment consists of three situations: training from scratch, only fine-tuning the classifier, and fine-tuning the entire network. During fine tuning, the network is initialized by parameters pretrained on AudioSet with the corresponding loss functions. The following two observations can be made from Table IV. 1) $\mathcal{L}_{\text{mpAUC}}$ outperforms $\mathcal{L}_{\text{BCE}}$ in terms of mAP, especially with limited training data like 10-shot. In comparison with $\mathcal{L}_{\text{BCE}}$, fine-tuning the classification head with $\mathcal{L}_{\text{mpAUC}}$ shows a relative mAP improvement of over 40%. 2) A well-initialized network leads to better performance, indicating that pretraining enhances significantly few-shot sound event classification on this dataset.

Due to redundancy among the 200 event classes in FSD50K, we remove all the intermediate nodes to ensure mutual exclusivity between events and retain only the leaf node events, resulting in a total of 135 event classes. We discard audio samples from the training, validation, and test sets that do not include the selected events, and the remaining samples constitute the final training, validation, and test sets. Moreover, during training, we vary the number of training clips per event to observe performance changes and the results as shown in Table V.

From Table V, it is seen that $\mathcal{L}_{\text{opAUC}}$ yields a great improvement in mAP as compared to $\mathcal{L}_{\text{BCE}}$, the absolute improvement in mAP ranges from 3% to 6% in the studied few-shot cases.

TABLE IV
PERFORMANCE [%] OF FEW-SHOT SOUND EVENT CLASSIFICATION ON ESC.THE HYPERPARAMETERS $(a, \frac{\delta}{a}, \beta_{\min})$ ARE SET TO $(10, 0.2, 0.1)$. THE RELU ACTIVATION FUNCTION AFTER THE DENSE LAYER IS ADDED.

		Scratch		Tuning classifier		Tuning all	
	Loss	mAP	mAUC	mAP	mAUC	mAP	mAUC
20-shot	$\mathcal{L}_{\text{BCE}}$	89.38	99.13	90.51	99.62	95.43	99.63
	$\mathcal{L}_{\text{mpAUC}}$	**91.19**	**99.26**	94.01	99.69	96.52	99.44

10-shot	$\mathcal{L}_{\text{BCE}}$	72.37	97.47	84.73	99.18	88.86	99.16
	$\mathcal{L}_{\text{mpAUC}}$	78.10	97.65	**91.23**	99.33	93.20	99.29
	$\mathcal{L}_{\text{opAUC}}$	**78.97**	**97.73**	90.75	**99.38**	**93.92**	**99.32**

TABLE V
MAP [%] OF FEW-SHOT SOUND EVENT CLASSIFICATION ON FSD50K. THE HYPERPARAMETERS $(a, \frac{\delta}{a}, \beta_{\min})$ ARE SET TO $(10, 0.2, 0.1)$. THE RELU ACTIVATION FUNCTION AFTER THE DENSE LAYER IS ADDED.

		Loss	5-shot	10-shot	20-shot	30-shot	All
Scratch	Test	$\mathcal{L}_{\text{BCE}}$	15.82	22.30	32.96	39.36	53.74
		$\mathcal{L}_{\text{opAUC}}$	**18.53**	**28.60**	**37.87**	**42.39**	**54.26**
	Valid	$\mathcal{L}_{\text{BCE}}$	16.44	23.97	33.97	41.19	55.74
		$\mathcal{L}_{\text{opAUC}}$	**19.26**	**29.77**	**39.36**	**44.26**	**56.60**
Tuning all	Test	$\mathcal{L}_{\text{BCE}}$	14.14	23.58	33.63	40.65	53.54
		$\mathcal{L}_{\text{opAUC}}$	**18.19**	**27.23**	**37.72**	**41.68**	**54.11**
	Valid	$\mathcal{L}_{\text{BCE}}$	14.97	25.13	35.02	41.36	56.34
		$\mathcal{L}_{\text{opAUC}}$	**18.78**	**29.19**	**38.89**	**43.66**	**56.42**

It is also seen from the FSD50K dataset that pre-training is helpful for BCE but not for $\mathcal{L}_{\text{opAUC}}$. The reason for this is under investigation. Another interesting observation is that the mAUC of $\mathcal{L}_{\text{opAUC}}$ is not as good as $\mathcal{L}_{\text{BCE}}$. For example, in the 10-shot scratch training scenario, the mAUC of $\mathcal{L}_{\text{BCE}}$ on the test set is 91.52%, while the mAUC of $\mathcal{L}_{\text{opAUC}}$ is 89.64%. This may be due to the decreased value of β.

V. SUMMARY

In this paper, we proposed two weighted binary cross entropy loss functions based on pAUC optimization for sound event representation learning and few-shot classification. Experimental results showed that the DNN trained with the proposed loss functions improves significantly both the representation and few-shot classification performance. Note that we found that the network structure, such as the ReLU activation function before the classification head, affects significantly the relative performance improvement of the proposed weighted BCEs as compared to the traditional BCE. The reason for this is not clear and currently under investigation. Also, in few-shot classification, the performance of the proposed loss functions in terms of mAUC is not as good as BCE. This is related to the hyperparameter $\beta_{\min}$, which will also be studied in the near future.

***Abstract*—Graph convolution neural network (GCN) has gained more attention in recent years. Data types like human skeleton joints which are in non-Euclidean space are suitable for GCN. However, due to the high computational complexity and data sparsity of GCN, it is common to have high latency or low power efficiency in CPU or GPU platforms. Therefore, dedicated hardware accelerators are critical for such tasks. In this paper, we proposed a highly parallelized and flexible architecture for the GCN layers of the Spatial-Temporal Graph Convolutional Networks (ST-GCN) model, which is a classic model and widely used in human action recognition. The accelerator also has high scalability due to our proposed method. Compared with the hardware implementation on ST-GCN, the proposed method reduces the latency by up to 39.5% and improves 1.46x on power efficiency.**

Keywords—graph convolutional neural network, hardware, accelerator, reconfigurable architecture, FPGA

I. INTRODUCTION

Human action recognition (HAR) has been used in different kinds of applications, such as medical health care [1], surveillance system [2], and VR gaming [3]. In the early stages, RGB images are the most common data type in HAR. Lots of deep learning methods have been proposed, such as 2D Convolutional Neural Network (CNN) [4], 3D CNN [5], and Recurrent Neural Network (RNN) [6]. However, models which use plain images as their input usually have limited performance due to variation backgrounds, illumination differences, and will be affected by irrelevant objects.

Skeleton data had gained more interest since it only focuses on human actions and is independent of background noises. The skeleton data can be obtained by post estimation algorithms on RGB videos or by depth camera. Even though there are still methods focusing on using CNN or RNN to extract features from skeleton data, it is clear that the data type between RGB image and skeleton data is quite different, while RGB image is categorized as Euclidean data, skeleton data is non-Euclidean space. For Euclidean data which is neatly aligned, it is easy and suitable to apply convolution operation. However, the model will lose the spatiality of the skeleton data if we apply the same convolution operation.

Therefore, Ref [7] proposed a GCN method which is called ST-GCN to handle the irregularity of skeleton data. Fig. 1 shows the graph structure of the skeleton sequence for ST-GCN. The blue dots represent the natural body joints and the lines between the dots within a frame are connected according to the human body structure. By applying GCN to the graph structure, the model can obtain spatial information about the human skeleton structure. ST-GCN also takes temporal information into account by connecting joints between different frames, and the results show that it can outperform other works which use CNN or RNN methods.

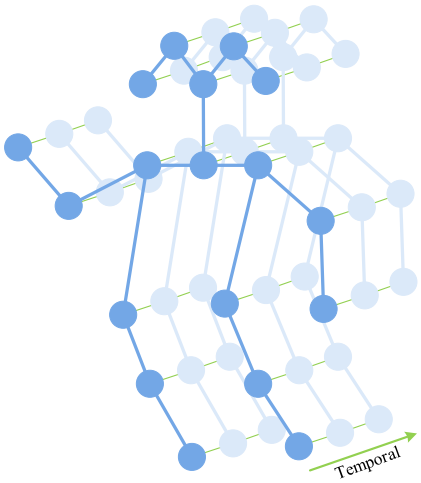

Fig. 1. The graph structure used in ST-GCN

Despite the success of GCN, the model still faces problems like large network architectures and is highly computationally intensive which takes a long time to inferencing on CPU or GPU platforms. Several papers have been presented to accelerate GCN on FPGA platforms. In [8], it proposed a fixed structure that concatenates the convolution engine and sparse matrix-vector multiplication (SpMxV) engine. However, with the design of using three parallel SpMxV engines based on the ST-GCN model which uses three adjacency matrices, it can cause more latency if the skeleton data contains more joints. STARS [9] proposed an architecture using high-level synthesis (HLS) to optimize the resources used on the FPGA. Nevertheless, different types of computation use different computational units and are independent of one another. This causes low resource utilization because when a computing kernel is operating, others remain inactive due to most parts of the ST-GCN process layer by layer. In this paper, we propose a reconfigurable hardware architecture to process the GCN layer. The main contributions in this paper are as follows:

- We design an architecture that can allocate various amounts of PEs for the aggregation engine to fit different kinds of skeleton structures with no delay increase.
- We design a general PE for all kinds of operations used in the GCN layer and also form a pipeline

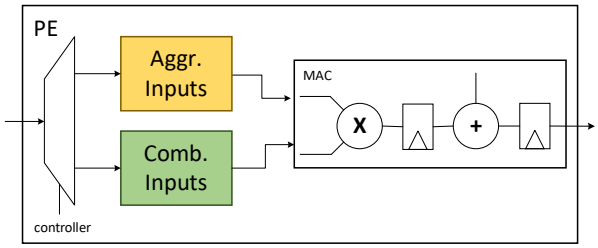

Fig. 4. PE architecture.

structure with the combination engine and aggregation engine to further improve hardware utilization.

- We implement our design on the FPGA platform and achieve better performance compared to the state-of-the-art.

The rest of the paper is organized as follows. Section II briefly explains how the GCN layer computes. Section III shows our overall architecture while section IV presents the experiment result and compares it with state-of-the-art papers. Finally, the paper is concluded in section V.

II. GCN Computation

ST-GCN is a GCN model which aims to exploit the spatiality and temporality of the skeleton joints. It constructs an undirected spatial-temporal graph $G = \{V, E\}$ on a skeleton sequence with N joints and T frames featuring both intra-frame and inter-frame connections. The node set $V = \{v_{ti} | t = 1, \dots, T, i = 1, \dots, N\}$ represent all skeleton joints contained in the action sequence. The edge set is composed of two parts: $E_s = \{v_{ti}v_{tj} | (i,j) \in H\}$ indicates the intra-skeleton connection in each frame, where H is the set of naturally connected human body joints, while $E_F = \{v_{ti}v_{(t+1)i}\}$ represents the inter-frame edges which are simply connected between two same joints in consecutive frames. The model can also support a different number of skeleton joints. For example, the Kinetics dataset [10] uses 18 joints as input, while the NTU-RGB+D dataset [11] contains 25 skeleton joints.

When applying spatial convolution to the input data, the formula can be expressed as follows:

$$f_{out} = \Lambda^{-\frac{1}{2}}(\mathrm{A} + \mathrm{I})\Lambda^{-\frac{1}{2}} f_{in} W \qquad (1)$$

Matrix A is an adjacency matrix that represents intra-body connections and matrix I represents self-connecting nodes to also takes its node information into account. The formula normalized the adjacency matrix by $\Lambda^{-\frac{1}{2}}(\mathrm{A} + \mathrm{I})\Lambda^{-\frac{1}{2}}$ to alleviate numerical instabilities and exploding/vanishing gradients when training a deep neural network model, where $\Lambda = \sum_j(\mathrm{A}_{ij} + \mathrm{I}_{ij})$. The normalized adjacency matrix can be computed in advance since the graph structure remains unchanged. Therefore, the formula can be simplified as $f_{out} = \mathrm{A}' f_{in} W$, which contains two different computations:

TABLE I. RESOURCE UTILIZATION COMPARISION

	ASICON 2019[8]	STARS[9]	OURS
LUT	44457/ 1182240	32995/ 53200	53431/ 230400
FF	34667 /2364480	36663/ 106400	49849/ 460800
BRAM	151/2160	87.5/280	183/312
DSP	228/6840	100/220	288/1728

TABLE II. LAYER BY LAYER PROCESSING TIME COMPARISON

ST-GCN layer latency(ms)	Input/Output Channels	ASICON 2019[8]	OURS
Layer1	3/64	2.61	4.38
Layer2-4	64/64	4.05	4.38
Layer5	64/128	8.03	8.76
Layer6-7	128/128	11.2	8.78
Layer8	128/256	22.3	13.17
Layer9-10	256/256	35.2	13.21

$A'f_{in}$ is a matrix-vector multiplication and $f_{in}W$ is known as a convolutional computation with the kernel size set as (1, 1). Fig. 2 shows the illustration of GCN computation, where the combination process represents convolutional computation and the aggregation process indicates matrix-vector multiplication.

Ref [7] also introduced different partition strategies for skeleton joints. With the traditional uni-labeling strategy, the model can lose the local differential properties due to the operation being equivalent to the inner product between the average feature vector of all neighboring nodes and the weight vector. ST-GCN model uses a spatial configuration partitioning strategy according to the motion of a body can be broadly categorized as concentric and eccentric motions. The strategy can separate the neighboring nodes into three parts: the root node, the centripetal group, and the centrifugal group. It can be expressed as follows:

$$l_{ti}(v_{tj}) = \begin{cases} 0 & if\ r_j = r_i \\ 1 & if\ r_j < r_i \\ 2 & if\ r_j > r_i \end{cases} \qquad (2)$$

Where r_i represents the distance between the skeleton gravity center and the root node. Therefore, group 0 contains all root nodes, group 1 includes all centripetal nodes which have shorter distances to the gravity center while group 2 has longer distances and will be categorized as the centrifugal group.

III. HARDWARE ARCHITECTURE

Fig. 3 shows our overall architecture. The design contains several SRAMs to store weights, edge information, and batch normalization parameters. Our computation unit uses a unified PE design but can be separated into two parts: combination PEs and aggregation PEs. First, the controller will receive the layer information and allocate a different amount of PEs for the combination and aggregation process,

TABLE III. OVERALL PERFORMANCE COMPARISON

	ASICON 2019[8]	STARS[9]	OURS
Quantification	Fixed-16	Fixed-16	Fixed-16
Clock (Hz)	188M	150M	158M
Power (W)	-	1.96	2.378
Latency (ms)	137.89	89.55	83.44
Peak Performance (GOPs)	46	73.4	91
Average Performance (GOPs)	23.505	36.192	64.269
Power Efficiency (GOPs/W)	-	18.47	27.03

which is shown in Fig. 4. Then, the weight data, edge information, and batch normalization parameters are transmitted from off-chip DRAM. Finally, the input feature maps will send into the architecture and compute the results at the same time. Before delivering the output feature maps to the off-chip DRAM, the data will go through the activation module which is set as ReLU in the ST-GCN network.

A. Combination Engine

The combination process takes input feature maps and weights from the input buffer and weight memory to generate temporary combination results. Each PE processes a skeleton joint feature one at a time. In our design, we use weight stationary dataflow due to the weight data in combination process is more likely to fit into the entire on-chip memory, therefore the accelerator will only read input feature map data and weight data once from DRAM, and the accelerator can operate while the input feature map data continuously being read in the design. For some layers of GCN in which its entire weight data cannot fit in the on-chip memory, the controller will split the layer into several processes, while the accelerator will use the maximum amount of PEs that are assigned for combination engine for maximum efficiency. Since the combination process forms a 1 x 1 convolution, the partial sum will always be stored in the local memory of its PE, which is also output stationary. With multiple PEs, it can generate different output channels of combination results.

It is worth noticing that generated output channels must be a multiple of three for aggregation engine to fully use all temporary results. In addition, the combination process will take up most of the processing time of a layer due to large input channels. Hence, the temporary combination result is sent to aggregation PEs to add bias.

B. Aggregation Engine

The aggregation engine can compute three processes, with the aggregation process being the main task, while adding bias and batch normalization process are also computed in its spare time to maximize the hardware efficiency. The aggregation process takes combination results and edges information from the combination buffer and edge memory to generate aggregation results. The aggregation process takes three input channels of combination results to operate matrix multiplication with the edge information due to the design of ST-GCN. To exploit high sparsity of the human skeleton

graph, the system only inputs non-zero values and their corresponding index of the edge information.

Each PE is assigned to process a skeleton joint aggregation. With different kinds of skeleton representations, different amounts of PEs can be assigned for the aggregation process. To minimize the latency of the overall process, we add bias in the aggregation engine. The aggregation engine also processes batch normalization operations due to the long processing time of the combination engine. Finally, the aggregation result is sent to the post process engine to perform the activation function.

C. Cooperation of Combination and Aggregation

When processing GCN layers, it is important to compute combination and aggregation processes at the same time to reduce the latency. First of all, the combination engine continuously generates temporary results for the aggregation engine to add biases. Then, the aggregation engine will send the combination results to the fmap tile for data reorganization. The fmap tile will reallocate the values to the corresponding joint memory for future aggregation computation.

To form an aggregation computation, all joint's feature vector information should be stored in the combination buffer. Due to the long operation time in the combination process, it is important to not have any kinds of data blockage which add even more time to the overall processing latency. However, the aggregation engine takes all joints but only three channels of information when operating the aggregation process, while the combination engine outputs all channels but only one joint of the feature vector. This causes new joint information will overwrite older joint information when the combination engine is processing at full speed. Hence, the combination buffer uses ping-pong RAM to solve the problem and elevate the overall processing speed of the accelerator.

With a simple graph representation of the human skeleton, a PE only needs 8 cycles to process aggregation and batch normalization process. In each combination processing time, the aggregation engine can compute 4 aggregation processes. For NTU-RGB+D and Kinetic-skeleton dataset, all aggregation processes can be done while the combination engine processes at full speed. The accelerator can process different kinds of human skeleton structures by reallocating different numbers of PEs to combination and aggregation engines, therefore, it can maximize PE utilization.

IV. Experiment Result

We implemented the proposed hardware architecture on ZCU104, and Table I shows the hardware utilization on the FPGA board. Although the resource usage of our work is higher than other works, STARS uses HLS to implement their work to optimize the hardware utilization but will potentially cause lower performance and power efficiency.

Table II analyzes the individual performance of each GCN layer. When comparing with ASICON 2019 [8], it shows that our work has a disadvantage when processing layer 1 since the input channel of the layer is only three, which causes the combination engine cannot work at full speed. Our accelerator shows an advantage at higher input channels due to the hardware architecture that can optimize the allocation of the combination PEs and split the layer into several processes properly.

Table III shows the overall comparison with other works which also realize the GCN part of the ST-GCN model for human action recognition. Our accelerator provides 1.65x and 1.07x speedup on latency, which is counted as the sum of the 10 layers of the GCN layer. Although our peak performance also outperforms other works, with limited clock frequency on the FPGA platform, peak performance is nearly proportional to the number of PE being used, which cannot reflect the hardware efficiency. Therefore, average performance is a fairer comparison to PE utilization. With the combination engine PEs continuously operating and aggregation engine performs not only aggregation but also bias and batch normalization operation, our average performance is 2.73x and 1.78x higher than other works. Our accelerator also improved by 1.46x on power efficiency than STARS.

V. Conclusion

GCN has become more popular since it can handle a wider range of data types, and it is proven to have higher accuracy in many tasks. In this paper, we proposed a reconfigurable hardware architecture for GCN to optimize the operations involved. The architecture separates PEs into two parts, each processes combination and aggregation respectively but also cooperates for maximum efficiency. The experiment results show that our accelerator has the best performance out of other hardware works with 1.46x power efficiency and up to 2.73x average performance. In the future, we will further optimize our architecture and complete other operations in the ST-GCN layer.

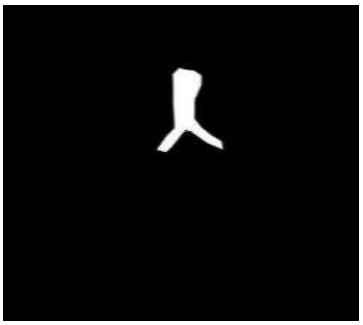
***Abstract*— A chest X-ray test is necessary to verify the correct positioning of several medical devices and to check for any issues that may have resulted from improper placement. The trachea, carina, and bronchi localization in chest radiography is a crucial test for patients in the Intensive Care Unit (ICU). Most of the images become affected by the machine or the shooting camera's position, so a physician is required to manually adjust the images to locate Carina. Therefore, this research aim is to automate Carina detection in chest X-ray images without manual adjustment. We proposed a Non-Overlapping Max Pooling (NOMP) connection and Cross-Squeeze Convolutional Attention (CSCA) to make up the design architecture. In addition, a convexity defect technique is combined with the post-processing algorithm to determine Carina's final placement. The experimental results show that the overall performance for average error distance is 0.3097 cm, the accuracy rate is 81.5% when the error falls within 0.5 cm, and the accuracy rate is 97% when the error falls within 1 cm.**



I. INTRODUCTION

Endotracheal intubation is a well-known life-sustaining medical procedure in the Intensive Care Unit (ICU) when patients cannot breathe independently. The appropriate position of the endotracheal tube is 5 ± 2 cm from the bifurcation point, and improper intubation may cause dangerous consequences. For example, Gupta et al. [1] explain in detail such as lung hyperinflation, lung collapse, or damage to the trachea. The method of confirming the correct position of the tube is most commonly performed on a chest X-ray (CXR), usually obtained with a portable X-ray image in the intensive care unit. The compact X-ray images are easily accessible throughout the hospital and also affordable. Chest X-rays proposed by Brunel et al. [2] are the traditional and frequently used method for intubation measurements due to their ability to be scaled on-screen. However, portable X-ray images are easily affected by external factors, resulting in unstable image quality, and it is difficult to judge the position of intubation appropriately. Therefore, in recent years, many researchers have paid more attention to Computer-Aided Diagnosis (CAD) methods, trying to improve the accuracy of tracheal intubation detection, thereby reducing the cost to physicians.

Deep learning has begun to be widely used in medical imaging fields, such as human pose improvement, brain activity, skin lesions, and the chest [3],[4],[5]. In recent years, many studies have used Convolutional Neural Networks (CNN) [7] to evaluate chest X-ray images for intubation. The model is being trained by fusing two pooling layers and adding a connection module for the center node. However, if many modules are included in the architecture, it causes an increase in data preprocessing cost, and parameters. The bifurcation endpoints and Carina prediction in of X-ray image are shown in Figures 1 (a) and (b).

(a)

(b)

Fig. 1. (a) The location of the tracheal bifurcation points in chest X-ray images and (b) the bifurcation points.

We have developed a deep learning algorithm to automatically detect tracheal bifurcation endpoints and Carina prediction on chest X-ray images. The proposed architecture improves the ability to extract model context information and retains useful feature information.

II. Related Works

Kara S. et al. [8] proposed an endotracheal tube identification and localization method that deleted 10% of the upper neck and 40% of the lower abdomen by cropping the Region of Interest (ROI). In addition, the retainer of the middle quarter of the horizontal axis of the X-ray image detection. Finally, adjust the image quality by enhancing contrast and morphology to find the location of the bronchial bifurcation. Jung et al. [9] used a Cascaded Neural Network (CNN) with a loss function and regression properties to find the position of the Endotracheal Tube Tip (ETT) and bronchial bifurcation point (Carina). Roy et al. created the model's detachable tracheal tube and bronchi and cut through the bounding box using concurrent spatial and channel squeeze & and excitation fully convolutional networks to create a two-stage model [10] design. Ultimately, the network is tasked with classifying the clipped data to decide whether the intubation position is adequate. Along with the U2-Net model, add the MA Block and the intermediate node layer. Then set the upper and lower bounds to find the position where the pixel contained for each horizontal axis, at least 0 in the range was the bronchial bifurcation point. Although they can concurrently locate the position of the endotracheal tube tip and the bronchial bifurcation point, the approaches rely on the configuration of hyperparameters to employ a multitasking strategy. The part about the location of the bifurcation point is still imprecise.

A variety of attention techniques have been employed in the past to address problems with picture vision, many of which were influenced by the attention strategy of Natural Language Processing (NLP). They create weights for each feature map value and instruct it to focus on particular areas, such as channel attention, spatial attention, and various attentional variants [11]. To address the issue of low interpretation in the fully connected layer, Hu et al. [12] proposed a Squeeze-and-Excitation Block (SE Block) through Global Average Pooling. As a result, Weighting is only carried out by feature maps, negating the need for parameter optimization and preventing overfitting. Lau et al. [13] used U-Net with a pre-trained ResNet-34 backbone network and added an SC-SE attention module in the decoder to improve the performance and segmentation accuracy of the model. Woo et al. [14] proposed a Convolutional Block Attention Module (CBAM) by combining two pooling techniques to obtain more accurate prediction results than adding an SE Block.

The fully convolutional neural network (Fully Connected Network, FCN) is the ancestor of the U-Net design [15]. It employs the skip connection to combine features and contracts the encoder's (Encoder) image through the contraction component before expanding it through the expansion part. As a result, even with tiny data sets, the U-shaped structure model [16] maintains high-quality feature maps and good performance for denoising image results.

The U-Net++ architecture [17] is a development of the U-Net model that uses several dense short connections in place of the skip connection used in U-Net for long-distance communication and the use of multiple U-Net models for merging. Combining feature maps with various up-sampling options improves the performance of the U-Net++ model. In addition, U-Net++ makes the model architecture more flexible by replacing the encoder with other backbones and can adjust the model depth according to experimental needs to improve the overall execution efficiency.

Qin et al. propose the U2-Net architecture [18] to compare the past module design methods and make a difference to the Feature Pyramid Networks (FPN) and earlier U-Net versions. The collection of residual U-blocks, also known as (RSU blocks), is included in the U2-Net using two layers. The RSU module builds a small U-Net based on the design of the feature pyramid network that can preserve high-resolution feature maps while enhancing the capacity to separate data at various scales through connections. We have adopted U2-Net as the backbone architecture for feature map classification by including the same modules. The proposed module reduces the overall computational cost by ignoring the unnecessary feature maps in segmentation tasks and highlighting the essential features.

III. Proposed Method

A. The Image Preprocessing

It is difficult to train the model with a limited number of datasets, making the model vulnerable to overfitting problems. We have used image data improvement methods to expand the data set. The data enhancements employed include picture random horizontal flip (Horizontal Flip), random zoom rotation (Shift Scale Rotate), and random contrast adaptive histogram equalization (CLAHE). The situation method enhances the simulation of reality. The scaling translation augments the unfixing angle of the chest X-ray images. The rotation and horizontal flip increase the diversity of patient shooting angles. The contrast adjustment simulates the unstable quality of portable chest X-ray images.

B. The NOMP-U2-Net

We have developed the NOMP-U2-Net model, as shown in Figure 2. It mainly consists of four sections: (1) each module uses the RSU-block, (2) the non-overlapping max pooling module, (3) The Cross -Squeeze Convolutional Attention, (4) The feature map fusion stage of each layer of Decoder.

1. The RSU-L module [19], where L is the number of layers of each module, has in the overall architecture. The first through fourth layers of the encoder contain the RSU-4 to RSU-7 module. In contrast, the fifth and sixth layers use the RSU-4F module in the encoder. These techniques utilize the dilation rates in the RSU Dilated convolution operation, which helps the model to get a broader receptive field when confronted with low-resolution feature maps, hence minimizing the loss of feature information.
2. The U2-Net model utilizes the RSU module to gather additional feature data. Deep semantic information is needed for this exertion to segment the entire bronchus. The NOMP convolutions between the encoder and decoder deal with shallow features. Figure 3 shows how the encoder combines after being pooled. The model performs better bronchial semantic segmentation while taking multi-scale input.
3. We have processed Cross-Spatial and Channel Residual (CSCR) attention. This simulation considers the original feature map and weighted feature map without adding additional information to the convolutional attention module. The Cross-Context Attention Mechanism (CCAM) enhances the model's capacity and gathers context information [20] to distinguish the foreground and background. Finally, the outcomes of cross-space and cross-channel residual attention are fed into the CCAM to generate Cross-Squeeze Convolutional Attention (CSCA), as shown in Figure 4.
4. Non-overlapping maximum pooling fuses the encoder's feature maps, resulting in the decoder getting more feature maps as input. The RSU module of each decoder layer will output the 64 feature maps. After integrating the decoders from each layer, the signal will pass through a convolutional layer and a single-row Sigmoid activation function.

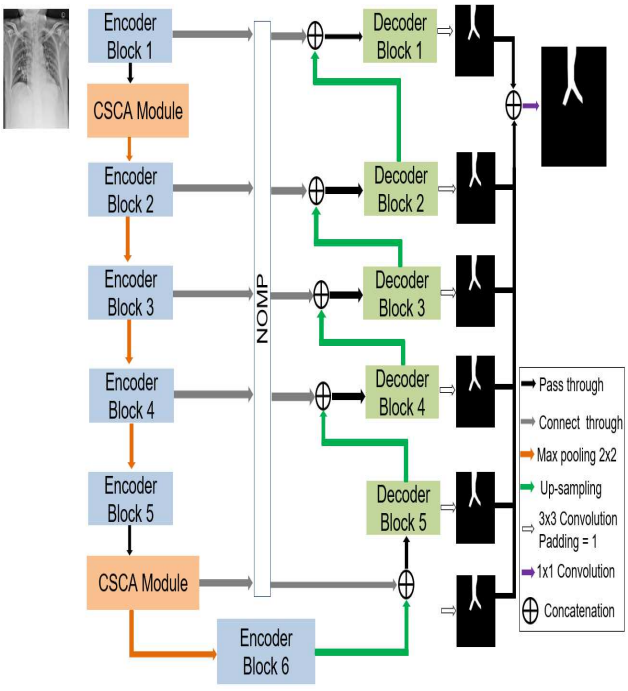


Fig. 2. NOMP U2-Net Structure Diagram.

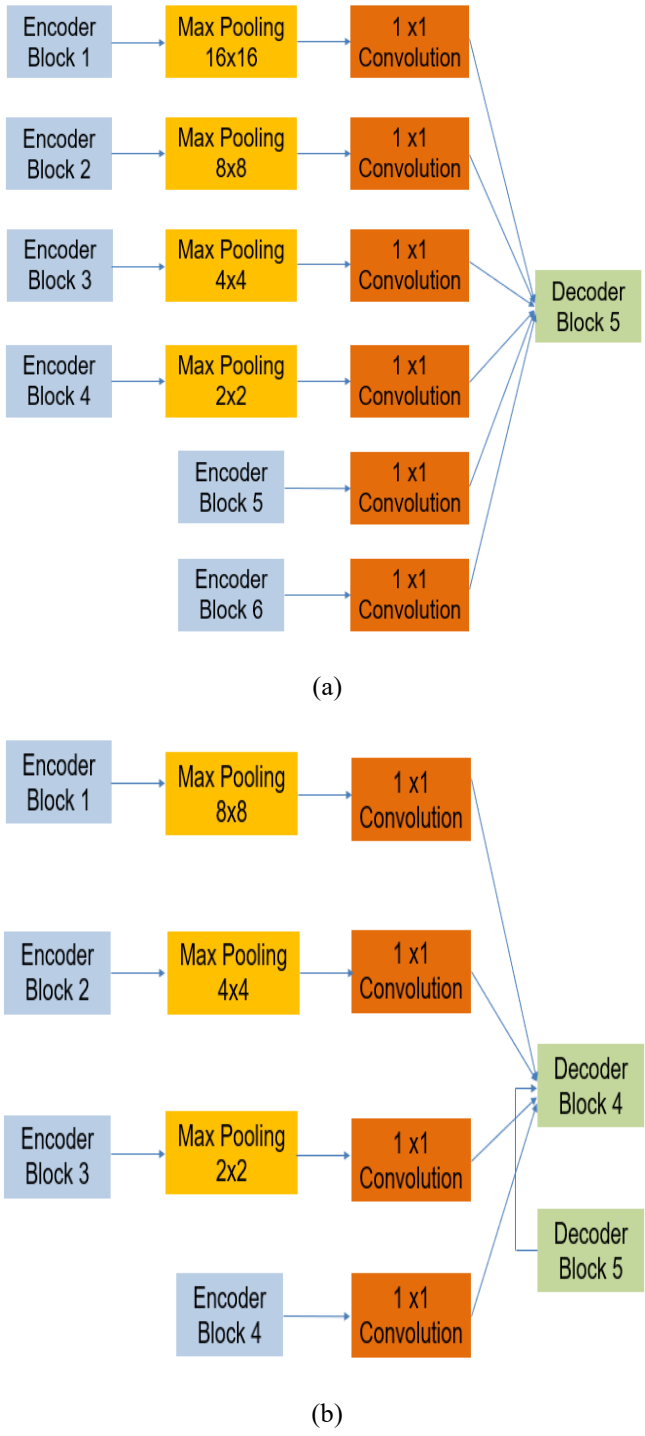

Fig. 3. (a) NOMP Decoder 5 link, (b) NOMP Decoder 4 link.

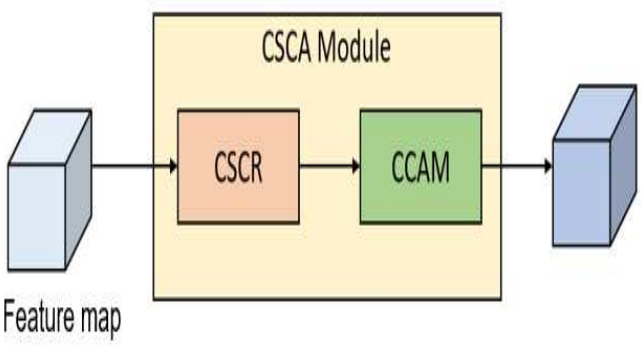

Fig. 4. CSCA module.

C. The Loss Function

The loss function clarifies how the actual value differs from the expected value. The deep learning training method involves minimizing the loss function. The projected value of the model approaches the actual value with decreasing loss functions. This work investigates Dice loss and BCE loss function to evaluate the model's performances [21]. Dice loss is often used in medical image segmentation when the background and foreground are unbalanced. The X and Y represent the pixel sets of prediction (Predict) and mask (Mask) consequently, and the range is between [0,1]. The dice loss equation (1) shows as follows:

$$\text{Dice loss} = 1 - \frac{2\,|X \cap Y|}{|X|+|Y|} \tag{1}$$

Binary Cross Entropy (BCE) cooperates with the Sigmoid function to calculate the loss of a single category. In bronchial segmentation, compare the predicted and masked bronchial parts, and adjust the model through the difference between the two values. In equation 2, N represents the pixel set of enter images, the y_i represents the mask, and $(\hat{y}_i)$ represents the prediction part, the range is between [0,2].

$$\text{BCE loss} = -\frac{1}{N}\sum_{i=1}^{N}\left(y_i * \log(\hat{y}_i) + (1-y_i) * \log(1-\hat{y}_i) \right) \tag{2}$$

Dice loss and BCE loss functions are combined to provide Dice_BCE loss shown in equation (3). The model is inclined to large gradient fluctuations, leading to unstable training. The model skews in favor of the background when BCE encounters an imbalance between the image's foreground and background. To address Dice loss and BCE loss functions and enhance the model's stability during training, two loss functions are combined in this work.

$$\text{Dice_BCE loss} = \text{Dice loss} + \text{BCE loss} \tag{3}$$

D. The Post-processing

Initially, the model predicts the bronchial segment as a contour of the bronchial mask and then counts the number of contours. The bifurcation locations and segmental bronchi are invisible without a contour. In the third step, concave points and edges are produced using convexity detection. The fourth part calculates the horizontal distance of each shape edge and selects the concave points corresponding to the two sides with the long distance as candidate points. The bronchial bifurcation point is the depression point that corresponds to the vertical gap between two sides of a massive space. The contour retains the largest gap effectively and solves the problem of noise interference, as shown in Figure 5.

The red color point is the bronchial bifurcation point obtained without setting the candidate point, and the green point is the setting candidate point, as shown in Figure 6. The resulting bronchial bifurcation points and blue dots are correctly labeled bronchial bifurcation points.

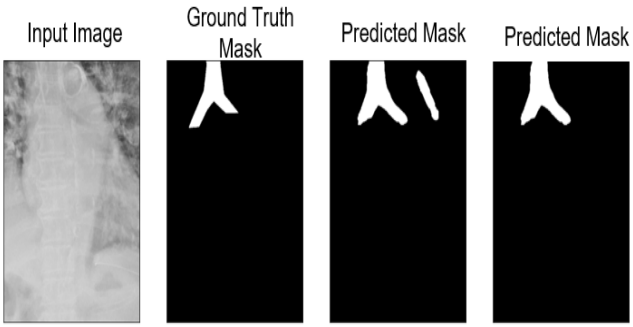

Fig. 5. Segmentation contours with large area preserved.

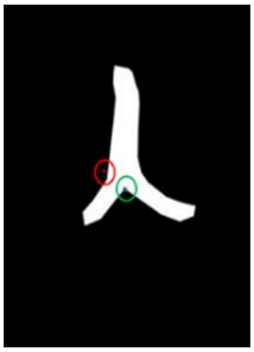

Fig. 6. Display of marked bronchial bifurcation points.

E. The Evaluation Criteria

This work uses four indicators to measure performance; Intersection over Union (IoU), average error distance (cm), accuracy within 0.5 cm, and 1 cm. The TP of IoU represents the total number of pixels that correctly predict the bronchi and are marked as positive. The FP is the total number of pixels that incorrectly predicts bronchi but is marked as positive. The FN is the total number of pixels wrongly forecasted as the background, marked as a negative value. The N represents the number of pictures in the test set, Y_i represents the mask, $(\hat{Y}_i)$ represents the prediction part, and P is 72 representing the total number of pixels converted to 1 cm.

$$\text{IoU score} = \frac{TP}{TP+FP+FN} \tag{4}$$

$$E_{_avg}\ (cm) = \frac{\frac{1}{N}\sum_{i=1}^{N}|Y_i-\hat{Y}_i|}{P} \tag{5}$$

$$E_{_0.5}\ (cm) = \frac{1}{N}\sum_{i=1}^{N} I_{0.5}\left(\left|Y_i-\hat{Y}_i\right| \le 0.5P\right) * 100\% \tag{6}$$

$$E_{1.0}\,(cm) = \frac{1}{N}\sum_{i=1}^{N} I_1\left(\left|Y_i - \hat{Y}_i\right| \le P\right) * 100\% \quad (7)$$

IV. Experimental Results

A. Dataset Rearrange

We obtained a real-case picture collection from a hospital for our research endeavor. There were 237 chest X-ray images. We have separated the data set into five folders, using three parts as training and two parts as validation and test datasets. In addition, did five times cross-validation to solve the overfitting problem caused by the scarcity of medical imaging samples.

B. Experimental Platform

We have used Pytorch 1.11 framework, and Adam optimizer for stochastic gradient descent to train the model. The number of iterations is 60, and the starting learning rate is 10^{-4}, so we decided to keep a batch size of 4. As a point of clarification, all testing has been performed on the Nvidia GeForce RTX 3080 GPU platform.

C. Experimental Results Analysis

The proposed NOMP U2-Net performs well in decreasing the error distance of the bronchial bifurcation point, with an average prediction error value of 0.3097 cm shown in Table 1. Besides, the internal accuracy is 0.815 percent for an error distance of 0.5 cm, and the accuracy is 0.970 cm for an error distance of 1.0 cm. The accuracy rate of error of 0.5 cm and 1 cm is enhanced after employing the proposed NOMP technique. The model concentrates on the segmentation of the bronchial component by adding the CSCA module. However, the cross-crowding method combines the channel's residual attention (CSCR) and cross-context attention mechanism (CCAM) in a Convolutional attention module CSCA, producing the best results for estimating the error distance of bronchial bifurcation points.

Table 1: Attention module ablation experiments

Attention	Dice_BCE	IoU	E_{avg}	$E_{0.5}$	$E_{1.0}$
CSCR	1.5267	0.707	0.421	0.780	0.940
CCAM	1.5262	0.713	0.405	0.801	0.957
CCAM & CSCR (Parallel)	1.5262	0.715	0.501	0.763	0.944
CCAM + CSCR (Series)	1.5259	0.717	0.415	0.741	0.953
CSCA Module	**1.5263**	**0.714**	**0.309**	**0.815**	**0.970**

Table 2 shows the result of the CSCA module connected to the intermediate layer of the encoder. The CSCA module restricted unnecessary features in the middle layers to perform well. The outcome of the first layer encoder using the attention module is utilized directly as the connection of the non-overlapping maximum pooling. The cross-squeezed convolutional attention module reduces the average error distance. The CSCA modules are incorporated to offer the maximum performance for forecasting the error distance of the bronchial bifurcation point in the middle layer, the fifth layer encoder, and the first layer.

Table 2: NOMP-U^2-Net Encoder Ablation Comparison

Structure	E_{avg}	$E_{0.5}$	$E_{1.0}$
NOMP U^2-Net	0.4079	0.8098	0.9618
U^2-Net + CSCA (**only en_1** add attention)	0.3634	0.7844	0.9491
U^2-Net + CSCA (**en_1 and en_1 connect** add attention)	0.4605	0.7335	0.9405
U^2-Net + CSCA (**only en_5** add attention)	0.3555	0.7755	0.9618
U^2-Net + CSCA **en_5 and en_5 connect** add attention)	0.3595	0.7715	0.966
U^2-Net + CSCA (**en_1 and en_5** add)	0.3848	0.7715	0.9364
U^2-Net + CSCA (**en_1 and en_5 and en_5 connect** add)	**0.3097**	**0.8157**	**0.9703**

V. Conclusions

We have adopted the U^2-Net model and modified it through Non-Overlapping Max Pooling (NOMP) operation to automatically detect the location of bifurcation points in chest X-ray images. In addition, we have developed a Cross-Squeeze Convolutional Attention (CSCA) link to make up the design of a neural network architecture. The proposed architecture retains essential and favorable feature information to achieve the best performance for predicting the error distance of bronchial bifurcation points. The result shows that the predicted average error distance of the bronchial bifurcation point is 0.3097 cm. Besides, the accuracy rate of detection error within 0.5 cm is 81.57%, and 1 cm is 97.03%. In the future, we will try to improve the structure of the model and try different attention mechanisms to see if we may achieve better performance by combining the Transformer modules to find the best model architecture.

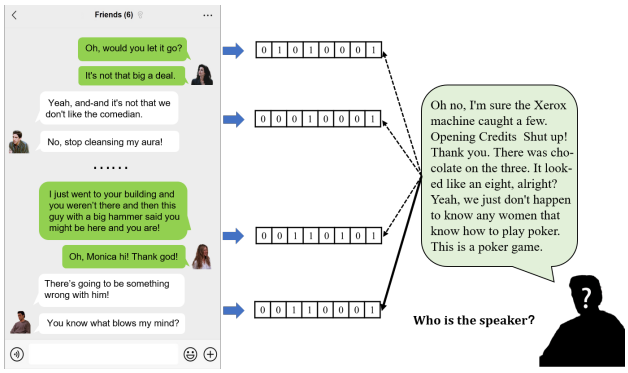

Fig. 1. An illustration of the process of identifying speaker with GCSH in group chat.

***Abstract*—Group chat brings great convenience to people's online social interaction. When identifying users in online social networks, individual speaking style of the member in group chat particularly plays an important role. In this paper, we propose a novel and efficient group chat hashing framework termed Group Chat Style Hashing(GCSH), which is the first work to utilize personal hashes in group chats to identify the speakers. GCSH combines a supervised VAE and a discriminator to extract accurate identity-related features and applies a new sample aggregation hash algorithm to generate an exclusive identity style hash for each one in the group chat. Our model fuses more context information to directly get the representative hashes, achieving an end-to-end identification model and sharply reducing the matching cost compared with previous text hashing methods. We conduct extensive experiments to prove the effectiveness and the generalization ability of our method across datasets.**

I. Introduction

With the internet fast developing, group chat scene has become a kind of conversation scene that people must come into contact with in the online social network. Numerous multi-person collaborative tasks and multi-person information sharing are realized through the group chat function of social software. Group chat involves rich multimodal information interaction. The members of group chat are able to send text, pictures, voice short videos and other forms of information to communicate with each other. Different from blogs and forums, contextual messages in group chat are more closely related. Group chat has the advantages of asynchronous communication and keeping users aware of the ongoing or past group agenda through traceable chat records. These features enable comfortable online group communication among members in different locations without disturbing their daily lives. With such rich and diverse interactive multimodal information, group chat is valuable for various research tasks. For example, it can help multimodal semantic comprehension tasks and multimodal content generation tasks.

In the group chat scene, user identification of group chat members has become a necessary research topic, which is also called authorship attribution in some studies. User identification is a task of identifying authors of anonymous content, according to the given examples of the writing of a predefined set of candidate authors [1]. In the task, we use given authors and content to analyze the features of each author, and distinguish the differences among the authors. In the test, the features extracted from each anonymous content are compared with those of known authors one by one. Among them, the author with the highest similarity to the anonymous content is most likely to be the author of the anonymous content. Therefore, in group chats, regardless of whether group chat members speak anonymously or not, we can target them easily. User identification now has been increasingly used in the fields of literature, intelligence, criminal law, civil law and computer forensics [2]. In addition, it also plays an important role in many areas such as information retrieval, information extraction and question answering.

Among the solutions to the user identification, text hashing has received widespread attention from researchers. Text hashing is a method that we can map the data points from the original space into the Hamming space of binary hash codes where the similarity in the original space is preserved in the Hamming space. By using binary hash codes to represent the original data, the storage cost can be dramatically reduced. Compared with using the classifier to solve the user identification problem, it is easier and faster to get high retrieval accuracy and high computational efficiency in the Hamming space by using text hashing.

Most of the existing methods using text hashing to solve the problem of user identification basically operate on traditional large-length texts such as news and literature. Few of them are suitable for short texts, especially in group chat scene because of a series of new challenges [3]. Compared with traditional scenes, what group chat members said are generally short in length and their personalities are not obvious [4]. The messages are mostly unstructured, informal and even grammatically incorrect, which are incomparable to elaborate literature and poetry in nature [5]. Only using the traditional

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

text hashing method can not solve the problem in group chat very well, their accuracy and performance are relatively poor in group chat scene.

In this paper, considering the particularity of short texts and the characteristics of group chat scene, we believe that the long-term speaking style of members in group chats and the personalities reflected in their words will have an important impact on the binary hash codes generated to distinguish different people. Therefore, we propose the Group Chat Style Hashing(GCSH), which is first work to generate group chat hashes to identify the speaker when someone speaks anonymously in online social networks. Figure 1 is an example, which illustrates the process of identifying speaker with our model in group chat. Our model contains a supervised Variational Auto-Encoder(VAE) [6], [7] and a discriminator. The encoder of VAE is responsible for extracting identity-related vectors and latent private vectors from the input message sentences. The decoder of VAE uses the above vectors to reconstruct the texts. The discriminator is used to form a Generative Adversarial Network(GAN) [8] framework with the decoder, which aims to help the decoder to get better performance. We also design a new sample aggregation hash algorithm. We aggregate the identity-related vectors of all of the messages belonging to one person together. So we can get the specific identity-related vectors of everyone to achieve high computational efficiency during identification.

The main contributions of this paper are summarized below:

- We propose the application of identifying the anonymous speakers in group chats with hashing, which can get accurate personal hashes from the messages of group chat members. To the best of our knowledge, this is the first work to generate personal hashes in group chats.
- We propose a novel supervised framework for group chat: Group Chat Style Hashing. We use the supervised VAE and the discriminator to extract accurate identity-related information of each member in group chats. We also design a new sample aggregation hash algorithm which averages the identity-related vectors of each person's messages so that we can get the exclusive personal style hashes for group chat members. With the supervised framework and the sample aggregation hash algorithm, we achieve an end-to-end generation of binary hash codes in group chats.
- A large number of experiments verify the advantages of our proposed model. We achieve better performance in group chats and significantly reduce the number of comparisons during the identification. Compared with previous text hashing methods, our model have higher identification accuracy and get better performance in terms of time consumption.

The rest of the paper is organized as follows. Section 2 reviews the related works of text hashing and group chat. Section 3 describes the proposed method in detail and experimental results are presented in Section 4. Finally Section 5 draws the conclusion of this paper.

II. Related Work

A. Group Chat

Group chat has attracted more and more attention from researchers in recent years. In [9], Soomin *et al.* proposed a bot named GroupfeedBot in group chat, which can facilitate group chat discussion more efficient by managing the discussion time, encouraging members to participate an organizing members' opinions. And another work [10] used emotion regulation and text analysis technology to propose a robot to guide the emotional enthusiasm of group chat. During the COVID-19 pandemic, some researchers analyzed the information of the group members from five dimension: participation, sentiment, negative emotions, topics, and message types [11]. They used this method to judge the opinions of the people and whether rumors had been spread in the telegram group. Tilda [12], a prototype system, was proposed to enable users more easily to make sense of the dialogues in group chat they missed. It enriched the representation of chat conversations, using techniques such as tagging and summary.

Some researches about response generation in group chats are also related. Ouchi *et al.* [13] proposes a framework called Dynamic-RNN to fulfil the response generation task. On this basis, SI-RNN [14] is raised to process group chat members in a role-sensitive manner, with which the performance of response generation is improved. But both of them are retrieval-based approaches and cannot generate diverse responses. Another work called GSN [15] designs a graph network to represent group chat members' interaction and generates responses. ICRED [16] models group chat members according to different roles, and then integrates the member information into the response generation. Although many valuable researches existed, there are still many research gaps in group chats presently.

B. Text Hashing

There have been many valuable research achievements in the field of text hashing. Locality Sensitive Hashing (LSH) [17] is one of the most popular unsupervised hashing methods, which simply used random linear projections to construct hash functions leading to better performance. Self Taught Hashing (STH) [18] is an excellent hashing method which excluded document features and only considered the document connectivity. In [19], Wang *et al.* proposed Semantic Hashing using Tags and Topic Model (SHTTM) to incorporate tags to obtain more effective hashing codes via a matrix factorization formulation.

Another great achievement in this field is semantic hashing [20]. It built a stack of restricted Boltzmann machines(RBMs) [21] to discover hidden binary units which could model input text data, i.e., word-count vectors. After learning a RBM through pre-training and tuning on a collection of documents, the hash code of the document could be acquired by the threshold of the output of the layers. The work [22] exploited convolutional neural network for text hashing, which embed the keyword features into compact binary code with

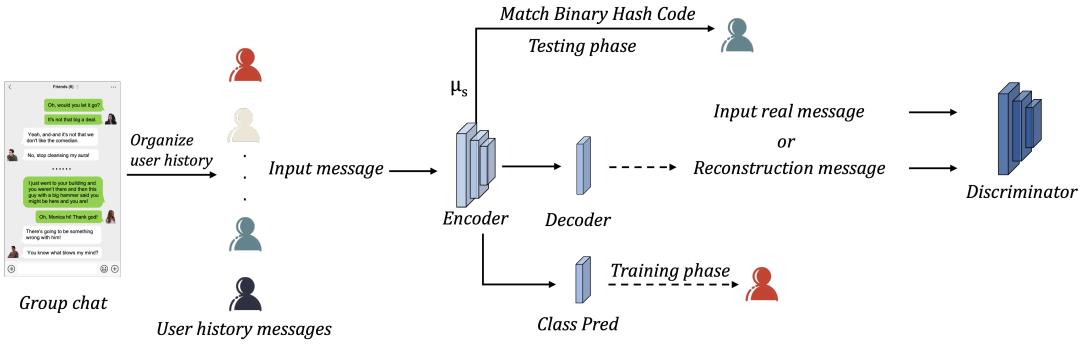

Fig. 2. Overview of the proposed model. We collated each user's historical chat data from user social group chats into the model. The encoder extracts the latent vectors and decoder reconstructs the message. The discriminator penalizes the framework for better reconstruction quality and more representative vectors. In the training phase, adding prediction branches helps the model learn better feature vectors. In the testing phase, the hash code is generated through the vector $\boldsymbol{\mu_s}$ learned by the encoder for direct user matching.

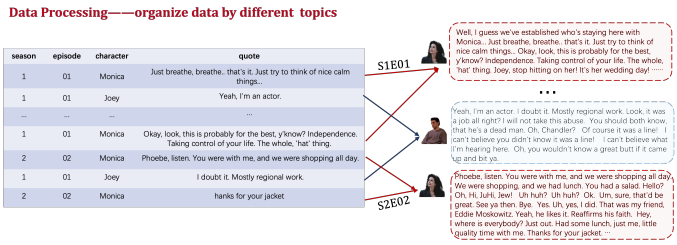

Fig. 3. An example of our data processing with the group chat messages in the sitcom "Friends". We categorize all the quote in the sitcom "Friends" by different episodes and different chat topics.

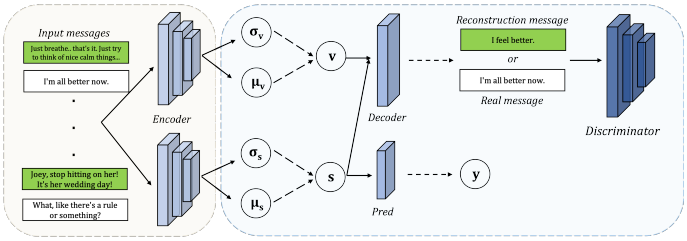

Fig. 4. a) The encoder extracts the identity-level vector $\boldsymbol{s}$ and private variables $\boldsymbol{v}$. b) The decoder reconstructs the message by the vector $\boldsymbol{s}$ and $\boldsymbol{v}$. c) The discriminator enables the framework to generate better reconstruction messages and more representative $\boldsymbol{s}$ and $\boldsymbol{v}$.

a locality preserving constraint. Meanwhile it combined the implicit features learned from word features and position features with the explicit features to fit the pre-trained binary code.

Deep generative models have made impressive progress with the introduction of the Variational Auto-Encoder(VAE) [6], [7] and Generative Adversarial Network(GAN) [8]. Some researchers applied these great achievements to text hashing. For example, Suthee *et al.* proposed the Variational Deep Semantic Hashing(VDSH) [23], an unsupervised model, which applied VAE into text hashing. At the same time, they also proposed a series of supervised models, i.e., VDSH-S and VDSH-SP. They generated hash codes by using the latent semantic vectors that generated from the encoders. And the supervised models enhanced the learning performance through using the labels in the decoders. In [24], with the use of BM25 as a weak annotator, Suthee *et al.* proposed a weak supervisied method based on the model in [23].

III. Group Chat Style Hashing

The proposed model is a group chat style hashing framework based on supervised VAE and the discriminator as shown in Figure 2, generating unique hashes for people for identification. Details will be shown in the following.

A. Group Chat Messages Organization

Messages in group chats are generally short in length, even unstructured and grammatically incorrect, which are very different from traditional texts. The length and content of any single message is not enough to obtain the style hash of a member in group chat. Due to the particularity of group chat messages, we need to process group chat messages differently than before. Figure 3 shows our data processing with an example.

The previous methods deal with data very little. In general, it is directly calculated with a piece of text. The data can be expressed by the formula as follows:

$$T = \{t_1, t_2, t_3, \cdots, t_{r-1}, t_r\} \tag{1}$$

where T represents the collection of all texts and t represents a piece of text in the collection. Such processing is obviously not suitable for group chat scenarios. In this paper, we collect all the historical conversations of group chat members first, which can be seen in the following equation:

$$C = \{C_{p_1}, C_{p_2}, C_{p_3}, \cdots, C_{p_{n-1}}, C_{p_n}\} \tag{2}$$

where C represents the total collection of all the messages spoken by everyone in the group chat. It contains all the messages in historical record. We categorize it by group chat members and we can get each person's message collection,

which is marked as $C_{p_i}, i \in [1, n]$, n is the number of the members in the group chat.

Then we classify all the chat messages of one member in group chat according to the topic and the dialogue scene. The dialogue scene mentioned here refers to a group chat conversation about one topic and the context is closely related. The following equation describes the classification result.

$$C_{p_i} = \left\{ C_{p_i}^{s_1}, C_{p_i}^{s_2}, C_{p_i}^{s_3}, \cdots, C_{p_i}^{s_{m-1}}, C_{p_i}^{s_m} \right\}, i \in [1, n] \quad (3)$$

where $C_{p_i}^{s_j}, i \in [1, n], j \in [1, m]$ is the message collection of the group chat member p_i in the dialogue scene s_j. m is the number of the topics or dialogue scenes that the group chat member p_i has participated in.

As for the collections $C_{p_i}^{s_j}, i \in [1, n], j \in [1, m]$, each of them contains all the messages of a group chat member in that scenario, and we put them together. It is shown as the following equation:

$$C_{p_i}^{s_j} = \{ s_1, s_2, s_3, \cdots, s_{q-1}, s_q \}, i \in [1, n], j \in [1, m] \quad (4)$$

where s represents a piece of message. The q in this formula is an indeterminate value, which is determined according to the amount of messages of the group chat member in the actual scene.

B. Hashing Architecture

The details of the model are shown in Figure 4. Let $\boldsymbol{x}$ be the bag-of-words representation of the messages of somebody in the group chat, and the latent vectors of the input message are obtained through the encoder. In the ordinary VAE framework, we usually reconstruct the texts by latent vectors without supervised labels.

However, in the group chat scenario, even if different people speak similar words, their identity-related high-level features such as personal speaking style are not the same. In other words, input text with similar content in the original space may not be similar in the identity-related feature space. Therefore, we need to use the person label information in the group chat to generate identity-related high-level features $\boldsymbol{s}$ for each person. There is another problem. Not in all cases, messages are always related to speaker characteristics. For example, someone who says "hi", "thank you", which have little relationship with their personalities. So we cannot extract unique identity-related features based on this. Inspired by VDSH-SP, we apply a supervised VAE with an extra latent private vector $\boldsymbol{v}$. Specifically, identity-related vector $\boldsymbol{s}$ extracts identity-related high-level features from input texts and label information while $\boldsymbol{v}$ only contains the input-specific information which is irrelevant to the identity label. Then, $\boldsymbol{s}$ and $\boldsymbol{v}$ jointly through the decoder to reconstruct the text. The class prediction is obtained from the $\boldsymbol{s}$ variable through the decoder and softmax function. In this way, we can ensure to the greatest extent that $\boldsymbol{s}$ contains valid identity features without other interference information. It is important for the subsequent generation of specific hashes for each person.

To enable the encoder-decoder structure to reconstruct more realistic texts and make the latent variables more in line with the original data distribution, we add a discriminator to the basic model to form a GAN framework with the decoder. The discriminator hopes to distinguish the reconstructed message from the original message as much as possible. While the generator, which means the decoder, expects the reconstructed text as similar as possible to the original text, thus fooling the discriminator. Finally, through the GCSH model, we can get an identity-related vector that is more consistent with the input to compute the binary hash code.

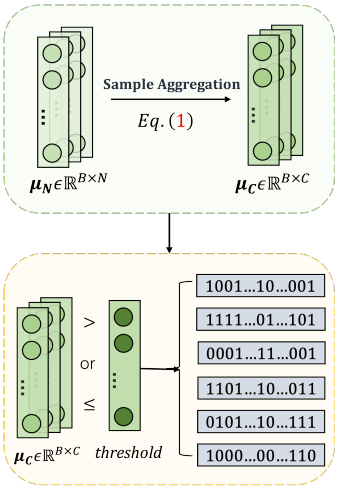

Fig. 5. The sample aggregation hash algorithm aggregates $\boldsymbol{\mu_N}$ to $\boldsymbol{\mu_c}$, then generate hash for each person by comparing $\boldsymbol{\mu_c}$ with threshold.

C. Sample Aggregation and Binary Hash Code

Different from traditional long texts such as news and articles, messages in group chats are usually short and informal. Due to the limited information and lack of rigorous text structure, it is difficult for us to obtain good contextual features. In addition, traditional retrieval or identification requires matching test data with all samples of all categories in the database, which is complicated and inefficient.

To address these issues, we propose a new sample aggregation hash algorithm to generate a unique hash for each person in the group chat, achieving an end-to-end identification framework. Specifically, we aggregate the identity-related variables $\boldsymbol{s}$ of samples belonging to the same person to directly obtain specific identity-related vectors of different people, as shown in the following equation and Figure 5.

$$\boldsymbol{\mu_c} = \frac{\sum_{k=1}^{N} \boldsymbol{\mu_k}}{N} \quad (5)$$

where N represents the total number of samples in each class, and we average each sample to their class to obtain the specific $\boldsymbol{\mu_c}$ value of each person. The expectation of $\boldsymbol{s}$ in the standard Gaussian distribution is $\boldsymbol{\mu}$, so the average of $\boldsymbol{s}$ is equal to the average of $\boldsymbol{\mu}$ in actual calculations.

Then, we take the median of $\boldsymbol{\mu_c}$ of all people as the threshold for obtaining the binary hash code [23]. If the m^{th} bit of $\boldsymbol{\mu_c}$ of someone is larger than the m^{th} bit of the threshold, the binary hash code of someone is set to 1, otherwise, it is 0.

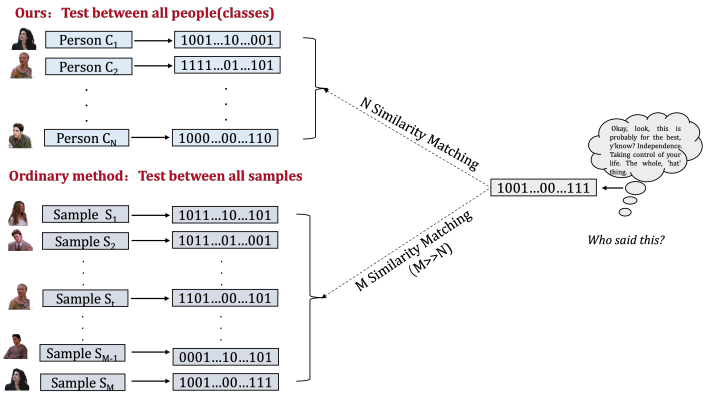

Fig. 6. Only need to compare the test data with each person's hash code instead of matching enormous samples.

It means, we generate the unique hash for each person in the group chat.

Through this strategy, we can not only directly obtain the representative style hash for each person, but also fuse more context information of multiple samples to obtain more accurate feature vectors. Instead of comparing all samples and then determining the final attribution of the test data based on the matched sample's label, we only need to compare the test data with each person's hash code during identification as shown in Figure 6. Therefore our method achieves an end-to-end identification framework, which is a complete process rather than multiple stages. Accordingly, the computational complexity during identification is reduced from the number of samples to the number of classes, which greatly reduces the magnitude of calculations.

D. Object Functions

The GAN structure composed of the decoder and discriminator uses the least-squares GANs[25] to optimize the GAN framework for more accurate identity-related vector $\boldsymbol{s}$ and improved quality of reconstructed texts, which can be formulated as follows:

$$\begin{aligned}\mathcal{L}_{\mathcal{D}} &= \frac{1}{2}\mathbb{E}_{\boldsymbol{x}}\left[D\left(\boldsymbol{x}\right)-1\right]^2+\frac{1}{2}\mathbb{E}_{\hat{\boldsymbol{x}}}\left[D(\hat{\boldsymbol{x}})\right]^2 \\ &+ \frac{1}{2}\mathbb{E}_{\boldsymbol{z}}\left[D(G(\boldsymbol{z})\right]^2 \end{aligned} \tag{6}$$

where $\boldsymbol{x}$ represents the input text, E is the encoder, G means the decoder and also generator, and D is the discriminator. The reconstructed text $\hat{\boldsymbol{x}}=G(E(\boldsymbol{x}))$. And $\boldsymbol{z}$ represents the random variable obtained from the standard normal distribution, used for the training of the discriminator.

The loss of the VAE is divided into three parts. The first part is the basic loss part, including the KL loss of $\boldsymbol{s}$ and $\boldsymbol{v}$ and the class prediction loss.

$$\mathcal{L}_{kl}=D_{KL}(Q(\boldsymbol{s})||P(\boldsymbol{s}))+D_{KL}(Q(\boldsymbol{v})||P(\boldsymbol{v})) \tag{7}$$

$$\mathcal{L}_{pred}=\ell_{CE}(\hat{\boldsymbol{y}},\boldsymbol{y}) \tag{8}$$

where the $Q(\boldsymbol{s})$ and $Q(\boldsymbol{v})$ represent the distribution of $\boldsymbol{s}$ and $\boldsymbol{v}$. It is worth noting that we usually assume that $\boldsymbol{s}$ and $\boldsymbol{v}$ obey the standard Gaussian distribution $P(\boldsymbol{s})$ and $P(\boldsymbol{v})$. The second part is the reconstruction loss of the decoder and the discrimination error of the discriminator.

$$\mathcal{L}_{re}=\frac{1}{2}(\alpha||\boldsymbol{x}-\hat{\boldsymbol{x}}||^2+||D(\boldsymbol{x})-D(\hat{\boldsymbol{x}})||^2) \tag{9}$$

where α denotes the weight of the reconstruction loss of the decoder and we set it to 0.01 in our experiment. The third part is the discrimination error of the random data.

$$\mathcal{L}_{dis}=\frac{1}{2}\mathbb{E}_{\boldsymbol{z}}\left[D(G(\boldsymbol{z})-1\right]^2 \tag{10}$$

Finally, the loss of VAE can be expressed as:

$$\mathcal{L}=\mathcal{L}_{kl}+\mathcal{L}_{pred}+\beta\mathcal{L}_{re}+\mathcal{L}_{dis} \tag{11}$$

where β is the weight of $\mathcal{L}_{re}$ and usually be seted to 0.01.

IV. Experiment

We collect two datasets by ourselves and we conduct our experiments on them. We will extract the group chat style hashes of members in group chats during the training stage, and then in the testing phase we will test on different datasets to identify the group chat members. In this section, we first introduce the datasets we bulit and the experiment setup. Then we present the experiment results and generalization analysis of our model.

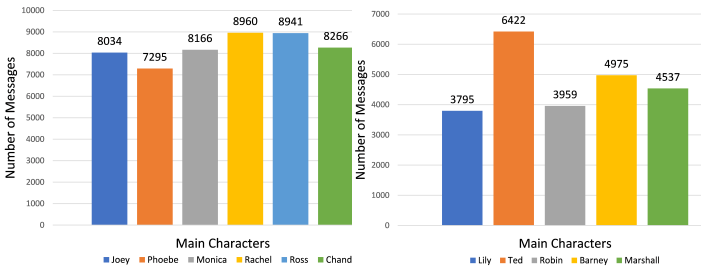
A. Datasets

For our experiments, We build two group chat dialogue datasets named "Friends" and "HIMYM" respectively, which contain intensive chat conversations among the main characters in different thematic scenarios. In this part, we first introduce the data collection procedure and then present the properties of these two datasets.

1) Data Collection: Due to the lack of high-quality group chat data and the copyright issues of private chat messages, we build two datasets of group chat dialogues in TV sitcoms to create a real group chat environment as much as possible. We choose the dialogue between the main characters in two sitcoms "Friends" and "How I Met Your Mother"(HIMYM) as the datasets. We believe that the scene in the sitcom "Friends" is more similar to the group chat scene, even the topics and the dialogue content in the sitcom "Friends" are richer. So we collect the Friends dataset. As for the sitcom "How I Met Your Mother", we believe that the protagonists in it have similar personalities to the protagonists in "Friends", and the dialogue content and chat themes are equally rich. Therefore, we collect the HIMYM dataset for cross-dataset test in the experiments.

After filtering out low quality and incomplete data, we finally collect 58,911 messages from lines in 236 episodes of the sitcom "Friends" and collect 34,589 messages from lines in 133 episodes of the sitcom "How I Met Your Mother". We will continue to expand the datasets in the future.

TABLE I



ACCURACY ON THE FRIENDS DATASET(TOP100/1089 MEANS THE PRECISION OF THE TOP 100 RETRIEVED TEXTS AMONG ALL SAMPLES. TOP1/6 MEANS THE PRECISION OF THE TOP 1 MATCHED AMONG SIX PEOPLE. PRECISION IS EQUIVALENT TO THE ACCURACY IN THIS TOP1 SITUATION)

Method	Top100/1089					Top1/6(Sample Aggregation)				
	8 bits	16 bits	32 bits	64 bits	128 bits	8 bits	16 bits	32 bits	64 bits	128 bits
VDSH-S	0.5270	0.5650	0.5501	0.5892	0.6054	0.6324	0.6397	0.6544	0.6618	0.6912
VDSH-SP	0.5982	0.6025	0.6607	0.6535	0.7001	0.6250	0.6471	0.7132	0.6838	0.7279
GCSH	**0.6409**	**0.6517**	**0.6911**	**0.6998**	**0.7190**	**0.6544**	**0.6838**	**0.7132**	**0.7353**	**0.7647**

Method	Top100/1089	Top50/1089	Top10/1089	Top1/1089	Top1/6
VDSH-SP	0.7001	0.7076	**0.7184**	0.7147	0.7279
GCSH	**0.7190**	**0.7206**	0.7162	**0.7426**	**0.7647**

(a) Friends Dataset. (b) HIMYM Dataset.

Fig. 7. Statistics of main characters messages in Friends and HIMYM Dataset

2) Data Statistics: The Friends dataset contains 58,911 messages spoken by all characters, from which the dialogues of six main characters are selected. Figure 7(a) illustrates the number of messages from six main characters. The number of messages from the five main characters exceeded 8,000, except for Phoebe, only 7,295. Categorized by different chat topics and different chat scenarios, we divide what they said into many pieces, each of which contains all the messages of one person in one scenarios, totaling 1362 pieces.

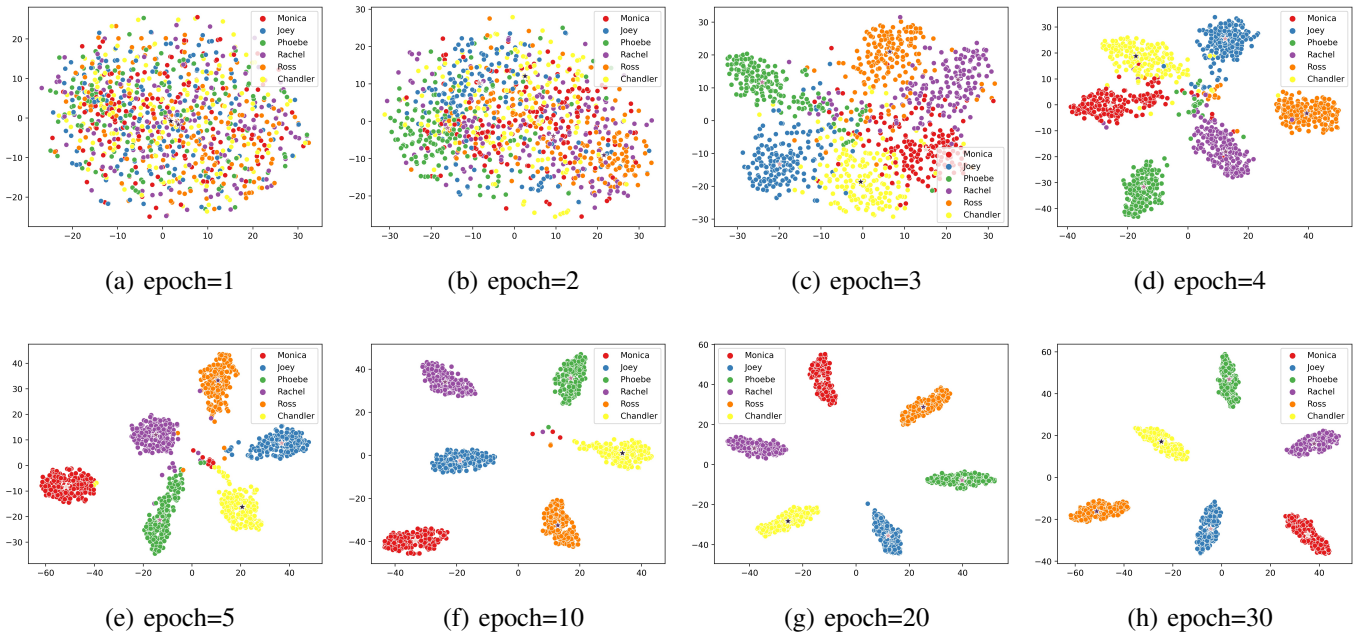
The HIMYM dataset contains 34,589 messages spoken by all characters. With filtering all the messages, we remove a series of low-quality dialogues and some dialogues of unimportant characters. Finally, we get the dialogues of the five main characters, which is shown in Figure 7(b) in detail. Because this dataset is mainly used for cross-dataset test, it is not as large as the Friends dataset. The same processing method as the Friends dataset is used for the HIMYM dataset. We divide the messages according to the dialogue scenes, and obtain a total of 663 pieces, which consist of the five main characters dialogues in different chat scenarios.

The Friends dataset was split into three subsets with roughly 80% for training, 10% for validation, and 10% for test. The HIMYM dataset is used to test the model's generalization ability across datasets in the experiments.

B. Implementation Details

There are three components in GCSH, i.e., encoder, decoder, and discriminator. We apply ReLU, Tanh, and Leaky ReLU activation functions to the encoder, decoder(generator), and discriminator respectively.

In addition, GCSH is implemented via PyTorch and optimized by Adam with the learning rate of 0.001. We trained all models with a batch size of 16 on NVIDIA GeForce GTX 1080 Ti GPU with 11GB V-RAM.



C. Experimental results and Ablation Study

We evaluate the proposed model on the Friends dataset together with the compared models, VDSH-S and VDSH-SP, proposed in [23] as shown in Table I. Obviously, our model gets better results than the baseline in all cases. The best accuracy is achieved to 0.7647 by our model using the new sample aggregation hash algorithm. The introduction of the discriminator allows us to get more realistic hashes than the baseline. We can also find that the best performance of all models is achieved when we use the 128-bit hash. The reason is that the hash of more bits can contain more information, which helps us to distinguish the different people better.

It is noteworthy that our sample aggregation hash algorithm plays an important role. The algorithm can increase the accuracy by 1%-5% and reduce the number of comparisons from 1089 to 6. The effect is especially obvious when using the 128-bit hash. We perform ablation studies to show the advantages of our algorithm more clearly as shown in Table II. As the retrieved samples decrease, the precision or accuracy(when Top1) is on the upward trend. Compared to the baseline VDSH-SP, the accuracy has increased from 0.7147 to 0.7426 when we utilize the discriminator. After the sample aggregation algorithm is adopted, the number of comparisons is reduced from 1089 to 6, but the accuracy does not decrease. Instead, the accuracy increases from 0.7426 to 0.7647, which proves the effectiveness of the algorithm. Figure 8 visualizes the different training phases of our proposed model. Each point in the figure represents a message someone said, and different colors refer to different people. As we can see in (a), the points are very messy at first. With the training of the model, the points gradually cluster together and the distances among clusters increase. In (h), different classes points have been completely separated.

D. Cross-Dataset Similarity Test and Generalization

To further validate GCSH can generate similar hashes for similar people, we calculate the Hamming distance to represent the similarity between different hashes. The smaller the distance, the greater the similarity. We set the similarity thresholds and divide the similarity among characters into three

(a) epoch=1 (b) epoch=2 (c) epoch=3 (d) epoch=4

(e) epoch=5 (f) epoch=10 (g) epoch=20 (h) epoch=30

Fig. 8. Visualization of the 16-dimensional identity-related vector $\boldsymbol{\mu}$ after dimensionality reduction.

TABLE III
THE SIMILARITY TEST RESULT ON THE FRIENDS DATASET (WE REPORTED THE DISTANCE BETWEEN HASHES RESPECTIVELY OBTAINED FROM THE TRAINING SET AND TEST SET FOR THE SAME PERSON, WHERE THE SMALL DISTANCE MEANS HIGH SIMILARITY.)

nbits	Monica	Joey	Phoebe	Rachel	Ross	Chandler
128 bits	22	26	32	**17**	36	33
64 bits	12	19	14	**3**	18	19
32 bits	9	10	10	**7**	9	9
16 bits	3	4	**1**	4	6	5
8 bits	2	**1**	2	2	2	**1**

TABLE IV
SIMILARITY TEST BETWEEN DIFFERENT CHARACTERS IN FRIENDS AND HIMYM WITH 128-BIT HASH

Character	Monica	Joey	Phoebe	Rachel	Ross	Chandler
Lily	59	65	76	63	64	**57**
Barney	78	**48**	73	70	67	48
Marshall	76	52	71	70	65	**50**
Robin	67	65	70	69	60	**53**
Ted	76	60	73	74	59	**42**

intervals, which are 0%-50%, 50%-70%, and 70%-100%. They represent the dissimilar, similar, and almost same respectively. We firstly conduct the similarity test on the Friends dataset, which calculates the similarity between the hash obtained from the training set and the hash obtained from the test set for the same person under different hash lengths. We find that almost all of the results in Table III are in the range of 70%-100% of their corresponding hash lengths(e.g. $1 - 17/128 \approx 87\%$). This means that our model can effectively generate almost the same exclusive hash for the same person with different test data. Very few results do not meet the conclusions because some words don't have personal characteristics, for example, hello, thanks. It is difficult to distinguish them accurately in the test.

To verify the generalization of our proposed model, we conduct a cross-dataset test between the Friends and HIMYM datasets. We want to know whether people with similar personalities in different datasets have similar hash codes, that is, how generalized the model is. Table IV indicates the distance between the characters in Friends and HIMYM under 128-bit length. According to our acknowledgment, there are two pairs of characters with similar personalities in these two sitcoms, namely Chandler and Marshall, Joey and Barney. The similarity of Barney-Joey is 62.5% and Marshall-Chandler is 60.9% which are in the range of 50%-70%. It meets the same conclusion as the actual personalities of characters in the sitcoms. This proves our model has great generalization ability that can generate similar hashes for similar people. For most people with different personalities, the results are almost all less than 50%. But there are also few abnormal results all related to Chandler. The reason is that Chandler has similarities with other characters and his character may not be clearly reflected in the lines, perhaps through tone and behavior.

V. CONCLUSION

In this paper, we proposed a novel group chat hashing model, which is called Group Chat Style Hashing(GCSH). It can generate personal style hashes of group chat members and achieve end-to-end identification in group chats efficiently. We designed a new sample aggregation hash algorithm, which helps us get the exclusive personal style hashes for group chat members and leads to a sharp reduction of the comparison number during the period of identification. Extensive experi-

ments demonstrate the superiority and good generalization of our model in the group chat scene.

Abstract — **Pose-based visual servoing (PBVS) can complement the frequent drift issue of light detection and ranging (LiDAR) coordinate of LiDAR-based simultaneous localization and mapping (SLAM), navigation, and servoing technology, especially when autonomous mobile robot (AMR) works on the automatic docking alignment missions for automatic pallet engaging or automatic battery charging whose alignment precision requirement is extremely stricter. But PBVS occasionally suffers from the poor detected image quality of ARTag landmark to cause the reading drift or error. This paper proposes the lightweight deep-learning binarization method to preprocess the image quality of ARTag landmarks so that PBVS can evaluate the distance and pose between the ARTag landmark and the camera sensor more accurately, promptly, and steadily, for better feasibility of PBVS on the automatic docking alignment missions. Experimental results show, against conventional image-processing-based binarization, conventional computer-vision-based binarization, and conventional deep-learning-based binarization, the proposed lightweight deep-learning binarization not only raises the accuracy and reliability of ARTag's reading, but also apparently improves the effectiveness and efficiency of PBVS's operation, especially under environmental conditions of shadow occlusion, image blurring, low contrast, uneven illumination, or complex background.**

I. INTRODUCTION

With the ever-increasing demand of automation transportation technologies in intelligent factories or intelligent warehouses, automatic mobile robot (AMR) without occupying a significant amount of fixed space to facilitate automatic material handling is the best choice [1], [2]. Consequently, research on AMRs has become more and more attractive in both academic and industrial fields, and has further extended its application to more scenes. In general, AMRs can be divided into two main categories: tracked AMRs and trackless AMRs. Tracked AMRs require the deployment of magnetic tracks, color tapes, or QR codes, and they can only move along these tracks. Parking, acceleration, deceleration, docking and rotation totally rely on the infrastructure of laid tracks on the floor. Moreover, the track redeployment is more time-consuming and cost-expensive to redesign the hardware and software of infrastructure. Tracked AMRs has poor flexibility and adaptability to complex or specific scenes, while it also has high maintenance costs. Trackless AMRs primarily utilize light detection and ranging (LiDAR) for positioning and navigation. Trackless AMRs can detect the contours of objects in intelligent factories or intelligent warehouses, build up the depth point cloud maps of the working area, and plan navigation routes without any infrastructure deployment of laid tracks. However, the frequent drift error of LiDAR coordinate adopted by trackless AMRs for positioning and navigation is essentially 5-10 cm at minimum if no other optimization firmware or preprocessing algorithm is further applied. Besides, since LiDAR sensors use infrared light as their light source, there are certain physical limitations. For example, infrared light can penetrate glass, infrared light is extraordinarily reflected by the metal plates of machinery equipment, and infrared light is completely absorbed by some materials like fabric and paper. Therefore, in specific situations, positioning failures and navigation errors are unavoidable.

However, on the automatic docking alignment missions of automatic pallet engaging or automatic battery charging whose alignment precision requirement is extremely stricter, trackless AMRs with the frequent drift error of LiDAR coordinate of 5-10 cm at minimum is not eligible to work, even not safe to work. As a result, pose-based visual servoing (PBVS) is the simplest

but practical solution for trackless AMRs [3], [4]. PBVS can estimate the distance and pose between the tag landmark on the docking destination and the camera sensor on the trackless AMR, and then control the motion and rotation of trackless AMR to approach and align the docking destination precisely. With a few wallpapered and radioless tag landmarks, PBVS can offer additional simultaneous localization and mapping (SLAM) information to LiDAR-based trackless AMR for precise alignment and immediate relocalization.

This paper adopts ARTag shown in Fig. 1 as the tag landmark for PBVS functionality of trackless AMRs. Through the PBVS functionality working onto ARTag landmarks [5], trackless AMRs can obtain the location of ARTag landmarks on 3D image (camera viewing) coordinate, specifically referring to the return value of "distance" and "pose" between the ARTag landmark on the docking destination and the camera sensor on the trackless AMR. The ARTag landmark is a marker system proposed by "ARToolKit" that is an open-source computer tracking library originally for creation of augmented reality applications on the real world, and recently for facility of trackless AMR applications on the automatic docking alignment missions. The ARTag landmark makes good use of a dual-tone planar pattern, and each pattern contains a unique ID number. Apart from QR code, the graphical simplicity of the ARTag makes itself detected at a farther distance and has itself favored in the PBVS field. Since the ARTag landmark has a simple square planar pattern and a black-and-white design with black tags and a white outer frame, the distance and pose of the detected corner features are relatively stable through the intersection points of the edge lines. Therefore, the open-source project *Ar_track_alvar* [6] is used to obtain the location of ARTag landmarks on 3D image (camera viewing) coordinate, as shown in Fig. 2. Under the known size of the ARTag landmark, the four corner features and four edges of the ARTag landmark can be used to estimate the distance and pose between the ARTag landmark on the docking destination and the camera sensor on the trackless AMR, through Homography (perspective) transformation.

Fig. 3 shows the overall flowchart of conventional trackless AMRs featuring with 4 operating modes of SLAM, navigation, PBVS, and dead reckoning. In general, the overall flowchart of conventional trackless AMRs, as shown in Fig. 3, can be divided 4 stages: 1) SLAM stage usually adopts Rao-Blackwellized Particle Filter (RBPF) [7] at the step of positioning estimation for SLAM and employs Occupancy Grid Mapping [8] at the step of map building. SLAM stage maps the scan of point cloud of 2D LiDAR sensor onto the real-world environment for construction of incremental map. 2) Navigation stage adopts Adaptive Monte Carlo Localization (AMCL) [9] at the step of positioning estimation for navigation, utilizes Dijkstra algorithm [10] at the step of path planning to obtain the global shortest or fastest path to the destination, and employs Timed Elastic Bands (TEB) [11] at the step of obstacle avoidance for local path planning of optimal collision avoidance trajectories. 3) Visual servoing stage involves both LiDAR-based visual servoing and pose-based visual servoing with ARTag landmarks. The 3D image (camera viewing) coordinate system built by the camera sensor (at origin) and ARTag landmark is used to estimate the distance and pose between the ARTag landmark on the docking destination and

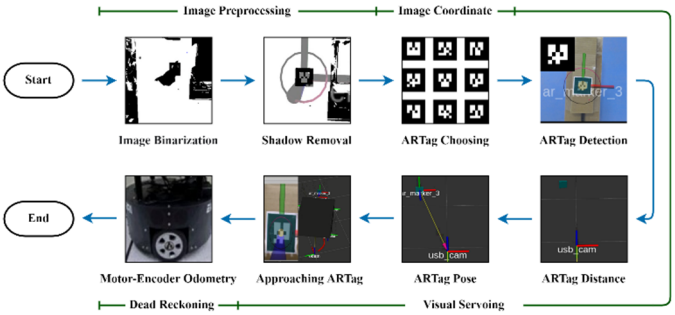

Fig. 4. Flowchart of conventional PBVS technology.

(a)

(b)

Fig. 5. Comparison between (a) high-quality image binarization and (b) poor-quality image binarization on ARTag landmark.

the camera sensor on the trackless AMR at the step of ARTag detection. Then, at the step of approaching ARTag, the trackless AMR is navigated by PBVS close to the ARTag landmark on the docking destination in the 3D image (camera viewing) coordinate system. 4) Dead reckoning stage leads the trackless AMR to the final destination inertially based on the wheel odometry [12], [13], according to the return value of "distance" and "pose" from the ARTag landmark at the last moment before the ARTag landmark gets too close to the camera sensor. After the ARTag landmark gets too close to the camera sensor, the ARTag landmark will get too large to be completely detected by the camera sensor, that is, ARTag landmark is out of view field of the camera sensor.

Among 4 stages of the overall flowchart of conventional trackless AMRs in Fig. 3, the accuracy, promptness, and steadiness of automatic docking alignment missions depends heavily upon the performance of PBVS at the stage of visual servoing. Fig. 4 shows the overall flowchart of conventional PBVS. It can be divided 4 stages: 1) Image preprocessing stage transforms the input image into a binary image at the step of image binarization. Then, shadow removal is performed on the image of ARTag landmarks to highlight the contours of ARTag landmarks for stable detection of the camera sensor at the step of shadow removal. 2) Image coordinate stage selects the ARTag landmark of the targeted ID of the automatic docking alignment and designates the location of the targeted ARTag landmark on 3D image (camera viewing) coordinate. 3) Visual servoing stage detects the targeted ARTag landmark, and estimates the distance and pose between the ARTag landmark on the docking destination and the camera sensor on the trackless AMR. Referring to the return value of "distance" and "pose" from the ARTag landmark, the trackless AMR is navigated by PBVS to approach the location of the targeted ARTag landmark on 3D image (camera viewing) coordinate. 4) Dead reckoning stage must be activated when the ARTag landmark becomes beyond the view field of the camera sensor, because the camera sensor on the trackless AMR approaches too close to the ARTag landmark on the docking destination. Finally, the automatic docking alignment of the trackless AMR to the final destination is achieved by the wheel odometry estimation and the inertial motion control.

Among 4 stages of the overall flowchart of conventional PBVS technology in Fig. 4, the accuracy, promptness, and steadiness of automatic docking alignment missions depends heavily upon the detected image quality at the stage of image preprocessing. The poor detected image quality sometimes causes the drift error on the return value of "distance" and "pose" from the ARTag landmark. It not only reduces the alignment precision of automatic docking alignment, but also decreases the docking efficiency (i.e., increases the docking iteration) of automatic docking alignment, even results in the failure or accident. Therefore, the step of image binarization at the stage of image preprocessing plays a crucial role in stabilizing the reading value of "distance" and "pose" between the ARTag landmark on the docking destination and the camera sensor on the trackless AMR. High-quality image binarization not only simplifies the background complexity but also diminishes the illumination interference, as shown in Fig. 5 (a). However, if shadow occlusion, image blurring, low contrast, uneven illumination, or complex backgrounds are happened with the ARTag landmark, Poor-quality or plain image binarization methods can not handle well with these difficult environmental conditions, probably fail to improve the clearness and contrast of the return value of "distance" and "pose" from the ARTag landmark, as shown in Fig. 5 (b).

II. Conventional Binarization Methods

In general, conventional and common image binarization methods can be divided into three main categories: 1) Image-processing-based binarization methods, including threshold

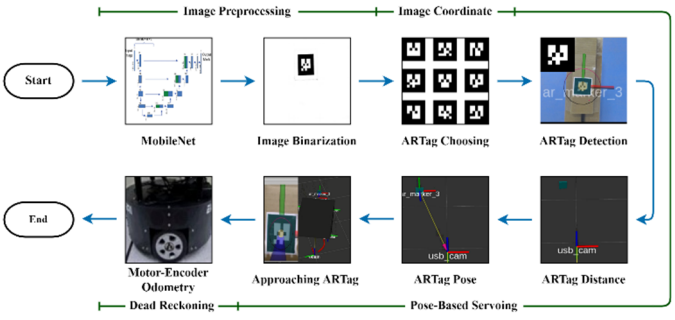

Fig. 6. Flowchart of proposed PBVS technology with lightweight deep-learning binarization.

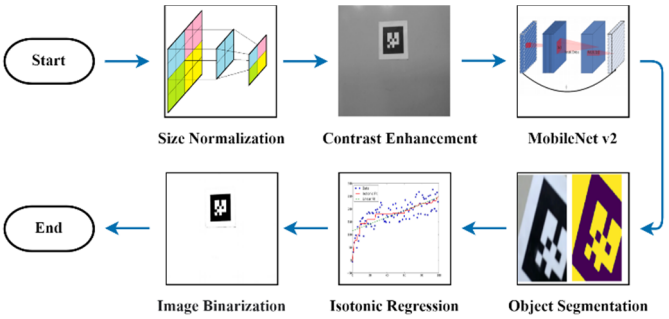

Fig. 7. Flowchart of proposed lightweight deep-learning binarization based on modified MobileNet v2.

from average of overall gray level [14] and dynamic threshold from maximum and minimum gray level [15]. 2) Computer-vision-based binarization methods, including threshold from gray-level histogram and Otsu optimization [16] and adaptive threshold from local histogram [17]. 3) Deep-learning-based binarization methods, including binarization with selectional auto-encoder (SAE) [18] and binarization with fully convolutional neural network [19].

However, image-processing-based binarization methods are not effective to generate proper binary images of ARTag landmarks under environmental conditions of shadow occlusion, image blurring, low contrast, uneven illumination, or complex background. Although image-processing-based binarization methods are efficient and straightforward in terms of computational complexity, they are not practical and feasible to real-world ARTag landmark detection issues. As for computer-vision-based binarization methods, they have better adaptability under environmental conditions of shadow occlusion, image blurring, low contrast, uneven illumination, or complex background. They can generate better binary images of ARTag landmarks while maintaining appropriate execution speed and computational efficiency. But, in some special real-world environmental conditions, they are still not good enough to completely eliminate adverse factors, especially resulting in accompanying noise in the binary images of ARTag landmarks. Finally, deep-learning-based binarization methods, as its name to make good use of deep learning techniques, exhibit high adaptability to various real-world environmental conditions and great capability to complex real-world environmental conditions. They can achieve the best binary images of ARTag landmarks in diverse situations. But, they require a large amount of computational time and it is contradictory for the stage of image preprocessing to consume too much computational time. In addition, deep-learning-based binarization methods may have poorer performance in binarizing low-resolution images of ARTag landmarks.

III. Proposed Lightweight Deep-Learning Binarization

This paper focuses on conventional deep-learning-based binarization methods and improves on its accuracy, promptness, and steadiness for ARTag landmark detection equivalently, against conventional image-processing-based binarization methods, conventional computer-vision-based binarization methods, and conventional deep-learning-based binarization methods. This paper develops a novel and practical method of lightweight deep-learning binarization at the stage of image preprocessing, as shown in Fig. 6, to enable PBVS to read the return value of “distance” and “pose” from the ARTag landmark exactly, quickly, and consistently.

In Fig. 6, at the stage of image preprocessing, a lightweight model modified from well-known MobileNet v2 [20] is proposed to address the issues of high computational requirements and poor binarization performance on low-resolution images in conventional deep-learning-based binarization methods. The detailed flowchart of proposed lightweight deep-learning binarization at the stage of image preprocessing of Fig. 6 is illustrated in Fig. 7.

In Fig. 7, the proposed lightweight deep-learning binarization can significantly reduce the architecture complexity of well-known MobileNet v2 network and further decrease the parameter amount of well-known MobileNet v2 network, without sacrifice of segmentation accuracy. Because the proposed lightweight deep-learning binarization simplifies depthwise separable convolution of MobileNet v2 network with adaptive kernel map to further reduce the redundancy in the convolutional kernel representation. Simplified depthwise separable convolution with adaptive kernel map during the inference process also can further reduce both memory consumption and computation time for predictions.

After the step of object segmentation, isotonic regression is also adopted to converge the training results, so higher

HW/SW specification of trackless AMR for experimental comparison is listed in Table I. The experimental comparison between conventional image-processing-based binarization, conventional computer-vision-based binarization, conventional deep-learning-based binarization, and proposed lightweight deep-learning binarization, is performed under 5 various environmental conditions: 1) shadow occlusion, 2) image blurring, 3) low contrast, 4) uneven illumination, and 5) complex background. The experimental comparison makes use ARTag landmark with size dimensions of 5 centimeters. The working range between the ARTag landmark on the docking destination and the camera sensor on the trackless AMR is within 1.5 meters. Figs. 9-13 show the return value of "distance" and "pose" of the ARTag landmark detected by the camera sensor with 4 various aforementioned image binarization methods, under 5 various environmental conditions: : 1) shadow occlusion, 2) image blurring, 3) low contrast, 4) uneven illumination, and 5) complex background, respectively. The ground truth of "distance" and "pose" between the ARTag landmark on the docking destination and the camera sensor on the trackless AMR is measured by the open-source project *Ar_track_alvar* and determined by the stationary mean of the return value. From Figs. 9-13, it is verified that the accuracy and reliability of the return value of "distance" and "pose" of the ARTag landmark detected by the camera sensor with proposed lightweight deep-learning binarization is the best under 5 various environmental conditions.

V. Conclusions

The proposed lightweight deep-learning binarization not only raises the accuracy and reliability of ARTag's reading, but also apparently improves the effectiveness and efficiency of PBVS's operation. Consequently, PBVS becomes more precise and reliable. Future work will involve implementing the proposed lightweight deep-learning binarization onto numerous types of trackless AMRs for versatile indoor or outdoor automatic docking alignment missions.

***Abstract* — Inhalation of foreign bodies in the airway is a rare event. Most cases of foreign body inhalation are eliminated through protective mechanisms of the body, such as coughing. However, there are some instances where the foreign body remains in the airway, even without the patient noticing. The symptoms of foreign body inhalation vary depending on the size and shape of the object. If it does not cause complete obstruction, it is often overlooked in image interpretation. In this study, the YOLOv5 is first used to locate the respiratory region in high-resolution computed tomography (HRCT), and this serves as the initial point for the 3D region growing. After identifying the airway using 3D region growing, the images are then analyzed using SEResNet18 to determine if any foreign bodies are present. The experimental results showed that using the primary YOLOv5's object detection method, an accuracy of 87.3% was achieved. After incorporating the SE channel attention mechanism into the YOLOv5 framework, the accuracy improved to 92.4%. In the foreign bodies classification, an accuracy of 85% was obtained.**

I. INTRODUCTION

When fish bones or thin bone fragments enter the airway, they most often get lodged in the narrower sections, especially at the bifurcation or carina of the bronchus. Due to their shape, it is difficult to cough them out. This can also cause physicians to mistake the fishbone or thin bone fragment as a ridge or prominence of the bronchus when observing high-resolution computed tomography images. There were many researchers focused on how to accurately segment the airway (including the trachea and finer bronchi) [1-3]. However, this paper focuses on detecting lesions within the airway, which still needs to be addressed. Therefore, this paper proposes a method that combines YOLOv5 [4] and 3D region growing locate airway region, and proposes a SEResNet18 for foreign object classification.

II. METHOD

Lesions in the airway may include secretions, foreign bodies, tumors, etc., which are referred to as respiratory foreign bodies in this paper. We use YOLOv5 combined with 3D region growing for airway detection and then using a SEResNet18 to detect airway foreign bodies. The system flowchart is shown in Figure 1. Table I shows the airway detection result with three different YOLOv5 backbones. The CSPNet achieved the highest accuracy of 87.3%. Figure 1 shows a case of foreign object detection result. The foreign objects classification results by SEResNet18 is 85%.

Real-Time Noise Suppression Using Harmonic/Percussive Separation with Morphological Operations for Hammering Test

Ryugo Uchiyama* and Nari Tanabe†

***Abstract*—This paper proposes a method to suppress noise in real-time using harmonic/percussive separation with morphological operations for hammering tests. The feature of the proposed method is that it focuses on the structure of the spectra of the hammering sound and noise obtained by analyzing the spectrogram of the signal observed in the hammering test and performs morphological operations using structuring elements suitable for each shape. This enables more appropriate extraction of the hammering sound than conventional methods. Although only the spectra of past time frames are used to achieve real-time noise suppression, the noise suppression performance is better than that of previous methods. The effectiveness of the proposed method is demonstrated by subjective and objective evaluations.**

I. Introduction

The walls of concrete structures such as bridges, highways, and tunnels are damaged daily by age-related deterioration, erosion caused by raindrops, and disasters such as earthquakes. The damage to walls varies from cracking, delamination, and hollowing. In particular, hammering test is used to inspect for internal damage such as delamination and hollowing, which are difficult to confirm visually, without destroying the object. In the hammering inspection method, the object is lightly struck with a hammer so as not to destroy it, and the inspector listens to the sound generated and examines abnormalities according to the difference in the sound.

In recent years, an accident occurred in Japan in which ceiling panels attached to ventilation ducts in tunnels have fallen [1]. This accident may have been caused by the fact that the damage to the wall surface had been confirmed visually and that the interior of the wall had not been inspected adequately by hammering inspection. In fact, there are quite a few deteriorations that cannot be detected simply by checking the concrete wall surface, and they are the cause of anchor bolt dropout and loosening of the ceiling panels. This incident led to a review of abnormality inspection methods of structural objects and reaffirmed the importance of hammering inspections. In this context, it is known that there are problems with the current hammering inspection method.

The first problem is the decrease in the volume of the hammering sound that accompanies the change in inspection hammers. In the conventional hammering test, inspectors lightly shook their wrists and struck the wall surface with an ordinary hammer. However, it is difficult to make accurate judgments because it is difficult inspect in high or narrow places, and the hammering sound that can be observed changes depending on the situation due to differences in inspectors, hammering speed, force, and surface of the structures. A new hammer was proposed to solve these problems. This new hammer generates sound by rolling a polygonal tangential surface while adjusting the angle and length, making it possible to efficiently observe hammering sound that are evenly spaced with even force in high or narrow locations. However, because of the specification of generating sound by rolling, there is a disadvantage in that the volume of the observed hammering sound is low.

The second problem is that environmental noise is superimposed on the hammering sound. In most cases, traffic control is imposed when conducting a hammering test, but it is impossible to close the road to traffic. This means that vehicles will be driving near the inspection site, so the sound of vehicles and wind noise will always be heard. In particular, inside the tunnel, the sound of ventilation and these sounds reverberate and become a complex noise, superimposed on the hammering sound whose volume was reduced in the first problem, making it extremely difficult to distinguish between the delicate sounds of the healthy and damaged areas.

To address these problems, it is necessary to extract the desired signal with noise suppression. Noise suppression methods include the spectral subtraction method, which suppresses noise by estimating it, and the method using Kalman filter algorithm with colored driving source [2]-[4]. These noise suppression methods are based on the assumption that the SNR is not that small, and that the power of the noise is lower than that of the hammering sound. Therefore, they are not suitable for wall inspections in low SNR environments such as inside tunnels. In addition, as the vehicle approaches the inspection position, the traveling sound causes a Doppler effect, and a sudden change in noise is observed. A noise suppression method that enables the desired hammering signal to be heard even in such a poor inspection environment is desirable.

This paper proposes a noise suppression method suitable for hammering tests inside tunnels, especially those with low SNR. By using a filter that acts directly on the spectrogram, it is robust to changes in sound in the time and frequency directions and can suppress noise by taking into account the structural features of the hammering sound that appear in the spectrogram. It can also process the signal input from the microphone to the device in real time and output the desired signal to the earphone. In hammering test, the condition of the wall surface must be distinguished "on the spot" in order to accurately record abnormalities on the wall surface at the inspection site. Therefore, when developing a system to support hammering test in actual tunnels, the hammering sound generated at the inspection site must be noise suppressed in real time and delivered to the operator's ears without delay.

II. Previous Method

Noise suppression methods for hammering tests have been studied as follows. In [2], hammering tests were conducted on an actual bridge and the effect of the presence or absence of defects inside the walls on the hammering sound was discussed. In this study, it was confirmed that the use of Self Organizing Maps can solve the problem of difficulty in discriminating between healthy and damaged areas because the frequency spectrum of the observed signal varies depending on the scale and condition of the defect. This experiment assumes a hammering inspection of an actual bridge. However, because it does not take into account the condition of noise superimposition, it is expected that errors will occur in discriminating healthy and damage areas.

In contrast, reference [3] proposes noise suppression using a Kalman filter algorithm with colored driving source. In the method, the minimum statistics method [4] is used as a noise estimation method. The minimum statistics method can track noise spectrum smaller than the hammering spectrum. but it cannot estimate the noise spectrum well for noise spectrum larger than the hammering spectrum, implying its insufficient noise suppression. In [3], based on the results of frequency analysis of actual hammering and noise signals, the authors found that noise signals are distributed mostly in the low-frequency band and used a Butterworth type high-pass filter (BW-type HPF) to suppress spectrum of low frequency before estimating noise spectrum using the minimum statistics method. This means that the large noise spectrum distributed at low frequencies is made smaller than the hammering spectrum, so that the noise estimation by the minimum statistics works.

However, such digital filters require a predefined cutoff frequency. Since the frequency of noise differs depends on the inspection environment and the frequency of hammering sound depending on the material and condition, parameters must be adjusted for each inspection. In most case, the low-frequency component of hammering sound is included in the low-frequency band where much of the noise is distributed in places where there is a lot of peeling, such as the interior walls of tunnels. Therefore, if the frequency band where noise is distributed is simply suppressed, the sound quality of the hammering sound will deteriorate, making it difficult to distinguish between healthy and damaged areas.

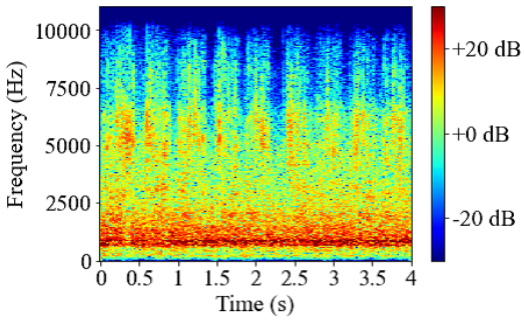

Fig. 1. Observed signal spectrum of the damaged area.

To address these problems, it is necessary to find "common features" that are independent of the test location. In this study, observing the spectrogram of the signal observed in a real environment brought attention to the spectral structure of the hammering signals and noise signals. Fig 1 shows that the spectral structure of the hammering signal in the spectrogram rises in the frequency axis direction at the moment (time) when the new hammer is rolled, while the spectral structure of the noise signal is continuous in the time axis direction. This structural feature is common and independent of the environment in general.

Such a method of separating each spectral structure has been widely studied in the field of source separation. As described in [5], source separation is an algorithm that separates the spectrogram into harmonic and percussive components, and is a technique used mainly for automatic musical notation and drum detection in musical components. Reference [6] uses a median filter to extract the harmonic and percussive components, and a Wiener filter to extract each component. On the other hand, reference [7] achieves better results in the extraction process of each component by applying a morphological filter [8], which is one of the nonlinear filters used in the field of image analysis processing. The method in [7] uses a property of mathematical morphology, i.e., the operation of extracting the characteristic structure of a figure in an image. This property is considered to be useful in sound source separation when the characteristic structure of the sound to be extracted can be represented as figures. As described in [9], there is a method of applying morphological filters to audio spectrograms, but it has been used as an adjunct to spectral subtraction methods.

In this study, the sound source separation technique used to extract specific sound source from a piece of music is considered to be able to extract the hammering signal by applying it to the observed signal of the hammering test. Since real-time implementation is being considered, it is desirable to achieve good accuracy with a relatively small amount of computation. Therefore, the reference [7] is modified to function in real time by adjusting it for hammering test, enabling noise suppression which retains some of the characteristics of the hammering

sound.

III. Mathematical morphology

In this section, we describe Morphology that is the fundamental principal of a Morphological filter used in our proposed method.

A. Basic morphological operations

Morphology is generally developed as a set theory in N-dimensional space, and in this section, we consider the case $N = 2$. Let A be a set in a 2-dimensional space and let a be a component of A, then the pixel value of A is 1 and the background pixel value is 0. The basic operation of morphology is Minkowski set theory, which consists of Minkowski sum and Minkowski difference, and using the set of structuring elements B and $b \in B$, the following equation is obtained.

$$A \oplus B = \bigcup_{b \in B} (A)_b, \tag{1}$$

$$A \ominus B = \bigcap_{b \in B} (A)_b, \tag{2}$$

where $(A)_b$ is the set obtained by moving the set A by b. If A^C and B^C are the complements of A and B, the following relation holds :

$$A \oplus B = (A^C \ominus B)^C, \tag{3}$$

$$A \ominus B = (A^C \oplus B)^C. \tag{4}$$

Thus, there is a duality between the Minkowski sum and the Minkowski difference.

Then applying the target set $B^S = -b : b \in B$ of B to (1) and (2), the following equation is given by

$$A \oplus B^S = \bigcup_{b \in B} (A)_{-b}, \tag{5}$$

$$A \ominus B^S = \bigcap_{b \in B} (A)_{-b}. \tag{6}$$

Equation (5) is dilation, (6) is erosion, which are basic operations in morphology. A morphological filter is defined by combining these basic operations

$$A \circ B = (A \ominus B^S) \oplus B, \tag{7}$$

$$A \bullet B = (A \oplus B^S) \ominus B, \tag{8}$$

where (7) is "Opening" and (8) is "Closing". "Opening" erodes the target set A and then dilates it, which has the effect of shaving off small protuberances on the outside of the target set A. "Closing" is process of dilating and then eroding the target set A, which has the effect of closing small holes or covers on the inside of the target set A.

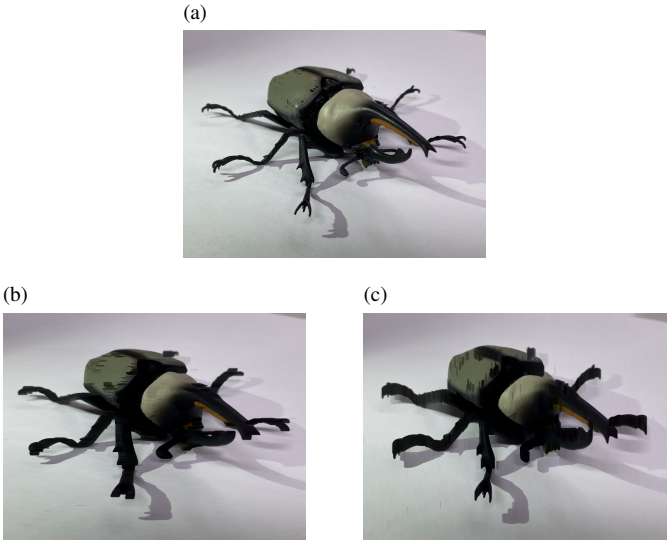

Fig. 2. (a) Original image, (b) Image erosion by a horizon line, (c) Image erosion by a vertical line.

B. Expansion to multi-valued functions

So far, the target to process has been discussed as a binary image. However, morphological operations can be extended to images with shading, i.e., functions that take various values.

First, give a two-dimensional vector $\boldsymbol{x}$ a third dimension y representing the pixel value $f(\boldsymbol{x})$, the following equation is given by

$$U(f) = \{(\boldsymbol{x}, y) : y \leq f(\boldsymbol{x})\}. \tag{9}$$

In this case, $U(f)$ is a shade. The shade can be calculated by the following equation :

$$f(\boldsymbol{x}) = \sup\{y \in \mathbb{R} : (\boldsymbol{x}, y) \in U(f)\}. \tag{10}$$

Then, since the shade is a binary image, the operations (5) and (6) are possible. The multi-valued Minkowski operation by the structuring function g of the function f is as follows :

$$(f \oplus g)(t) = \max_{\substack{t-u \in F \\ u \in G}} \{f(t-u) + g(u)\}, \tag{11}$$

$$(f \ominus g)(t) = \min_{\substack{t-u \in F \\ u \in G}} \{f(t-u) - g(u)\}, \tag{12}$$

where F and G are the domain of the functions f and g, respectively, and $-\infty$ is excluded from the domain. (11) and (12) are dilation and erosion in multi-valued functions, respectively. The detailed derivation of the morphological filter is described in [8].

Fig 2 shows a multi-valued image with erosion applied by two different structuring elements. Horizontal erosion can be confirmed by comparing (a) and (b), and vertical erosion can be confirmed by comparing (a) and (c). From this comparison, it can be seen that the shape of the structuring element greatly affects the distortion of the multi-valued function.

IV. Proposed Method

A. Spectral analysis and scaling

First, since the hammering sound is recorded as a stereo audio signal at the site, two-channel signals (left and right) are observed. Using the hammering signal $s_{L/R}(t)$ and the noise signal $n_{L/R}(t)$, the observed signal $x_{L/R}(t)$ at time t is expressed as follows :

$$x_{L/R}(t) = s_{L/R}(t) + n_{L/R}(t). \tag{13}$$

Next, this input signal is computed in the frequency domain. The observed signal $x_{L/R}(t)$ is divided into short time (frame) intervals, and its short-time Fourier transform (STFT) is calculated at each interval. By STFT, the observed signal spectrum $X_{L/R}(\lambda, k)$ is as follows :

$$X_{L/R}(\lambda, k) = \sum_{\mu=0}^{W-1} x_{L/R}(\lambda N + \mu) \cdot h(\mu) \cdot \exp\left(-j\frac{2\pi\mu k}{W}\right), \tag{14}$$

where λ is the frame number, k is the discrete Fourier transform (DFT) frame length ($W = 2048$), and N is the frame shift length ($N = W/2 = 1024$). In this case, a Hanning window is used as the window function, and the window functions overlap each other by half. Then, the observed signal spectrum $X_{L/R}(\lambda, k)$ can be expressed as follows using the hammering signal spectrum $S_{L/R}(\lambda, k)$ and the noise signal spectrum $N_{L/R}(\lambda, k)$:

$$X_{L/R}(\lambda, k) = S_{L/R}(\lambda, k) + N_{L/R}(\lambda, k). \tag{15}$$

It is inconvenient to apply a filter used for image processing with the obtained spectrum data as it is. Therefore, the obtained spectrum is converted to the logarithmic representation $\hat{X}_{L/R}(\lambda, k)$ by the following equation :

$$\hat{X}_{L/R}(\lambda, k) = 10\log(|X_{L/R}(\lambda, k)|^2). \tag{16}$$

Furthermore, based on the gray-scale spectrogram, expressing the log-display spectrum from -40 to $+40[dB]$ in 256 gradations from 0 to 255, the scaled spectrum $\tilde{X}_{L/R}(\lambda, k)$ is

$$\tilde{X}_{L/R}(\lambda, k) = \frac{255}{80}(\hat{X}_{L/R}(\lambda, k) + 40). \tag{17}$$

B. Harmonic/percussive component enhancement by morphological filter

In the spectrogram of the observed signal, since the features of the hammering component appear along the frequency axis (vertical direction), it is considered to be the percussive component, and since the features of the noise component are continuous along the time axis (horizontal direction), it is considered to be the harmonic component. Therefore, applying "Opening" to the spectrogram with a long vertical structuring element and a long horizontal structuring element, enhances each component.

Reference [7] prepared not only $n \times 1$ structuring elements but also several complex shapes, because the characteristic

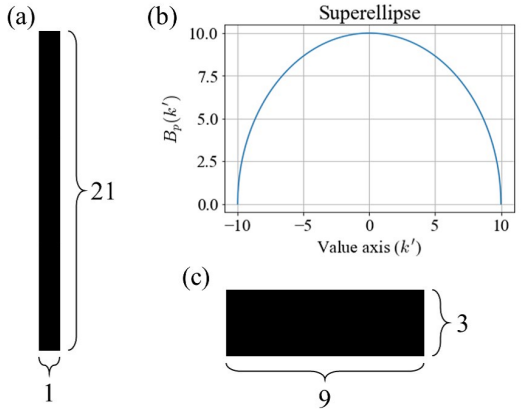

Fig. 3. (a) Shape of structuring element for masking percussive components, (b) Structuring function for masking percussive components, (c) Shape of structuring element for masking harmonic components.

percussive components appearing in the frequency direction are also spread a little horizontally at low frequencies. As a result, the separation performance was higher when $n \times 1$ structuring elements were used. However, it has been shown that the separation performance was lower when the structuring elements with the complex shapes are large. The hammering sound of the observed signal has characteristics that appear sparsely in the middle range, in an elliptical shape. To guarantee high separation accuracy even for signals with these characteristics, the proposed method considers the characteristics of noise components whose pitch varies with time (harmonic components), such as the Doppler effect due to moving noise sources.

Since the structuring element in the frequency axis direction is a single variable function of the frequency bin number k, the following superelliptic equation was used for the structure function $B_p(k')$ to better enhance the characteristics of the hammering sound.

$$B_p(k') = \begin{cases} b\left(1 - \left|\frac{k'}{a}\right|^p\right)^{\frac{1}{p}} & (-a \le k' \le a) \\ -\infty & (otherwise) \end{cases}. \tag{18}$$

The shape of the structuring function of the super-ellipse is determined by three parameters : the value axis b, the window width $2a$, and p. The horizontal structuring element is set to $k' = 0$, making it a flat structuring function. The shapes of the structuring elements are shown in Fig 3.

"Opening" is applied to the scaled spectrum $\tilde{X}_{L/R}(\lambda, k)$ for one frame by applying a structuring element for masking percussive components to enhance the vertical percussive component :

$$\tilde{P}_{L/R}(\lambda, k) = \tilde{X}_{L/R}(\lambda, k) \circ B_p(k'), \tag{19}$$

where $\tilde{P}_{L/R}(\lambda, k)$ is a scaled spectrum that enhances the percussive component.

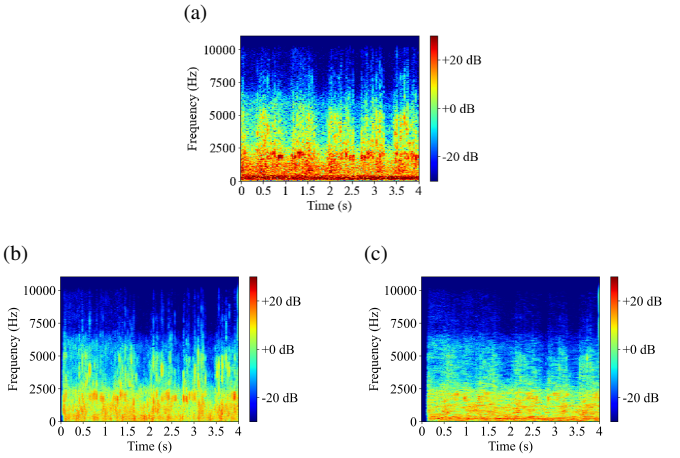

Fig. 4. (a) Observed signal spectrogram, (b) Spectrogram with enhanced percussive components, (c) Spectrogram with enhanced harmonic components.

Next, to enhance the harmonic component, scaled spectra for the past few frames are stored and "Opening" is applied with structuring elements for masking harmonic components.

$$\tilde{H}_{L/R}(\lambda, k) = \tilde{X}_{L/R}(\lambda, k) \circ B_h(\lambda', k'), \tag{20}$$

where $\tilde{H}_{L/R}(\lambda, k)$ is the scaled spectrum enhanced harmonic component and $B_h(\lambda', k')$ is the horizontal structuring element.

Each enhanced component $\tilde{P}_{L/R}(\lambda, k)$, $\tilde{H}_{L/R}(\lambda, k)$ can be output as a spectrogram, as shown in Fig 4.

C. Extraction of hammering components by Wiener filter

Next, a Wiener filter for masking the percussive component is applied to the enhanced scaled spectrum to calculate the percussive component. Before that, the scaled spectra $\tilde{P}_{L/R}(\lambda, k)$ and $\tilde{H}_{L/R}(\lambda, k)$ with each component highlighted are converted to Spectral values using (16) and (17). Then, according to [10], the Spectrogram can be considered to contain a residual component in addition to the harmonic and percussive components. If there is a sound that has the characteristics of both harmonic and percussive components, the harmonic and percussive components can be clearly separated by assigning the residual component to this sound. Therefore, the Wiener filter for takes the residual component into account is given by

$$M^P_{L/R}(\lambda, k) = \frac{\left(P_{L/R}(\lambda, k)\right)^2}{\left(P_{L/R}(\lambda, k)\right)^2 + \alpha \left(H_{L/R}(\lambda, k)\right)^2}, \tag{21}$$

where $H_{L/R}(\lambda, k)$ and $P_{L/R}(\lambda, k)$ are the harmonic and percussive component enhanced spectrum. The range of α is $1.0 \leq \alpha \leq 10.0$, and the larger the value, the larger the residual component. In this method, $\alpha = 2.0$ was used to take into account the existence of the residual component. This value was set experimentally. The separated percussive component $\tilde{S}_{L/R}(\lambda, k)$ is calculated by the following :

$$\tilde{S}_{L/R}(\lambda, k) = M^P_{L/R}(\lambda, k) \cdot X_{L/R}(\lambda, k). \tag{22}$$

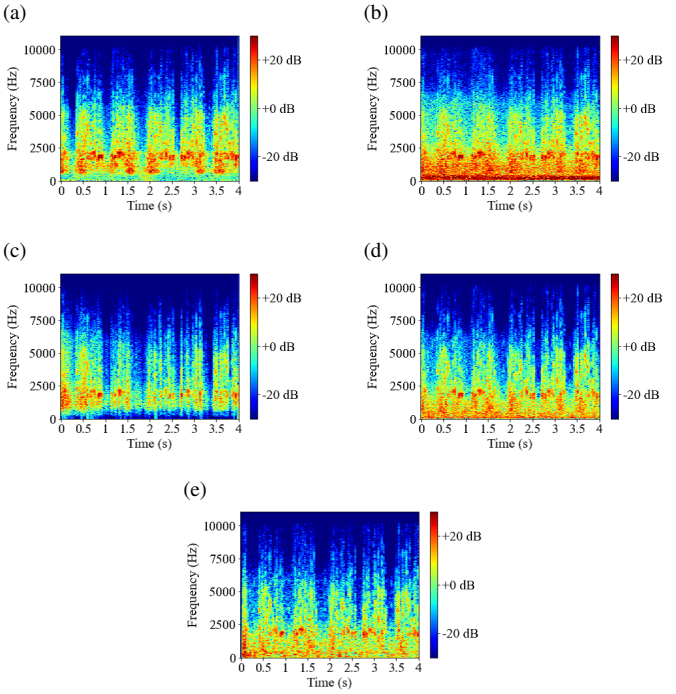

Fig. 5. (a) Spectrogram of clean hammering signal, (b) Spectrogram of observed signal, (c) Noise suppressed spectrogram by [3], (d) Noise suppressed spectrogram by [6], (e) Noise suppressed spectrogram by proposed method.

Finally, the separated hammering signal can be obtained by inverse short-time Fourier transform (ISTFT) as shown below :

$$\tilde{s}_{L/R}(t) = ISTFT\left(\tilde{S}_{L/R}(\lambda, k) e^{i\angle\theta}\right), \tag{23}$$

where θ is the phase spectrum of $X_{L/R}(\lambda, k)$.

V. Simulations

In this study, the observed signals used in the simulation are based on sounds collected at the actual site of a hammering test. For example, there is a method of testing by using the sound of a wall (mock-up specimen) that has a cavity inside to simulate a deteriorated condition. Using this method, it is possible to obtain a clean, noise-free hammering sound. However, this sound is noise-free, therefore making the hammering sound very different from the actual noisy environment. By using the actual sound as much as possible, the behavior of the noise suppressor can be confirmed to be similar to that of the on-site inspection. Thus, the observed signals used in this study were recorded in a relatively quieter environment than the tunnel, and then the loud noises in the tunnel were added. In detail, stereo audio signals with a sampling frequency f_s of 44100 Hz and SNRs of -5.62 dB and -4.79 dB for the left and right channels, respectively, were used.

A. Subjective evaluation

The spectrograms of the noise suppressed signals using the [3] and [6] are shown in Fig 5. First, a comparison of (a) and (b) shows that continuous noise is added in the low frequency time axis direction. It can also be seen that

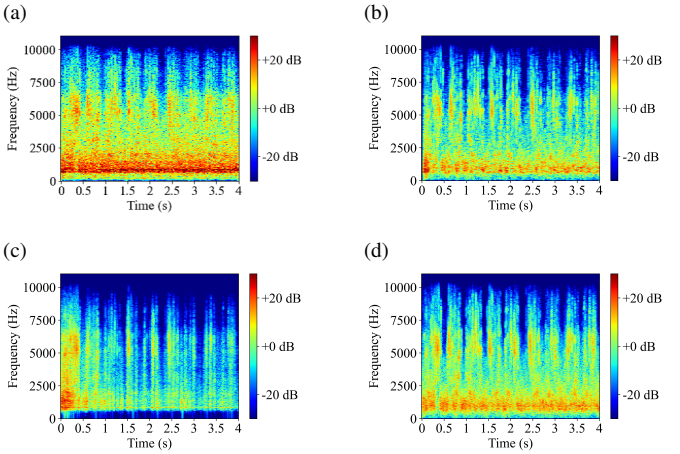

Fig. 6. (a) Spectrogram of actual observed signal, (b) Noise suppressed spectrogram by proposed method, (c) Noise suppressed spectrogram by [3], (d) Noise suppressed spectrogram by [6].

non-integer harmonic of the noise and reflected noise are spread to higher frequencies. The spectrogram (c) of [3] suppresses the hammering sound too much and sounds lighter. The spectrogram (d) of [6] retains the characteristics of the hammering sound well, but the harmonic components are not well extracted, and it is clear that the noise is not fully suppressed. On the other hand, the spectrogram of the proposed method, (e), shows that the noise component is suppressed better than spectrograms of [3] and [6]. Furthermore, the low frequencies are not completely suppressed but are moderately preserved, and the low pitched sounds of hammering sound are also successfully preserved. These results indicate that the proposed method is capable of capturing the structural features of sounds appearing in the spectrogram.

In addition, Fig 6 shows a similar experiment on an observation signal recorded during an actual tunnel hammering test, in which noise was convolved with the hammering sound. The spectrogram (c) of [3] shows that the sound is too much suppressed even in the actual observation signal. The spectrogram (d) of [6] shows that the sound is uniformly suppressed, so that noise remains and the hammering sound is muffled. The spectrogram (b) of the proposed method is able to suppress noise while preserving the structure of low and mid-frequency hammering sounds better than the conventional method. These results show that the proposed method works well in the actual tunnel hammering test and can extract features better than the conventional method.

B. Objective evaluation

In this section, we evaluate the performance using specific indices. First, we used three indices proposed in [11]. SI-SDR (scale-invariant signal-to-distortion ratio) is the ratio of the estimated separated sound to the residual noise, SI-SIR (scale-invariant source to interference ratio) is the ratio of the separated sound to the source-derived interference noise, and SI-SAR (scale-invariant source to artifact ratio) is defined as the ratio of the separated sound to the algorithm-derived noise.

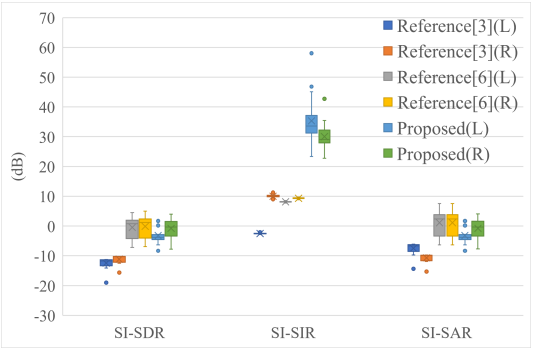

Fig. 7. SDR / SIR / SAR comparison.

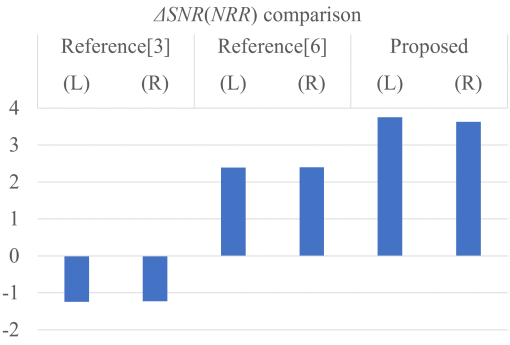

Fig. 8. Δ SNR comparison.

The larger the value of these indices, the better the performance. By comparing SI-SIR and SI-SAR, it is possible to determine whether source-derived noise or algorithm-derived noise dominates.

As shown in the box-and-whisker plot in Fig 7, the SI-SIR of the proposed method is extremely higher than that of any of the other methods. This indicates that the proposed method has less source-derived noise than any of the methods. Overall, the proposed method outperforms [3] in all indices, and its SI-SDR and SI-SAR are as good as [6].

Next, the SNR improvement rates (Δ SNR) were compared and evaluated. This value is expressed as the difference between the output signal SNR, and the input signal SNR, and is equivalent to the noise reduction ratio (NRR). In other words, the degree of noise suppression can be evaluated by Δ SNR and the larger the value, the better the performance. Since this index indicates noise reduction ratio, it can be compared and evaluated with [3] and [6].

The results are shown in Fig 8. As the graphs show, the proposed method performs good noise suppression.

As a general comment on the objective evaluation, the proposed method distorts the extracted hammering sound, but its high accuracy in classifying harmonic and percussive components indicates that it has good noise suppression accuracy.

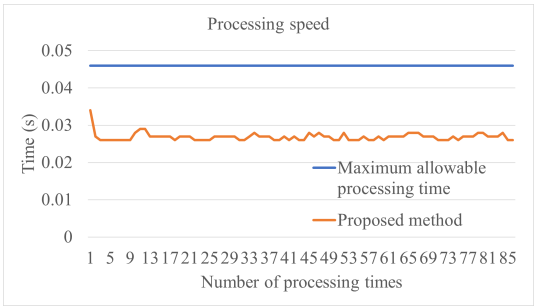

Fig. 9. Processing speed evaluation.

C. Processing speed evaluation

Finally, the processing speed is evaluated to confirm the real-time performance of the proposed method. Fig 9 shows the processing time per frame. The time per frame τ can be obtained by W/f_s, where $W = 2048$ and $f_s = 44100$ Hz, $\tau = 0.046$ s. To extract the desired signal in real-time, the processing of one DFT frame must be completed within the time of one frame. As shown in Fig 7, the processing time of the proposed method is below the maximum allowable processing time, indicating that real-time processing is possible.

VI. Conclusions

This paper proposed a real-time noise suppression method using harmonic/Percussive separation by morphological operations for hammering test. The main two features of the proposed method are as follows. First is that the "Opening" process is applied vertically and horizontally according to the distinctive features in the structures of the spectrograms of hammering sound and noise to enhance the hammering and noise components. Second is the masking of the hammering spectrum with a Wiener filter that considers a residual component, resulting in a high separation performance. Also, the effectiveness of the proposed method was demonstrated by comparing (i) spectrograms after noise suppression in a subjective evaluation, (ii) performance with specific numerical values in an objective evaluation, and (iii) processing speeds. Through the evaluation (iii), the proposed method guarantees real-time performance.

The proposed method does not aim at off-line noise suppression, such as estimating hitting sound by solving machine learning algorithms or mathematical optimization. Since the purpose of the proposed method is to provide the desired hammering sound to the inspector in real time at a hammering inspection site, it is considered to be an effective method when the desired signal must be extracted with high accuracy at low cost from an observed signal whose desired signal is degraded by noise or other factors.

One of the future works include developing a noise suppression system that can extract buried sounds (evidence of a damaged part) in highly noisy environments, such as tunnels, without sacrificing the quality of the sound.

***Abstract*—$\Delta\Sigma$ modulators have been utilized for analog-to-digital converters (ADCs). The performance of a $\Delta\Sigma$ modulator can be enhanced if it is designed by taking into account the characteristics of the system that uses the $\Delta\Sigma$ modulator. This paper considers $\Delta\Sigma$ modulators for discrete-time closed loop control systems. In the control system, quantization may degrade control performance and leads to oscillations of the system outputs, whereas saturation of the control input may cause windup phenomena such as overshoots of the system outputs and instability of the control system. This paper jointly mitigates the effects of quantization and saturation in a discrete-time closed loop control system, by minimizing the norm of the quantization error at the system output under a stability condition on the closed-loop system. Numerical examples are provided to see the effectiveness of our proposed design.**

I. Introduction

Digital communication technologies have been developed, and many devices have been connected to the Internet. To employ digital communication, analog signals have to be quantized into digital signals.

$\Delta\Sigma$ modulators have been utilized as efficient analog-to-digital converters (ADCs). (See, e.g., [1] and references therein). A $\Delta\Sigma$ modulator consists of a conventional (usually uniform) quantizer and a filter that feeds back the quantization error of the conventional quantizer to the input to the conventional quantizer. The feedback filter can be optimized to minimize the effect of the quantization by exploiting the system's characteristics [2], [3]. In this paper, we design a $\Delta\Sigma$ modulator for a discrete-time closed loop control system with quantization and saturation.

For a control system, if ideal actuators capable of realizing any desired controller outputs are available, one could design any kind of controller. However, in practice, there are always limitations on the actuator outputs, and the acceptable input range to the actuator is restricted. If the control input exceeds this range, input saturation is occurred. Therefore, for a system with input saturation, careful input design becomes necessary. Neglecting input saturation when designing a controller can lead to severe deterioration of control performance, such as overshoots of system outputs or instability in closed-loop systems, known as windup phenomena.

Input saturation can be modeled as a saturator followed by the controller. In most anti-windup controllers, the input and output of the saturator are fed back to the controller to mitigate the windup phenomena. (See, e.g., [4] and references therein.) [5] utilize a linear condition to design anti-windup controllers.

To reduce the effect of quantization errors on control systems, *dynamic quantizers* have been employed, where the quantizer parameters are designed using linear programming (LP) [6] or convex optimization [7]. However, most of these methods do not consider stability in the presence of input saturation. This paper proposes a method to jointly mitigate the effects of quantization and saturation.

We propose a design method of the $\Delta\Sigma$ modulator to reduce the l_2 norm of the quantization error at the system output under a stability condition on the closed-loop system. The l_2 norm is evaluated by the H_∞ norm of the transfer function from the quantization error to the system output, whereas the stability condition is described by the circle criterion obtained by [8]. Both conditions are expressed as bilinear matrix inequalities (BMI) that involve multiplications of design variables. Allowing to share a common Lyapunov matrix, our design problem is converted into a convex optimization, which can be solved numerically. The effectiveness of proposed method is verified through numerical examples.

II. Control Systems with Input Quantization and Saturation

Let us consider a discretized feedback system as shown in Fig. 1. For the sake of simplicity, we assume that the plant and the controller are single-input and single-output linear time-invariant systems, whose transfer functions are denoted as $P[\mathrm{z}]$ and $C[\mathrm{z}]$, respectively. The orders of $P[\mathrm{z}]$ and $C[\mathrm{z}]$ are denoted as n_p and n_c. We express the z-transform of a causal discrete-time signal denoted by a lowercase letter as its corresponding uppercase letter.

In Fig. 1, $u_r(k) \in \mathbb{R}$ is the reference signal at time k, $e(k) \in \mathbb{R}$ is the control deviation, $y_c(k) \in \mathbb{R}$ is the output of the controller, $u(k) \in \mathbb{R}$ is the input of a plant, and $y(k) \in \mathbb{R}$ is the control output.

We express the state space representations of the plant and the controller as

$$x_p(k+1) = A_p x_p(k) + B_p u(k) \tag{1}$$
$$y(k) = C_p x_p(k) \tag{2}$$

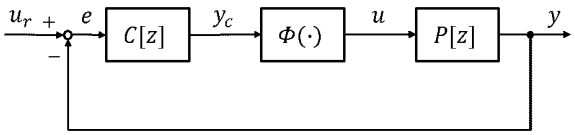

Fig. 1. Feedback control system with a constraint on the range of the control input.

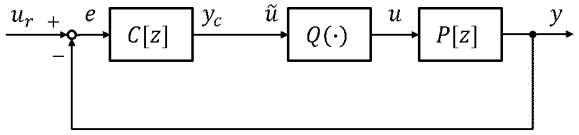

Fig. 2. Feedback control system with quantization and saturation.

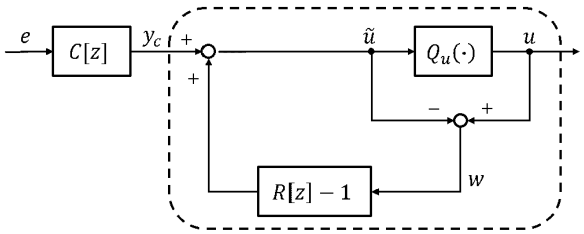

Fig. 3. $\Delta\Sigma$ modulator.

and

$$x_c(k+1) = A_c x_c(k) + B_c e(k) \tag{3}$$
$$y_c(k) = C_c x_c(k) \tag{4}$$

with $A_p \in \mathbb{R}^{n_p \times n_p}$, $B_p \in \mathbb{R}^{n_c \times 1}$, $C_p \in \mathbb{R}^{1 \times n_c}$, $A_c \in \mathbb{R}^{n_c \times n_c}$, $B_c \in \mathbb{R}^{n_c \times 1}$, and $C_c \in \mathbb{R}^{1 \times n_c}$, where $x_p(k) \in \mathbb{R}^{n_p}$ and $x_c(k) \in \mathbb{R}^{n_c}$ are state vectors of the plant and the controller.

For a real number $L > 0$, the range of the input of the plant is assumed to be limited between $[-L, L]$. (The range is assumed to be symmetric around 0 just for simplicity of presentation.) When the output of the controller exceeds the range of the control input, that is, $|y_c(k)| > L$, the input $u(k)$ to the plant is saturated, which is described by using the saturation element $\Phi(\cdot)$ in Fig. 1 defined as

$$\Phi(y_c(k)) = \begin{cases} L\text{sgn}(y_c(k)), & |y_c(k)| > L \\ y_c(k), & |y_c(k)| \le L \end{cases} \tag{5}$$

where sgn$(\cdot)$ is the sign function.

The difference between the output of the controller and the input to the plant is expressed as

$$w_a(k) := u(k) - y_c(k). \tag{6}$$

The value of $w_a(k)$ is non-zero only when $|y_c(k)| > L$. If $w_a(k)$ remains large for a certain period of time, the control deviation increases because the feedback is not functioning properly due to saturation. Consequently, the signals in the controller with integrators become large, leading to phenomena such as overshoot of the control output and system instability.

Now, let's consider that the controller output is transmitted to the plant through a digital communication channel. When transmitting an analog signal through a digital communication channel, the analog signal needs to be converted into a digital signal through quantization. If the channel has limited capacity, even the digital signal may be quantized into a low-resolution form.

Let the saturation levels of the quantizer be the same as the saturation levels of the plant. Thus, the feedback control system with input saturation and quantization can be illustrated as shown in Fig. 2, where $Q(\cdot)$ is the quantizer that satisfies

$$Q(x) = L\text{sgn}(x), \quad |x| > L \tag{7}$$

for a scalar input x.

To mitigate the quantization error and address the windup phenomena, we employ a $\Delta\Sigma$ modulator for our quantizer. The block diagram of a $\Delta\Sigma$ modulator is depicted inside the broken line in Fig. 3. Here, $w(k)$ represents the quantization error at time k, defined as

$$w(k) = u(k) - \tilde{u}(k) \tag{8}$$

and $R[\text{z}]$ is an n_r-order filter, known as the noise transfer function (NTF) or noise shaping filter (NSF), satisfying $R[\infty] = 1$. Note that the first term of the impulse response of $R[\text{z}] - 1$ is zero, ensuring there is no algebraic loop in the $\Delta\Sigma$ modulator. Moreover, $Q_u(\cdot)$ represents a static uniform quantizer. It is worth noting that when $R[\text{z}] = 1$, there is no feedback, and the $\Delta\Sigma$ modulator simplifies to a static quantizer.

III. $\Delta\Sigma$ MODULATOR FOR QUANTIZATION AND SATURATION

Let us design a $\Delta\Sigma$ modulator to reduce the effects of the quantization error under a stability condition to mitigate the windup phenomena.

The transfer function from the quantization error of the $\Delta\Sigma$ modulator to the system output is given by $P[\text{z}]/(1+P[\text{z}]C[\text{z}])$. Thus, the z-transform $Y[\text{z}]$ of the system output can be expressed by

$$Y[\text{z}] = \frac{P[\text{z}]C[\text{z}]}{1 + P[\text{z}]C[\text{z}]} U_r[\text{z}] + \frac{P[\text{z}]R[\text{z}]}{1 + P[\text{z}]C[\text{z}]} W[\text{z}]. \tag{9}$$

Here, $U_r[\text{z}]$ and $W[\text{z}]$ represent the z-transforms of the reference signal $u_r(k)$ and the quantization error $w(k)$ of the static quantizer, respectively.

The first term on the right-hand side of (9) corresponds to the system output without quantization, while the second term represents the error signal at the system output, which needs to be minimized.

Our design variable is the NTF $R[\text{z}]$ of the $\Delta\Sigma$ modulator, or equivalently, the feedback filter $R[\text{z}] - 1$. Let us express the state space representation of the filter $R[\text{z}] - 1$ as

$$x_r(k+1) = A_r x_r(k) + B_r w(k) \tag{10}$$
$$y_r(k) = C_r x_r(k) \tag{11}$$

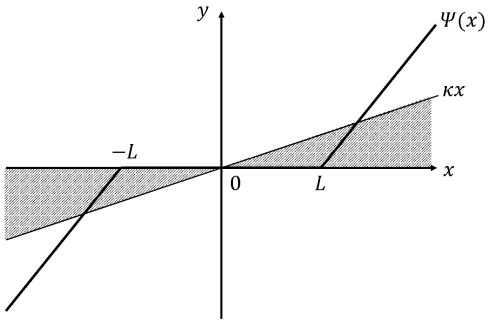

Fig. 4. Dead zone element and sector area.

with $x_r(k) \in \mathbb{R}^{n_r}$ the state vector, $A_r \in \mathbb{R}^{n_r \times n_r}$, $B_r \in \mathbb{R}^{n_r \times 1}$, and $C_r \in \mathbb{R}^{1 \times n_r}$.

A. Mitigation of Quantization effects

In equation (9), the transfer function from the quantization error $w(k)$ of the static quantizer to the system output $y(k)$ is denoted as $G_{yw}[\mathrm{z}]$, given by

$$G_{yw}[\mathrm{z}] = \frac{P[\mathrm{z}]R[\mathrm{z}]}{1 + P[\mathrm{z}]C[\mathrm{z}]}. \tag{12}$$

To mitigate the effect of the quantization error $w(k)$ on the system output, we impose a constraint on the norm of $G_{yw}[\mathrm{z}]$. Specifically, we consider the performance condition:

$$\|G_{yw}[\mathrm{z}]\|_\infty < \epsilon \tag{13}$$

where $\|G_{yw}[\mathrm{z}]\|_\infty$ is the H_∞ norm of $G_{yw}[\mathrm{z}]$ defined as

$$\|G_{yw}[\mathrm{z}]\|_\infty = \max_{|\omega| \le \pi} |G_{yw}[e^{j\omega}]| \tag{14}$$

and ϵ is a positive parameter. It should be noted that alternative norms, such as the H_2 norm, can be used to achieve similar results as discussed below.

From the definition of the augmented state equation, the system output can be expresses as

$$y(k) = C_{yw}x(k) \tag{15}$$

with $C_{yw} = [C_c, 0, 0]$.

It is known that (13) is satisfied if and only if there exists a positive definite matrix of $P_1 \succ 0$ that satisfies

$$\begin{bmatrix} P_1 & AP_1 & B & \mathbf{0} \\ P_1A^T & P_1 & \mathbf{0} & P_1C_{yw}^T \\ B^T & \mathbf{0} & I_n & \mathbf{0} \\ \mathbf{0} & C_{yw}P_1 & \mathbf{0} & \epsilon \end{bmatrix} \succ 0 \tag{16}$$

with $n = n_c + n_p + n_r$.

B. Condition for Stability

We utilize a traditional condition for the stability of a closed-loop non-linear systems. For simplicity, we temporarily assume that there is no quantization error in the range $|\tilde{u}(k)| \le L$ in this subsection.

We introduce a dead zone element $\Psi(\cdot)$ defined as

$$\Psi(x) = x - Q_u(x). \tag{17}$$

Let us denote the output of the dead zone element as $\tilde{w}(k) = -w(k)$. Fig. 4 shows the input and output relationship of the dead zone element. The gray zone corresponds to the sector area which is surrounded by $y = 0$ and $y = \kappa x$ for $0 \le \kappa \le 1$. It is easy to see that $\Psi(x)$ exists in this sector area if and only if the following sector condition is satisfied:

$$\Psi(x)[\Psi(x) - \kappa x] \le 0. \tag{18}$$

It follows from the small gain theorem that if the saturation error remains the sector area, then the system is l_2-stable. The condition on the saturation error leads to the well-known circle criterion: Let $G_{\tilde{u}\tilde{w}}[\mathrm{z}]$ be the transfer function from $\tilde{w}(k)$ to $\tilde{u}(k)$. Then, it follows from the small gain theorem that: When

$$(1 - \kappa G_{\tilde{u}\tilde{w}}(e^{j\theta})) + (1 - \kappa G_{\tilde{u}\tilde{w}}(e^{j\theta}))^* > 0, \ (\theta \in [0, 2\pi)) \tag{19}$$

the system is l_2-stable if $\tilde{w}(k)$ for $k \ge 0$ are in the sector area.

Let us define a augmented state vector from the state vectors $x_c(k)$, $x_p(k)$, and $x_r(k)$ of the controller, the plant, and the NTF as

$$x(k) = \begin{bmatrix} x_c(k+1) \\ x_p(k+1) \\ x_r(k+1) \end{bmatrix}. \tag{20}$$

The state equation is given by

$$x(k+1) = Ax(k) + B\tilde{w}(k) \tag{21}$$

where

$$A = \begin{bmatrix} \tilde{A} & \tilde{B}C_r \\ \mathbf{0} & A_r \end{bmatrix}, \quad B = \begin{bmatrix} \tilde{B} \\ B_r \end{bmatrix} \tag{22}$$

with $\mathbf{0}$ a zero matrix of an appropriate dimension,

$$\tilde{A} = \begin{bmatrix} A_c & -B_cC_p \\ B_pC_c & A_p \end{bmatrix}, \quad \tilde{B} = \begin{bmatrix} \mathbf{0} \\ -B_p \end{bmatrix}. \tag{23}$$

Then, we obtain

$$\tilde{u}(k) = C_{\tilde{u}\tilde{w}}x(k) \tag{24}$$

where

$$C_{\tilde{u}\tilde{w}} = \begin{bmatrix} C_c & \mathbf{0} & -C_r \end{bmatrix}. \tag{25}$$

Using the KYP lemma [9], we can show that the condition (19) is equivalent to the existence of a positive definite matrix $P_2 \succ 0$ that satisfies the following matrix inequality:

$$\begin{bmatrix} -P_2 & -B & AP_2 \\ -B^T & -2I_n & \kappa C_{\tilde{u}\tilde{w}}P_2 \\ P_2A^T & \kappa P_2C_{\tilde{u}\tilde{w}}^T & -P_2 \end{bmatrix} \prec 0. \tag{26}$$

C. Design of $\Delta\Sigma$ modulators

The value for ϵ should be decreased to reduce the effect of the quantization, whereas the value for κ should be increased to enhance the stability. In general, there is a trade-off between reducing the effect of quantization and enhancing stability. Let us consider the minimization of ϵ for a given κ.

Formally, our problem can be stated as follows:

$$\min_{P_1,P_2,A_r,B_r,C_r} \epsilon \tag{27}$$

subject to (16) and (26). Unfortunately, since the conditions are BMIs, our problem is of NP-hard, which is difficult to be solved globally.

To address this problem, we adopt the Lyapunov sharing paradigm, as suggested by [10]. By setting the two Lyapunov matrices to be identical, we introduce an additional constraint on the Lyapunov matrices. However, it should be noted that the global solution cannot be generally obtained due to this constraint.

If we set the order of the NTF to be

$$n_r = n_c + n_p := m, \tag{28}$$

then, by using the change of variables proposed independently in [10] and [11], the condition $P_2 = P_1$ leads to the following convex optimization problem with respect to $m \times m$ real positive definite matrices P_f and P_g , $W_f \in \mathbb{R}^{1\times m}$, $W_g \in \mathbb{R}^{m\times 1}$, and $H \in \mathbb{R}^{m\times m}$:

$$\min_{P_f,P_g,W_f,W_g,H} \epsilon \tag{29}$$

subject to

$$\begin{bmatrix} M_P & M_A & M_B & \mathbf{0} \\ M_A^T & M_P & \mathbf{0} & M_{C_2}^T \\ M_B^T & \mathbf{0} & I & \mathbf{0} \\ \mathbf{0} & M_{C_2} & \mathbf{0} & \epsilon \end{bmatrix} \succ 0 \tag{30}$$

$$\begin{bmatrix} -M_P & -M_B & M_A \\ -M_B^T & -2I & \kappa M_{C_1} \\ M_A^T & \kappa M_{C_1}^T & -M_P \end{bmatrix} \prec 0, \tag{31}$$

where matrices $\{M_P, M_A, M_B, M_{C_1}, M_{C_2}\}$ are defined as

$$M_P = \begin{bmatrix} P_f & I \\ I & P_g \end{bmatrix} \tag{32}$$

$$M_A = \begin{bmatrix} \tilde{A}P_f + \tilde{B}W_f & \tilde{A} \\ H & P_g\tilde{A} \end{bmatrix}, \quad M_B = \begin{bmatrix} \tilde{B} \\ W_g \end{bmatrix} \tag{33}$$

$$M_{C_1} = \begin{bmatrix} [C_c & \mathbf{0}]P_f - W_f[C_c & \mathbf{0}] \end{bmatrix} \tag{34}$$

$$M_{C_2} = \begin{bmatrix} [C_c & \mathbf{0}]P_f & [C_c & \mathbf{0}] \end{bmatrix}. \tag{35}$$

Since the objective in (29) is linear, and (30) and (31) are LMIs that are convex, the minimization problem is a convex optimization, which can be solved numerically.

Once $\{P_f, P_g, W_f, W_g, H\}$ are obtained, $\{A_r, B_r, C_r\}$ are given by

$$A_r = [\tilde{B}W_f - P_g^{-1}(H - P_g\tilde{A}P_f)](P_f - P_g^{-1})^{-1} \tag{36}$$

$$B_r = \tilde{B} - P_g^{-1}W_g \tag{37}$$

$$C_r = W_f(P_f - P_g^{-1})^{-1}. \tag{38}$$

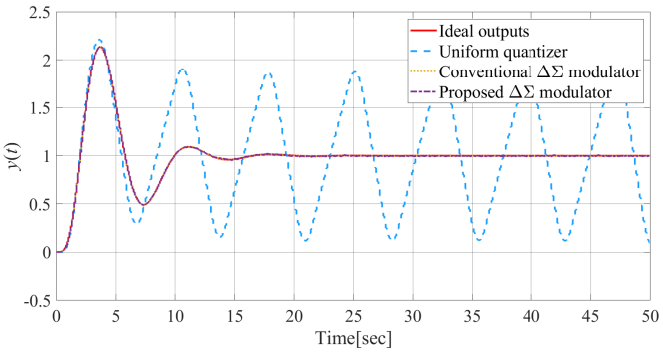

Fig. 5. System outputs $y(t)$ of plant ($d = 1, L = 2$).

IV. Numerical Examples

We consider a control system composed of a continuous-time plant P_c and controller C_c whose (A, B, C) matrices are given by

$$\begin{bmatrix} -0.01 & 1 \\ 0 & -0.01 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 \end{bmatrix} \tag{39}$$

and

$$\begin{bmatrix} 0 & 1.000 & -2.414 & 2.414 \\ -2.414 & -2.414 & -2.000 & 1.000 \\ 1.000 & 0 & -2.414 & 2.414 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix},$$
$$\begin{bmatrix} 2.414 & 2.414 & 1.000 & 0 \end{bmatrix},$$

respectively. The continuous-time system is discretized using the zero-order hold method and sampled with a period of $T_s = 0.1$ to obtain its equivalent discrete-time model, as described in [12].

The coefficient κ, which determines the sector area, is set to be $\kappa = 0.87$. We numerically solve our optimization problems using CVX, a package for specifying and solving convex programs, as introduced in [13], a package for specifying and solving convex programs.

We employ a mid-tread uniform quantizer whose quantization width is d that produces

$$Q_u(x) = id, \text{ for } x \in \left[\left(i - \frac{1}{2}\right)d, \left(i + \frac{1}{2}\right)d\right), |x| \le L \tag{40}$$

for x a scalar input with i an integer.

For the reference signal $u_r(t) = 1$ for $t \ge 0$, we compare the following systems: the ideal system without saturation and quantization, the system with a conventional uniform quantizer instead of the $\Delta\Sigma$ modulator, the system with the $\Delta\Sigma$ modulator proposed by [3], and our proposed system. In figures, their legends are *Ideal output*, *Uniform quantizer*, *Conventional $\Delta\Sigma$ modulator*, and *Proposed $\Delta\Sigma$ modulator*, respectively. They are plotted using red, dashed blue, dotted cyan, and dashed-dotted magenta curves, respectively.

Fig. 5 displays the system outputs $y(t)$ of the plant for the case where $d = 1$ and $L = 2$. We use a large quantization

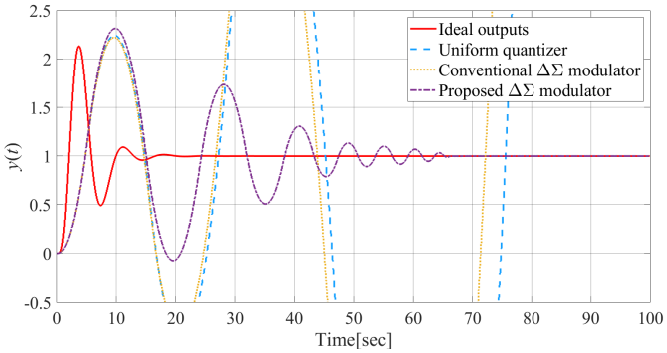

Fig. 6. System outputs $y(t)$ of plant ($d = 0.05, L = 0.1$).

width and a sufficiently large saturation level to observe the performance against quantization errors. Since the quantization level L is large enough, no windup phenomenon can be observed. The system outputs with the conventional $\Delta\Sigma$ modulator and our proposed $\Delta\Sigma$ modulator are almost identical to the ideal system output. However, the system output with the conventional uniform quantizer fluctuates due to quantization errors. This demonstrates that our proposed $\Delta\Sigma$ modulator exhibits similar robustness to quantization errors as the $\Delta\Sigma$ modulator proposed by [3].

In the next case, we examine the performance against saturation. Contrary to the previous case, we choose a small quantization width d and a smaller saturation level L, setting $d = 0.05$ and $L = 0.1$.

Figure 6 compares the system outputs of the four systems. As the saturation level is small, the system outputs with the uniform quantizer and the $\Delta\Sigma$ modulator of [3] diverge, exhibiting windup phenomena. On the other hand, the system output with our proposed $\Delta\Sigma$ modulator converges, although it fluctuates more than the ideal system output. This verifies that our design is robust to saturation.

V. Conclusions

In this study, we have proposed a design method for $\Delta\Sigma$ modulators that addresses the combined effects of quantization and saturation. Our approach aims to minimize the l_2 norm of the quantization error at the system output while satisfying a stability condition for the closed-loop system. By allowing the sharing of a common Lyapunov matrix, we have transformed our design problem into a convex optimization, which can be solved numerically. We have provided numerical examples to demonstrate the effectiveness of our proposed design approach.

***Abstract*—This paper considers sparse Bayesian learning (SBL) in the linear regression model used in signal processing. An estimation performance of the method is analyzed in the asymptotic case where the sample size and the number of regression coefficients both increase. This subject has two cases: one is the dependence of performance on the hyperparameters in prior distribution and the other is how the performance depends on the sample size and the number of nonzero components in regression coefficients. To address this subject, we employ methods of statistical mechanics in physics. An equivalent of thermodynamic potential is calculated, following some similarities between Bayes inference and statistical mechanics. It is known in physics that the potential provides physical quantities. In a similar way, the equivalent of potential provides us with the asymptotic evaluation of estimation performance instead of physical quantities. The estimation performance in the two cases appears to have sharply divided regions in which the estimation succeeds and fails. These results are compared with related studies.**

I. Introduction

This paper deals with sparse estimation problem in signal processing through Bayesian linear regression model. The sparse estimation promotes zero estimation of variables which are the target of estimation, expecting variables have some zero components. In particular, the sparse estimation of regression coefficients in linear regression models has a wide range of applications. For example, it arises in the signal processing problems such as basis selection [1], genome-wide association studies [2], and compressed sensing [3], [4].

In order to perform sparse estimation, various methods have been developed. For example, lasso [5] is influential in this field of sparse estimation from a frequentist point of view. The minimization of L1 norm under certain constraint is pivotal as well in the context of compressed sensing [3]. Further we can also perform the sparse estimation in the framework of Bayesian inference such as Bayesian Lasso [6]. This paper concentrates our attention to a method called sparse Bayesian learning (SBL) [7] and its estimation performance in linear regression model among those methods. This issue has two aspects. One side is the dependence of performance on the hyperparameters in prior distribution. Another aspect is how the performance depends on the sample size n, the number of signal components p, and that of nonzero components in signal. The estimation performance of SBL was previously investigated using certain data with fixed n and p, and the effectiveness of SBL in basis selection and compressed sensing was numerically demonstrated [1], [4]. Additionally, hyperparameters dependence of estimation performance was numerically examined in specific data analysis on diffuse optical tomography using SBL with variational inference [8], [9]. These previous studies [8], [9] observed that the dependence has two regions, and then the estimation performance appears to be robust to variations in hyperparameters within each region.

Given the numerical demonstration of effectiveness of SBL in the case of finite n and p, we shall analyze its estimation performance in linear regression model in the asymptotic case where the number of samples n and that of signal components p both increase at once. This asymptotic evaluation is performed without specific factors like variational inference and diffuse optical tomography data included in previous studies. Such an analysis allows us to observe the asymptotic estimation performance of SBL without the influence of the specific factors and the finiteness of n and p, which contributes to understanding of further properties of SBL and its effectiveness in signal processing.

We explain the reason to focus on the asymptotic evaluation that takes the limit of both n and p, rather than the standard asymptotic evaluation that takes the limit of n with fixing p. The evaluation based on the former asymptotics is associated with the emergence of data in which p is comparable to n [10], [11], [12], [13], [14], [15]. With the emergence of such data, analyzing asymptotic properties of statistical models based on the asymptotics taking limit of both n and p has gained attention [10], [11], [12], [13], [14]. Following this direction, this paper analyzes the asymptotic estimation performance of SBL which is the important method in the field of signal processing.

We analyze the estimation performance using methods in statistical mechanics which is a branch of physics. There are some similarities between statistical mechanics and Bayes inference, and issues in statistics have been analyzed using statistical mechanics through these similarities [16]. For example, the estimation performance in the asymptotic case taking limit of both n and p was analyzed using the replica method

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

of statistical mechanics in the context of several methods for signal reconstruction [17], [18]. Given these analysis cases, we employ the replica method and analyze the performance of SBL with it.

II. Bayes model and population distribution of data

A. Bayes model of sparse Bayesian learning

Let $\{(y_i, \boldsymbol{x}_i); i = 1, \cdots, n\}$ be data sets where y_i and $\boldsymbol{x}_i \in \mathbb{R}^p$ are response variable and explanatory variable, respectively. Here we define $\boldsymbol{y} \coloneqq (y_i, \cdots, y_n)^{\mathrm{T}} \in \mathbb{R}^n$ and $\boldsymbol{X} \coloneqq (\boldsymbol{x}_1, \cdots, \boldsymbol{x}_n)^{\mathrm{T}} \in \mathbb{R}^{n \times p}$ as observation vector and design matrix, respectively.

In linear regression model, an structure connecting $\boldsymbol{y}$ and $\boldsymbol{X}$ is modeled using the regression coefficient or signal $\boldsymbol{w} \in \mathbb{R}^p$ as follows:

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{w} + \boldsymbol{\varepsilon}, \tag{1}$$

where $\boldsymbol{\varepsilon} = (\varepsilon_1, \cdots, \varepsilon_n)^{\mathrm{T}}$ is an error vector whose components are frequently assumed to independently, identically distributed according to normal distribution with zero mean and σ^2 as variance. In this situation, the likelihood function is given as

$$P(\boldsymbol{y}|\boldsymbol{X}, \boldsymbol{w}) = \left(\frac{1}{2\pi\sigma^2}\right)^{n/2} \exp\left(-\frac{1}{2\sigma^2}\|\boldsymbol{y} - \boldsymbol{X}\boldsymbol{w}\|^2\right), \tag{2}$$

where $\|\cdot\|$ is Euclidean norm.

To perform Bayes inference for the linear regression model, we shall equip the regression coefficient $\boldsymbol{w}$ in (1) with prior distribution. The framework of sparse Bayesian learning requires hierarchical prior distribution [7]. It is assumed that prior distribution for $\boldsymbol{w}$ is component-wise normal distribution as follows:

$$P(\boldsymbol{w}|\boldsymbol{\tau}) = \prod_{j=1}^{p} \left(\frac{\tau_j}{2\pi}\right)^{1/2} \exp\left(-\frac{\tau_j}{2} w_j^2\right), \tag{3}$$

where $\boldsymbol{\tau} \coloneqq (\tau_1, \cdots, \tau_p)^{\mathrm{T}}$ is additional parameter distributed like component-wise Gamma distribution, i.e.,

$$P(\boldsymbol{\tau}) = \prod_{j=1}^{p} \frac{b^a}{\Gamma(a)} \tau_j^{a-1} e^{-b\tau_j}. \tag{4}$$

The hyperparameters $a > 0$ and $b > 0$ in (4) are shape and rate parameters, respectively. Marginalizing the product of $P(\boldsymbol{w}|\boldsymbol{\tau})$ and $P(\boldsymbol{\tau})$ with respect to $\boldsymbol{\tau}$ gives the prior distribution of $\boldsymbol{w}$ alone as follows:

$$P(\boldsymbol{w}) = \prod_{j=1}^{p} \frac{\Gamma(a + 1/2) b^a}{\sqrt{2\pi}\Gamma(a)} \left(b + \frac{w_j^2}{2}\right)^{-(a+1/2)}. \tag{5}$$

The likelihood function (2) and prior distribution (5) lead us to make the posterior distribution of $\boldsymbol{w}$ as follows:

$$P(\boldsymbol{w}|\boldsymbol{y}, \boldsymbol{X}) = \frac{1}{Z} P(\boldsymbol{y}|\boldsymbol{X}, \boldsymbol{w}) P(\boldsymbol{w}), \tag{6}$$

where

$$Z = \int d\boldsymbol{w}\, P(\boldsymbol{y}|\boldsymbol{X}, \boldsymbol{w})\, P(\boldsymbol{w}) \tag{7}$$

is the marginal likelihood or evidence as normalization factor.

B. population distribution of data

To analyze estimation performance we assume that $\boldsymbol{y}$ and $\boldsymbol{X}$ are truly linearly connected. In addition, details of distribution for data $(\boldsymbol{y}, \boldsymbol{X})$ together with true signal are set.

We assume that the true regression coefficiet or signal $\boldsymbol{v} \in \mathbb{R}^p$ is distributed according to spike and slab prior as follows:

$$r(\boldsymbol{v}) = \prod_{j=1}^{p} \left\{(1 - \rho)\delta(v_j) + \rho \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{1}{2} v_j^2\right)\right\}, \tag{8}$$

where $\delta(v_j)$ represents Kronecker delta and ρ takes values in the range of $[0, 1] \subset \mathbb{R}$ meaning the ratio of the number of nonzero components. Further design matrix $\boldsymbol{X}$ is assumed to be random matrix whose components are distributed like normal distribution with zero mean and $1/p$ as variance, i.e.,

$$r(\boldsymbol{X}) = \prod_{i=1}^{n} \prod_{j=1}^{p} \left(\frac{p}{2\pi}\right)^{1/2} \exp\left(-\frac{p}{2} x_{ij}^2\right). \tag{9}$$

We consider that $\boldsymbol{y}$ is obtained through (1) with $\boldsymbol{v}$ and $\boldsymbol{X}$ generated from (8) and (9), respectively. In this case, substituting (2) for $r(\boldsymbol{y}|\boldsymbol{X}, \boldsymbol{v}) = \left(2\pi\sigma^2\right)^{-n/2} \exp\left(-\|\boldsymbol{y} - \boldsymbol{X}\boldsymbol{v}\|^2/(2\sigma^2)\right)$, the distribution of data together with $\boldsymbol{v}$ is given as

$$r(\boldsymbol{y}, \boldsymbol{X}, \boldsymbol{v}) = r(\boldsymbol{y}|\boldsymbol{X}, \boldsymbol{v})\, r(\boldsymbol{v})\, r(\boldsymbol{X}). \tag{10}$$

III. Statistical physical analysis of estimation performance

A. an equivalent of thermodynamic potential

We use statistical mechanics to analyze the asymptotic estimation performance. Based on the similarities between the marginal likelihood (7) in Bayesian inference and the partition function in statistical mechanics, which have been proposed so far, the analog of thermodynamic potential calculated in this paper is given as follows:

$$\phi(a, b, \alpha, \rho) = \lim_{n,p \to \infty} \frac{1}{p} \mathbb{E}_{r(\boldsymbol{y}, \boldsymbol{X}, \boldsymbol{v})}\big[\ln Z\big], \tag{11}$$

where Z is (7) and asymptotic limit associated with n and p is incorporated into the right-hand side. The limit of both n and p is taken so that $n/p \to \alpha \in (0, \infty) \subset \mathbb{R}$. We note that $\mathbb{E}_{r(\boldsymbol{y}, \boldsymbol{X}, \boldsymbol{v})}[\cdot]$ in (11) means the calculation of expected value with respect to (10). This potential, (11), is thought of as a function of (a, b, α, ρ) where (a, b) are hyperparameters in prior distribution ((4) and (5)) and ρ is the ratio of nonzero components in the true signal appeared in (8). In addition α represents converging value of n/p as both n and p approach infinity.

B. calculation of potential

Equation (11) is calculated using the replica method of statistical physics [19], [17], [18], [20] together with replica symmetry. To investigate the noise-free estimation performance, we consider (11) in the case of $\sigma^2 \to 0$ in (2) and $r(\boldsymbol{y}|\boldsymbol{X}, \boldsymbol{v}) = \left(2\pi\sigma^2\right)^{-n/2} \exp\left(-\|\boldsymbol{y} - \boldsymbol{X}\boldsymbol{v}\|^2/(2\sigma^2)\right)$ in (10). The overview of calculation in (11) is concisely explained in

the later appendix. This section mainly describes the results. The calculation result of (11) is

$$\phi(a,b,\alpha,\rho) = -\frac{\alpha}{2}\left\{\ln[2\pi\,(Q-q)] + \frac{\rho-2m+q}{Q-q}\right\} + \frac{1}{2}\tilde{Q}Q + \frac{1}{2}\tilde{q}q - \tilde{m}m + \mathbb{E}_{r(\theta,v)}[\ln z\,(\theta,v)], \quad (12)$$

where

$$r(\theta,v) = r(\theta)r(v) = \frac{\exp(-\theta^2/2)}{\sqrt{2\pi}}\left\{(1-\rho)\delta(v) + \frac{\rho}{\sqrt{2\pi}}\exp\left(-\frac{v^2}{2}\right)\right\}. \quad (13)$$

In addition, $z\,(\theta,v)$ in (12) is

$$z\,(\theta,v) = \int dw\;\psi(w,\theta,v), \quad (14)$$

where the integrand is expressed as

$$\psi(w,\theta,v) = \left(b+\frac{w^2}{2}\right)^{-a-1/2} \times \exp\left\{-\frac{1}{2}(\tilde{Q}+\tilde{q})w^2 + \left(\sqrt{\tilde{q}}\theta + \tilde{m}v\right)w\right\}. \quad (15)$$

Here v in (12)-(15) is any one univariate in $\boldsymbol{v} \in \mathbb{R}^p$ without subscript $j \in \{1,\cdots,p\}$ for v_j. In the same way, w in (14) and (15) is any one univariate in $\boldsymbol{w} \in \mathbb{R}^p$ without subscript. Besides, $Q, q, m, \tilde{Q}, \tilde{q}, \tilde{m}$ in (12)-(15) satisfy following equations:

$$\tilde{Q} = \alpha\left\{\frac{1}{Q-q} - \frac{\rho-2m+q}{(Q-q)^2}\right\}, \quad (16)$$

$$\tilde{q} = \alpha\left\{-\frac{1}{Q-q} + \frac{\rho-2m+Q}{(Q-q)^2}\right\}, \quad (17)$$

$$\tilde{m} = \frac{\alpha}{Q-q}, \quad (18)$$

$$Q = \mathbb{E}_{r(\theta,v)}\left[\left\langle w^2\right\rangle\right], \quad (19)$$

$$q = \mathbb{E}_{r(\theta,v)}\left[\left\langle w\right\rangle^2\right], \quad (20)$$

$$m = \mathbb{E}_{r(\theta,v)}\left[v\left\langle w\right\rangle\right], \quad (21)$$

where $\left\langle w^k\right\rangle$ with $k=1$ or 2 is expressed as

$$\left\langle w^k\right\rangle = \frac{1}{z\,(\theta,v)}\int dw\;w^k\;\psi(w,\theta,v). \quad (22)$$

We note that these (14)-(21) are also thought of as the functions of (a,b,α,ρ) like $\phi(a,b,\alpha,\rho)$ in (11) and (12). The notation that $z(\theta,v)$, $\psi(w,\theta,v)$, $\tilde{Q}$, $\tilde{q}$, $\tilde{m}$, Q, q, and m are the functions of (a,b,α,ρ) has been omitted for simplicity.

C. measure of estimation performance

The asymptotic mean square error (MSE) which is the measure of estimation performance is given as

$$\mathrm{MSE}(a,b,\alpha,\rho) = \lim_{n,p\to\infty}\frac{1}{p}\mathbb{E}_{r(\boldsymbol{y},\boldsymbol{X},\boldsymbol{v})}\left[\left\|\mathbb{E}_{P(\boldsymbol{w}|\boldsymbol{y},\boldsymbol{X})}[\boldsymbol{w}] - \boldsymbol{v}\right\|^2\right] = \rho - 2m + q, \quad (23)$$

using m and q required in the process of calculating analog of thermodynamic potential (12) together with ρ in (8).

To analyze the estimation performance based on statistical physics, it is required to calculate the analog of thermodynamic potential (11). Here, we have obtained the form of (12) for (11) using the method of statistical physics such as the replica method. Since (12) includes $\tilde{Q}$, $\tilde{q}$, $\tilde{m}$, Q, q, and m that satisfy (16)-(21), we are required to evaluate them. On this occasion, the asymptotic estimation performance is obtained from (23). However the nonlinear equations for (16)-(21) cannot be solved explicitly. Therefore we evaluate $\tilde{Q}$, $\tilde{q}$, $\tilde{m}$, Q, q, and m through iterative calculation for (16)-(21). In the iterative calculation, we are confronted with the integrals with respect to (22) and $\mathbb{E}_{r(\theta,v)}[\cdot]$ in (19)-(21) that cannot be calculated analytically. The former and latter integrals are treated as numerical integral of Gaussian quadrature and that of Simpson's rule [21], respectively.

To sum up, examining the value of MSE (23) takes further the three steps following the statistical physical calculation from (11) to (12) as follows: First the specific value of (a,b,α,ρ) is fixed where (a,b), ρ, and α are hyperparameters in prior distribution, the ratio of nonzero components in the true vector (8), and the converging value of n/p as $n,p\to\infty$, respectively. Second the specific values of $\tilde{Q}$, $\tilde{q}$, $\tilde{m}$, Q, q, and m are determined through the iterative calculation for (16)-(21). Finally we observe the value of MSE substituting the obtained m and q into (23) together with ρ specified in the first step.

IV. ESTIMATION PERFORMANCE

A. hyperparameters dependence of estimation performance

To investigate the dependence of estimation performance on hyperparameters (a,b) in (4) and (5), we fix the remaining variables as $(\alpha,\rho) = (0.85, 0.5)$ as a representative case. This setting means the task of estimating a signal containing $p\times 0.5$ zero components using SBL under $n \sim 0.85p(<p)$ measurements. We obtain MSE for various values of (a,b) from the aforementioned procedures in Sec. III-C. The result is plotted in Fig. 1. In the current work, MSE could not be obtained in the upper right and lower right regions around $(a, a/b) \sim (10^2, 10^{-5})$ and $(a, a/b) \sim (10^2, 10^5)$. This issue will be discussed in the later section V.

The previous studies [8], [9] plotted a measure of estimation performance on $(a, a/b)$ plane. To compare Fig. 1 with the previous studies, MSE is plotted on $(a, a/b)$ plane instead of, for instance, (a,b) plane. The results of previous researches [8], [9] included the specific factors such as variational inference and diffuse optical tomography data. In addition, those were

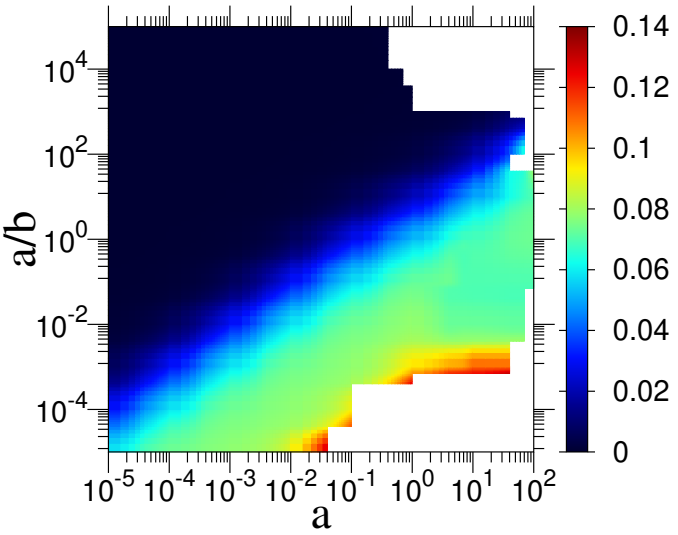

Fig. 1. Mean squared error ($\mathrm{MSE}(a, b, \alpha = 0.85, \rho = 0.5)$) is plotted in heat map format on $(a, a/b)$ with a logarithmic scale. The range of shape parameter is $a \in \{\xi \times 10^{\eta}; \xi = 1, 4, 7, \quad \eta = -5, -4, -3, -2, -1, 0, 1, 2\}$ while that of the ratio is $a/b \in \{\xi \times 10^{\eta}; \xi = 1, 4, 7, \quad \eta = -5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5\}$. We note that a/b means mean parameter of Gamma distribution in (4). To facilitate comparison with previous studies [8], [9], MSE is plotted on $(a, a/b)$ plane instead of, for instance, (a, b) plane. The case of $\mathrm{MSE} \sim 0$ in the region where a is small and a/b is large represents success of estimation, while that of $\mathrm{MSE} \nsim 0$ represents failure.

not the results of asymptotic analysis. Therefore our attention should be paid to overall appearance comparison rather than detailed and quantitative comparison. Overall, as shown in Fig. 1, the MSE values are clearly divided between the small-a, large-a/b region and the large-a, small-a/b region. This overall picture of divided estimation performance is roughly in agreement with the observation by [8], [9], apart from in which regions the error is smaller. The result of this paper may differ from those of [8], [9] in terms of in which region the error is smaller. Reference [8] examined the dependence of the error on shape parameter a by analyzing the iterative formula of variational inference in a simplified one-dimensional case of $n = p = 1$ together with $a/b \to \infty$. According to that result of Fig. 7 in [8], the estimation error is smaller in the region where shape parameter is smaller. Therefore, our Fig. 1 that MSE is smaller in the small-a, large-a/b region does not contradict the result of Fig. 7 in [8]. However, Fig. 1 may contradict the heat maps of Fig. 5 in [8] and Fig. 7 in [9]. In those heat maps, at least as far as the author has seen, it seems that the error become large in the small-a, large-a/b region and it is small in the large-a, small-a/b region. If this is true, Fig. 1 is not consistent with those heat maps provided by [8], [9]. Although the cause of this discrepancy is not clear at this time, it may be due to the differences in the analysis settings. The settings used in [8], [9] are as follows: the specific finite size data for diffuse optical tomography, the noisy case of $\sigma^2 \neq 0$, the non-asymptotic evaluation with approximation of posterior distribution using variational inference. On the other hand, the settings in this paper are as follows: the data according to population distribution explained in II-B, the noise-free case of $\sigma^2 \to 0$, the asymptotic evaluation without approximation of posterior distribution. We consider that these differences in settings may make the inconsistency between our Fig. 1 and the heat maps of Fig. 5 in [8] and Fig. 7 in [9].

We shall turn our attention to the results in Fig. 1 itself from the comparison with previous studies. In the upper left region around $(a, a/b) \sim (10^{-5}, 10^{5})$, τ_j in prior distribution (4) behaves as $1/\tau_j \sim 0$ in the sense of average, because the mean of τ_j, a/b, becomes large ($a/b \sim 10^{5}$). This case also represents $w_j \sim 0$ because $1/\tau_j (\sim 0)$ plays the role of variance of (3) whose mean is zero per component. Therefore we consider zero components in signal to be easily estimated. Moreover, since the variance of τ_j in (4), a/b^2, becomes large ($a/b^2 \sim 10^{15}$), the mass of prior density is also distributed to $1/\tau_j \nsim 0$ which corresponds to the estimation of nonzero components in signal. As a result of these two aspects, we interpret that the MSE takes the values close to zero in Fig. 1, which suggests the success in estimating signal in the upper left region around $(a, a/b) \sim (10^{-5}, 10^{5})$. We also recognize, in the upper left region, that the prior distribution (4) is close to Jeffreys noninformative prior $P(\tau_j) \propto 1/\tau_j$. Thus Fig. 1 shows that the choice of the noninformative prior results in a low-error estimation, at least within the settings in Sec. II. In contrast to the upper left region around $(a, a/b) \sim (10^{-5}, 10^{5})$, both the mean (a/b) and variance (a/b^2) of τ_j in prior distribution (4) are small in the lower right region with $\mathrm{MSE} \nsim 0$. Such a prior is considered to estimate all of the components in signal to be nonzero, failing sparse estimation.

B. (α, ρ) dependence of estimation performance

Continuing from the previous subsection IV-A we examine the dependence of estimation performance on (α, ρ) instead of (a, b). Recall that α represents the convergence of sample size (n) per the number of signals (p), and ρ is the ratio of nonzero components in the true signal in (8). The hyperparameters in (4) and (5) are fixed as $(a, b) = (10^{-5}, 10^{-5}) \leftrightarrow (a, a/b) = (10^{-5}, 1)$ as the representative case. This selection has two implications. This point belongs to the region with $\mathrm{MSE} \sim 0$ in Fig. 1. Although Fig. 1 is the result of fixing (α, ρ) to $(0.85, 0.5)$, we would expect the selection as $(a, b) = (10^{-5}, 10^{-5})$ to be non-singular situation in the present context of (α, ρ) dependence on MSE in the sense that $(a, a/b) = (10^{-5}, 1)$ is not close to the boundary between $\mathrm{MSE} \sim 0$ and $\mathrm{MSE} \nsim 0$ in Fig. 1. Additionally, $(a, b) = (10^{-5}, 10^{-5})$ is close to the setting of $(a, b) = (10^{-6}, 10^{-6})$ which was used as noninformative prior in terms of Jeffreys prior in the context of relevance vector machine [22]. Although we do not calculate the case of just $(a, b) = (10^{-6}, 10^{-6})$ in this study, the difference from $(a, b) = (10^{-5}, 10^{-5})$ is only one digit. In this sense, it is considered that there is no significant difference in the result within this study. Therefore we regard $(a, b) = (10^{-5}, 10^{-5})$ as the canonical setting close to the noninformative prior. Values of MSE are obtained for various

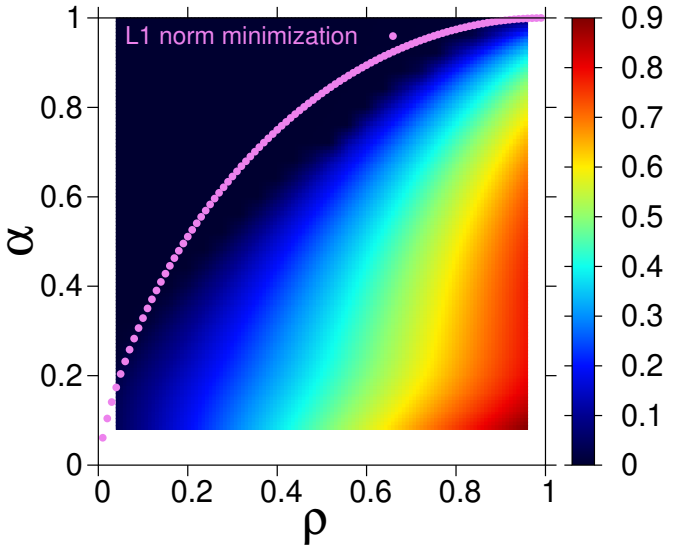

Fig. 2. Mean squared error (MSE($a = 10^{-5}, b = 10^{-5}, \alpha, \rho$)) is plotted in heat map format on (ρ, α). The range of percentage of nonzero components in (8) is $\rho \in \{0.04 \times \xi; \xi = 1, 2, 3, 4, 5, \cdots 20, 21, 22, 23, 24\}$. The range of convergence of sample size (n) per the number of signals (p) is $n/p \to \alpha \in \{0.04 \times \xi; \xi = 2, 3, 4, 5, 6, \cdots, 21, 22, 23, 24, 25\}$. The boundary between zero and nonzero of MSE is also plotted in the case of L1 norm minimization [17]. It was confirmed $\mathrm{MSE} = 0$ in the region above this boundary, while $\mathrm{MSE} \neq 0$ in the region below the boundary [17]. The case of $\mathrm{MSE} \sim 0$ of SBL in the upper left region around $(\alpha, \rho) \sim (1, 0)$ represents success of estimation. The case of $\mathrm{MSE} \nsim 0$ of SBL in the lower right region around $(\alpha, \rho) \sim (0, 1)$ means failure in estimating the signal.

values of (α, ρ) from the procedure described in Sec III-C. The result is plotted in Fig. 2.

The boundary between zero and nonzero of MSE by L1 norm minimization [17] is also plotted in Fig. 2 for comparison. This boundary was previously provided in [17]. In the region above this boundary, MSE with L1 norm minimization takes zero while it takes nonzero values in the region below the boundary. Both the boundary of L1 minimization and that of SBL exhibit similar behavior in the sense that the boundaries between $\mathrm{MSE} \sim 0$ and $\mathrm{MSE} \nsim 0$ appear to be located in an arc from $(\alpha, \rho) = (0, 0)$ to $(1, 1)$. The position of SBL boundary is not as clear as that of L1, however below the L1 boundary, a small region of $\mathrm{MSE} \sim 0$ is observed in the SBL heat map of Fig. (2). In such a region, the MSE of L1 minimization takes nonzero values while that of SBL could be close to zero. In other words, SBL could reduce the MSE to near zero with fewer observations than L1 minimization method, recalling that α is the (convergence of) measurements n per signals p. In this sense, Fig. 2 suggests that SBL could have a potential to perform well than L1 minimization method.

V. DISCUSSION AND CONCLUSION

This paper has analyzed the estimation performance of sparse Bayesian learning (SBL) in the linear regression model in the asymptotic case of both the sample size and the number of regression coefficients or signal components. We have calculated the analog of thermodynamic potential (11), importing the methods and concepts of physics into this subject. The analog of potential has provided us with two estimation performances. One is the dependence of the performance on hyperparameters in prior distribution as shown in Fig. 1. The other is how the performance depends on the sample size and the number of nonzero components in signal as shown in Fig. 2. We have observed that both the estimation performances have sharply divided regions in which the estimation succeeds and fails.

We discuss the numerical integrations of (22) and $\mathbb{E}_{r(\theta,v)}[\cdot]$ in (19)-(21). We have faced these numerical integrations in the iterative calculation of (16)-(21) to obtain the MSE. These have required a large amount of computation and computational time. Once this problem is overcome, we would examine the estimation performance in more detail such as the cases of $(a, b, \alpha \neq 0.85, \rho \neq 0.5)$ in Fig. 1 and $(a \neq 10^{-5}, b \neq 10^{-5}, \alpha, \rho)$ in Fig. 2. Another problem is that we have encountered the situations where the numerical integrals cannot be calculated at some points of (a, b, α, ρ), meaning that MSE also cannot be calculated. For example, these cases are the upper right and lower right regions around $(a, a/b) \sim (10^2, 10^{-5})$ and $(a, a/b) \sim (10^2, 10^5)$ in Fig. 1. The cause of this problem is not clear at present, however the prior distribution becoming sharp or flat in these regions might be related to the failure of numerical integrations. Although there is room for improvement in this study, we hope that the results obtained in this study are shared.

We mention directions for future research. The first is an analysis of estimation performance in the presence of noise. In this paper, we have analyzed the performance in the idealized noise-free situation of $\sigma^2 \to 0$ in (2) and $r(\boldsymbol{y}|\boldsymbol{X}, \boldsymbol{v}) = \left(2\pi\sigma^2\right)^{-n/2} \exp\left(-\|\boldsymbol{y} - \boldsymbol{X}\boldsymbol{v}\|^2/(2\sigma^2)\right)$ in (10). Further analysis of performance in the noisy case of $\sigma^2 \neq 0$ is expected to provide additional insights into estimation performance in realistic situations. The second direction is to investigate the estimation performance when the posterior distribution of signal $\boldsymbol{w}$ and its expected value is determined by practical approximation algorithms. In this paper, we have obtained the results when no approximation algorithms have been applied to the posterior distribution. However, Bayesian sparse estimations of signal have often been performed with efficient approximation algorithms. For example, the variational Bayesian inference and Type-II algorithm based on evidence maximization were applied to the Bayes model of SBL [22], [1], [4]. The practicality of Type-I algorithm based on a maximum a posteriori and Type-II algorithm was further discussed by [23] in a framework that encompasses related methods for sparse estimation problem. Reference [23] proposed the sparse estimation using the power exponential scale mixture family, and showed that Type-II algorithm has better approximation performance than Type-I algorithm. These previous studies [22], [1], [4], [23] showing the affinity between Bayesian sparse estimations and the approximation algorithms motivate us to analyze the estimation performance when the approximation algorithms are applied to the posterior distribution.

APPENDIX: OVERVIEW OF SPECIFIC CALCULATION OF POTENTIAL

Based on advice from the reviewers, we concisely explain the overview of the calculation to obtain (12)-(23) from (11). We refer to [19], [17], [18], [20] for the calculation. Please note that the replica method described below may have a problem with its mathematical rigor depending on certain situation. This appendix does not discuss this mathematical subtlety for the sake of simplicity. See [19], [17], [18], [20] for the subtlety.

step1: evidence replication and expectation with population distribution

It is difficult to directly calculate the expected value with $r(\boldsymbol{y}, \boldsymbol{X}, \boldsymbol{v})$ in (11). Therefore, in the replica method, (11) is transformed as follows:

$$\phi(a,b,\alpha,\rho) = \lim_{c\to 0}\frac{\partial}{\partial c}\lim_{n,p\to\infty}\frac{1}{p}\ln \mathbb{E}_{r(\boldsymbol{y},\boldsymbol{X},\boldsymbol{v})}\big[Z^c\big], \tag{24}$$

where c is interpreted as an integer ($c \in \mathbb{Z}_{>0}$). For any $k \in \{1,\cdots,c\}$, one see that the signal $\boldsymbol{w}$ and evidence Z are replicated as follows:

$$Z_k = \int d\boldsymbol{w}^k\, P\left(\boldsymbol{y}|\boldsymbol{X},\boldsymbol{w}^k\right) P\big(\boldsymbol{w}^k\big), \tag{25}$$

$$\boldsymbol{w}^k = \left(w_1^1,\cdots,w_j^k,\cdots,w_p^m\right)^{\mathrm{T}} \in \mathbb{R}^p. \tag{26}$$

Please imagine that the Bayesian model is replicated with index $k \in \{1,\cdots,c\}$, and the total number of copies is c. In this situation, Z^c in (24) is expressed as the product of copies as follows:

$$Z^c = \prod_{k=1}^{c} Z_k = \int \prod_{k=1}^{c}\Big\{d\boldsymbol{w}^k\, P\left(\boldsymbol{y}|\boldsymbol{X},\boldsymbol{w}^k\right) P\big(\boldsymbol{w}^k\big)\Big\}. \tag{27}$$

Calculating the expectation of integrand with respect to $r(\boldsymbol{y}, \boldsymbol{X}, \boldsymbol{v})$, we obtain the following equation using a certain function $\Phi(\cdot)$:

$$\mathbb{E}_{r(\boldsymbol{y},\boldsymbol{X},\boldsymbol{v})}\big[Z^c\big] = \int \prod_{k,l=1}^{c} dq_{kl} \int \prod_{k=1}^{c} dm_k \exp\big\{p\times\Phi\left(\boldsymbol{Q},\boldsymbol{m}\right)\big\}, \tag{28}$$

where the details of components of matrix $\boldsymbol{Q} = (q_{kl}) \in \mathbb{R}^{c\times c}$ and vector $\boldsymbol{m} = (m_k) \in \mathbb{R}^c$ are

$$q_{kl} = \frac{1}{p}\left(\boldsymbol{w}^k\right)^{\mathrm{T}}\boldsymbol{w}^l, \quad \forall k,l \in \{1,\cdots,c\} \tag{29}$$

and

$$m_k = \frac{1}{p}\boldsymbol{v}^{\mathrm{T}}\boldsymbol{w}^k, \quad \forall k \in \{1,\cdots,c\}, \tag{30}$$

respectively.

step2: integral calculation with Laplace's method

In (24), the limit of $n,p\to\infty$ is waiting for the next step. Therefore, one treat the integral in (28) using Laplace's method and obtain the following equation:

$$\phi(a,b,\alpha,\rho) = \max_{\boldsymbol{Q},\boldsymbol{m}}\Big\{\lim_{c\to 0}\frac{\partial}{\partial c}\Phi\left(\boldsymbol{Q},\boldsymbol{m}\right)\Big\}, \tag{31}$$

where an exchange of $\lim_{c\to 0}\partial_c$ and the maximization coming from Laplace's method is assumed.

step3: employing replica symmetry

Since c in (24) has been regarded as the integer at the beginning of step 1, $\lim_{c\to 0}\partial_c$ in (31) is not performed as it is. A concept called replica symmetry in replica method is the prescription for this issue. The replica symmetry expresses the property related to the exchange of subscripts in q_{kl} and m_k. Specifically, $\boldsymbol{Q} = (q_{kl}) \in \mathbb{R}^{c\times c}$ and $\boldsymbol{m} = (m_k) \in \mathbb{R}^c$ which have replica symmetry are expressed as follows: for any $k,l \in \{1,\cdots,c\}$

$$q_{kl}^{\mathrm{RS}} = \begin{cases} Q & \cdots k = l \\ q & \cdots k \neq l \end{cases} \tag{32}$$

and

$$m_k^{\mathrm{RS}} = m. \tag{33}$$

The calculation of $\lim_{c\to 0}\partial_c$ in (31) is performed by substituting $\boldsymbol{Q}^{\mathrm{RS}} = (q_{kl}^{\mathrm{RS}})$ and $\boldsymbol{m}^{\mathrm{RS}} = (m_k^{\mathrm{RS}})$ into $\Phi\left(\boldsymbol{Q},\boldsymbol{m}\right)$. We obtain

$$\phi(a,b,\alpha,\rho) = \max_{Q,q,m,\tilde{Q},\tilde{q},\tilde{m}}\Big\{\Phi(Q,q,m,\tilde{Q},\tilde{q},\tilde{m})\Big\}, \tag{34}$$

where $(\tilde{Q},\tilde{q},\tilde{m})$ are auxiliary variables introduced in the process of calculation. The detail of $\Phi(Q,q,m,\tilde{Q},\tilde{q},\tilde{m})$ is formally the same as the right side of (12) with (13)-(15). The equations for maximizing $\Phi(Q,q,m,\tilde{Q},\tilde{q},\tilde{m})$ are (16)-(21). In (12), we have reexpressed the detail of $\Phi(Q,q,m,\tilde{Q},\tilde{q},\tilde{m})$ as $\phi(a,b,\alpha,\rho)$, imposing the maximizing condition (16)-(21) on the detail of $\Phi(Q,q,m,\tilde{Q},\tilde{q},\tilde{m})$.

From the knowledge of statistical mechanics, Q, q, and m are expected to be

$$Q = \lim_{n,p\to\infty}\frac{1}{p}\mathbb{E}_{r(\boldsymbol{y},\boldsymbol{X},\boldsymbol{v})}\Big[\mathbb{E}_{P(\boldsymbol{w}|\boldsymbol{y},\boldsymbol{X})}[\boldsymbol{w}^{\mathrm{T}}\boldsymbol{w}]\Big], \tag{35}$$

$$q = \lim_{n,p\to\infty}\frac{1}{p}\mathbb{E}_{r(\boldsymbol{y},\boldsymbol{X},\boldsymbol{v})}\Big[\mathbb{E}_{P(\boldsymbol{w}|\boldsymbol{y},\boldsymbol{X})}[\boldsymbol{w}]^{\mathrm{T}}\mathbb{E}_{P(\boldsymbol{w}|\boldsymbol{y},\boldsymbol{X})}[\boldsymbol{w}]\Big], \tag{36}$$

and

$$m = \lim_{n,p\to\infty}\frac{1}{p}\mathbb{E}_{r(\boldsymbol{y},\boldsymbol{X},\boldsymbol{v})}\Big[\boldsymbol{v}^{\mathrm{T}}\mathbb{E}_{P(\boldsymbol{w}|\boldsymbol{y},\boldsymbol{X})}[\boldsymbol{w}]\Big], \tag{37}$$

respectively. Furthermore, Q, q, and m are reduced from the right side of (35)-(37) to the univariate expressions such as the right side of (19)-(21) through the calculation of replica method explained in this appendix. Therefore, MSE is expressed as the right most side of (23) ($\rho - 2m + q$).

***Abstract*—In this paper, we propose convolutional multidimensional amplitude spectrum nuclear norm (CMASNN) for the task of frequency-domain robust principal component analysis (FRPCA). Principal component extraction (PCE) from observed signals, particularly in the presence of outliers, has long been recognized as a fundamental challenge in the field of signal processing. Although RPCA has demonstrated its efficacy as a technique, it suffers significant limitations when confronted with misaligned principal components due to its reliance on the low-rankness assumption. To address this issue, we initially introduced ASNN, which leverages the invariant property of amplitude spectra under (circular) shifts, enabling the robust extraction of principal components from observed signals by incorporating the ASNN into RPCA. Building upon this foundation, the CMASNN further enhances the ASNN by unifying multiple signals into a higher dimensional representation. This enhancement enables us to discriminate between true principal components and outliers more effectively. By substituting the CMASNN for the ASNN in FRPCA, our experimental results show that the proposed CMASNN-based FRPCA outperforms the performance of its conventional counterpart.**

I. Introduction

Convex optimization employing sparse and low-rank modeling has proven to be highly effective in various domains of modern signal processing and machine learning, and so on [1]–[7]. Among these applications, a particularly noteworthy one is principal component extraction (PCE) from observed signals in the presence of outliers [8]–[16]. The fundamental approach is robust principal component analysis (RPCA), which aims to extract principal components in a low-dimensional subspace by utilizing low-rank modeling with nuclear norm regularization (see Fig. 1(a)). However, a limitation of RPCA lies in its sensitivity to shifts or misalignments in the target components, which increases the rank of principal components (Fig. 1(b)).

In order to address this issue, we introduced amplitude spectrum nuclear norm (ASNN) in our previous study [17]. Fundamentally, a signal and its shifted counterpart exhibit identical amplitude spectra, indicating that both possess low-rank amplitude spectra in the frequency domain. Taking this into consideration, we substituted the ASNN, which evaluates the nuclear norm of signal amplitude spectra, with NN in RPCA. This modified approach, known as frequency-domain RPCA (FRPCA), robustly extracts principal components from a data matrix even in the presence of misalignment and outliers.

In this paper, we enhance the robustness of principal component extraction by customizing the ASNN. An inherent limitation of the ASNN arises from its treatment of each observation as a one-dimensional signal, where a signal containing outliers may resemble a shifted version of another signal (Fig. 1(b)), leading to nearly identical amplitude spectra. Consequently, the precise separation of principal components and outliers becomes challenging. To address this issue, we propose a modified version of the ASNN called convolutional multidimensional ASNN (CMASNN). The CMASNN combines multiple observations into a multidimensional signal in a convolutional fashion and evaluates the low-rankness of its amplitude spectra (Fig. 1(c)). By unifying multidimensional signals that incorporate shifted principal components and outliers, the probability of signal matching under circular shifts is reduced. Experimental results demonstrate that replacing the ASNN with the CMASNN enables more accurate extraction of principal components.

The rest of this paper is organized as follows. Sec. II reviews the fundamentals of convex optimization and the ASNN/FRPCA. Sec. III introduces the proposed OMdASNN. The proposed methods are evaluated in Sec. IV. Finally, this paper concludes in Sec. V.

II. Preliminaries

A. Notations

Bold-faced lower-case letters and upper-case letters are vectors and matrices, respectively. The other mathematical notations are summarized in Table I.

B. Convex Function

A function $f : \mathbb{R}^N \to \mathbb{R}$ is said to be a convex (scalar-valued) function [18] if and only if, for ${}^\forall\mathbf{x},\ \mathbf{y} \in \mathbb{R}^N$ and ${}^\forall\alpha \in [0,1]$, $f(\alpha\mathbf{x} + (1-\alpha)\mathbf{y}) \leq \alpha f(\mathbf{x}) + (1-\alpha)f(\mathbf{y})$.

C. Epigraph

Epigraph of a function $f \in \Gamma_0(\mathbb{R}^N)$ ($\Gamma_0(\mathbb{R}^N)$ is the set of proper lower semicontinuous convex functions on $\mathbb{R}^N$) is a subset of the product space $\mathrm{epi}_f \subset \mathbb{R}^N \times \mathbb{R}$ defined by $\mathrm{epi}_f := \{(\mathbf{x}, \xi) \in \mathbb{R}^N \times \mathbb{R} \mid f(\mathbf{x}) \leq \xi\}$ [19].

TABLE I: Basic notations

Notation	Terminology
A^N and $A^{M\times N}$ $(A \subset \mathbb{C})$	N- and $M \times N$-dimensional vectors/matrices with elements in A
$\mathbf{I}$, $\mathbf{J}$, $\mathbf{O}$	Identity, reversal identity, and zero matrix
$\mathbf{X}^\top$	Transpose of $\mathbf{X}$
$\otimes$	Kronecker product
x_n and $[\mathbf{x}]_n$	n-th element of a vector $\mathbf{x}$
$X_{m,n}$ and $[\mathbf{X}]_{m,n}$	(m,n)-th element of a matrix $\mathbf{X}$
$\lvert\mathbf{x}\rvert \in \mathbb{R}^N$, $\lvert\mathbf{X}\rvert \in \mathbb{R}^{M\times N}$ $(\mathbf{x} \in \mathbb{C}^N, \mathbf{X} \in \mathbb{C}^{M\times N})$	Element-wise absolute value, $[\lvert\mathbf{x}\rvert]_n = \lvert x_n\rvert$, $[\lvert\mathbf{X}\rvert]_{m,n} = \lvert X_{m.n}\rvert$
$\mathrm{vec}(\mathbf{X}) \in \mathbb{R}^{MN}$	Vectorization of $\mathbf{X} \in \mathbb{R}^{M\times N}$, $x_{Mn+m} = X_{m,n}$
$\mathrm{vec}^{-1}(\mathbf{x}) \in \mathbb{R}^{M\times N}$	Matricization of $\mathbf{x} \in \mathbb{R}^{MN}$, $X_{m,n} = x_{Mn+m}$
$\lVert\mathbf{x}\rVert_p$ $(p \in [1,\infty))$	ℓ_p-norm, $\lVert\mathbf{x}\rVert_p = \left(\sum_{n=1}^N \lvert x_n\rvert^p\right)^{\frac{1}{p}}$
$\mathcal{B}_p(\mathbf{y},\epsilon)$ $p \in [1,\infty]$	$\mathbf{y}$-centered ℓ_p-norm ball with the radius of ϵ, $\mathcal{B}_p(\mathbf{y},\epsilon) = \{\mathbf{x} \in \mathbb{R}^N \mid \lVert\mathbf{x}-\mathbf{y}\rVert_p \le \epsilon\}$
$\lVert\mathbf{X}\rVert_*$ or $\lVert\mathbf{x}\rVert_*$	Nuclear norm, $\lVert\mathbf{X}\rVert_* = \sum_{r=1}^R \sigma_r(\mathbf{X})$ or $\lVert\mathbf{x}\rVert_* = \lVert\mathrm{vec}^{-1}(\mathbf{x})\rVert_*$ ($\sigma_r(\mathbf{X})$: r-th singular value of $\mathbf{X}$)
$\lVert\mathbf{X}\rVert_{\mathrm{op}}$	Induced norm (Schatten ∞-matrix norm), $\lVert\mathbf{X}\rVert_{\mathrm{op}} = \lVert\mathbf{X}\rVert_{S_\infty} = \max_{\lVert\mathbf{v}\rVert_2\le 1} \lVert\mathbf{X}\mathbf{v}\rVert_2$
$\mathbf{x} \le \mathbf{y}$ $(\mathbf{x},\mathbf{y} \in \mathbb{R}^N)$	$x_n \le y_n$ $(1 \le {}^\forall n \le N)$.

D. Indicator Function

ι_C is the indicator function of C defined by $\iota_C(\mathbf{x}) := 0$ $(\mathbf{x} \in C)$, $\iota_C(\mathbf{x}) := \infty$ $(\mathbf{x} \notin C)$.

E. Proximity Operator and Projection onto Convex Set

The proximity operator, denoted as $\mathrm{prox}_{\gamma f} : \mathbb{R}^N \to \mathbb{R}^N$, is defined for a function $f \in \Gamma_0(\mathbb{R}^N)$ and an index $\gamma \in (0,\infty)$ by $\mathrm{prox}_{\gamma f}(\mathbf{x}) := \underset{\mathbf{y}\in\mathbb{R}^N}{\mathrm{argmin}}\, \gamma f(\mathbf{y}) + \frac{1}{2}\lVert\mathbf{x}-\mathbf{y}\rVert_2^2$.

The projection onto a convex set $C \subset \mathbb{R}^N$, denoted as $\mathcal{P}_C(\mathbf{x}) : \mathbb{R}^N \to \mathbb{R}^N$, is one the special cases of the proximity operator, which can be represented as $\mathrm{prox}_{\gamma\iota_C}(\mathbf{x}) := \underset{\mathbf{y}\in\mathbb{R}^N}{\mathrm{argmin}}\, \gamma\iota_C(\mathbf{y}) + \frac{1}{2}\lVert\mathbf{x}-\mathbf{y}\rVert_2^2 = \underset{\mathbf{y}\in C}{\mathrm{argmin}}\, \lVert\mathbf{x}-\mathbf{y}\rVert_2^2 =: \mathcal{P}_C(\mathbf{x})$.

TABLE II: Proximity operator and computational complexity

Function f	Proximity operator $\widetilde{\mathbf{x}} = \mathrm{prox}_{\gamma f}(\mathbf{x})$ and computational complexity for N- and $M\times N$-dimensional vectors/matrices
$\lVert\cdot\rVert_1$	Soft-thresholding $\widetilde{\mathbf{x}} = \mathcal{T}_\gamma(\mathbf{x})$ [19], $\mathcal{O}(N)$ $(\widetilde{\mathbf{x}}_n = [\mathcal{T}_\gamma(\mathbf{x})]_n = \mathrm{sign}(x_n)\max\{\lvert x_n\rvert - \gamma, 0\}$)
$\iota_{\mathcal{B}_1(\mathbf{y},\epsilon)}(\cdot)$	Using projection onto the simplex [21], $\mathcal{O}(N\log N)$.
$\lVert\mathbf{X}\rVert_*$	Soft-thresholding on singular values of $\mathbf{X} \in \mathbb{R}^{M\times N}$ [19], $\mathcal{O}(MN\min\{M,N\})$ $\boldsymbol{\sigma} = [\sigma_1 \ \dots \ \sigma_r]^\top$ $(\mathbf{X} = \mathbf{U}\mathrm{diag}(\boldsymbol{\sigma})\mathbf{V}^\top)$, $\widetilde{\mathbf{X}} = \mathbf{U}\mathrm{diag}(\mathcal{T}_\gamma(\boldsymbol{\sigma}))\mathbf{V}^\top$.

F. Projection onto the Epigraph of ℓ_2-norm

For ${}^\forall(\mathbf{x},\xi) \in \mathbb{R}^N \times \mathbb{R}$, the projection onto the epigraph of the (scaled) ℓ_2-norm ($\tau\lVert\cdot\rVert_2$, $\tau > 0$) is expressed as [20]:

$$\mathcal{P}_{\mathrm{epi}_{\tau\lVert\cdot\rVert_2}}(\mathbf{x},\xi) = \begin{cases} (\mathbf{x},\xi) & (\tau\lVert\mathbf{x}\rVert_2 \le \xi) \\ (\mathbf{0},0) & (\lVert\mathbf{x}\rVert_2 < -\tau\xi) \\ \alpha\,(\mathbf{x}, \tau\lVert\mathbf{x}\rVert_2) & (\text{otherwise}) \end{cases}, \quad (1)$$

where $\alpha = \frac{1}{1+\tau^2}\left(1 + \frac{\tau\xi}{\lVert\mathbf{x}\rVert_2}\right)$.

G. Fenchel-Rockafellar conjugate function and its proximity operator

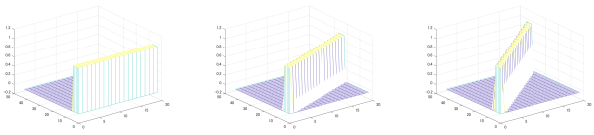
For ${}^\forall f \in \Gamma_0(\mathbb{R}^p)$, the conjugate function f^* of f is defined as $f^*(\boldsymbol{\xi}) := \sup_{\mathbf{x}\in\mathbb{R}^N} \langle\mathbf{x},\boldsymbol{\xi}\rangle - f(\mathbf{x})$, and the proximity operator of the conjugate function is calculated as: $\mathrm{prox}_{\gamma f^*}(\mathbf{x}) = \mathbf{x} - \gamma\mathrm{prox}_{\frac{1}{\gamma}f}\left(\frac{1}{\gamma}\mathbf{x}\right)$ [22].

H. Primal-dual Splitting

Consider the following convex optimization problem to find

$$\mathbf{x}^\star \in \underset{\mathbf{x}\in\mathbb{R}^N}{\mathrm{argmin}}\, G(\mathbf{x}) + H(\mathbf{A}\mathbf{x}) \ (\neq \emptyset), \quad (2)$$

where $G \in \Gamma_0(\mathbb{R}^N)$, $H \in \Gamma_0(\mathbb{R}^M)$, and $\mathbf{A} \in \mathbb{R}^{M\times N}$, respectively. We assume that the solution set of (2) is nonempty. Then the PDS algorithm [23]–[27] for solving (2) is given as follows:



$$\begin{cases} \mathbf{x}^{(n+1)} = \mathrm{prox}_{\gamma_1 G}[\mathbf{x}^{(n)} - \gamma_1\mathbf{A}^\top\mathbf{z}^{(n)}] \\ \mathbf{z}^{(n+1)} = \mathrm{prox}_{\gamma_2 H^*}[\mathbf{z}^{(n)} + \gamma_2\mathbf{A}(2\mathbf{x}^{(n+1)} - \mathbf{x}^{(n)})] \end{cases}, \quad (3)$$

where prox denotes the proximity operator and H^* is the conjugate function of H.

According to Theorem 3.3 in [24], for given $\gamma_1 > 0$ and $\gamma_2 > 0$ satisfying $\gamma_1\gamma_2\lVert\mathbf{A}\rVert_{\mathrm{op}} \le 1$ (the definition of the induced norm, see Table I), the sequence of $\{\mathbf{x}^{(n)}\}_{n=0}^\infty$ in (3) converges to a minimizer $\mathbf{x}^\star$ of (2). Thanks to the convexity nature, the initial value of $\mathbf{x}^{(0)}$ and $\mathbf{z}^{(0)}$ can be chosen arbitrarily.

I. Amplitude Spectrum Nuclear Norm and Its Application to Frequency-domain RPCA

This section reviews the ASNN for PCE [17]. Low-rank modeling is one of the most effective approaches for PCE [8]–[16], and robust PCA (RPCA) [8], [9], [14], [16] is known as the standard technique that can extract principal components lying in a low-dimensional subspace from an observed matrix in the presence of outliers. An example of 1-dimensional (1D)

(a) Shift:0, $\widehat{\mathbf{L}}_0$ (b) Shift:1, $\widehat{\mathbf{L}}_1$ (c) Shift:2, $\widehat{\mathbf{L}}_2$

Fig. 2: Examples of target signals.

principal components $\widehat{\mathbf{L}}_0 \in \mathbb{R}^{25\times 20}$ is shown in Fig. 2(a), where m-th column of $\widehat{\mathbf{L}}_s$ is set as

$$[\widehat{\mathbf{L}}_s]_{m,n} = \begin{cases} 1 & (sn \le m \le sn+4) \\ 0 & (\text{otherwise}) \end{cases}. \tag{4}$$

The problem formulation for RPCA is given as follows [9]:

$$\{\mathbf{L}^\star,\ \mathbf{S}^\star\} \in \underset{\mathbf{L},\ \mathbf{S}}{\operatorname{argmin}} \|\mathbf{L}\|_* + \phi(\mathbf{S}) \ \text{ s.t. } \ \mathbf{X} = \mathbf{L} + \mathbf{S}, \tag{5}$$

where ϕ is a sparsity-promoting function, e.g., the ℓ_1-norm and the indicator function of the ℓ_1-norm ball constraint[1].

One of the drawback of RPCA is the sensitivity against the shift or the misalignment of target components. Fig. 2(b) and (c) show target components shifted every one and two sample $\widehat{\mathbf{L}}_1,\ \widehat{\mathbf{L}}_2 \in \mathbb{R}^{25\times 20}$, respectively. When target components are not aligned exactly due the shift (Fig. 2(b) and (c)), they are not lying low-dimensional subspace any more. Consequently, RPCA cannot extract the principal components precisely.

To resolve this drawback, we utilize the fundamental signal processing theory: the amplitude spectra of an original and its (circularly) shifted signals are the same. For example, for given $\widehat{\mathbf{L}}_s = \begin{bmatrix}\widehat{\boldsymbol{\ell}}_{s,1} & \cdots & \widehat{\boldsymbol{\ell}}_{s,N}\end{bmatrix} \in \mathbb{R}^{M\times N}$, $|\mathbf{W}_M \widehat{\boldsymbol{\ell}}_{s,n_1}| = |\mathbf{W}_M \widehat{\boldsymbol{\ell}}_{s,n_2}|$, where $\mathbf{W}_M \in \mathbb{C}^{M\times M}$ denotes the nomalized DFT matrix ($[\mathbf{W}_M]_{m_1,m_2} = \frac{1}{\sqrt{M}}\exp\left(-\mathrm{j}\frac{2\pi}{M}m_1 m_2\right)$) and the definition $|\cdot|$ for vectors and matrices is given in Table I. According to this nature, we design the ASNN $\|\cdot\|_{\mathrm{ASNN}} : \mathbb{R}^{M\times N} \to \mathbb{R}$ for a set of 1D signals $\mathbf{X} = \begin{bmatrix}\mathbf{x}_1 & \cdots & \mathbf{x}_N\end{bmatrix}$ as:

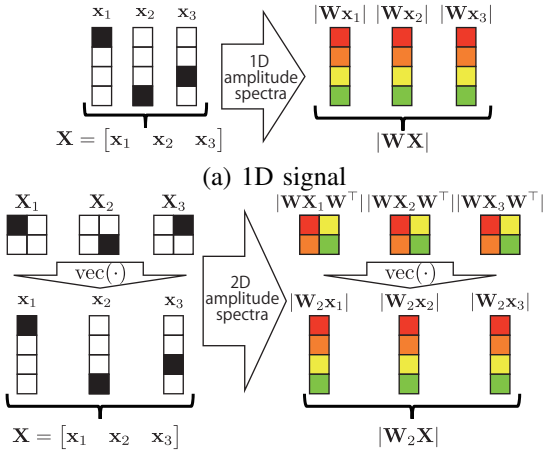
$$\|\mathbf{X}\|_{\mathrm{ASNN}} := \||\mathbf{W}_M \mathbf{X}|\|_*, \tag{6}$$

where $|\mathbf{W}_M\mathbf{X}|$ denotes the amplitude spectra of input 1D signals $\mathbf{X}$. The ASNN takes small value when columns in $\mathbf{X}$ have an isomorphic structure even in the presence of shift. The ASNN can be considered as a 2-layered composite function as follows:

$$\begin{aligned} \||\mathbf{W}_M\mathbf{X}|\|_* &= \||(\mathbf{C}_M - \mathrm{j}\mathbf{S}_M)\mathbf{X}|\|_* \\ &= \left\|\mathbf{P}^{(1)}\begin{bmatrix}\mathbf{C}_M^\top & -\mathbf{S}_M^\top\end{bmatrix}^\top \mathbf{X}\right\|_{2,*} \\ &= \|\mathbf{T}\mathbf{L}\|_{2,*}, \end{aligned} \tag{7}$$

where $[\mathbf{C}_M]_{m_1,m_2} = \frac{1}{\sqrt{M}}\cos\left(\frac{2\pi}{M}m_1m_2\right)$, $[\mathbf{S}_M]_{m_1,m_2} = \frac{1}{\sqrt{M}}\sin\left(\frac{2\pi}{M}m_1m_2\right)$, $\mathbf{P}^{(1)}$ is a permutation matrix, and $\|\cdot\|_{2,*} : \mathbb{R}^{2M\times N} \to \mathbb{R}$ is defined as:

$$\begin{aligned} \mathbf{X} &:= \begin{bmatrix}\mathbf{x}_{1,1} & \cdots & \mathbf{x}_{1,N} \\ \vdots & \ddots & \vdots \\ \mathbf{x}_{M,1} & \cdots & \mathbf{x}_{M,N}\end{bmatrix}, \ (\mathbf{x}_{m,n} \in \mathbb{R}^2) \\ \|\mathbf{X}\|_{2,*} &:= \|g_{\|\cdot\|_2}(\mathbf{X})\|_*, \\ g_{\|\cdot\|_2}(\mathbf{X}) &:= \begin{bmatrix}\|\mathbf{x}_{1,1}\|_2 & \cdots & \|\mathbf{x}_{1,N}\|_2 \\ \vdots & \ddots & \vdots \\ \|\mathbf{x}_{M,1}\|_2 & \cdots & \|\mathbf{x}_{M,N}\|_2\end{bmatrix}. \end{aligned} \tag{8}$$



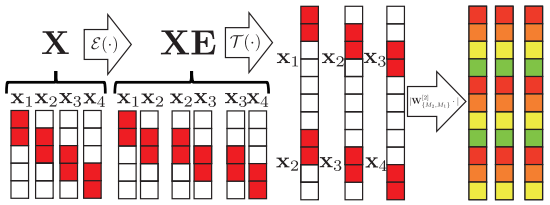
As shown in [17], since the nuclear norm is not a non-decreasing function on $\mathbb{R}_+^{M\times N}$, $\|\cdot\|_{2,*}$ is not even a convex function.

The ASNN for 1D signals can be generalized to the one for MD signals $\{\mathcal{X}_n\}_{n=1}^N \subset \mathbb{R}^{M_1\times M_2\times\cdots\times M_D}$, which is denoted as multidimensional ASNN (MASNN) [17] with multidimensional separable DFT $\mathbf{W}^{[D]}_{\{M_d\}_{d=D}^1}$, as in the following:

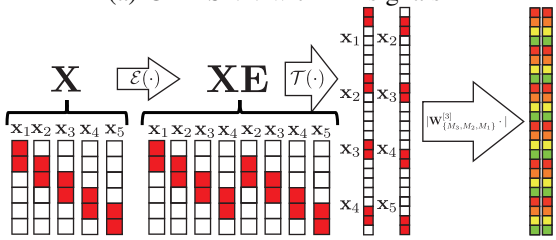
$$\begin{aligned} \|\mathbf{X}\|_{\mathrm{MASNN}} &:= \||\mathbf{W}^{[D]}_{\{M_d\}_{d=D}^1}\mathbf{X}|\|_* = \|\mathbf{T}\mathbf{X}\|_{2,*}, \\ \mathbf{X} &= \begin{bmatrix}\mathrm{vec}(\mathcal{X}_1) & \cdots & \mathrm{vec}(\mathcal{X}_N)\end{bmatrix} \in \mathbb{R}^{\Pi_{d=1}^D M_d\times N}, \\ \mathbf{W}^{[D]}_{\{M_d\}_{d=D}^1} &= \mathbf{W}_{M_D}\otimes\cdots\otimes\mathbf{W}_{M_1}, \\ \mathbf{T} &= \mathbf{P}^{(2)}\begin{bmatrix}\mathbf{T}_r^\top & \mathbf{T}_i^\top\end{bmatrix}^\top, \end{aligned} \tag{9}$$

where $\mathbf{P}^{(2)}$ is a permutation matrix and $\mathbf{T}_r$ and $\mathbf{T}_i$ are the combination of the Kronecker products of $\mathbf{C}_{M_d}$ and $\mathbf{S}_{M_d}$. For example $D = 2$, the construction of $|\mathbf{W}^{[2]}_{\{M_2,M_1\}}\mathbf{X}|$ is illustrated in Fig. 3(b), where

$$\begin{aligned} \mathbf{W}^{[2]}_{\{M_2,M_1\}} &= \mathbf{W}_{M_2}\otimes\mathbf{W}_{M_1} \\ &= (\mathbf{C}_{M_2} - j\mathbf{S}_{M_2})\otimes(\mathbf{C}_{M_1} - j\mathbf{S}_{M_1}), \\ \mathbf{T}_r &= (\mathbf{C}_{M_2}\otimes\mathbf{C}_{M_1}) - (\mathbf{S}_{M_2}\otimes\mathbf{S}_{M_1}), \\ \mathbf{T}_i &= -((\mathbf{C}_{M_2}\otimes\mathbf{S}_{M_1}) + (\mathbf{S}_{M_2}\otimes\mathbf{C}_{M_1})). \end{aligned} \tag{10}$$



(a) 1D signal



(b) 2D signal

Fig. 3: ASNN for multidimensional signals.

[1]Although the original RPCA [9] employs the ℓ_1-norm as ϕ, we use the ℓ-norm ball constraint for experiments in Sec. IV for fair performance comparison between nuclear norm, the ASNN, and the CMASNN.

III. Convolutional Multidimensional Amplitude Spectrum Nuclear Norm for Frequency-domain Robust Principal Component Analysis

A. Definition of Overlapped Multidimensional Amplitude Spectrum Nuclear Norm

In this section, we extend the conventional MASNN to the CMASNN for more robust PCE. As mentioned in Sec. I, a limitation of FRPCA when using the conventional ASNN is its tendency to struggle in distinguishing principal components from outliers. This occurs when observed principal components, along with outliers, closely resemble shifted versions of other observations, as depicted in Fig. 1. To enhance the accuracy of PCE, we unify multiple observations into a higher-dimensional signal with overlapping and evaluate the low-rankness of its amplitude spectra using the ASNN. Essentially, when two high-dimensional signals are shifted versions of one another, their amplitude spectra exhibit identical patterns. Furthermore, the introduction of a higher-dimensional signal is expected to mitigate the possibility of principal components with outliers aligning under circular shifts. With this in mind, we introduce the CMASNN in the following way:

$$\begin{aligned}\|\{\mathcal{X}_n\}_{n=1}^N\|_{\mathrm{CMASNN}} &:= \||\mathbf{W}^{[D]}_{\{M_d\}_{d=D}^1}\mathcal{T}(\mathcal{E}(\{\mathcal{X}_n\}_{n=1}^N)|\|_* \\ &= \left\|\mathbf{T}\mathcal{T}(\mathcal{E}(\{\mathcal{X}_n\}_{n=1}^N))\right\|_{2,*}, \end{aligned} \tag{11}$$

where $\mathbf{W}^{[D]}_{\{M_d\}_{d=D}^1}$ and $\mathbf{T}$ are the same matrices in Sec. II-I and the operator $\mathcal{E}$ duplicates signals in $\{\mathcal{X}_n\}$ and $\mathcal{T}$ is an unifying operator that unifies several signals into a (vectorized) higher-dimensional tensor. Fig. 4 shows an example of the CMASNN which embeds several 1D signals into a 2D or 3D signal in a convolutional fashion and calculates the 2D or 3D amplitude spectra, where $\{\mathcal{X}_n\}_{n=1}^N$ is simply denoted as the matrix $\mathbf{X}$ and $\mathcal{E}(\mathbf{X}) = \mathbf{XE}$ ($\mathbf{E}$ duplicates columns of $\mathbf{X}$).

B. Algotithm for Convolutional Multidimensional Amplitude Spectrum Nuclear Norm Minimization with PDS

Now we modify the cost function of RPCA by using the CMASNN, which is termed as frequency-domain RPCA ($\mathcal{F}$RPCA). For simplicity, we consider the case of PCE from 1D observations using CMASNN with multidimensional tensors as:

$$\begin{aligned}\{\mathbf{L}^\star,\ \mathbf{S}^\star\} \in \underset{\mathbf{L},\ \mathbf{S}}{\operatorname{argmin}} &\|\mathbf{L}\|_{\mathrm{CMASNN}} + \phi(\mathbf{S}) \ \text{ s.t. } \ \mathbf{X} = \mathbf{L} + \mathbf{S} \\ = \underset{\mathbf{L},\ \mathbf{S}}{\operatorname{argmin}} &\||\mathbf{W}^{[D]}_{\{M_d\}_{d=D}^1}\mathcal{T}(\mathbf{LE})|\|_* \\ &+ \ \phi(\mathbf{S}) + \iota_{\{\mathbf{X}\}}(\mathbf{L}+\mathbf{S}) \\ = \underset{\mathbf{L},\ \mathbf{S}}{\operatorname{argmin}} &\|\mathbf{T}\mathcal{T}(\mathbf{LE})\|_{2,*} + \widetilde{\phi}(\mathbf{L},\mathbf{S},\mathbf{X}) \end{aligned} \tag{12}$$

where $\widetilde{\phi}(\mathbf{L},\mathbf{S},\mathbf{X}) = \phi(\mathbf{S}) + \iota_{\{\mathbf{X}\}}(\mathbf{L}+\mathbf{S})$. Unfortunately the above optimization problem is nonconvex due to nonconvexity of $\|\cdot\|_{2,*}$. Furthermore, the closed-form proximity operator of $\|\cdot\|_{2,*}$ cannot be calculated trivially. Thus, we find an approximated solution for the problem (12) by using epigraphical relaxation (ERx) [17] which decouple a non-proximable composite function into a outermost norm and an epigrahical constraint as follows:

$$\begin{aligned}&\underset{\mathbf{L},\ \mathbf{S}}{\operatorname{argmin}} \|\mathbf{Z}\|_* + \widetilde{\phi}(\mathbf{L},\mathbf{S},\mathbf{X}) \text{ s.t. } g_{\|\cdot\|_2}(\mathbf{T}\mathcal{T}(\mathbf{LE})) = \mathbf{Z}, \\ \xrightarrow{\text{ERx}}\ &\underset{\mathbf{L},\ \mathbf{S}}{\operatorname{argmin}} \|\mathbf{Z}\|_* + \widetilde{\phi}(\mathbf{L},\mathbf{S},\mathbf{X}) \text{ s.t. } g_{\|\cdot\|_2}(\mathbf{T}\mathcal{T}(\mathbf{LE})) \le \mathbf{Z}, \\ =\ &\underset{\mathbf{L},\ \mathbf{S}}{\operatorname{argmin}} \|\mathbf{Z}\|_* + \widetilde{\phi}(\mathbf{L},\mathbf{S},\mathbf{X}) + \iota_{\mathrm{epi}_{\|\cdot\|_2}}(\mathbf{T}\mathcal{T}(\mathbf{LE}),\mathbf{Z}), \end{aligned} \tag{13}$$

Finally we can apply PDS by reformulating the above optimization with vector notations as:

$$\{\widetilde{\boldsymbol{\ell}},\ \widetilde{\mathbf{s}}\} \in \underset{\boldsymbol{\ell},\ \mathbf{s}}{\operatorname{argmin}} \|\mathbf{z}\|_* + \widetilde{\phi}(\boldsymbol{\ell},\mathbf{s},\mathbf{x}) + \iota_{\mathrm{epi}_{\|\cdot\|_2}}\left(\widehat{\mathbf{T}}\boldsymbol{\ell},\mathbf{z}\right), \tag{14}$$

where $\mathbf{x} = \mathrm{vec}(\mathbf{X})$, $\boldsymbol{\ell} = \mathrm{vec}(\mathbf{L})$, $\mathbf{s} = \mathrm{vec}(\mathbf{S})$, and $\widehat{\mathbf{T}} = \mathbf{I}\otimes\mathbf{T}\widetilde{\mathbf{E}}$. The matrix $\widetilde{\mathbf{E}}$ duplicates subvectors in the vectorized data $\boldsymbol{\ell}$. For example, let $\mathbf{L} = \begin{bmatrix}\boldsymbol{\ell}_1 & \boldsymbol{\ell}_2 & \boldsymbol{\ell}_3 & \boldsymbol{\ell}_4\end{bmatrix}$ and consider the case shown in Fig. 4(a). Then, the matrix $\widetilde{\mathbf{E}}$ maps $\boldsymbol{\ell} = \mathrm{vec}(\mathbf{L}) = \begin{bmatrix}\boldsymbol{\ell}_1^\top & \cdots & \boldsymbol{\ell}_4^\top\end{bmatrix}^\top$ to $\begin{bmatrix}\boldsymbol{\ell}_1^\top & \boldsymbol{\ell}_2^\top & \boldsymbol{\ell}_2^\top & \boldsymbol{\ell}_3^\top & \boldsymbol{\ell}_3^\top & \boldsymbol{\ell}_4^\top\end{bmatrix}^\top$.

Since the objective function in the last line of (14) is convex, the global minimizer can be found by the PDS algorithm. Note that the problem (14) is obtained by epigraphical relaxation, the minimizer for (13) is not the one for (12). The minimization problem can be solved by the PDS algorithm as

$$\begin{aligned}&\mathbf{p} = \begin{bmatrix}\boldsymbol{\ell}^\top & \mathbf{s}^\top & \mathbf{z}^\top\end{bmatrix}^\top,\ G(\mathbf{p}) = \mathbf{0}, \\ &H(\mathbf{q}) = \|\mathbf{q}_1\|_* + \phi(\mathbf{q}_2) + \iota_{\{\mathbf{x}\}}(\mathbf{q}_3) + \iota_{\mathrm{epi}_{\|\cdot\|_2}}(\mathbf{q}_4,\mathbf{q}_5), \\ &\mathbf{q} = \mathbf{A}\mathbf{p},\ \mathbf{A} = \begin{bmatrix}\mathbf{O} & \mathbf{O} & \mathbf{I} & \widehat{\mathbf{T}}^\top & \mathbf{O} \\ \mathbf{O} & \mathbf{I} & \mathbf{I} & \mathbf{O} & \mathbf{O} \\ \mathbf{I} & \mathbf{O} & \mathbf{O} & \mathbf{O} & \mathbf{I}\end{bmatrix}^\top. \end{aligned} \tag{15}$$

The detailed algorithm is summarized in Algorithm 1, where the proximity operator of the nuclear norm $\|\cdot\|_*$ is in Table II and that of $\iota_{\mathrm{epi}_{\|\cdot\|_2}}$ is computed by (1).

  $\mathbf{q}_3^{(n+1)} = \mathbf{t}_3^{(n)} - \gamma_2 \mathrm{prox}_{\frac{1}{\gamma_2}\iota_{\{\mathbf{x}\}}}\left(\frac{1}{\gamma_2}\mathbf{t}_3^{(n)}\right)$.
  $(\mathbf{q}_4^{(n+1)}, \mathbf{q}_5^{(n+1)}) = (\mathbf{t}_4^{(n)}, \mathbf{t}_5^{(n)}) - \gamma_2 \mathrm{prox}_{\frac{1}{\gamma_2}\mathrm{epi}\|\cdot\|_2}\left(\frac{1}{\gamma_2}(\mathbf{t}_4^{(n)}, \mathbf{t}_5^{(n)})\right)$.
  $n = n + 1$.
end while
Output $\mathbf{x}^{(n)}$.

IV. Experimental Results

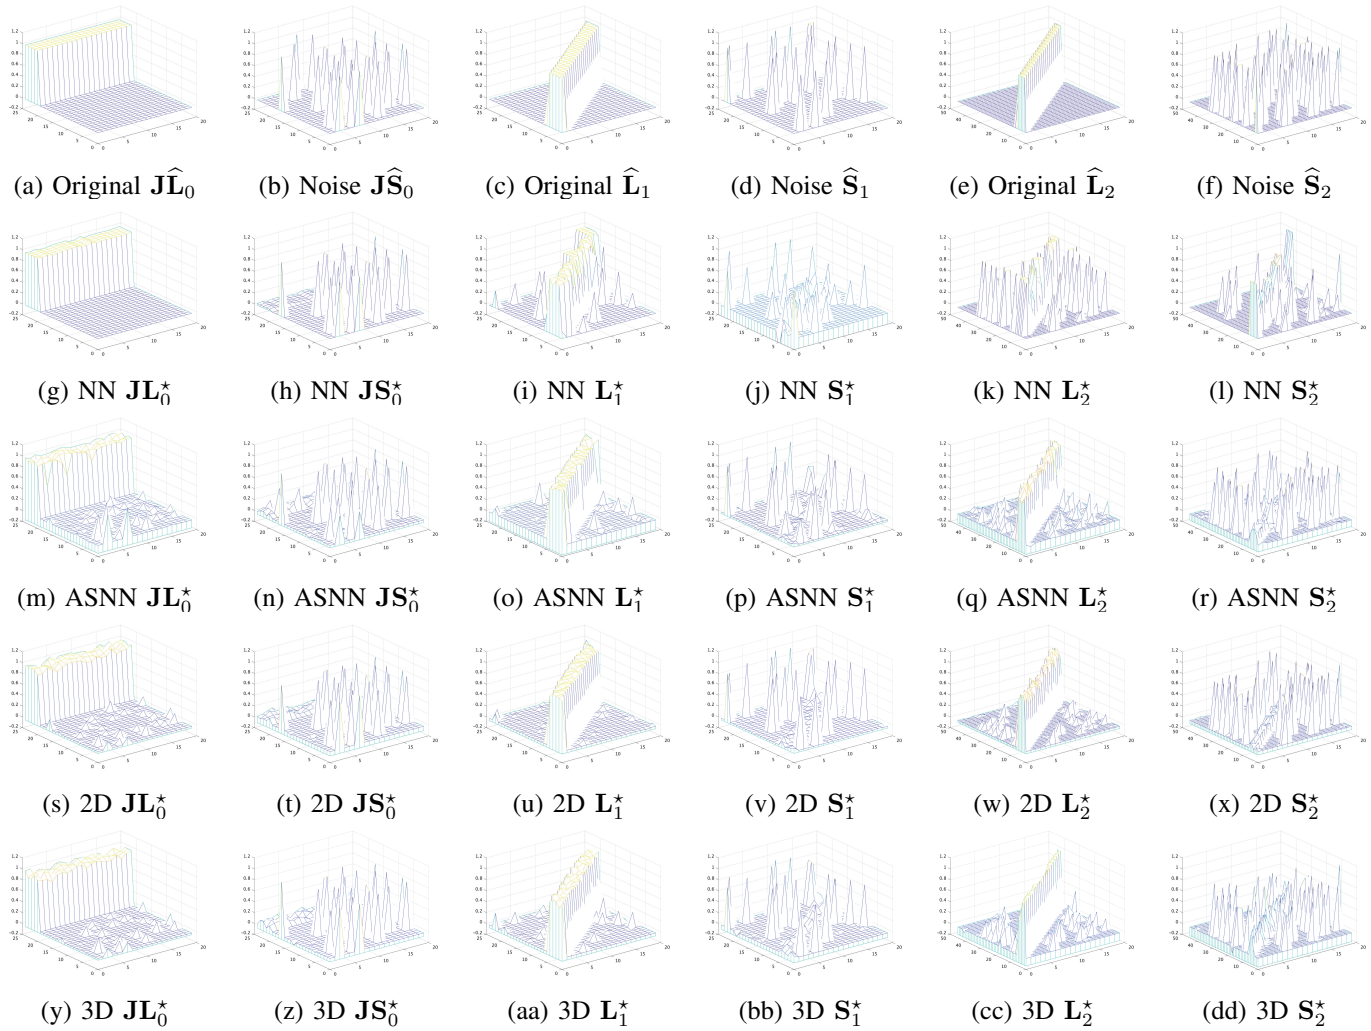
This section compares the performance of FRPCA by the CMASNN presented in Sec. III with RPCA by the NN and FRPCA by the ASNN. Two types of the proposed method, one is the CMASNN with 2D signals (Fig. 4(a)) and the other is the CMASNN with 3D signals (Fig. 4(b)) are evaluated (both methods are denoted as CMASNN-2D and CMASNN-3D, respectively). In this experiment, we extract target components with an isomorphic structure $\widehat{\mathbf{L}}_s$ from an observed signal corrupted with sparse noise as $\mathbf{X} = \widehat{\mathbf{L}}_s + \widehat{\mathbf{S}}_s$. The target components used in this experiment are $\widehat{\mathbf{L}}_0$, $\widehat{\mathbf{L}}_1$, and $\widehat{\mathbf{L}}_2$ given in Fig. 2. The sparse noise $\widehat{\mathbf{S}}_s \in \{0,1\}^{43\times 20}$ contains 1s in the region of $\mathcal{N}_s = \{(m,n) \in \{1,2,\ldots,43\}\times\{1,2,\ldots,20\} \mid [L_s]_{m,n} = 0\}$ with the probability of $p = 0.05, 0.1, 0.15$. We apply RPCA, FRPCA-ASNN, FRPCA-CMASNN-2D, and FRPCA-MASNN-3D to extract the target component $\widehat{\mathbf{L}}_s$. ϕ is set to the ℓ_1-ball constraint as $\phi(\mathbf{s}) = \mathcal{B}_1(\mathbf{s}, \epsilon)$ where ϵ is set as the oracle value, i.e., $\epsilon = \|\widehat{\mathbf{S}}_s\|_1$. The stop criteria in Algorithm 1 is $\epsilon_{\rm stop} = 10^{-5}$.

Fig. 5 shows the estimated components $\mathbf{L}_s^\star$ and $\mathbf{S}_s^\star$ ($p = 0.1$) obtained from the proposed and conventional methods, respectively. Note that, in Fig. 5, the estimates are flipped as $\mathbf{J}\widehat{\mathbf{L}}_0$ and $\mathbf{J}\widehat{\mathbf{S}}_0$ for clearer visualization. In the case of the shift of 0, the target components $\widehat{\mathbf{L}}_0$ are lying in 1-dimensional subspace. In this case, RPCA decomposes the target components and the noise components almost perfectly by minimizing the nuclear norm. On the other hand, the results from FRPCA-CMASNN-2D/FRPCA-CMASNN-3D are worse than RPCA but outperforms FRPCA-ASNN because the CMASNN involving multidimensional ASNN enables us to distinguish principal components and outliners more robustly. In the case of the shift of 1 and 2, FRPCA-CMASNN-2D/FRPCA-CMASNN-3D can estimate the original component $\widehat{\mathbf{L}}_s$ much better than RPCA/FRPCA-ASNN due to the enhancement of low-rankness promoting for amplitude spectrum. As well as subjective quality, FRPCA-CMASNN-2D or FRPCA-CMASNN-3D achieved higher PSNR than RPCA and FRPCA-ASNN as shown in Table III.

TABLE III: Numerical results (PSNR [dB])

		$p = 0.05$	$p = 0.1$	$p = 0.15$
Shift:0	RPCA	**40.75**	**30.19**	**30.39**
	FRPCA-ASNN	29.16	22.96	20.54
	FRPCA-CMASNN-2D	34.74	25.20	23.01
	FRPCA-CMASNN-3D	37.45	24.65	23.07
Shift:1	RPCA	16.71	14.89	13.98
	FRPCA-ASNN	25.96	21.24	20.19
	FRPCA-CMASNN-2D	**29.72**	**23.24**	**23.75**
	FRPCA-CMASNN-3D	28.10	21.70	21.29
Shift:2	RPCA	15.83	12.98	11.52
	FRPCA-ASNN	29.71	23.87	17.70
	FRPCA-CMASNN-2D	**34.05**	**27.04**	**19.31**
	FRPCA-CMASNN-3D	25.59	21.05	18.20

V. Conclusions



In this manuscript, we propose the use of the CMASNN for robust PCE. The conventional ASNN tends to fail in distinguishing principal components from outliers. This occurs when observed principal components, along with outliers, closely resemble shifted versions of other observations. To enhance the accuracy of PCE, we unified multiple observations into a higher-dimensional signal in a convolutional way and evaluate the low-rankness of its amplitude spectra using the ASNN. This customization aids in the discrimination between true principal components and outliers more efficiently. By substituting the CMASNN for the ASNN in FRPCA, experimental results demonstrate that the proposed CMASNN-based FRPCA achieves superior performance compared to the conventional approaches.

***Abstract*—This paper proposes a proximal variant of the alternating direction method of multipliers (ADMM) for distributed optimization. Although the current versions of ADMM algorithm provide promising numerical results in producing solutions that are close to optimal for many convex and non-convex optimization problems, it remains unclear if they can converge to a stationary point for weakly convex and locally non-smooth functions. Through our analysis using the Moreau envelope function, we demonstrate that MADM can indeed converge to a stationary point under mild conditions. Our analysis also includes computing the bounds on the amount of change in the dual variable update step by relating the gradient of the Moreau envelope function to the proximal function. Furthermore, the results of our numerical experiments indicate that our method is faster and more robust than widely-used approaches.**

I. Introduction

Many systems, like the internet-of-things (IoT) and cyber-physical systems, comprise distributed devices and sensors that gather data for inference and decision-making. Building distributed models in such systems without data transfer to a central hub calls for distributed optimization methods involving peer-to-peer interactions. In addition, these methods allow for coping with resource constraints, e.g., computational resources, battery power, communication bandwidth, and privacy protection [1]–[3].

There is a large body of work on distributed optimization methods from different perspectives. The most direct approach to the design of distribution optimization methods is via message-passing implementations of subgradient computation within subgradient descent methods [4]–[6]. Gradient methods are generalized to solve structured optimization problems using proximal methods [7], [8]. Additionally, variational methods for probabilistic models lend themselves naturally to optimization algorithms, such as variants of belief propagation [9]. The subgradient method is well-known for its ease of implementation, wherein a subgradient is taken at each step, followed by an average with neighbors. On the downside, subgradient descent has a sublinear convergence rate and requires tuning of the step size. Meanwhile, ADMM performs fast and accurately in many practical convex and non-convex optimization problems. For convex objective functions, subgradient methods and ADMM are guaranteed to converge to a global optimum under suitable parameter choices [6], [10], [11]. However, the analysis of these methods for non-convex problems is challenging due to the potential ill-behavior of the objective function. The convergence analysis for ADMM in non-convex problems is particularly more challenging as it requires analyzing the convergence of multiple sub-problems with different structures and assumptions.

One important family of non-convex optimization problems is weakly convex problems. Several such problems arise in machine learning, including robust phase retrieval [12], blind deconvolution [13], biconvex compressive sensing [14], and dictionary learning [15]. Smooth functions, or functions with Lipschitz continuous gradients, are weakly convex functions. Several non-convex optimization algorithms are proposed based on the smoothness assumption (e.g., [16], [17]); however, weakly convex functions are not restricted to smooth functions, and non-smooth functions can also be weakly convex [18]. Existing work on distributed optimization of weakly convex functions includes [19]. However, in the subgradient-based algorithm in [19], the local functions must satisfy the bounded subgradient assumption, and the accuracy of the estimation depends on the step size. Although ADMM is a powerful algorithm applicable to many problems, it is not currently used to solve weakly convex problems. As seen in [20]–[23], several ADMM-based works study non-convex optimization; however, these works require a smooth objective function. It is still necessary to provide a distributed ADMM-based algorithm that could work in the weakly convex setting without having any Lipschitz differentiability condition.

We propose a Moreau envelope-based ADMM (MADM), suitable for distributed optimization where local objectives are weakly convex and not necessarily smooth. We chose the Moreau envelope-based ADMM approach because it allows us to guarantee a decrease in each primal update step and bound the amount of change in the dual update step by primary variables. This is achieved by incorporating the relationship between the Moreau envelope function and proximal function. Therefore, by selecting appropriate penalty parameters under mild conditions, including weakly convexity of each

local function, a connected network, and the boundness of augmented Lagrangian function, we can ensure that the algorithm converges to a stationary point. The Moreau envelope-based ADMM approach stands out from other penalty-based ADMM algorithms due to its superior theoretical convergence properties. We conduct illustrative numerical experiments to verify the convergence properties of the proposed method. The experiments demonstrate the robustness of the proposed algorithm when we fix the penalty parameters and step size, and the problem structure remains the same. Unlike subgradient-based methods, the MADM approach ensures faster and more reliable convergence in this setting.

Mathematical Notations: Scalars, column vectors, and matrices are respectively denoted by lowercase, bold lowercase, and bold uppercase letters. The operator $(\cdot)^{\mathrm{T}}$ denotes transpose of a matrix, and the jth column of matrix $\mathbf{A}$ is denoted by $\mathbf{A}_j$. The set $\{1, \cdots, L\}$ is denoted by $[L]$. For a function $h : \mathbb{R}^n \to \mathbb{R}$ and penalty parameter $\gamma > 0$, $\mathcal{M}_h(\mathbf{w};\gamma) = \min_{\mathbf{x}} \left\{h(\mathbf{x}) + \frac{1}{2\gamma}\|\mathbf{x}-\mathbf{w}\|_2^2\right\}$ is the Moreau envelope function [24], and $\mathrm{Prox}_h(\mathbf{w};\gamma) = \arg\min_{\mathbf{x}} \left\{h(\mathbf{x}) + \frac{1}{2\gamma}\|\mathbf{x}-\mathbf{w}\|^2\right\}$ is its associated proximal operator.

II. Problem formulation

Suppose L agents solve the following problem:

$$\min_{\mathbf{x}} \sum_{i=1}^{L} f_i(\mathbf{x}), \tag{1}$$

where $f_i(\cdot) : \mathbb{R}^N \to \mathbb{R}$ represents the local objective function that is only known to agent i. Additionally, each agent may exchange information with its neighbors through the underlying undirected communication network, which can be modeled as a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = [L]$ represents the set of agents and $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$ represents the set of edges. In other words, the existence of $e_{i,j} \in \mathcal{E}$ indicates that i and j can exchange information. Due to the fact that both $e_{i,j}$ and $e_{j,i}$ denote the same edge, we merely use the expressions $e_{i,j}$ (if $i < j$) or $e_{j,i}$ (if $j < i$) to avoid repetition. Additionally, $E = |\mathcal{E}|$ is the total number of edges, and $|\mathcal{N}_i|$ is the number of neighbors for node i in which $\mathcal{N}_i$ is its set of neighbors. In order to apply ADMM, one can rewrite (1) in the form of an edge consensus problem as follows:

$$\begin{aligned} \min_{\{\mathbf{x}_1,\cdots,\mathbf{x}_L,\mathbf{Z}\}} \quad & \sum_{i=1}^{L} f_i(\mathbf{x}_i) + g(\mathbf{Z}) \\ \text{subject to} \quad & \mathbf{x}_i = \mathbf{z}_{i,j}, \mathbf{x}_j = \mathbf{z}_{i,j}, \quad \forall e_{i,j} \in \mathcal{E} \end{aligned} \tag{2}$$

where each $\mathbf{Z} = \{\{\mathbf{z}_{i,j}\}_{j\in\mathcal{N}_i, j>i}\}_{i=1}^{L}$ are auxiliary variables, and $g(\cdot) = 0$. The augmented Lagrangian of (2) is:

$$\begin{aligned} \mathcal{L}_{\rho_\lambda}(\mathbf{X},\mathbf{Z},\boldsymbol{\lambda}) = \sum_{i=1}^{L} f_i(\mathbf{x}_i) + \sum_{e_{i,j}\in\mathcal{E}} \Big(& (\boldsymbol{\lambda}_{i,j}^{i})^{\mathrm{T}}(\mathbf{x}_i - \mathbf{z}_{i,j}) \\ + (\boldsymbol{\lambda}_{i,j}^{j})^{\mathrm{T}}(\mathbf{x}_j - \mathbf{z}_{i,j}) + \frac{\rho_\lambda}{2}\|\mathbf{x}_j - \mathbf{z}_{i,j}\|^2 + \frac{\rho_\lambda}{2}\|\mathbf{x}_i - \mathbf{z}_{i,j}\|^2 \Big), \end{aligned} \tag{3}$$

where $\mathbf{X} = [\mathbf{x}_1, \cdots, \mathbf{x}_L]$, $\boldsymbol{\lambda} = \{\{\boldsymbol{\lambda}_{i,j}^{i}, \boldsymbol{\lambda}_{i,j}^{j}\}_{j\in\mathcal{N}_i, j>i}\}_{i=1}^{L}$ are dual variables, and ρ_λ is a penalty parameter. Distributed ADMMs are iterative procedures that involve three steps at each iteration. The first step is to minimize $\mathcal{L}_{\rho_\lambda}$ with respect to $\mathbf{X}$. Afterward, $\mathcal{L}_{\rho_\lambda}$ is minimized based on $\mathbf{Z}$. In the last step, a dual gradient-ascent iteration is used to update $\boldsymbol{\lambda}$.

Definition 1. *A function $f(x)$ is $\rho-$weakly convex ($\rho > 0$) if there exists a convex function $h(x)$ such that $h(x) = f(x) + \rho\|x\|^2$.*

Weakly convex local functions pose a challenge to distributed ADMM convergence because it can both be non-convex and non-smooth. In the absence of Lipschitz differentiability, which is coming from smoothness, and convexity of the objective function, existing distributed ADMM-based approaches cannot guarantee convergence. In the following section, we present an ADMM-based algorithm can deal with weakly convex functions, regardless of whether they are smooth.

III. Moreau envelope ADMM

The proximal augmented Lagrangian of (2) can be derived as:

$$\Psi_{\rho_\lambda,\rho_\beta}(\mathbf{X},\mathbf{Z},\boldsymbol{\beta},\boldsymbol{\lambda}) = \mathcal{L}_{\rho_\lambda}(\mathbf{X},\mathbf{Z},\boldsymbol{\lambda}) + \frac{\rho_\beta}{2}\|\mathbf{Z}-\boldsymbol{\beta}\|_F^2, \tag{4}$$

where $\boldsymbol{\beta} = \{\{\boldsymbol{\beta}_{i,j}\}_{j\in\mathcal{N}_i, j>i}\}_{i=1}^{L}$ are auxiliary variables, and ρ_β is a penalty parameter. In (4), The proximal term plays a crucial role in obtaining convergent results. It regulates the behavior of the algorithm in both the $\mathbf{Z}$-update step and indirectly in the $\boldsymbol{\lambda}$-update step by incorporating the Moreau envelope function, resulting in provable convergence. According to our proposed proximal ADMM algorithm, the $(k+1)$th iteration is as follows:

$$\mathbf{X}^{(k+1)} = \arg\min_{\mathbf{x}} \Psi_{\rho_\lambda,\rho_\beta}\left(\mathbf{X}, \mathbf{Z}^{(k)}, \boldsymbol{\beta}^{(k)}, \boldsymbol{\lambda}^{(k)}\right), \tag{5a}$$

$$\mathbf{Z}^{(k+1)} = \arg\min_{\mathbf{Z}} \Psi_{\rho_\lambda,\rho_\beta}\left(\mathbf{X}^{(k+1)}, \mathbf{Z}, \boldsymbol{\beta}^{(k)}, \boldsymbol{\lambda}^{(k)}\right), \tag{5b}$$

$$\boldsymbol{\beta}^{(k+1)} = \boldsymbol{\beta}^{(k)} - \eta\left(\boldsymbol{\beta}^{(k)} - \boldsymbol{Z}^{(k+1)}\right), \tag{5c}$$

$$\boldsymbol{\lambda}_{i,j}^{i,(k+1)} = \boldsymbol{\lambda}_{i,j}^{i,(k)} + \rho_\lambda\left(\mathbf{x}_i^{(k+1)} - \mathbf{z}_{i,j}^{(k+1)}\right), \forall e_{i,j} \in \mathcal{E} \tag{5d}$$

$$\boldsymbol{\lambda}_{i,j}^{j,(k+1)} = \boldsymbol{\lambda}_{i,j}^{j,(k)} + \rho_\lambda\left(\mathbf{x}_j^{(k+1)} - \mathbf{z}_{i,j}^{(k+1)}\right), \forall e_{i,j} \in \mathcal{E} \tag{5e}$$

where $\eta \in (0, 2)$.

More precisely, each $\mathbf{x}_i$ can be updated individually in update-step $\mathbf{X}$, which after several simplifications, can be stated as follows:

$$\begin{aligned} \mathbf{x}_i^{(k+1)} = \mathrm{Prox}_{f_i}\Bigg(& \frac{\sum_{j\in\mathcal{N}_i, j>i} \mathbf{z}_{i,j}^{(k)} - \frac{\lambda_{i,j}^{i,(k)}}{\rho_\lambda}}{|\mathcal{N}_i|} \\ & + \frac{\sum_{j\in\mathcal{N}_i, j<i} \mathbf{z}_{j,i}^{(k)} - \frac{\lambda_{j,i}^{i,(k)}}{\rho_\lambda}}{|\mathcal{N}_i|}; \frac{1}{\rho_\lambda|\mathcal{N}_i|}\Bigg) \end{aligned} \tag{6}$$

Algorithm 1: Moreau envelope ADMM for distributed optimization (MADM)

Initialize $\mathbf{X}^{(0)}$, $\mathbf{Z}^{(0)}$, $\boldsymbol{\beta}^{(0)}$, $\boldsymbol{\lambda}^{(0)}$, ρ_β, ρ_λ and $\eta \in (0,2)$;
repeat
  for $i \in [L]$ **do**
    Update $\mathbf{x}_i$ as:
    $$\mathbf{x}_i^{k+1} = \text{Prox}_{f_i}\left(\sum_{j\in\mathcal{N}_i} \frac{\mathbf{z}_{i,j}^{(k)} - \frac{\lambda_{i,j}^{i,(k)}}{\rho_\lambda}}{|\mathcal{N}_i|}; \frac{1}{\rho_\lambda|\mathcal{N}_i|}\right);$$
  end
  Each agent sends its local vector $\mathbf{x}_i^{k+1}$ to neighboring agents;
  for $i \in [L]$ **do**
    for $j \in \mathcal{N}_i$ **do**
      Update $\mathbf{z}_{i,j}$ as: $\mathbf{z}_{i,j}^{(k+1)} = \frac{\rho_\lambda\left(\mathbf{x}_j^{(k+1)}+\mathbf{x}_i^{(k+1)}\right)+\rho_\beta\boldsymbol{\beta}_{i,j}^{(k)}+\lambda_{i,j}^{i,(k)}+\lambda_{i,j}^{j,(k)}}{2\rho_\lambda+\rho_\beta}$;
      Update $\boldsymbol{\beta}_{i,j}$ as: $\boldsymbol{\beta}_{i,j}^{(k)} - \eta\left(\boldsymbol{\beta}_{i,j}^{(k)} - \boldsymbol{z}_{i,j}^{(k+1)}\right)$;
      Update $\boldsymbol{\lambda}_{i,j}^{i}$ as:
      $\boldsymbol{\lambda}_{i,j}^{i,(k+1)} = \boldsymbol{\lambda}_{i,j}^{i,(k)} + \rho_\lambda\left(\mathbf{x}_i^{(k+1)} - \mathbf{z}_{i,j}^{(k+1)}\right)$;
      Update $\boldsymbol{\lambda}_{i,j}^{j}$ as:
      $\boldsymbol{\lambda}_{i,j}^{j,(k+1)} = \boldsymbol{\lambda}_{i,j}^{j,(k)} + \rho_\lambda\left(\mathbf{x}_j^{(k+1)} - \mathbf{z}_{i,j}^{(k+1)}\right)$;
    end
  end
until *the convergence criterion is met*;

Also, in the $\mathbf{Z}$-update step, $\mathbf{z}_{i,j}$ can be updated separately as:

$$\begin{aligned}\mathbf{z}_{i,j}^{(k+1)} = \arg\min_{\mathbf{z}_{i,j}} \Big(&(\lambda_{i,j}^{i,(k)})^{\mathrm{T}}(\mathbf{x}_i^{(k+1)} - \mathbf{z}_{i,j}) \\ &+ (\lambda_{i,j}^{j,(k)})^{\mathrm{T}}(\mathbf{x}_j^{(k+1)} - \mathbf{z}_{i,j}) + \frac{\rho_\lambda}{2}\|\mathbf{x}_j^{(k+1)} - \mathbf{z}_{i,j}\|^2 \\ &+ \frac{\rho_\lambda}{2}\|\mathbf{x}_i^{(k+1)} - \mathbf{z}_{i,j}\|^2 + \frac{\rho_\beta}{2}\|\mathbf{z}_{i,j} - \boldsymbol{\beta}_{i,j}^{(k)}\|^2\Big), \quad (7)\end{aligned}$$

which can be simplified as follows:

$$\mathbf{z}_{i,j}^{(k+1)} = \frac{\rho_\lambda\left(\mathbf{x}_j^{(k+1)} + \mathbf{x}_i^{(k+1)}\right) + \rho_\beta\boldsymbol{\beta}_{i,j}^{(k)} + \lambda_{i,j}^{i,(k)} + \lambda_{i,j}^{j,(k)}}{2\rho_\lambda + \rho_\beta}. \quad (8)$$

Moreover, for each $\boldsymbol{\beta}_{i,j}$ we have:

$$\boldsymbol{\beta}_{i,j}^{(k+1)} = \boldsymbol{\beta}_{i,j}^{(k)} - \eta\left(\boldsymbol{\beta}_{i,j}^{(k)} - \boldsymbol{z}_{i,j}^{(k+1)}\right). \quad (9)$$

By introducing $\boldsymbol{\lambda}_{i,j}^{i}$, $\boldsymbol{\lambda}_{i,j}^{j}$, $\mathbf{z}_{i,j}$, and $\boldsymbol{\beta}_{i,j}$ to represent $\boldsymbol{\lambda}_{j,i}^{i}$, $\boldsymbol{\lambda}_{j,i}^{j}$, $\mathbf{z}_{j,i}$, and $\boldsymbol{\beta}_{j,i}$, respectively in each agent i, the proposed method is simplified and summarized in Algorithm 1.

IV. Convergence proof

This section presents the convergence analysis for Algorithm 1. Several conventional assumptions are made to build our convergence proof.

Assumption 1. *The undirected graph $\mathcal{G}$ is connected.*

Assumption 2. *$\Psi_{\rho_\lambda,\rho_\beta}\left(\mathbf{X}^{(k)}, \mathbf{Z}^{(k)}, \boldsymbol{\beta}^{(k)}, \boldsymbol{\lambda}^{(k)}\right)$ is lower bounded, and $\left(\mathbf{X}^{(k)}, \mathbf{Z}^{(k)}, \boldsymbol{\beta}^{(k)}, \boldsymbol{\lambda}^{(k)}\right)$ are bounded, in each iteration k.*

Remark. *It can be shown that for coercive functions*[1] *Assumption 2 holds true.*

Assumption 3. *Local objectives $f_i(\cdot), \forall i \in [L]$, are continuous, and weakly convex by parameter ρ_f.*

The proof of convergence relies on a canonical methodology as described in [25, Theorem 2.9]. Each algorithm iteration has only one increasing step, which is the $\boldsymbol{\lambda}$-update step. As the gradient of the Moreau envelope is related to the proximal function, the amount of increase in the $\boldsymbol{\lambda}$-update step ($\rho_\lambda^{-1}\|\boldsymbol{\lambda}^{(k+1)} - \boldsymbol{\lambda}^{(k)}\|^2$), is bounded based on the primal and auxiliary variables. Thus, tuning the parameters lets us guarantee the *sufficient decrease condition* of [25, Theorem 2.9]. In addition, the subgradient of the proximal augmented Lagrangian based on each of its inputs can easily be shown to be bound in each iteration, which is sufficient to validate the *bounded subgradient condition* of the [25, Theorem 2.9]. Finally, by having the boundedness assumption and knowing that the proximal augmented Lagrangian is continuous based on each of its inputs, it can be shown that the *continuity condition* of [25, Theorem 2.9] holds.

Lemma 1. *Function $g(\cdot)$, $\forall \mathbf{u}, \mathbf{v} \in \mathbb{R}^n$, satisfies condition:*

$$\|\nabla\mathcal{M}_{g(\cdot)}(\mathbf{u},\gamma) - \nabla\mathcal{M}_{g(\cdot)}(\mathbf{v},\gamma)\| = 0. \quad (10)$$

Lemma 2. *If Assumption 1 is held, for any $m \geq 1$, the following inequality is held:*

$$\begin{aligned}&\|\boldsymbol{\lambda}^{(k+1)} - \boldsymbol{\lambda}^{(k)}\|_F^2 \leq \\ &\qquad \rho_\beta^2\left(\|\mathbf{Z}^{(k+1)} - \mathbf{Z}^{(k)}\|_F^2 + \|\boldsymbol{\beta}^{(k)} - \boldsymbol{\beta}^{(k-1)}\|_F^2\right) \quad (11)\end{aligned}$$

Proof. The lemma is proved by combining Lemma 1 with [26, Lemma 4]. □

Lemma 3. *Assuming Assumptions 1, 2, and 3 and $\rho_\lambda|\mathcal{N}_i| > \rho_f, \forall i \in [L]$, the following inequality holds:*

$$\begin{aligned}&\Psi_{\rho_\lambda,\rho_\beta}\left(\mathbf{X}^{(k)}, \mathbf{Z}^{(k)}, \boldsymbol{\beta}^{(k)}, \boldsymbol{\lambda}^{(k)}\right) - \\ &\qquad \Psi_{\rho_\lambda,\rho_\beta}\left(\mathbf{X}^{(k+1)}, \mathbf{Z}^{(k+1)}, \boldsymbol{\beta}^{(k+1)}, \boldsymbol{\lambda}^{(k+1)}\right) \geq \quad (12a)\\ &C(\rho_\lambda)\|\mathbf{X}^{(k+1)} - \mathbf{X}^{(k)}\|_F^2 + \left(\frac{\rho_\lambda}{2} + \frac{\rho_\beta}{2}\right)\|\mathbf{Z}^{(k+1)} - \mathbf{Z}^{(k)}\|_F^2 \quad (12b)\\ &\qquad + \frac{\rho_\beta}{2}\left(\frac{2}{\eta} - 1\right)\|\boldsymbol{\beta}^{(k+1)} - \boldsymbol{\beta}^{(k)}\|_F^2 \quad (12c)\\ &-\rho_\lambda^{-1}\rho_\beta^2\left(\|\mathbf{Z}^{(k+1)} - \mathbf{Z}^{(k)}\|_F^2 + \|\boldsymbol{\beta}^{(k)} - \boldsymbol{\beta}^{(k-1)}\|_F^2\right), \quad (12d)\end{aligned}$$

where $C(\cdot)$ is a function with positive value for ρ_λ.

Proof. Equation (12b) is derived based on the weak convexity of local functions, and $g(\cdot)$, while (12c) is the result of

[1] A function $f(\cdot)$ is coercive if $f(\mathbf{x})\mathbf{x} \to \infty$ as $\|\mathbf{x}\| \to \infty$

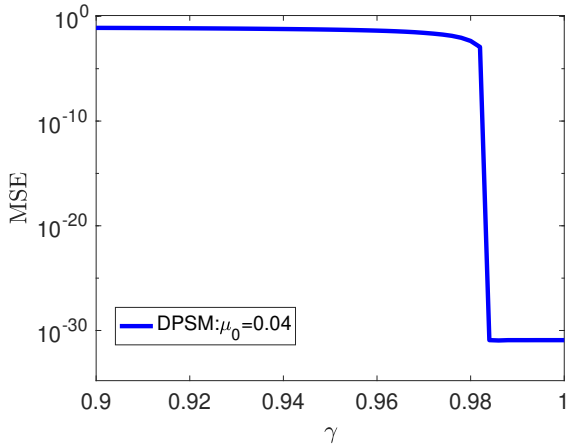

Fig. 1: MSE versus γ

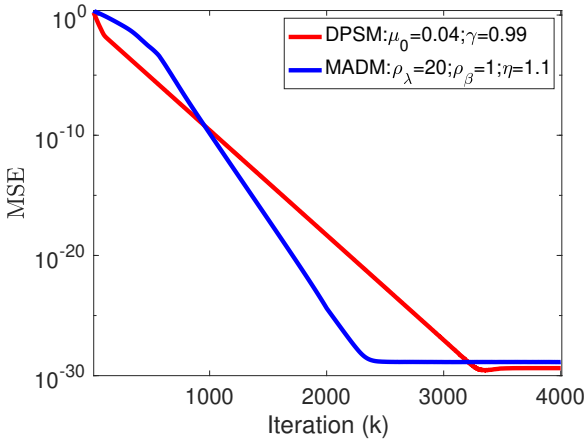

Fig. 2: MSE versus iteration

expanding the amount of change from the $\boldsymbol{\beta}$-update step. Further, (12d) derives from multiplying the bound obtained from Lemma 2 with $-\rho_\lambda^{-1}$, which gives an upper bound for the amount of change in the $\boldsymbol{\lambda}$-update step. □

Theorem 1. *By having* $\rho_\lambda|\mathcal{N}_i| > \rho_f, \forall i \in [L]$, $\frac{1}{\eta} \geq \frac{1}{2} + \rho_\lambda^{-1}\rho_\beta$, *and* $\rho_\lambda \geq \frac{(2\sqrt{2}-1)}{2}\rho_\beta$, *if Assumptions 1,2, and 3 hold, the algorithm 1 converges to a stationary point.*

Proof. The *sufficient decrease condition* of [25, Theorem 2.9] holds when ρ_λ, ρ_β, and ρ_β satisfy the condition of Theorem 1, by Lemma 3. The same results are obtained for the *bounded subgradient condition* of [25, Theorem 2.9] when it depends on the norm of the successive difference of the variables. Finally, employing Assumption 2 and knowing that the proximal augmented Lagrangian is continuous for each of its inputs, we can prove the *continuity condition* of [25, Theorem 2.9], which completes the proof. □

V. Simulation Results

In this section, we evaluate the performance of the MADM by conducting simulations of distributed robust phase retrieval with the objective function:

$$\hat{\mathbf{x}} = \min_{\mathbf{x}} \frac{1}{m} \sum_{i=1}^{L} |\langle \mathbf{a}_i, \mathbf{x}\rangle^2 - b_i^2|, \tag{13}$$

where $\mathbf{x}$ is the target signal, $\mathbf{a}_i$ is the measurement and b_i is the observation in node i. We assume that each node i has one measurement and observation, $\mathbf{a}_i \in \mathbb{R}^N \overset{\text{i.i.d}}{\sim} \mathcal{N}(\mathbf{0}, \mathbf{1}), \forall i \in [L]$, and $\mathbf{x} \in \mathbb{R}^N \sim \mathcal{N}(\mathbf{0}, \mathbf{1})$. For simplicity, we assume a noiseless setting with $b_i = \langle \mathbf{a}_i, \mathbf{x}\rangle, \forall i \in [L]$. All simulations are performed by averaging over 50 trials, and in each case, an Erdös-Rényi graph consisting of $L = 50$ nodes was generated as the communication network. To evaluate the performance of this method, we also simulated the distributed projected subgradient method (DPSM) proposed in [19]. The mean square error (MSE) $:= \frac{\sum_{i=1}^{L} ||\hat{\mathbf{x}}_i - \mathbf{x}||_2^2}{L}$ was utilized as the performance measure. Moreover, $\mathbf{z}_{i,j}^{(0)}, \forall e_{i,j} \in \mathcal{E}$ in MADM and $\mathbf{x}_i^{(0)}, \forall i \in \mathcal{V}$ in DPSM were initialized based on the procedure proposed in [27, Sec. 4.2].

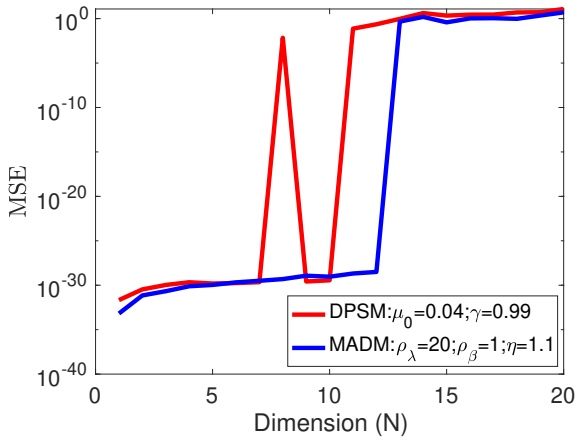

Fig. 3: MSE versus dimension

We first compare the convergence rate and efficiency of the two algorithms. The dimension of the target signal was $N = 10$, and for the DPSM, μ_0 was 0.04, while γ was chosen through a grid search to achieve a minimum and stable error with fast convergence. Fig. 1 illustrates the results of the grid search. We see that the DPSM highly depends on the choice of γ. In our algorithm we set $\rho_\lambda = 20$, $\rho_\beta = 1$, and $\eta = 1.1$. These values satisfy the conditions in Theorem 1. Fig. 2 shows that MADM can achieve a faster convergence rate than DPSM while maintaining a similar MSE.

Next, we study the robustness of the algorithms as a function of the dimension of the target signal for fixed parameters; N ranged from 1 to 20. A comparison of MADM and DPSM behavior under different dimensions is illustrated in Fig. 3. We see that MADM is more stable than DPSM when parameters are fixed. Although Fig. 1 indicates $\gamma = 0.99$ is in the safe zone for $N = 10$, it fails for $N = 8$ and $N > 10$.

VI. Conclusions

This paper presented a new proximal variant of the ADMM algorithm, named MADM, for solving distributed optimization problems. Our analysis demonstrated that the proposed method could be applied to weakly convex functions under mild conditions. In particular, we derived a bound on the change in the dual variable update step by leveraging the relationship between the gradient of the Moreau envelope function and the proximal function. This allowed us to ensure convergence to a stationary point. The simulation results showed that MADM outperforms subgradient methods in terms of speed and robustness. These findings suggest that MADM can be a promising tool for solving a wide range of distributed optimization problems in practice.

Abstract — **Previous research has shown that auditory and visual inputs are not asynchronous in the human brain, and that visual cues can enhance attention in the hearing process. Therefore, this study proposes audio-visual speech enhancement (SE) with 3D image features (AV-3D-SE) that imitates the auditory process of humans to elevate listening quality. More specifically, AV-3D-SE uses the FlowNet3D model to predict temporal facial motion from the recorded 3D image combining with features for SE applications. The evaluation results showed that the average scores of perceptual evaluation of speech quality and short-time objective intelligibility in 3 dB signal-to-noise ratio increased to 3.229 and 0.914, respectively, while the average hearing aid speech quality index significantly outperformed baseline SE systems (audio-only and audio-visual-2D) in seven typical types of hearing loss with high hearing aid speech perception index. In conclusion, the proposed AV-3D-SE enhances the effectiveness of the SE system and can increase the listening satisfaction of hearing aid users.**

Keywords: deep learning, point cloud, scene flow, hearing aid and speech enhancement.

I. INTRODUCTION

Hearing is one of the most important human senses. It provides the ability to communicate with people, detect danger, and appreciate aesthetics. However, the human ear may be unable to detect sounds below 35 decibels (dB) due to various reasons — such as aging, trauma, viral infection, or long-term exposure to noisy environments — called hearing loss [1,2]. According to the World Health Organization, more than 430 million people worldwide suffer from hearing loss. Furthermore, it is estimated that the proportion of the global population with hearing loss will reach 10% by 2050; that is, more than 700 million people will have problems associated with hearing loss [2]. Consequently, it is crucial to help patients with hearing loss strengthen their semantic comprehension and improve their speech quality. To solve these problems, hearing-assistive devices, such as hearing aids, are mostly used to help people with hearing loss communicate better.

Previous studies have pointed out that patients with hearing loss can significantly improve their speech comprehension ability when using hearing aids in a quiet environment; however, 66% of users indicated that they still struggle to listen clearly amidst noisy surroundings [3]. In other words, there may still be limitations to hearing aids in environments with background noise. Speech enhancement (SE) technology has been proposed to alleviate these problems and improve the speech intelligibility of hearing aid users operating in noisy environments. The purpose of SE is to remove background noise and avoid speech distortion after processing [4,5]. Well-known SE systems have been developed over the past few decades, including the log minimum mean square error (MMSE) [6], Wiener filter [7], Karhunen-Loeve transform [8], and the Generalized Maximum a Posteriori Spectral Amplitude [9]. Although the above SE technologies provide a suitable performance for users in stationary noise scenarios, there is still room for improvement for those in challenging listening conditions (e.g., nonstationary and competing noise) [10].

Recently, deep-learning technology has been used to design SE systems and has been proven to provide better performance than the conventional SE methods mentioned above under challenging listening conditions. Wang et al. [11] have proposed a SE system using a deep neural network (DNN) and a support vector machine-based classification approach to estimate an ideal binary mask. The study indicated that the signal-to-noise ratio (SNR) increased by 2.5 dB compared with SE using MMSE. In 2018, Luo et al. [12] proposed the Conv-TasNet system that uses an end-to-end DNN architecture to implement speech separation technology. Using this model, the target speaker can be predicted in a noisy environment with two or three speakers. Lai at el. [13] proposed a SE system called a "multi-objective learning-based deep denoising autoencoder" (MDDAE). The MDDAE-SE system provides higher scores on the hearing aid speech quality index (HASQI) [14] and hearing

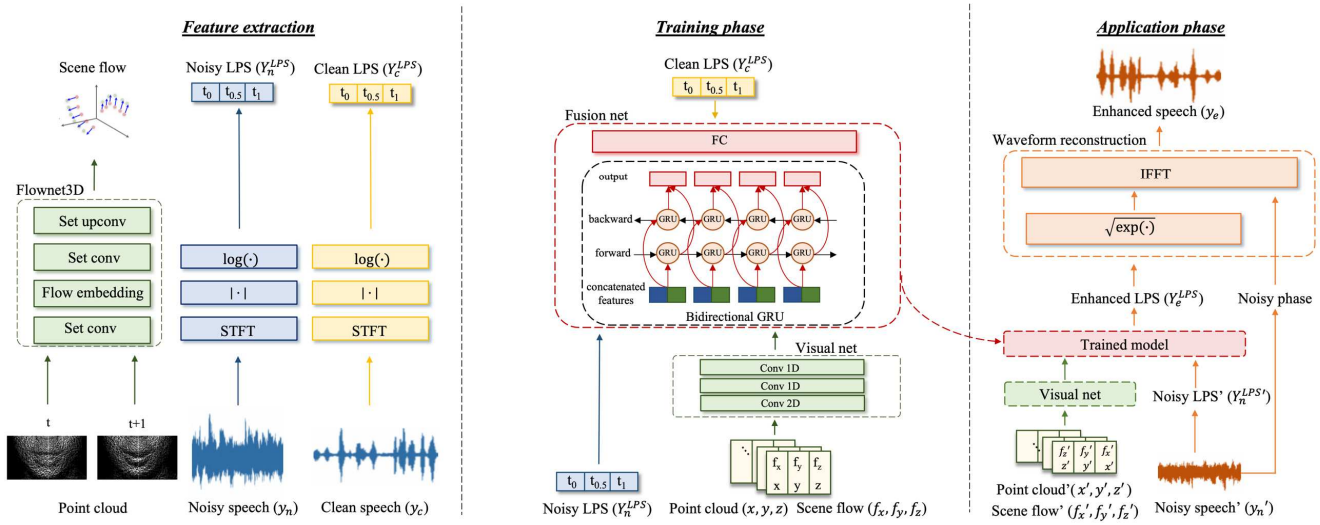

Fig. 1 Flowchart of the proposed AV-3D-SE system.

aid speech perception index (HASPI) [15] than classical SE approaches. Although the audio-only (AO) model (the input feature of the SE system only uses audio features) provides suitable performance for users, there is still room for improvement in the effect of AO-SE due to the similarity between background noise and the target voice or the complexity of the background noise type [16].

When communicating with people, we depend not only on auditory information, but on visual information as well [17-20]. In a 2013 study conducted by Golumbic et al. [21], the results show that an increase in visual information resulted in better speech comprehension than under AO information conditions. Furthermore, some scholars have speculated that, because visual information is transmitted to the brain faster than sound, vision has a predictive auxiliary effect on the auditory system, improving the brain's concentration on sound [22-24]. Based on the above physiological research results, a model combining visual information with voice information, called the audio-visual (AV) model, has been proposed in recent years and has proven to have better results than AO models. For instance, Hou et al. [25] combined 2D image features and acoustic features of the lips of the face to build an AV deep convolutional neural network SE model (AV-2D-SE in this study), showing that, when compared with the AO-SE system, the AV-2D-SE model has made significant progress in both objective and subjective evaluations. This result shows that audio features combined with visual information can help the SE system perform better than AO information.

At present, all AV models use 2D plane images as inputs. However, the movements of facial muscles and joints when humans speak are 3D and undergo continuous changes [26]. Planar images may lose some facial depth change features. In other words, if we can obtain the 3D features of human facial movements while speaking, more accurate information can be provided to obtain a better AV-SE model. One method can obtain 3D features of human facial movement, such as a time-of-flight camera [27], while scene flow [28] technology can extract key features from the recorded 3D image (the so-called point cloud). The scene flow proposed by Vedula et al. [29, 30] describes the change in each point in two adjacent frames in a 3D space, and which can extract useful features for different applications. For example, Menze et al. [31] used scene flow combined with deep learning to conduct related research on automatic driving image recognition. The results indicate a 36% reduction in the root-mean-square error when comparing the 3D scene flow method with the 2D flow method. Recently, a novel deep-learning-based 3D feature extraction model — FlowNet3D [32] — was proposed, and which not only achieves a significantly lower 3D endpoint error [33] but also outperforms conventional methods [34]. Following the success of the FlowNet3D technology, this study proposes an AV-SE system called Audio Visual-3D-SE (AV-3D-SE) to enhance noisy speech for hearing aid users, whereby audio and 3D point-cloud image features are used. The FlowNet3D model is used as a feature extractor for the proposed system. Several objective evaluation metrics for hearing aids were used to ensure the benefits of the proposed AV-3D-SE system.

II. Proposed System

A flowchart of the proposed AV-3D-SE system is shown in Fig. 1; it is divided into three stages: feature extraction, training phase, and application phase. In the feature extraction stage, we extracted the scene flow from the point cloud data using FlowNet3D and the noisy log power spectrum (LPS) [35] Y_n^{LPS} from the noisy speech y_n using Short-time Fourier transform (STFT). In the training phase, the point cloud and scene flow were used as inputs for the visual net. Second, the outputs of the visual net and Y_n^{LPS} were used as the inputs of the fusion net to obtain an enhanced LPS, Y_e^{LPS}. Finally, in the application phase, the enhanced speech y_e is reconstructed using an

inverse fast Fourier transform (IFFT), with the phase derived from the y_n' and Y_e^{LPS}. The details of each stage are as follows:

A. Feature extraction stage

1. 3D image feature

Because the region of facial deformation during speech is around the lips, we first captured a point cloud image around this area during the preprocessing stage. We then applied it to the FlowNet3D model, which is pretrained using the FlyingThings3D dataset, for scene flow feature extraction. The FlowNet3D model architecture (Fig. 2) can be divided into three main processing layers: (1) set conv, (2) flow embedding, and (3) set upconv layers. First, two sets of conv layers take the point clouds of consecutive frames. The set conv layer uses the farthest point sampling to sample the representative key points of the point cloud image and groups these sampling points with radius, *r,* using a ball query. Next, they are connected to PointNet [36], which learns the local features of each group of points using a multilayer perceptron. Finally, the most representative features from each point group were selected via the max-pooling layer. Subsequently, the flow-embedding layer learns the feature similarities and spatial relationships between two adjacent point-cloud frames to mix them. More precisely, the flow embedding layer uses the point cloud at frame *t* to find the nearest k points within radius *r* at frame *t*+1 and then uses a PointNet to learn the flow of the area in the current and next frame features. Finally, the set upconv layer is used to upsample according to the point cloud and features of the flow embedding, and to predict the flow direction of all original points in the last layer.

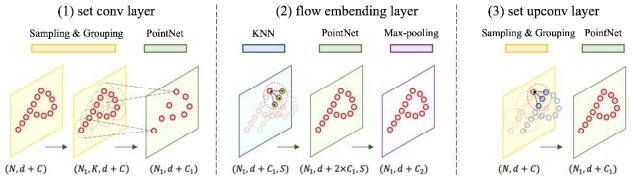

Fig. 2 The FlowNet3D model architecture: (1) set conv layer, (2) flow embedding layer, and (3) set upconv layer.

2. Audio features

In this study, the LPS feature was used as the auditory feature input for the multimodal SE system. First, we computed the STFT for each frame of noisy speech and target speech to obtain its energy and phase. The formula used is as follows:

$$\mathrm{Y}(k) = \sum_{l=0}^{L-1} y(l)h(l)e^{-\frac{j2\pi kl}{L}} \quad k = 0,1,\dots,L-1 \tag{1}$$

where $y(l)$ is the input speech of the frame, k is the frequency bin index, and $h(l)$ is the Hamming window function. The LPS feature of voice $\mathrm{Y}(k)$ can then be obtained by taking the logarithm of the energy spectrum, as follows:

$$\mathrm{Y}^{LPS}(k) = \log|\mathrm{Y}(k)|^2 \quad k = 0,1,\dots,L/2 \tag{2}$$

B. Model training and application phases

After obtaining Y_n^{LPS} from y_n, a fusion net was used to obtain the Y_e^{LPS}. The point cloud data (*x,y,z*) and their corresponding scene flow features (f_x, f_y, f_z) at time *t* were concatenated and then input into the three visual nets. The visual net contains a 2D convolution layer and two 1D convolution layers to identify the relationship between the adjacent point cloud and scene flow. The outputs of the three visual nets are superimposed with the audio signal LPS at times *t*, *t*+0.5, and *t*+1 and input to the bidirectional gated recurrent unit (BGRU) [37], which prevents the vanishing gradient problem and reduces the computing time. The design of the gated recurrent unit module was based on long short-term memory (LSTM), which has a simpler structure. It only needs to reset and update the gate to achieve the same benefits as the LSTM with a small number of parameters. Finally, we obtain Y_e^{LPS} by integrating the feature information through a fully connected (FC) network. We calculated the loss between the predicted LPS, Y_e^{LPS}, and the clean LPS, Y_c^{LPS}, using the MMSE loss function with Adam optimizer and learning rate of 5×10^{-5}. The loss function is expressed as follows:

$$\theta = \min\left(\frac{1}{K}\sum_{i=1}^{K}(\mathrm{Y}_e^{LPS} - \mathrm{Y}_c^{LPS})^2\right) \quad i = 1,\dots,\mathrm{K} \tag{3}$$

where K denotes the total frame number, and i is the frame index.

In the application phase, we can convert noisy speech y_n' into y_e with a visual net, a trained model, and waveform reconstruction. First, we input the visual information (point clouds and scene flows) into the visual net. The output of the visual net and its corresponding $\mathrm{Y}_n^{LPS\prime}$ can then be fed into the trained model to obtain Y_e^{LPS}. Additionally, by incorporating the phase of y_n' during waveform reconstruction, we can obtain y_e.

III. Experiment Design and Results

A. Material

This research recorded audio and visual signals with a Focus Vision RL100 Pro sensor, shooting at 50 fps, and with a

microphone to simultaneously capture 2D images, 3D images, and audio with 20 ms frame size and 10 ms frame shift, respectively. The frame size and shift can be adjusted to reduce group delays in the hearing aid application scenario. Furthermore, to ensure that the number of points in the 3D image remained the same, 1,050 points were randomly selected from the original 3D images to represent 3D features. The 2D images were scaled to 66 pixels × 85 pixels so as to ensure that the size of each dataset was the same. The distance between the microphone and camera was approximately 25–30 cm, and video and audio were recorded by the same Taiwanese man. In the training phase, three sets of 80 sentences from the Taiwan Mandarin hearing-in-noise test were used, with 15 types of noise at a 3 dB SNR level. Hence, 3,600 noisy speech sentences and videos were generated to train the model. In the testing phase, the remaining 50 sentences were mixed with 11 types of noise (not included in the training phase) at two SNR levels (0 and 3 dB).

B. Procedure

To verify the effectiveness of the proposed AV-3D-SE system, the AO-SE and AV-2D-SE models were used as baseline systems. The AO-SE model directly inputs the Y_n^{LPS} features into a single BGRU layer and then connects it to a single FC layer to output the Y_e^{LPS}. For the AV-2D-SE system, we refer to the visual net in [25], which extracts the image features through three 2D convolutional layers and then stacks the features with the Y_n^{LPS}. These features were used as inputs to a single BGRU layer and an FC layer to obtain Y_e^{LPS}. Detailed settings of the AV-2D-SE models can be found in [25]. To compare the three systems' performance, we used four common evaluation metrics — perceptual evaluation of speech quality (PESQ) [38], short-time objective intelligibility (STOI) [39], HASQI [14], and HASPI [15] — to compare the benefits of SE between the proposed system and two baseline systems. PESQ is an automatic and objective evaluation of speech quality standards which is used to quantify the difference between the original and processed speech in mean option score with numbers from -0.5 to 4.5. The higher the number, the better the quality. The STOI is an objective speech comprehension evaluation method that is highly correlated with the comprehension of time-frequency-weighted noisy speech. STOI scores range from 0 to 1, with higher values indicating better speech comprehension. HASPI and HASQI are indices used to evaluate the performance of hearing aids in improving speech comprehension and quality in people with hearing loss. Table 1 shows the seven types of typical hearing loss types [40] used in this study. Both HASPI and HASQI provide scores ranging from 0 to 1, with higher scores indicating better speech perception and quality.

Table 1. The seven typical hearing loss audiograms [40].

	Frequency (kHz) in dB HL					
Audiogram	**0.25**	**0.5**	**1**	**2**	**4**	**6**
1	60	60	60	60	60	60
2	70	70	70	50	10	10
3	40	40	50	60	65	65
4	0	0	0	60	80	90
5	0	15	30	60	80	85
6	14	14	11	14	24	39
7	24	24	25	31	46	60

C. Results of objective evaluation metrics

Tables 2 and 3 present the average PESQ and STOI scores for 50 sentences in 11 types of noise situations for each approach, including the original noisy speech, AO-SE, AV-2D-SE, and proposed AV-3D-SE systems at SNRs of 0 and 3 dB.

Table 2. Average PESQ scores of the proposed and baseline systems at SNR 0 and 3 dB.

SNR level	**Noisy**	**AO-SE**	**AV-2D-SE**	**AV-3D-SE**
0 dB	1.687	2.334	2.485	**3.084**
3 dB	1.826	2.519	2.581	**3.229**

Table 3. Average STOI scores of the proposed and baseline systems at SNR 0 and 3 dB.

SNR level	**Noisy**	**AO-SE**	**AV-2D-SE**	**AV-3D-SE**
0 dB	0.659	0.752	0.807	**0.899**
3 dB	0.735	0.791	0.830	**0.914**

First, the PESQ and STOI scores of all SE models were higher than those of the original y_n. Second, the model combining visual and voice information had better speech quality and speech understanding than the AO-SE model. The proposed AV-3D-SE system exhibited the highest PESQ and STOI scores. The PESQ score improved from 1.687 to 3.084 at an SNR of 3 dB, and from 1.826 to 3.229 at an SNR of 0 dB. The STOI scores increased by approximately 0.24 and 0.196, respectively. Comparing the AV-3D-SE model with the AV-2D-SE model, whether at an SNR of 0 or 3 dB, the PESQ and STOI scores increased significantly. From the above results, we infer that point clouds and scene flows as model inputs can better represent face deformation when speaking than that of 2D images. Accordingly, this shows that the AV-3D-SE model improves speech quality and comprehension compared to the other models.

Fig. 3 (A) and (B) present the average HASQI scores of the proposed and baseline systems at SNRs of 0 and 3 dB, respectively. From these results (at two SNR levels), among the

seven types of hearing loss, these three systems can provide enhancement benefits compared with those of noisy conditions; the AV-3D-SE model has the best performance, followed by the AV-2D-SE and AO-SE models. The three models also showed significant differences ($p<0.001$). However, compared with AO-SE, the performance of the AV-2D-SE model did not significantly improve under the conditions of audiograms 1, 2, and 3. The performance of AV-3D remained the best. For steep-drop-type high-frequency hearing loss (audiograms 4 to 7), the benefit of the AO-SE system is much lower, whereas the two systems with visual assistance maintain good performance. Consequently, we believe that it can improve the ability of hearing-impaired people to concentrate and improve the quality of their hearing with 3D facial structures and deformations similar to those of the human brain processes mentioned earlier. Thus, 3D images and scene flows are helpful in improving the speech quality perceived by hearing-impaired people.

Tables 4 and 5 show the average HASPI scores for different types of hearing loss in 11 noise situations. After the three SE systems were processed at two different SNR levels, the HASPI scores of different hearing-impaired individuals improved to a very high level. Although the score of the AV-3D-SE system is higher than that of the other two baseline systems, the difference in listening comprehension between the three is not obvious, which indicates that the processed speech of the three systems can be understood by different hearing-impaired individuals when listening.

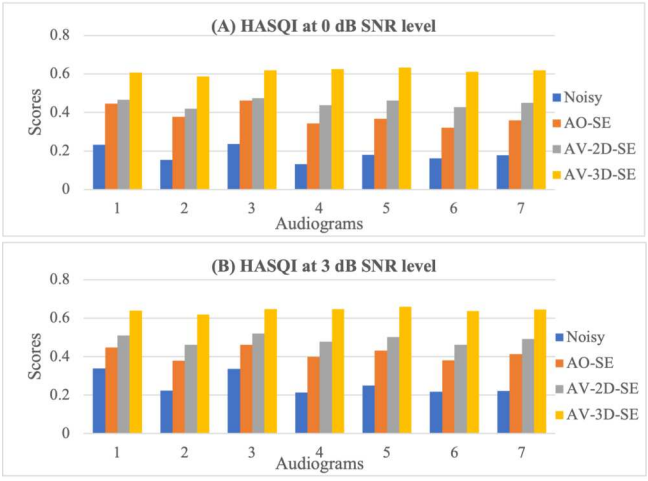

Fig. 3 Average HASQI scores of the proposed and baseline systems at (A) 0dB and (B) 3dB SNR levels.

IV. Conclusion

This study used the FlowNet3D model to extract the scene flow features of facial deformation around the lips when speaking. This information can be combined with audio information to create an innovative and progressive AV-3D-SE system for improving the noise reduction effect of hearing aids in noisy environments. The PESQ and STOI scores show that speech quality and comprehension are significantly improved compared with the other models. We used the HASPI and HASQI to compare the speech quality and comprehension of hearing-impaired individuals. The results show that all models perform intelligibly. However, in terms of speech quality, the AV-3D-SE model showed improved speech quality compared to the other algorithms. Finally, we showed that scene flow is a potential visual feature that enhances the benefits of the SE model and proved the effectiveness of the AV-3D-SE model proposed in this study.

Table 4. Average HASPI scores of the proposed and baseline systems at 0 dB SNR level.

Audiogram	Noisy	AO-SE	AV-2D-SE	AV-3D-SE
1	0.9640	0.9990	0.9988	**0.9998**
2	0.8316	0.9968	0.9961	**0.9997**

***Abstract*—In order to improve both the separation performance and the convergence speed, several geometrically constrained independent vector analysis (GC-IVA) algorithms have been developed. Those algorithms are based on the multiplicative transfer function model, which assumes that the analysis window length is longer than the effective part of the room impulse responses. However, this assumption does often not hold in reverberant environments, particularly if the reverberation is strong, which makes the algorithms suffer from significant performance degradation. To circumvent this issue, an algorithm was developed, which jointly optimizes the weighted prediction error (WPE) dereverberation method and GC-IVA (GC-WPE-IVA). While it has demonstrated promising performance, this joint optimization method involves matrix inversion; so it is computationally very expensive. This work attempts to improve the efficiency and stability of GC-WPE-IVA. We develop an iterative source steering (ISS) updating algorithm in the framework of GC-WPE-IVA. The experimental results show that the developed method is computationally much more efficient yet it can achieve comparable separation performance in reverberation environments as compared to GC-WPE-IVA.**

I. Introduction

Speech enhancement is vital in speech communications systems as the source signals are always contaminated by interference, reverberation, and background noise [1]–[4]. When multiple sources are active simultaneously and no prior information is available, blind source separation (BSS) is usually used to separate source signals [1]. Independent component analysis (ICA) [5], one of the most adopted BSS methods, achieves source separation by exploiting the statistical independence among the sources. But it suffers from the problem of permutation. By considering the relationship among different frequency components, independent vector analysis (IVA) [6], [7], which is an extension of ICA, was developed to deal with the frequency permutation problem [8]. To accelerate the convergence and improve the robustness of IVA, the auxiliary function technique was developed [9] and the so-called iteration projection (IP) [9] and iterative source steering (ISS) [10] rules were proposed to optimize the auxiliary function. Although IVA has attracted great attention for its performance, the separated signals are in a random output order, which is known as the global permutation problem. In many applications, such as speech recognition, it is of great importance to match the separated sources and the corresponding speakers.

In real-world applications, the geometry of the array is fixed and the locations of the sources are often known or can be estimated [11]. To make use of such information, geometrically constrained independent vector analysis (GC-IVA) [12]–[16] algorithms were proposed. Recently, GC-IVA with the ISS-based updating rules (GC-IVA-ISS) was introduced, which demonstrated promising performance [17]; but its performance suffers from dramatic degradation if the reverberation is strong, which happens often in practice.

In order to mitigate the impact of reverberation on BSS, the weighted prediction error (WPE) [18], [19], one of the most widely used blind dereverberation methods, is usually implemented before separation [20]. Recently, convolutional beamformer (CBF) [21], which jointly updates the WPE and separation filters, was developed to improve the source extraction performance in strong reverberant environments. The source-wise factorization of the CBF [22] was further developed to reduce the computational complexity. ILRMA-T-ISS [23] is another work that deals with source separation in heavy reverberant environments with low computational cost. To cope with the problem of global permutation, the spatial information of the target source is used in the CBF framework (GC-WPE-IVA) [24], resulting in better performance than the conventional methods. Although GC-WPE-IVA is the state-of-the-art source separation method with dereverberation, it is still computationally costly due to the IP-based updating rules for the separation filters.

This work attempts to improve the efficiency and stability of the algorithm developed in [24]. We develop an ISS updating algorithm in the framework of GC-WPE-IVA, leading to a new algorithm called GC-WPE-IVA-ISS. Experiments are carried out and the results show that GC-WPE-IVA-ISS is computationally much more efficient yet it can achieve better or at least comparable separation performance in reverberation environments as compared to GC-WPE-IVA. Besides, since the spatial information of the sources is used, the global permutation problem is naturally solved with GC-WPE-IVA-ISS.

II. Signal model and problem formulation

Assume that there are N sources and M microphones. The source signals and observed signals can be expressed in a vector form as

$$\boldsymbol{s}_{f,t} = [s_{1,f,t} \quad s_{2,f,t} \quad \cdots \quad s_{N,f,t}]^{\mathsf{T}} \in \mathbb{C}^{N\times 1}, \tag{1}$$

$$\boldsymbol{x}_{f,t} = [x_{1,f,t} \quad x_{2,f,t} \quad \cdots \quad x_{M,f,t}]^{\mathsf{T}} \in \mathbb{C}^{M\times 1}, \tag{2}$$

where $(\cdot)^{\mathsf{T}}$ denotes transpose, $s_{n,f,t}$ and $x_{m,f,t}$ represent, respectively, the nth source signal and mth microphone observation signal in the short-time Fourier transformation (STFT) domain, $f = 1 \cdots F$ and $t = 1 \cdots T$ are frequency bin and time frame indexes with F and T being, respectively, the numbers of frequency bins and frames. $\boldsymbol{x}_{f,t}$ can be expressed as

$$\boldsymbol{x}_{f,t} = \sum_{\tau=0}^{L_A-1} \boldsymbol{A}_{f,\tau}\boldsymbol{s}_{f,t-\tau}, \tag{3}$$

where $\boldsymbol{A}_{f,\tau} \in \mathbb{C}^{M\times N}$ is the convolutional mixing matrix at time lag τ, and L_A is the order of time-lagged mixing filters. In this work, we only consider the determined case where $N = M$. Based on the multi-input multi-output (MIMO) CBF formulation [21], the beamformer's output can be expressed as

$$\boldsymbol{y}_{f,t} = \boldsymbol{W}_{f,0}\boldsymbol{x}_{f,t} + \sum_{\tau=D}^{L+D-1} \boldsymbol{W}_{f,\tau}\boldsymbol{x}_{f,t-\tau}, \tag{4}$$

where $\boldsymbol{W}_{f,0} \in \mathbb{C}^{N\times M}$ and $\boldsymbol{W}_{f,\tau} \in \mathbb{C}^{N\times M}$ are the coefficient matrix of CBF, $\boldsymbol{y}_{f,t} = [y_{1,f,t} \quad y_{2,f,t} \quad \cdots \quad y_{N,f,t}]^{\mathsf{T}} \in \mathbb{C}^{N\times 1}$ consists of the N separated signals, D and L are the time delay and the length of the CBF filters, respectively. According to source-wise factorization of CBF [22], the nth separated signal in $\boldsymbol{y}_{f,t}$ can be rewritten into two following form

$$\boldsymbol{z}_{n,f,t} = \boldsymbol{x}_{f,t} - \boldsymbol{G}_{n,f}^{\mathsf{H}}\overline{\boldsymbol{x}}_{f,t}, \tag{5}$$

$$y_{n,f,t} = \boldsymbol{q}_{n,f}^{\mathsf{H}}\boldsymbol{z}_{n,f,t}, \tag{6}$$

where $(\cdot)^{\mathsf{H}}$ represents conjugate transpose, $\overline{\boldsymbol{x}}_{f,t} = [\boldsymbol{x}_{f,t-D}^{\mathsf{T}} \quad \boldsymbol{x}_{f,t-D-1}^{\mathsf{T}} \quad \cdots \quad \boldsymbol{x}_{f,t-L-D+1}^{\mathsf{T}}]^{\mathsf{T}} \in \mathbb{C}^{ML\times 1}$ contains past observed signals, $\boldsymbol{G}_{n,f} \in \mathbb{C}^{ML\times M}$ is the MIMO WPE filter, $\boldsymbol{z}_{n,f,t}$ is the dereverberated signal of nth source and $\boldsymbol{q}_{n,f}$ is the demixing filter. Note that (5) and (6) are strictly equal to (4) when $\boldsymbol{q}_{n,f}^{\mathsf{H}} = \boldsymbol{w}_{n,f,0}$ and $-\boldsymbol{q}_{n,f}^{\mathsf{H}}\boldsymbol{G}_{n,f}^{\mathsf{H}} = [\boldsymbol{w}_{n,f,D} \quad \boldsymbol{w}_{n,f,D+1} \quad \cdots \quad \boldsymbol{w}_{n,f,L+D-1}]$, where $\boldsymbol{w}_{n,f,\tau}$ is the nth row of $\boldsymbol{W}_{f,\tau}$.

To exploit the dependency between different frequency bins and thereby avoid the frequency permutation problem as IVA, CBF assumes that the sources follow a multivariate Gaussian distribution with time dependent variance $r_{n,t} = \sum_f |y_{n,f,t}|^2/F$. Therefore, the negative log-likelihood cost function can be derived as [22]

$$\mathcal{L} = -2\sum_f \log|\det \boldsymbol{Q}_f| + \frac{1}{T}\sum_{n,f,t}\left(\log r_{n,t} + \frac{|y_{n,f,t}|^2}{r_{n,t}}\right), \tag{7}$$

where $\boldsymbol{Q}_f = [\boldsymbol{q}_{1,f} \quad \boldsymbol{q}_{2,f} \quad \cdots \quad \boldsymbol{q}_{N,f}]^{\mathsf{H}}$ is the demixing matrix.

III. Proposed method

A. A Probabilistic model

In order to deal with the global permutation problem in strong reverberation conditions, we introduce the geometrical constraints [25] to the conventional CBF, which is expressed as

$$\mathcal{L}_{\mathrm{GC}} = \sum_{n,\varphi,f} \lambda_{n,\varphi}|\boldsymbol{q}_{n,f}^{\mathsf{H}}\boldsymbol{d}_{\varphi,f} - c_{n,\varphi}|^2, \tag{8}$$

where $\lambda_{n,\varphi}$ is a non-negative weighting coefficient, $\boldsymbol{d}_{\varphi,f}$ is the steering vector along the direction φ and $c_{n,\varphi}$ is a non-negative-valued constraint. Note that if $c_{n,\varphi} = 1$, optimizing (8) gives the conventional delay-and-sum beamformer, which is steered to φ to extract the target signal whereas setting $c_{n,\varphi}$ to a small value will create a spatial null to suppress interference incident from the direction φ [14]. Combining (8) and (7) gives the cost function for the proposed method, i.e.,

$$\begin{aligned}\mathcal{L}(\Theta) = &-2\sum_f \log|\det \boldsymbol{Q}_f| + \frac{1}{T}\sum_{n,f,t}\left(\log r_{n,t} + \frac{|y_{n,f,t}|^2}{r_{n,t}}\right)\\ &+ \sum_{n,\varphi,f}\lambda_{n,\varphi}|\boldsymbol{q}_{n,f}^{\mathsf{H}}\boldsymbol{d}_{\varphi,f} - c_{n,\varphi}|^2,\end{aligned} \tag{9}$$

where $\Theta = \{\Theta_{\boldsymbol{G}}, \Theta_{\boldsymbol{Q}}, \Theta_r\}$ is the parameter set to be estimated, $\Theta_{\boldsymbol{G}} = \{\boldsymbol{G}_{n,f}\}$, $\Theta_{\boldsymbol{Q}} = \{\boldsymbol{Q}_f\}$, and $\Theta_r = \{r_{n,t}\}$.

B. Optimization algorithm

According to the coordinate ascent method [20], each parameter in (9) can be updated iteratively by fixing the others until convergence.

1) Update of $\Theta_{\boldsymbol{G}}$: To update the WPE filter $\boldsymbol{G}_{n,f}$, the cost function (9) can be rewritten by fixing other parameters and ignoring the constant terms as

$$\mathcal{L}(\Theta_{\boldsymbol{G}}) = \frac{1}{T}\sum_{n,t,f}|\boldsymbol{q}_{n,f}^{\mathsf{H}}(\boldsymbol{x}_{f,t} - \boldsymbol{G}_{n,f}^{\mathsf{H}}\overline{\boldsymbol{x}}_{f,t})|^2/r_{n,t}. \tag{10}$$

Note that (10) is a quadratic function with respect to $\Theta_{\boldsymbol{G}}$. So, the parameter that minimizes (10) is [22]

$$\boldsymbol{G}_{n,f} \leftarrow \boldsymbol{R}_{n,f}^{-1}\boldsymbol{P}_{n,f}, \tag{11}$$

where

$$\boldsymbol{R}_{n,f} = \sum_t \frac{\overline{\boldsymbol{x}}_{f,t}\overline{\boldsymbol{x}}_{f,t}^{\mathsf{H}}}{r_{n,t}}, \tag{12}$$

$$\boldsymbol{P}_{n,f} = \sum_t \frac{\overline{\boldsymbol{x}}_{f,t}\boldsymbol{x}_{f,t}^{\mathsf{H}}}{r_{n,t}}, \tag{13}$$

are spatio-temporal covariance matrices.

2) Update of $\Theta_{\boldsymbol{Q}}$: By fixing $\Theta_{\boldsymbol{G}}$ and Θ_r, the cost function (9) can be simplified to

$$\begin{aligned}\mathcal{L}(\Theta_{\boldsymbol{Q}}) = &-2\sum_f \log|\det \boldsymbol{Q}_f| + \sum_{n,f} \boldsymbol{q}_{n,f}^{\mathsf{H}} \boldsymbol{U}_{n,f} \boldsymbol{q}_{n,f} \\ &+ \sum_{n,\varphi,f} \lambda_{n,\varphi} |\boldsymbol{q}_{n,f}^{\mathsf{H}} \boldsymbol{d}_{\varphi,f} - c_{n,\varphi}|^2,\end{aligned} \tag{14}$$

where

$$\boldsymbol{U}_{n,f} = \frac{1}{T}\sum_t \frac{\boldsymbol{z}_{n,f,t}\boldsymbol{z}_{n,f,t}^{\mathsf{H}}}{r_{n,t}} \tag{15}$$

is the weighted covariance matrix of $\boldsymbol{z}_{n,f,t}$. To accelerate the convergence of updating $\Theta_{\boldsymbol{Q}}$, instead of using the IP-based method that updates each row of $\boldsymbol{Q}_f$ iteratively [14] (which requires N times matrix inversion), the proposed method adopts the ISS updating rule [10] in which the whole filter is updated with a rank-1 matrix as

$$\boldsymbol{Q}_f \leftarrow \boldsymbol{Q}_f - \boldsymbol{v}_{k,f}\boldsymbol{q}_{k,f}^{\mathsf{H}}, \tag{16}$$

where $\boldsymbol{v}_{k,f} \in \mathbb{C}^{N\times 1}$ is a vector to be estimated. The update of $\boldsymbol{Q}_f$ will be repeated for $k = 1, ..., N$. Substituting (16) into the cost function (14) gives

$$\begin{aligned}\mathcal{L}_{\mathrm{ISS}}(\boldsymbol{v}_{k,f}) = &-2\sum_f \log|\det(\boldsymbol{Q}_f - \boldsymbol{v}_{k,f}\boldsymbol{q}_{k,f}^{\mathsf{H}})| \\ &+ \sum_{n,f} (\boldsymbol{q}_{n,f} - v_{n,k,f}^*\boldsymbol{q}_{k,f})^{\mathsf{H}} \boldsymbol{U}_{n,f} (\boldsymbol{q}_{n,f} - v_{n,k,f}^*\boldsymbol{q}_{k,f}) \\ &+ \sum_{n,\varphi,f} \lambda_{n,\varphi} |(\boldsymbol{q}_{n,f} - v_{n,k,f}^*\boldsymbol{q}_{k,f})^{\mathsf{H}}\boldsymbol{d}_{\varphi,f} - c_{n,\varphi}|^2,\end{aligned} \tag{17}$$

where $v_{n,k,f}$ is the nth element of $\boldsymbol{v}_{k,f}$ and $(\cdot)^*$ denotes complex conjugate. Solving the equation $\partial\mathcal{L}_{\mathrm{ISS}}(\boldsymbol{v}_{k,f})/\partial v_{n,k,f}^* = 0$, which is inspired by the work in [17], we obtain the update rules for $v_{n,k,f}$, which is divided into the following two cases:

- $n \neq k$: In this case, the update rule is

$$v_{n,k,f} = \frac{\boldsymbol{q}_{n,f}^{\mathsf{H}}\boldsymbol{U}_{n,f}\boldsymbol{q}_{k,f} + \sum \lambda_{n,\varphi}(g_{n,\varphi,f} - c_{n,\varphi})g_{k,\varphi,f}^*}{\boldsymbol{q}_{k,f}^{\mathsf{H}}\boldsymbol{U}_{n,f}\boldsymbol{q}_{k,f} + \sum \lambda_{n,\varphi}|g_{k,\varphi,f}|^2}; \tag{18}$$

- $n = k$: In this case, $v_{k,k,f}$ is updated according to

$$v_{k,k,f} = \begin{cases} 1 - (\alpha_{k,f})^{-1/2} & \text{if } \beta_{k,f} = 0, \\ 1 - \beta_{k,f}^* \frac{|\beta_{k,f}| + \sqrt{|\beta_{k,f}^2| + 4\alpha_{k,f}}}{2\alpha_{k,f}|\beta_{k,f}|} & \text{otherwise,} \end{cases} \tag{19}$$

where

$$g_{n,\varphi,f} = \boldsymbol{q}_{n,f}^{\mathsf{H}}\boldsymbol{d}_{\varphi,f}, \tag{20}$$

$$\alpha_{k,f} = \boldsymbol{q}_{k,f}^{\mathsf{H}}\boldsymbol{U}_{k,f}\boldsymbol{q}_{k,f} + \sum_{\varphi} \lambda_{k,\varphi}|g_{k,\varphi,f}|^2, \tag{21}$$

$$\beta_{k,f} = \sum_{\varphi} \lambda_{k,\varphi} c_{k,\varphi} g_{k,\varphi,f}. \tag{22}$$

Once $\boldsymbol{v}_{k,f}$ is obtained, $\boldsymbol{Q}_f$ can be updated through (16).

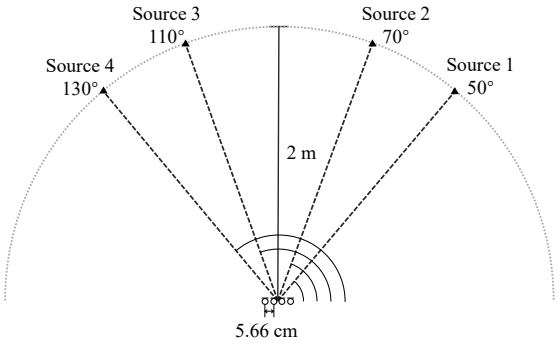

Fig. 1. Simulation layout.

3) Update of Θ_r: After updating the dereverberation ($\boldsymbol{G}_{n,f}$) and separating ($\boldsymbol{Q}_f$) filters, new separated signals $\boldsymbol{y}_{f,t}$ can be obtained through (5) and (6). Then, the time-varying variance $r_{n,t}$ is updated as

$$r_{n,t} \leftarrow \frac{1}{F}\sum_f |y_{n,f,t}|^2. \tag{23}$$

IV. Experiment

A. Experimental setup

The observation signals are generated by convolving the speech signals from the TIMIT database [26] with the room impulse responses (RIRs) from the RWCP dataset [27]. For every mixed signal, 4 speech segments, which are arbitrarily selected from different speakers, are concatenated to form 10 s long clean speech signals. The room reverberation time T_{60} is selected to 300 ms and 600 ms. The white Gaussian noise is added to control the signal-to-noise ratio (SNR) to 30 dB. The layout of sources and microphones is illustrated in Fig. 1, where a 4-element uniform linear microphone array (ULA) with an inter-element spacing of 5.66 cm is used. There are four sources in the sound field and the DOAs of the four sources are 50°, 70°, 110°, and 130°, respectively. The distance between the ULA center and the sources is 2 m. To measure the separation performance, twenty-five Monte Carlo simulations are carried out. All observed signals are sampled at 16 kHz and the STFT is conducted with the Hann window of 64 ms (1024 samples) and a window shift of 16 ms (256 samples).

We define two matrices, i.e., $\boldsymbol{\Lambda} = [\boldsymbol{\lambda}_1 \ \ \boldsymbol{\lambda}_2 \ \cdots \ \boldsymbol{\lambda}_N]^{\mathsf{T}}$ and $\boldsymbol{C} = [\boldsymbol{c}_1 \ \ \boldsymbol{c}_2 \ \cdots \ \boldsymbol{c}_N]^{\mathsf{T}}$, with the parameters in (8) where $\boldsymbol{\lambda}_n = [\lambda_{n,\varphi_1} \ \ \lambda_{n,\varphi_2} \ \cdots \ \lambda_{n,\varphi_N}]^{\mathsf{T}} \in \mathbb{R}^{N\times 1}$, $\boldsymbol{c}_n = [c_{n,\varphi_1} \ \ c_{n,\varphi_2} \ \cdots \ c_{n,\varphi_N}]^{\mathsf{T}} \in \mathbb{R}^{N\times 1}$ and $\Phi = \{\varphi_1, \varphi_2, \cdots, \varphi_N\}$ is the set of DOAs. According to the work in [17], we set $\boldsymbol{C} = \boldsymbol{E}$ so the output order is the same as the order of the input DOA and we use *NULL* constraints $\boldsymbol{\Lambda} = \Lambda(\boldsymbol{J} - \boldsymbol{E})$ where Λ is a non-negative number, $\boldsymbol{J}$ is an all-one matrix and $\boldsymbol{E}$ is the identity matrix. We initialize Λ as 8000 and decrease it over iterations according to [13], i.e.,

$$\Lambda_i = \Lambda_0\alpha^i, \tag{24}$$

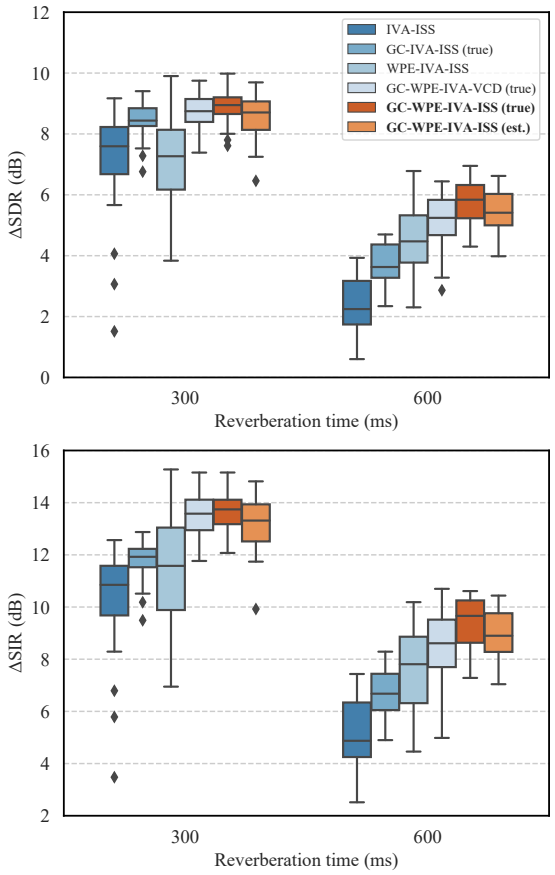

Fig. 2. Performance of the studied methods under different reverberation conditions.

where i represents the current number of iterations, Λ_0 is the initial value of Λ and the factor α is set to 0.8. For the WPE filter, the time delay D and filter length L are set to 2 and 10, respectively. The results for all the methods are obtained with 50 iterations and the WPE filter is updated every 10 iterations so both the convergence speed and computational cost are jointly considered. All the algorithms are implemented on a workstation powered by Intel Xeon E3-1505M. The improvement of signal-to-distortion ratio (ΔSDR) and signal-to-interference ratio (ΔSIR) [28] are used as the metrics to evaluate the separation performance.

The separation performance of the proposed algorithm (denoted as GC-WPE-IVA-ISS) is compared with IVA-ISS [10], GC-IVA-ISS [17], the joint optimization algorithm of WPE and IVA [22] with the ISS update method (WPE-IVA-ISS) and the geometrically constrained WPE-IVA with the vectorwise coordinate descent update method (GC-WPE-IVA-VCD) [24].

B. Experimental results

The SDR and SIR improvements of all the studied methods under different reverberation conditions are shown in Fig. 2. For the proposed GC-WPE-IVA-ISS, both the ground truth DOAs $\Phi_{\text{True}} = \{50°, 70°, 110°, 130°\}$ (denoted as true) and the DOAs with observation error $\Phi_{\text{True}} + \varepsilon$ (est.) are considered,

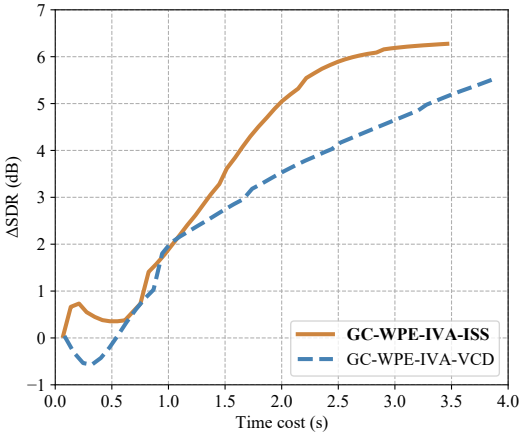

Fig. 3. Convergence speed of GC-WPE-IVA-ISS and GC-WPE-IVA-VCD.

where the error ε is computer generated random number with a uniform distribution in $[-15°, 15°]$ for every source. As seen from Fig 2, in the light reverberation condition with T_{60} = 300 ms, the ΔSDR of GC-IVA-ISS is close to that of the proposed method even without dereverberation. However, as the reverberation becomes stronger (with T_{60} = 600 ms), the separation performance of GC-IVA-ISS decreases significantly. In comparison, with the joint optimization of dereverberation filters and separation filters and the ISS-based updating rules, the proposed method generates a much better ΔSDR and ΔSIR than the compared conventional methods. In the presence of DOA errors, which is inevitable in practical applications with multi-sources and reverberation, the separation performance of the developed method decreases slightly. But its performance is still better than, or at least comparable to the compared conventional methods.

Figure 3 plots the convergence curves of GC-WPE-IVA-ISS and GC-WPE-IVA-VCD with ground true DOA. Note that the updating of the WPE filter is time-consuming. To better illustrate the acceleration of the convergence speed brought by the ISS-based optimization, the results in Fig. 3 show only the time cost for updating the separation filters. The results demonstrate that, due to the efficiency and stability of ISS, the developed method gets convergence with a much lower time cost than GC-WPE-IVA-VCD.

The accuracy of the output channel order of the proposed GC-WPE-IVA-ISS as well as GC-IVA-ISS, GC-WPE-IVA-VCD is listed in Table I. Note that the results of IVA-ISS and WPE-IVA-ISS are not presented here since their output orders are random. From Table I, it is seen that in the light reverberation condition, all the studied methods are able to produce accurate output order. But as the reverberation time becomes longer, the output accuracy of the conventional methods is affected while the proposed method can still guarantee the accuracy of the output order.

V. Conclusion

To make efficient use of the *a priori* spatial information of the sound sources, thereby improving the source separation

TABLE I
THE ACCURACY OF THE OUTPUT CHANNEL ORDER OF THE STUDIED METHODS UNDER DIFFERENT REVERBERATION CONDITIONS.

T_{60}	GC-IVA-ISS	GC-WPE-IVA-VCD	GC-WPE-IVA-ISS
300 ms	100%	100%	100%
600 ms	96%	96%	100%

performance in reverberant environments, we presented in this work a geometrically constrained algorithm, which jointly optimizes source separation and dereverberation filters with the ISS-based optimization. The experimental results show that the developed method is computationally much more efficient yet it can achieve better or at least comparable separation performance in reverberation environments as compared to the studied baseline algorithms. It is also robust to DOA estimation error. Another merit of the developed algorithm is that it is able to deal with the global permutation problem inherently.

***Abstract*—The performance of speech processing models trained on clean speech drops significantly in noisy conditions. Training with noisy datasets alleviates the problem, but procuring such datasets is not always feasible. Noisy speech simulation models that generate noisy speech from clean speech help remedy this issue. In our work, we study the ability of Generative Adversarial Networks (GANs) to simulate a variety of noises. Noise from the Ultra-High-Frequency/Very-High-Frequency (UHF/VHF), additive stationary and non-stationary, and codec distortion categories are studied. We propose four GANs: the non-parallel translators, SpeechAttentionGAN, SimuGAN, and MaskCycleGAN-Augment, and the parallel translator, Speech2Speech-Augment. We achieved improvements of 55.8%, 28.9%, and 22.8% in terms of Multi-Scale Spectral Loss (MSSL) and 49.3%, 28.8%, and 18.2% in terms of Log Spectral Distance (LSD) as compared to the baseline for the RATS, TIMIT-Cabin, and TIMIT-Helicopter datasets, respectively, after training on small datasets of about 3 minutes.**

I. Introduction

Audio processing has wide-ranging applications in a multitude of tasks. Advancements in deep learning have further enabled the large-scale use of audio processing in tasks like Automatic Speech Recognition and Speech Enhancement [1]–[3]. The major challenge, however, is that the noisy environments that these models are exposed to in the real world severely impact their performance, making exposure to noise during training essential for good performance. Several works [4]–[6] use corpora of noises obtained from real-world settings. However, gathering noise datasets with sufficient variations and volume is not always economical or feasible.

Artificially generating noisy data is one viable option to remedy this issue. Several traditional models exist for audio augmentation, including parallel model matching [7], HMM adaptation using vector Taylor series [8], and stochastic matching [9]. There have also been works that directly add short static noise clips to clean audios for augmentation [10]. Obtaining significant durations of real-world noise, however, is often infeasible. Works like [11], and [12] use codecs to simulate distortion. Most of these traditional augmentation methods are based on using short clips of noise or pre-defined processing techniques. Using short noise clips entails the drawback of exposing the model to low levels of variation and hence lowers the model's generalizability to the broader variation levels present in the real world. Furthermore, if the augmentation techniques are predefined and not learned, they cannot adapt to different noise types.

Techniques involving deep learning or differentiable digital signal processing (DDSP) [13], [14] where model parameters are learned show potential in being more adaptable to different noise domains. Among deep learning techniques, Generative Adversarial Networks (GANs) show great promise in boosting model performance in noisy conditions due to their ability to simulate data realistically. GANs have the ability to perform both parallel and non-parallel translations from one domain to another. Parallel translation involves training the translation model with pairs of corresponding data points from both domains in a supervised fashion. On the other hand, non-parallel translation does not require training with input-target pairs, and hence, training is done in an unsupervised manner.

SimuGAN [15] has shown promise in simulating noise by learning noise statistics and has been shown to boost the performance of Automatic Speech Recognition (ASR). However, it has only been tested on a single type of noise and does not explore the usability of this GAN-based technique with other noise categories. DENT-DDSP [14] uses differentiable digital signal processing for parallel translation from the clean to the noisy domain in a very data-efficient manner. However, obtaining parallel data is difficult, and this may make the method unusable in applications where only non-parallel data is available.

There has been limited exploration of the ability of GANs to simulate noises of different types under conditions of low data volume constraints. In our work, we aim to explore the ability of four types of GANs to simulate four types of noises. We use SpeechAttentionGAN, MaskCycleGAN-Augment, and SimuGAN for non-parallel translation and Speech2Speech-Augment for parallel translation. SpeechAttentionGAN and MaskCycleGAN-Augment belong to the cycleGAN [16] family and use the 'Filling in Frames' technique during training. In addition, SpeechAttentionGAN uses attention masks for translation. SimuGAN uses the PatchNCE [17] loss for content preservation. Speech2Speech-Augment uses supervised learning with L1 loss to learn the translation. Furthermore, we use the RATS dataset, cabin and helicopter noise from the TIMIT dataset, and codec2 to represent the noise categories of Ultra-High-Frequency/Very-High-Frequency (UHF/VHF),

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

additive stationery, additive non-stationary, and codec-based distortion, respectively. We also compare the performance of noise simulation with GANs against a baseline.

Our work proves that GANs can be used to simulate noisy speech through experimental evidence. All four types of GANs show superior simulation quality in terms of LSD and MSSL when compared against the baseline. Unlike the traditional models, our proposed models learn to simulate the noise and are not based on a fixed processing algorithm or directly adding real-world noise clips. It thus provides great flexibility to be used for various kinds of noisy environments, as demonstrated by the experiments with multiple noise types. We also propose three GANs for non-parallel translation, which overcome the drawbacks of learning-based techniques like DENT-DDSP [14] that cannot be used without parallel data. Furthermore, our experiments were conducted using only about 3 minutes of clean and noisy clips each, demonstrating a way to effectively simulate noise even when the volume of data available is extremely low. Moreover, while traditional and learning-based methods involving DDSP cannot be used to simulate dynamic noise, we prove experimentally that GANs can successfully perform this task. Finally, the detailed experimental results provide researchers and developers of audio augmentation models with a comprehensive framework to use the correct type of GAN for the right kind of noise simulation task.

II. Methodology

A. Overview of the Audio Processing Pipeline

Figure 1 gives an overview of the prominent steps in the pipeline that convert a clean audio file to a noisy audio file. These steps are performed as follows. The loudness of the audio clip is first normalized to a fixed value. This is followed by Short Time Fourier Transform (STFT) to get a magnitude and phase spectrogram. Further processing is only done on the magnitude spectrogram. The phase spectrogram will be recycled and used in inverse STFT. The magnitude spectrogram goes through padding and componentization, which will be explained in detail in the following subsection. Each component then undergoes several processing steps, including conversion to decibels and scaling between 0 to 255. The magnitude spectrogram initially shows the lower frequencies on top and higher frequencies on the bottom. We flip it vertically to reverse this order. The components are then processed by the model to give us the generated components. The generated components are concatenated, and any padding added during componentization is removed. The magnitude spectrogram thus obtained is flipped, appropriately scaled, and converted to power from decibels. Inverse STFT is now performed using this generated magnitude spectrogram and the original phase spectrogram (from the clean audio) to get the target noisy audio clip.

B. Componentization

The lengths of spectrograms are variable and depend on the lengths of the audio clips. Longer audio clips would have longer spectrograms, while shorter audio clips would have

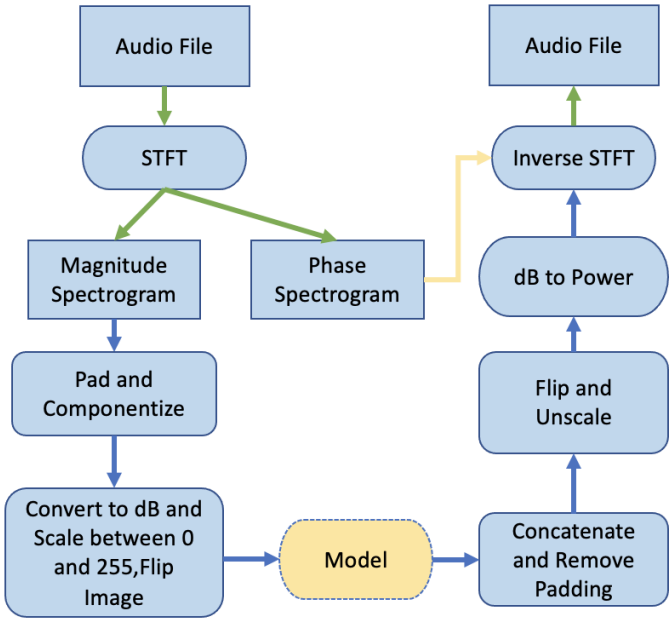

Fig. 1. Overview of the Audio Processing Pipeline. The trainable model is depicted by the yellow component. The flow of the magnitude spectrogram is depicted by blue arrows, the flow of the phase spectrogram is depicted by the yellow arrows, and the combined information flow is depicted by green arrows.

shorter ones along the horizontal axis. The height of the spectrogram depends on the window length (after padding) parameter of the STFT and would remain constant as this parameter is kept constant for all audio samples. During componentization, the spectrogram is broken into components of constant length, and the last component is padded with the required number of frames from the start of the spectrogram if it is not long enough. This ensures that the model inputs are kept at constant dimensions and helps a single audio clip serve as multiple training points if it is long enough.

C. GANS

1) SpeechAttentionGAN: SpeechAttentionGAN uses the base model architecture from AttentionGAN [18], [19], which was designed to be used for the non-parallel translation of images in a data-efficient manner. Information flow in SpeechAttentionGAN is depicted in figure 2.

In the proposed model, we introduce two novel modifications on top of the base model to help the model learn spectrogram structures better and to remedy the statistical averaging caused by the cycle consistency loss [16]. They are the addition of an input mask to implement the 'Filling in Frames' (FIF) approach in model training and a second adversarial loss, respectively.

To implement FIF, we generate a mask of zeros and ones by which the input spectrogram is then multiplied. The mask is generated in such a way that all frequencies for a random range of time frames of the spectrogram are removed during training. The masked spectrogram and the mask are given as inputs to

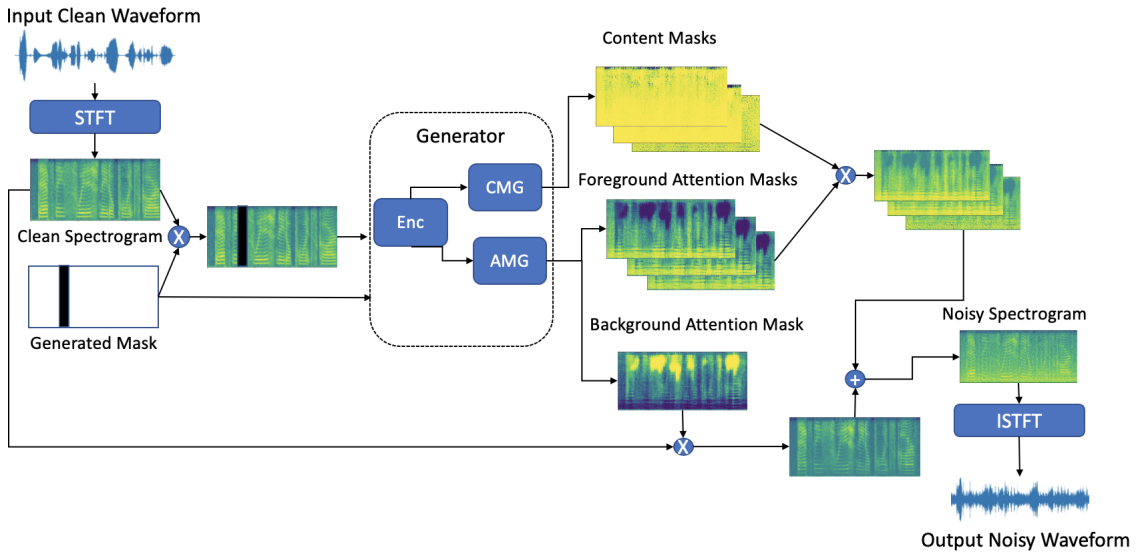

Fig. 2. SpeechAttentionGAN. The figure depicts the overall flow of data in one direction in the SpeechAttentionGAN pipeline with Filling in Frames. The generator consists of three parts - the Encoder (Enc), the Attention Mask Generator(AMG), and the Content Mask Generator(CMG). In this figure, spectrogram refers to magnitude spectrogram, STFT refers to Short-Time Fourier Transform, and ISTFT refers to Inverse Short-Time Fourier Transform.

the model. By training in this fashion, the model is forced to predict the missing content from the surrounding information and thus implicitly learn the spectrogram's structure. During testing, the entire mask is set to one, and no information loss takes place.

The second adversarial loss [20] is very similar in structure to the general adversarial loss [21] used in GANs. The difference lies in the fact that instead of using the real input and the output generated by one generator, the second adversarial loss uses real inputs and cycled outputs (outputs that have been cycled through both generators back to the original domain). The second adversarial loss for the translation from domain A to domain B and back to domain A (A→B→A) is described in (1). The second adversarial loss for the direction B→A→B is computed in a similar manner. In order to compute the second adversarial loss, we use two additional discriminators with identical architecture to the original two. We use one discriminator each to compute this loss in the two directions.

$$L_{adv2}^{A->B->A} = E_{a\sim A}[D'_A(a)] + E_{a\sim A}[D'_A(G_{B->A}(G_{A->B}(a)))] \quad (1)$$

In (1), $G_{A->B}$ represents the generator that translates from domain A to domain B, $G_{B->A}$ represents the generator that translates from domain B to domain A, D'_A represents the discriminator used to compute this loss in the direction A→B→A, and a represents a data point from domain A.

2) MaskCycleGAN-Augment: The MaskCycleGAN-Augment model uses the base architecture and framework followed by MaskCycleGAN-VC [20]. MaskCycleGAN-VC uses MelGAN [22] for the conversion between audio files and spectrograms. This approach, however, does not work well for our use case of converting clean speech to noisy speech. In particular, upon conversion of a noisy spectrogram to an audio clip, MelGAN performs poorly and outputs unintelligible clips. The reason for this behavior is that MelGAN is not explicitly designed to work with noisy spectrograms or noisy audio clips and, consequently, does not work well in our use case, which involves noisy audio clips and spectrograms. As a remedy to this issue, MaskCycleGAN-Augment uses the audio processing pipeline described in subsection II-A.

3) SimuGAN: SimuGAN [15] tackles the problem of non-parallel translation and does not use cycle consistency loss [16]. Instead, it promotes content preservation by encouraging the model to generate outputs such that the corresponding patches in the input and output spectrograms have more similar latent representations than the non-corresponding patches using a patchNCE loss [17].

4) Speech2Speech-Augment: Speech2Speech-Augment uses the base architecture of the Pix2Pix [23] model, which was designed for parallel image translation. It uses the adversarial loss [21] along with an L1 loss to encourage the model to produce outputs close to the expected targets.

III. Experiments and Results

A. Datasets

In order to study the potency and performance of GANs in simulating a wide range of noises, we select noises from 4 different categories. These include Ultra-High-Frequency/Very-High-Frequency (UHF/VHF) noise represented by the RATS dataset [24], additive stationary and non-stationary noises represented by the cabin and helicopter noises from the TIMIT dataset [25], respectively, and codec distortion generated using codec2 [26]. The RATS dataset consists of clean and noisy speech. The TIMIT dataset, however, consists of clean clips along with clips of pure noise. We use the method described in [27] to generate noisy speech clips using clean clips and

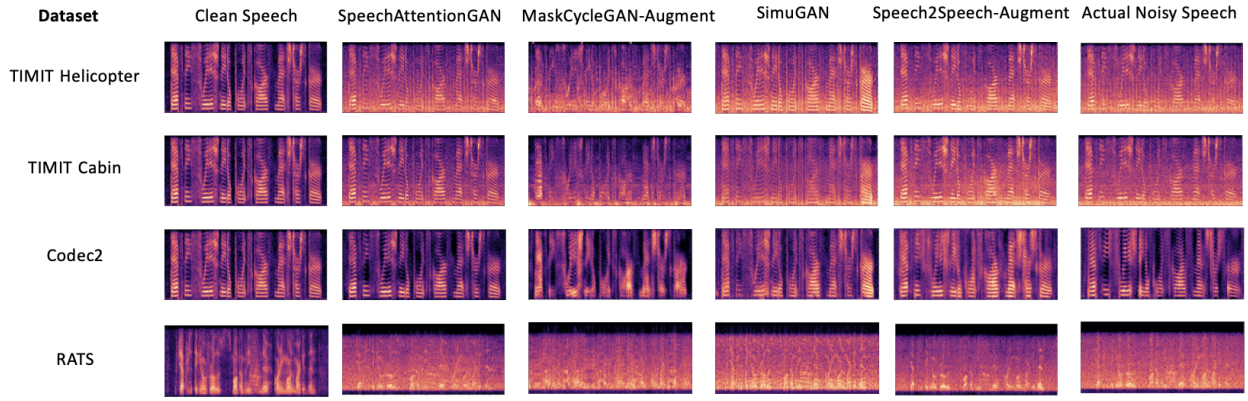

Fig. 3. Generated Samples. This figure shows the noisy spectrogram samples generated by the four models for each of the four noise types. It also shows the clean and actual noisy spectrogram samples from the four datasets.

noise clips. Similarly, we use the clean clips from the TIMIT dataset and pass them through the codec to get noisy speech clips with codec distortion. All datasets used are in the English language.

We prepare both parallel and non-parallel training sets for each type of noise. The training sets for all types of noises include approximately 3 minutes each of noisy and clean audio clips. The validation and test sets, respectively, contain approximately 100 and 200 seconds each of clean and noisy audio clips.

Furthermore, for the TIMIT stationary and non-stationary datasets, as well as the codec2 dataset, we ensured that there were no common speakers between any two of the three splits.

B. Experimental Setup

During training, model checkpoints are saved once every fixed number of epochs. In the validation phase, the validation set is used to evaluate model performance at different checkpoints. The model checkpoint with the best performance on the validation set is picked and used to generate simulations on the test set.

Furthermore, as a second mode of evaluation, we also calculate performance metrics across all checkpoints to compute the average performance of the model when we do not have a parallel validation dataset to pick the best checkpoint.

We use the augmentation technique of aggregating noise and adding it to the clean speech, then passing it through a codec (g726[28]) to introduce distortions as a baseline.

Generated samples from experiments can be heard at this website [1]. The codebase for training and testing the GANs can be found at this online repository[2].

C. Metrics Used

To measure model performance, we use the metrics Log Spectral Distance (LSD) [29] and Multi-Scale Spectral Loss (MSSL)[13]. Both of these metrics measure the distance or dissimilarity between the generated output and the target output, which implies that the lower the value of these metrics, the better the quality of the generated output. Prior to metric computation, the ground truth and generated audio clips go through normalization, energy equalization, and time alignment.

$$LSD = \frac{1}{L}\sum_{l=0}^{L-1}\sqrt{\frac{1}{N}\sum_{k=0}^{N-1}[10\log_{10}\frac{|\hat{\chi}(l,k)|^2}{|\chi(l,k)|^2}]^2} \quad (2)$$

The computation of LSD is described in (2), where l denotes the frame index, k denotes the index of the frequency bin, L is the total number of frames, and N is the total number of frequency bins. $\chi(l,k)$ and $\chi(\hat{l},k)$ denote the Discrete Fourier Transform (DFT) coefficients for the ground truth and generated audio clips, respectively, at the lth frame and kth frequency bin.

MSSL provides the benefit of averaging the distance between the spectrograms computed using multiple window sizes during STFT. A lower window size results in spectrograms with higher resolution in the time domain but lower resolution in the frequency domain. On the other hand, a higher window size results in spectrograms with higher resolution along the frequency domain but a lower resolution along the time domain. MSSL helps to average out this trade-off to an extent by taking into account multiple window sizes.

D. Result Analysis

The metrics computed for the test set using the GAN model checkpoints with the best validation MSSL are shown in Table I. The average of metrics for the validation set computed across all the checkpoints of the GANs is shown in Table II. Sample spectrograms from the experiments are depicted in figure 3

1) RATS Dataset (UHF/VHF): For the RATS dataset, we find that SimuGAN outperforms the other models when we pick the best checkpoint using a validation set. It outperforms the baseline by 49.3% and 55.8% with respect to LSD and MSSL, respectively. However, on computing the average of

TABLE I
RESULTS USING THE VALIDATION SET TO PICK THE BEST CHECKPOINT. LSD STANDS FOR LOG SPECTRAL DISTANCE, AND MSSL STANDS FOR MULTI-SCALE SPECTRAL LOSS. CABIN AND HELICOPTER CORRESPOND TO NOISE TYPES FROM THE TIMIT DATASET.

Dataset	Model	Mean LSD	Mean MSSL	Mode
RATS	SpeechAttentionGAN	7.29	5.98	Non Parallel
	MaskCycleGAN-Augment	7.24	6.10	Non Parallel
	SimuGAN	**6.23**	**5.26**	Non Parallel
	Speech2Speech-Augment	7.02	5.83	Parallel
	Baseline	12.29	11.91	-
Cabin	SpeechAttentionGAN	6.35	4.92	Non Parallel
	MaskCycleGAN-Augment	7.56	6.12	Non Parallel
	SimuGAN	**5.48**	4.84	Non Parallel
	Speech2Speech-Augment	5.95	**4.69**	Parallel
	Baseline	7.70	6.60	-
Helicopter	SpeechAttentionGAN	7.16	**5.32**	Non Parallel
	MaskCycleGAN-Augment	8.50	6.48	Non Parallel
	SimuGAN	**6.98**	5.61	Non Parallel
	Speech2Speech-Augment	7.17	5.39	Parallel
	Baseline	8.53	6.90	-
Codec2	SpeechAttentionGAN	**6.18**	6.78	Non Parallel
	MaskCycleGAN-Augment	8.09	7.54	Non Parallel
	SimuGAN	6.28	7.04	Non Parallel
	Speech2Speech-Augment	6.55	**6.58**	Parallel

metrics across all checkpoints, we find that Speech2Speech-Augment has the best results with an improvement of 43.5% and 50.5% as compared to the baseline in terms of LSD and MSSL, respectively.

2) TIMIT Cabin Noise (Stationary Additive): In Table I, in terms of LSD, SimuGAN gives the best performance with an improvement of 28.8% as compared to the baseline. Speech2Speech-Augment performs the best in terms of MSSL, with an improvement of 28.9% with respect to the baseline. Using the second mode of evaluation as shown in Table II, we find that Speech2Speech-Augment gives the best performance in terms of both LSD and MSSL with improvements of 17.1% and 21.2% respectively, as compared to the baseline.

3) TIMIT Helicopter Noise (Non-Stationary Additive): Using the validation set, we find that SimuGAN outperforms other techniques in terms of LSD with an improvement of 18.1% over the baseline. SpeechAttentionGAN performs the best in terms of MSSL, with an improvement of 22.8% with respect to the baseline when we use the same evaluation metric. Using the average across checkpoints, we find that Speech2Speech-Augment outperforms the other models in terms of both LSD and MSSL with improvements of 11.7% and 16.9%, respectively, over the baseline.

4) Codec2: For Codec2 distortions, we find that SpeechAttentionGAN gives the most desirable LSD in both evaluation modes. Speech2Speech-Augment gives the most desirable MSSL in both modes.

E. Limitations

This work has two main limitations that can be explored and worked upon in future research. Firstly, we do not study how the performance of GANs varies across different languages, accent variations, age groups, and genders. Secondly, we only generate the magnitude spectrogram using GANs and recycle the phase spectrogram from the clean speech. Using GANs or other models to simulate the phase spectrogram would be a promising exploration avenue to improve simulation performance further.

IV. CONCLUSIONS

We perform a detailed study of the use of GANs in simulating different varieties of noises, including UHF/VHF, Additive Stationary and Non-Stationary, and Codec distortion. Through the study, we demonstrate that different types of GANs can be successfully used for noise simulation and that the performance of these GANs varies depending on the noise types. In addition, we show that GANs can be used for noise simulation even with small training datasets of the magnitude of 3 minutes. We also find that GANs give significant improvements over the baseline technique of using aggregated noise followed by codec (g726) distortion. We explore both parallel and non-parallel translation to evaluate the capacity of GANs in both modes of translation. These results would, in turn, help train more robust models for downstream processes. Finally, we document the performance of the various GANs on different datasets in terms of LSD and MSSL, which would help provide a framework to pick the right type of GAN for the desired task.

Step Size Control of Shared-error Normalized Least Mean Square Algorithm for Acoustic Echo and Noise Canceller

Kenta Iwai* and Takanobu Nishiura*
* Ritsumeikan University, Japan
E-mail: {iwai18sp@fc}{nishiura@is}.ritsumei.ac.jp

***Abstract*—We propose a step size control method for an acoustic echo and noise canceller (AENC) based on a shared-error normalized least mean square (SENLMS) algorithm. The conventional AENC based on the SENLMS algorithm can optimize both the acoustic echo canceller (AEC) and the adaptive noise canceller (ANC). However, it is difficult to set the step size parameters to prevent the divergence of the conventional AENC because of the optimization of both AEC and ANC. To solve this problem, we investigate the constraint for the step size parameters of the AENC with the SENLMS algorithm and propose a step size control method. The constraint for the step size parameters is derived from the mean square value of the *a posteriori* error. Then, the step size parameter of the AEC is determined by the nonparametric variable step size (VSS) NLMS algorithm. Finally, the step size parameter of the ANC is automatically determined by the constraint and the variable step size parameter of the AEC. Simulation results show that the proposed AENC with the VSS-SENLMS algorithm can simultaneously prevent the divergence and maintain its the capability to reduce background noise and acoustic echo.**

I. Introduction

Hands-free telecommunication and video conference systems have developed significantly in recent years [1], [2]. Although the World Health Organization (WHO) had declared that Coronavirus disease (COVID-19) no longer represents a global health emergency [3], video conference systems continue to be used in many situations. The problems plaguing these systems are disturbance caused by acoustic echo and background noise. An acoustic echo is generated by acoustic coupling between a loudspeaker and a microphone. Telecommunication systems also suffer from the noise problem. To solve these problems, acoustic echo and noise cancellers (AENCs) have been developed [4]–[8]. An AENC [4]–[7] mainly consists of an acoustic echo canceller (AEC) and a noise suppressor.

We have proposed the AENC based on a shared-error normalized least mean square (SENLMS) algorithm [9]. This AENC consists of an AEC and Widrow's adaptive noise canceller (ANC) [10] with time-domain adaptive digital filters and can optimize both the AEC and ANC by the SENLMS algorithm. However, it is difficult to set the step size parameters to prevent the divergence of the conventional AENC because of the optimization of both AEC and ANC.

In this study, we investigate the constraint for the step size parameters of the AENC with the SENLMS algorithm and propose a step size control method. The constraint for the step size parameters is derived from the mean square value of the *a posteriori* error. Then, the control method for the step size parameters are derived on the basis of the constraint. The capability to reduce the acoustic echo and background noise is evaluated by computer simulations.

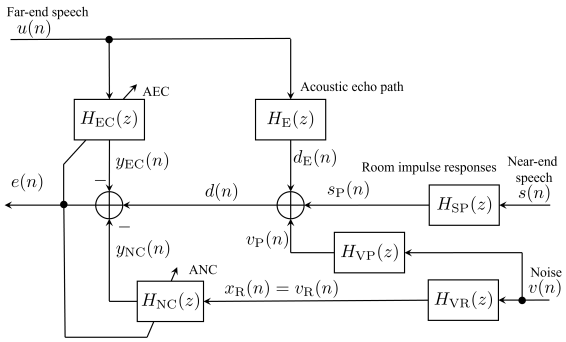

Fig. 1: Block diagram of AENC with shared-error NLMS (SENLMS) algorithm.

II. AENC with SENLMS algorithm [9]

This AENC utilizes a SENLMS algorithm that updates the coefficients of two adaptive filters for echo cancelling and noise reduction by using a shared error signal. The block diagram of the AENC utilizing the SENLMS algorithm is shown in Fig. 1. As shown in Fig. 1, the AENC with the SENLMS algorithm combines the AEC with the time-domain adaptive filter and Widrow's ANC [10]. With this structure, the AENC with the SENLMS algorithm can optimize the adaptive filters for the ANC and AEC simultaneously.

When the ANC and AEC are connected in parallel, their output signals interfere with each other; hence, their error signals become the same. Here, the error signals of the ANC and AEC are expressed as

$$e_{\mathrm{NC}}(n) = v_{\mathrm{P}}(n) - y_{\mathrm{NC}}(n) + d_{\mathrm{E}}(n) - y_{\mathrm{EC}}(n) + s_{\mathrm{P}}(n), \quad (1)$$

$$e_{\mathrm{EC}}(n) = d_{\mathrm{E}}(n) - y_{\mathrm{EC}}(n) + v_{\mathrm{P}}(n) - y_{\mathrm{NC}}(n) + s_{\mathrm{P}}(n), \quad (2)$$

where $v_{\mathrm{P}}(n)$, $d_{\mathrm{E}}(n)$, and $s_{\mathrm{P}}(n)$ are the background noise, acoustic echo, and near-end speech, and $y_{\mathrm{NC}}(n) = \mathbf{h}_{\mathrm{NC}}^{\mathrm{T}}(n)\mathbf{x}_{\mathrm{R}}(n)$ and $y_{\mathrm{EC}}(n) = \mathbf{h}_{\mathrm{EC}}^{\mathrm{T}}(n)\mathbf{u}(n)$ are the output signals of the ANC and AEC, respectively. Also, $\mathbf{h}_{\mathrm{NC}}(n)$ and $\mathbf{h}_{\mathrm{EC}}(n)$ are the filter coefficient vectors of the ANC and AEC,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

$\mathbf{x}_{\mathrm{R}}(n)$ and $\mathbf{u}(n)$ are the input signal vectors of the ANC and AEC, respectively. As can be seen from (1) and (2), the error signals $e_{\mathrm{NC}}(n)$ and $e_{\mathrm{EC}}(n)$ are the same. In Fig. 1, $d_{\mathrm{E}}(n)$ is disturbance for the ANC. In the case that the AEC converges to the optimal filter, the output of the AEC becomes

$$y_{\mathrm{EC}}(n) \approx d_{\mathrm{E}}(n). \tag{3}$$

Then, $d_{\mathrm{E}}(n)$ is cancelled by $y_{\mathrm{EC}}(n)$ and the error signal of the ANC becomes

$$e_{\mathrm{NC}}(n) \approx v_{\mathrm{P}}(n) - y_{\mathrm{NC}}(n) + s_{\mathrm{P}}(n). \tag{4}$$

Equation (4) is the ideal condition of the ANC. Similarly, $v_{\mathrm{P}}(n)$ is the disturbance for the AEC. In the case that the ANC converges to the optimal filter, the output of the ANC becomes

$$y_{\mathrm{NC}}(n) \approx v_{\mathrm{P}}(n). \tag{5}$$

Then, $v_{\mathrm{P}}(n)$ is cancelled by $y_{\mathrm{NC}}(n)$ and the error signal of the AEC becomes

$$e_{\mathrm{EC}}(n) \approx d_{\mathrm{E}}(n) - y_{\mathrm{EC}}(n) + s_{\mathrm{P}}(n). \tag{6}$$

Equation (6) is the ideal condition of the AEC. Thus, the AENC with the SENLMS algorithm realizes the optimal conditions of ANC and AEC simultaneously.

The adaptive filters of the ANC and AEC are updated by a normalized least mean square (NLMS) algorithm [11]–[13] combined with the shared error signal $e(n)$. The cost functions of the ANC and AEC are defined as

$$J_{\mathrm{NC}}(n) = e^2(n)/\|\mathbf{x}_{\mathrm{R}}(n)\|^2, \tag{7}$$
$$J_{\mathrm{EC}}(n) = e^2(n)/\|\mathbf{u}(n)\|^2, \tag{8}$$

where $e(n) = e_{\mathrm{NC}}(n) = e_{\mathrm{EC}}(n)$ is the shared error signal and $\|\cdot\|$ represents the norm of the vector. By partial differentiation of $J_{\mathrm{NC}}(n)$ and $J_{\mathrm{EC}}(n)$ with respect to $\mathbf{h}_{\mathrm{NC}}^{\mathrm{T}}(n)$ and $\mathbf{h}_{\mathrm{EC}}^{\mathrm{T}}(n)$, we can obtain the update rules of the ANC and AEC as

$$\mathbf{h}_{\mathrm{NC}}(n+1) = \mathbf{h}_{\mathrm{NC}}(n) + \alpha_{\mathrm{NC}} \frac{e(n)\mathbf{x}_{\mathrm{R}}(n)}{\|\mathbf{x}_{\mathrm{R}}(n)\|^2 + \beta_{\mathrm{NC}}}, \tag{9}$$
$$\mathbf{h}_{\mathrm{EC}}(n+1) = \mathbf{h}_{\mathrm{EC}}(n) + \alpha_{\mathrm{EC}} \frac{e(n)\mathbf{u}(n)}{\|\mathbf{u}(n)\|^2 + \beta_{\mathrm{EC}}}, \tag{10}$$

where α_{NC} and α_{EC} are the step size parameters of the ANC and AEC, and β_{NC} and β_{EC} are the regularization parameters of the ANC and AEC, respectively.

However, it is difficult to set the step size parameters to prevent the divergence of the conventional AENC because of the joint optimization of the ANC and AEC. Hence, we investigate the constraint for the step size parameters and propose the control method for the step size parameters.

III. Step size control of SENLMS algorithm

As mentioned in Sect. II, the AENC with the SENLMS algorithm has the problem of divergence depending on the fixed step size parameters. In this section, we investigate the constraint for the step size parameters and propose the control method for the step size parameters.

A. A posteriori error of SENLMS algorithm

In [14], a nonparametric VSS-NLMS (NP-VSS-NLMS) algorithm is derived via a mean square value of the *a posteriori* error signal of an adaptive digital filter. We investigate the constraint for the step size parameters on the basis of this idea. Firstly, the *a posteriori* error signal of the AENC with the SENLMS algorithm is represented by

$$\begin{aligned}\varepsilon(n) = {} & v_{\mathrm{P}}(n) - \mathbf{h}_{\mathrm{NC}}^{\mathrm{T}}(n+1)\mathbf{x}_{\mathrm{R}}(n) \\ & + d_{\mathrm{E}}(n) - \mathbf{h}_{\mathrm{EC}}^{\mathrm{T}}(n+1)\mathbf{u}(n) + s_{\mathrm{P}}(n).\end{aligned} \tag{11}$$

Here, we modify the update equations (9) and (10) as

$$\mathbf{h}_{\mathrm{NC}}(n+1) = \mathbf{h}_{\mathrm{NC}}(n) + \alpha_{\mathrm{NC}}(n)e(n)\mathbf{x}_{\mathrm{R}}(n), \tag{12}$$
$$\mathbf{h}_{\mathrm{EC}}(n+1) = \mathbf{h}_{\mathrm{EC}}(n) + \alpha_{\mathrm{EC}}(n)e(n)\mathbf{u}(n), \tag{13}$$

where $\alpha_{\mathrm{NC}}(n)$ and $\alpha_{\mathrm{EC}}(n)$ are the variable step size parameters of the ANC and AEC, respectively. From (11)–(13) the mean square value of (11) is represented by

$$\mathbb{E}\left[\varepsilon^2(n)\right] = \sigma_e^2(n)\left[1 - \|\mathbf{x}_{\mathrm{R}}(n)\|^2\alpha_{\mathrm{NC}}(n) - \|\mathbf{u}(n)\|^2\alpha_{\mathrm{EC}}(n)\right]^2, \tag{14}$$

where $\sigma_e^2(n) = \mathbb{E}\left[e^2(n)\right]$. Here, $\|\mathbf{x}_{\mathrm{R}}(n)\|^2$ and $\|\mathbf{u}(n)\|^2$ are treated as constants. Since the *a posteriori* error is obtained using $\mathbf{h}_{\mathrm{NC}}(n+1)$ and $\mathbf{h}_{\mathrm{EC}}(n+1)$, then $\mathbb{E}\left[\varepsilon^2(n)\right] = \mathbb{E}\left[s_{\mathrm{P}}^2(n)\right] = \sigma_s^2(n)$. Hence, the constraint of the variable step size parameters are derived as

$$\|\mathbf{x}_{\mathrm{R}}(n)\|^2\alpha_{\mathrm{NC}}(n) + \|\mathbf{u}(n)\|^2\alpha_{\mathrm{EC}}(n) = 1 - \sqrt{\frac{\sigma_s^2(n)}{\sigma_e^2(n)}}. \tag{15}$$

Here, the LHS of (15) is a function of $\alpha_{\mathrm{NC}}(n)$ and $\alpha_{\mathrm{EC}}(n)$. Therefore, (15) cannot be solved for $\alpha_{\mathrm{NC}}(n)$ and $\alpha_{\mathrm{EC}}(n)$. In this proposed method, we should firstly determine $\alpha_{\mathrm{NC}}(n)$ or $\alpha_{\mathrm{EC}}(n)$ before adopting (15).

B. Step size control of SENLMS algorithm

We utilize the NP-VSS-NLMS algorithm [14] to determine one of the variable step size parameters in the VSS-SENLMS algorithm. In this work, we apply the NP-VSS-NLMS algorithm to the update equation of the AEC (13). The update equation is modified as [1]

$$\alpha_{\mathrm{EC}}(n) = \frac{\alpha_{\mathrm{VSS,EC}}(n)}{\|\mathbf{u}(n)\|^2} = \frac{1}{\|\mathbf{u}(n)\|^2}\left[1 - \sqrt{\frac{\sigma_{v,\mathrm{EC}}^2(n)}{\sigma_e^2(n)}}\right], \tag{16}$$

where $\sigma_{v,\mathrm{EC}}^2(n) = \mathbb{E}\left[\{v_{\mathrm{P}}(n) - y_{\mathrm{NC}}(n) + s_{\mathrm{P}}(n)\}^2\right]$. From (15) and (16), the variable step size parameter of the ANC $\alpha_{\mathrm{NC}}(n)$ is automatically determined as

$$\alpha_{\mathrm{NC}}(n) = \frac{1}{\|\mathbf{x}_{\mathrm{R}}(n)\|^2}\left[1 - \sqrt{\frac{\sigma_s^2(n)}{\sigma_e^2(n)}} - \alpha_{\mathrm{VSS,EC}}(n)\right]. \tag{17}$$

[1] Considering only the AEC, $v_{\mathrm{P}}(n)$, $y_{\mathrm{NC}}(n)$, and $s_{\mathrm{P}}(n)$ are disturbances of the AEC.

As can be seen from (16) and (17), we should estimate the variances $\sigma_e^2(n)$, $\sigma_s^2(n)$, and $\sigma_{v,\mathrm{EC}}^2(n)$. $\sigma_e^2(n)$ is estimated in [14] as

$$\sigma_e^2(n) = \lambda\sigma_e^2(n-1) + (1-\lambda)\, e^2(n), \tag{18}$$

where λ is a small constant for averaging. Since $s_{\mathrm{P}}(n)$ and $v_{\mathrm{EC}}(n) = v_{\mathrm{P}}(n) - y_{\mathrm{NC}}(n) + s_{\mathrm{P}}(n)$ cannot be obtained directly, $\sigma_s^2(n)$ and $\sigma_{v,\mathrm{EC}}^2(n)$ are estimated in [15] as

$$\sigma_s^2(n) = \sigma_e^2(n) - \frac{\|\mathbf{r}_{eu}(n)\|^2}{\sigma_u^2(n)} - \frac{\|\mathbf{r}_{ex}(n)\|^2}{\sigma_x^2(n)}, \tag{19}$$

$$\sigma_{v,\mathrm{EC}}^2(n) = \sigma_e^2(n) - \frac{\|\mathbf{r}_{eu}(n)\|^2}{\sigma_u^2(n)}, \tag{20}$$

$$\sigma_x^2(n) = \lambda\sigma_x^2(n-1) + (1-\lambda)\, x_{\mathrm{R}}^2(n), \tag{21}$$

$$\sigma_u^2(n) = \lambda\sigma_u^2(n-1) + (1-\lambda)\, u^2(n), \tag{22}$$

$$\mathbf{r}_{eu}(n) = \lambda\mathbf{r}_{eu}(n-1) + (1-\lambda)\, e(n)\mathbf{u}(n), \tag{23}$$

$$\mathbf{r}_{ex}(n) = \lambda\mathbf{r}_{ex}(n-1) + (1-\lambda)\, e(n)\mathbf{x}_{\mathrm{R}}(n). \tag{24}$$

IV. Simulation results

We conducted computer simulations to evaluate the capability of the proposed AENC to utilize the variable step size parameters. The proposed AENC was compared with the conventional AENC [9]. In the simulation, the room impulse responses (RIRs) generated by the RIR simulator [16] were used. Here, the near-end speech was neglected because the objective of the simulation was to evaluate the capability of the proposed AENC to reduce acoustic echo and noise. This is equivalent to neglecting the double-talk condition. The RIRs were generated under the arrangement shown in Fig. 2. The generated RIRs are shown in Fig. 3. The ratio of the direct component to reverberant components, that is, the direct-to-reverberant ratio (DRR) [17], was about 26 dB in Fig. 3 (a).

The simulation conditions are shown in Table I. In the simulations, for the conventional AENC, the step size parameters for the ANC and AEC $(\alpha_{\mathrm{NC}}, \alpha_{\mathrm{EC}})$ were set to $(0.07, 0.03)$ and $(0.09, 0.09)$, which are hereafter referred to as "pattern 1" and "pattern 2," respectively. The averaging factor λ for the proposed AENC was set to $1 - 1/50N$, where N is the tap length of the adaptive digital filter. The capability to reduce acoustic echo and noise was respectively evaluated by echo return loss enhancement (ERLE) and reduction defined as

$$\mathrm{ERLE}(n) = 10\log_{10}\left[\frac{\sum_{i=0}^{N-1} d_{\mathrm{E}}^2(n-i)}{\sum_{i=0}^{N-1}\left\{d_{\mathrm{E}}(n-i) - y_{\mathrm{EC}}(n-i)\right\}^2}\right], \tag{25}$$

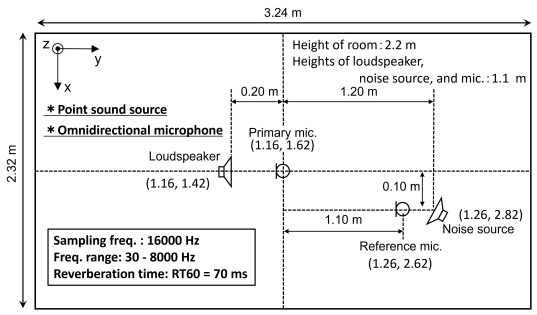
$$\mathrm{Re}(n) = 10\log_{10}\left[\frac{\sum_{i=0}^{N-1} v_{\mathrm{P}}^2(n-i)}{\sum_{i=0}^{N-1}\left\{v_{\mathrm{P}}(n-i) - y_{\mathrm{NC}}(n-i)\right\}^2}\right]. \tag{26}$$

In the simulation, (25) and (26) were calculated every $N = 1024$ samples. The time waveforms of the acoustic echo and background noise are shown in Fig. 4.

The time waveforms of the observed and error signals are shown in Fig. 5. As seen in Fig. 5, the proposed AENC prevents the divergence and maintains almost the same capability to reduce the background noise and acoustic echo. On the other hand, the conventional AENC with pattern 2 diverges after 25 s. This is because the step size parameters are too large to prevent the divergence.

TABLE I: Simulation conditions.

Far-end speech	Female speech (F1, Aesop)[18]
Background noise	Office noise [19]
Signal-to-noise ratio (SNR)	-5 dB
Sampling frequency	16 kHz
Tap length of each path	1024
Tap length of ADF of ANC	1024
Tap length of ADF of AEC	1024
Regularization parameter	1.0×10^{-6}



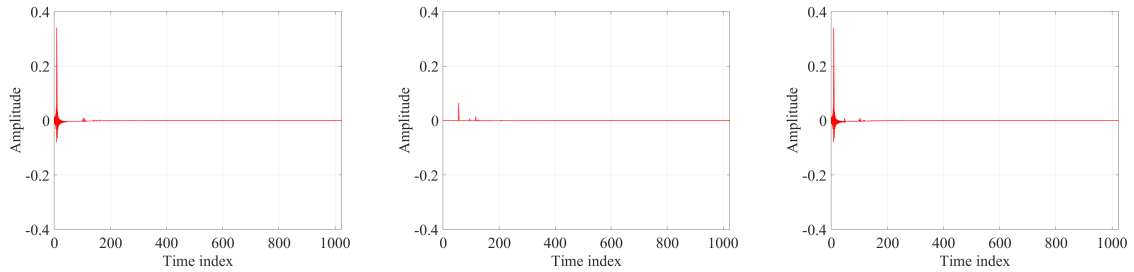


Fig. 2: Arrangement for RIR generation.

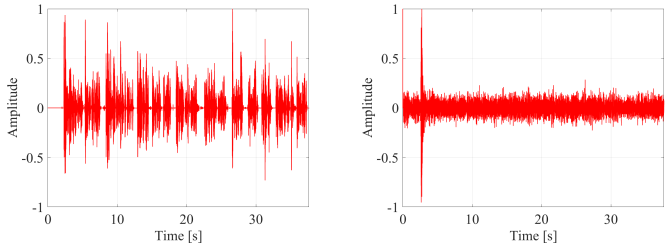
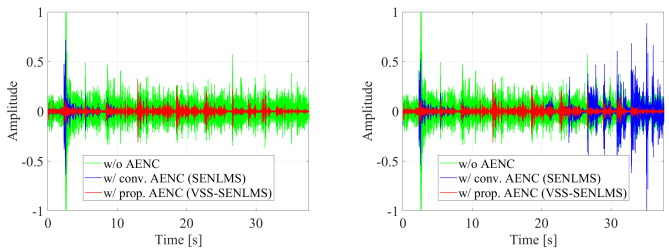


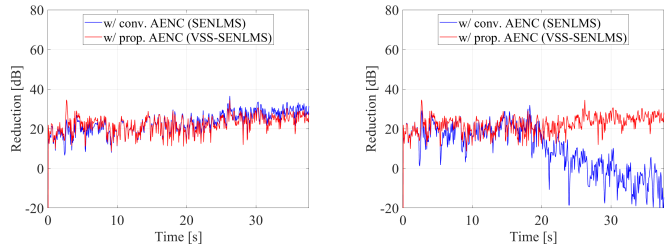
The amounts of noise reduction and ERLE are shown in Figs. 6 and 7. From Fig. 6, the proposed AENC is seen to reduce the background noise by about 25 dB when the conventional AENC with pattern 1 reduces the noise by about 28 dB. Moreover, from Fig. 7, the proposed AENC reduces the acoustic echo by about 13 dB when the conventional AENC with pattern 1 reduces the noise by about 20 dB. This is because the proposed AENC uses the estimates of each variance obtained using (18)–(24). These results can be explained by the dynamics of the variable step size parameters as shown in Fig. 8.

In Fig. 8(a), the variable step size parameter of ANC becomes a small value of about 5×10^{-3}, which leads to the prevention of the divergence of the AENC. Moreover, from Fig. 8(b), the variable step size parameter of AEC is a value of around 1×10^{-1}, which enables adaptation to the rapid fluctuations of acoustic echo. Thus, two variable step size parameters are adjusted to adequate values to a certain extent. On the other hand, the variable step sizes are smaller than those of the conventional AENC with pattern 1. This leads to small amounts of reduction of the background noise and acoustic echo. This is because the variances of each signal are estimated using (18)–(24) when the variable step size parameters are calculated. In this simulation, the office noise and speech signal are used, which are nonstationary signals. Hence, the variances obtained by the averaging process are not adequate for the variable step size parameters. Also, after 3 s, the variable step size for the ANC (17) is less than 1.0×10^{-2} while that for the AEC (16) is approximately 1.0×10^{-1}. This is because $\alpha_{\mathrm{VSS,NC}}(n) = 1 - \alpha_{\mathrm{VSS,EC}}(n)$ in a single-talk condition, and $\alpha_{\mathrm{VSS,NC}}(n) < \alpha_{\mathrm{VSS,EC}}(n)$ when



(a) Echo path (b) Noise path (primary microphone) (c) Noise path (reference microphone)

Fig. 3: Impulse responses of each path.



(a) Acoustic echo (b) Background noise

Fig. 4: Time waveforms of acoustic echo and background noise.

(a) Pattern 1 (b) Pattern 2

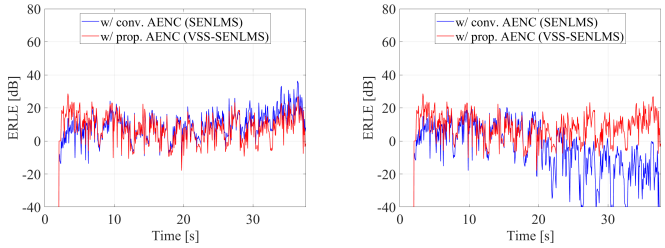


Fig. 5: Time waveforms of observed signals and outputs of AENCs .

(a) Pattern 1 (b) Pattern 2

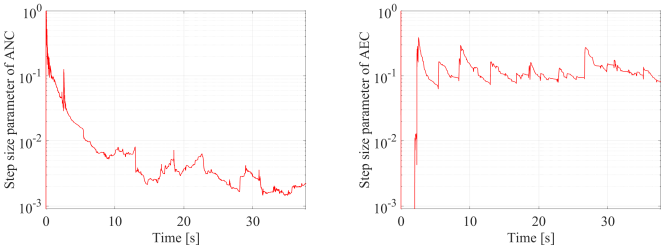

Fig. 6: Amount of noise reduction.

$\alpha_{\mathrm{VSS,NC}}(n)$ is small. However, the proposed AENC achieves almost the same amounts of reduction of the background noise and acoustic echo as the conventional AENC with pattern 1.

(a) Pattern 1 (b) Pattern 2

Fig. 7: Amount of ERLE.

(a) ANC (b) AEC

Fig. 8: Dynamics of variable step size parameters.

From the above results, it can be considered that the proposed AENC is effective in reducing both the acoustic echo and the background noise and preventing the divergence.

V. Conclusion

In this paper, we investigated the constraint for the step size parameters of the AENC with the SENLMS algorithm and proposed a step size control method. Simulation results showed that the proposed AENC with the VSS-SENLMS algorithm can simultaneously prevent the divergence and maintain its capability to reduce background noise and acoustic echo. In the future, we will investigate the step size control scheme for the double-talk condition and improve the accuracy of the estimation method for the variances for each signal.

***Abstract*—It is challenging to deploy Transformer-based audio classification models on common terminal devices in real situations due to their high computational costs, increasing the importance of transferring knowledge from the larger Transformer-based model to the smaller convolutional neural networks (CNN)-based model via knowledge distillation (KD). Since an audio spectrogram can be regarded as an image, image-based models with CNN-based structures are used as the aforementioned smaller model for KD in several studies. However, the physical meanings of spectrograms differ from that of images in general. This fact possibly leads to the issue that the image-based model may not effectively extract features from a pure spectrogram. Thus, improving the spectrogram can help these models perform better on audio classification tasks. To implement our hypothesis, we propose a new Time-Frequency Enhancer (TFE), which is designed to learn how to enhance input spectrograms to make them effective for audio classification. In addition, we also propose TFE-ENV2, which extends EfficientNetV2 (ENV2), an image-based backbone model. To verify the effectiveness of the proposed method, we compare the performance between the original ENV2 and the proposed TFE-ENV2. In our experiments, the proposed TFE-ENV2 outperformed the original ENV2 on the ESC-50 and Speech Commands V2 datasets, demonstrating that the proposed TFE enhances spectrograms to assist image-based models in audio classification.**

I. Introduction

Audio classification task is aimed at classifying various audios and understanding the acoustic environment [1]. It has been used to assist speech enhancement [2], recognizing speech commands [3], and automatic speech recognition (ASR) [4], etc.

Convolutional Neural Network (CNN)-based models [5] have built-in inductive biases, which enable them to learn from limited audio data with small sizes [6, 7]. Recently, researchers have integrated image-based models with CNN architectures into audio classification tasks, leveraging their superior performance in the image domain to classify the spectrogram, which could be considered as the generalized image. At the same time, although some Transformer-based models [8–10] have shown better performance than CNN recently by incorporating techniques such as attention mechanisms [11], they typically have larger sizes and require higher computational costs, making them impractical for low-resource devices. For more usability on terminal devices in practical circumstances, previous studies have done research to transfer knowledge from larger Transformer-based models to smaller CNN-based models using knowledge distillation (KD) [12].

To enable both parameter/computationally efficiency and a high-performance model for audio classification tasks, this study focuses on training image-based models with CNN architectures via transferring knowledge from a large, high-performance Transformer-based model using KD. Both the Transformer-based model and the image-based model take the spectrogram as input.

Instead of feeding the original spectrogram to image-based models, we think that improving the spectrograms can help these models perform better on audio classification tasks since spectrograms and common images have different physical meanings. Values in spectrograms describe the energy distribution of the audio signal in the time-frequency domain, while images do not have this physical meaning.

To address the issue, we propose a new Time-Frequency Enhancer (TFE) to enhance the features of spectrograms in the time-frequency domain. The TFE consists of several learnable Enhancer Blocks, which are responsible for extracting features and generating a mask used for enhancing the spectrogram. The mask assigns importance weights to the features in the spectrogram, resulting in enhanced spectrograms. The TFE module is trained jointly with the image-based model using KD. While the TFE acts as a front end to provide enhanced spectrograms, the image-based model serves as the backbone. This joint optimization enables them to work together and achieve improved performance in audio classification. The TFE learns to enhance the spectrogram, thereby enhancing the audio classification performance.

Cross-Model Knowledge Distillation (CMKD) method [13] has been proven to be effective for transferring knowledge on audio classification. Besides, the Audio Spectrogram Transformer (AST) model has outstanding performance on audio classification [8] and EfficientNet (EN) models [14, 15] have been proven to perform well on audio classification in previous studies [9, 13]. Among all EN models, EfficientNetV2 (ENV2) [16] has been proven to outperform previous work on the ImageNet [17] dataset. The employment of the Fused-Mobile Convolution (Fused-MBConv) blocks [18] in the early stages of ENV2 can reduce training time and provide better efficiency for image classification tasks. Thus, to further improve the performance of audio classification, we transfer knowledge

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

from an AST model with good performance to the audio classification model with the backbone of ENV2 through CMKD.

The remainder of the paper is organized as follows: Section II provides an overview of the related work in this paper. In Section III, we introduce the proposed method and discuss its architecture. Experimental settings and results are presented in Section IV. Finally, in Section V, we conclude the paper.

II. Related Work

A. Audio Spectrogram Transformer

Audio Spectrogram Transformer (AST) [8] is a Transformer-based model for audio classification tasks that outperformed other CNN-based models at the time. Unlike CNN-based models for audio classification, AST works purely based on the Self-Attention mechanism [19] to capture long-range global information from spectrograms. However, AST is large and needs large-scale datasets for training, which leads to high training costs and high computational complexity. Thus, it is difficult to deploy AST on typical terminal devices in practical settings.

B. EfficientNet Model for Audio Classification

EfficientNet (EN) is a CNN-based model originally proposed for image classification tasks. EN works based on the structure of multiple Mobile Convolution (MBConv) blocks [20]. MBConv is a residual block with Squeeze-and-Excitation (SE) module [21], which is designed to capture channel-wise dependencies and generate importance weights for different channels. Several studies have used AudioSet [22] to pretrain EN to further improve audio classification performance. However, direct pretraining EN on AudioSet is time-consuming and leads to high training costs. Transferring knowledge from pretrained models to EN is important for this reason.

C. Cross-Model Knowledge Distillation

Cross-Model Knowledge Distillation (CMKD) [13] method is aimed at transferring knowledge between audio classification models with different architectures using KD, which is a common method allowing small student models to learn from large teacher models [23]. In the original paper of CMKD, KD is employed to transfer knowledge from a pretrained AST to an EN. It has been demonstrated that EN performs better after learning from pretrained AST. Therefore, CMKD is a practical method to obtain an audio classification model with good performance and a smaller size.

D. Learnable Frontend for Audio Classification

The related work Learnable Frontend (LEAF) [24] for audio classification is designed as a replacement for mel-filterbank. It learns audio feature extraction and converts the audio signal from the time domain into the time-frequency domain. However, due to KD being used for training, the input for the image-based CNN model is expected to be the same as that for the AST model, which is the Log Mel Spectrogram, a typical representation of audio signals in the time-frequency domain. Thus, enhancing the spectrogram in the time-frequency domain is required for image-based models rather than feature extraction from the time domain to the time-frequency domain.

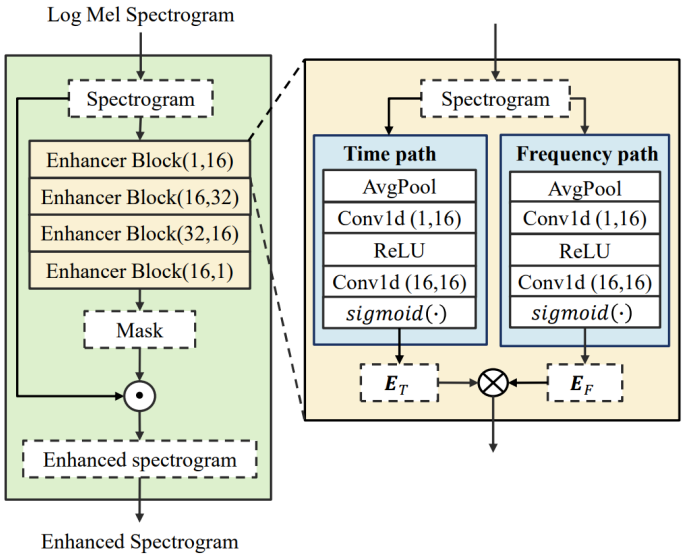

Fig. 1. Illustration for the architecture of the proposed TFE module

III. Proposed Method

We propose a new Time-Frequency Enhancer (TFE), which is intended to enhance the original spectrogram and provide the enhanced spectrogram as input for image-based models. In addition, we propose TFE-ENV2, in which we apply TFE as a front end to ENV2 for audio classification.

A. Time-Frequency Enhancer (TFE)

We propose the TFE module, inspired by Time-Frequency Attention (TFA) [25], which was designed for the speech enhancement task. TFA is a lightweight attention mechanism that provides the mask for the spectrogram in the time-frequency domain. It can be regarded as an Enhancer Block for the spectrogram, which employs two independent feature extractors with the same structures for the time frame path and the frequency bin path in the spectrogram, respectively. Both extractors consist of the average pooling layer (AvgPool), 1D convolution layer (Conv1d), ReLU activation function (ReLU), and Sigmoid activation function ($sigmoid(\cdot)$). In each path, at first, the 2D spectrogram is compressed into a 1D feature map through the average pooling operation. Then the 1D convolution layer is employed to extract features from the 1D feature map. Each extractor outputs an enhanced 1D feature vector. Two 1D vectors from the time path and frequency path would be used to generate a 2D mask for the input spectrogram by matrix multiplication, which can be written as

$$\mathbf{M} = \mathbf{E_T} \otimes \mathbf{E_F}, \tag{1}$$

where $\mathbf{M}$ represents the 2D mask, $\mathbf{E_T}$ represents the enhanced feature vector from the time path, $\mathbf{E_F}$ represents the enhanced

feature vector from the frequency path, and $\otimes$ represents matrix multiplication. The architecture of the Enhancer Block is shown in the yellow block (right) of Fig. 1.

The structure of the proposed TFE module, made up of multiple Enhancer Blocks, is shown in the green block (left) of Fig. 1. In the remaining paper, we use TFE(**n**) to represent the TFE module, which consists of **n** Enhancer Blocks. The TFE module in Fig. 1 includes 4 Enhancer Blocks, denoted as TFE(4). Compared with TFA, which uses only one Enhancer Block for spectrogram enhancement, the proposed TFE(**n**) module works based on **n** Enhancer Blocks to enhance the spectrogram in multiple channels. By deepening the network structure, the proposed TFE(**n**) should learn rich features that enable the model to capture more helpful information from the spectrogram. The TFE(**n**) module takes the original Log Mel Spectrogram as the input and generates the mask through **n** Enhancer Blocks. After that, the mask and input spectrogram are combined into the enhanced spectrogram using the element-wise product, which is expressed as

$$\widetilde{\mathbf{S}} = \mathbf{S} \odot \mathbf{M}, \tag{2}$$

where $\mathbf{S}$ represents the original spectrogram, $\mathbf{M}$ represents obtained mask, $\widetilde{\mathbf{S}}$ represents the enhanced spectrogram, and $\odot$ represents the element-wise product.

The proposed TFE module produces an attention mask to enhance the original spectrogram by multiplying two feature vectors, which are output from the time path and frequency path in the spectrogram, respectively. These two vectors emphasize the important points in these two paths based on the energy distribution of the spectrogram, respectively. As a result, the attention mask is intended to emphasize the important points in the whole spectrogram and provide significance weights for the spectrogram. Thus, as the combination of the attention mask and the original spectrogram, the enhanced spectrogram should provide more helpful features for audio classification.

B. EfficientNetV2 with TFE module (TFE-ENV2)

In this work, we propose a combined structure for audio classification that integrates EfficientNetV2 with the TFE module. This structure, named TFE-ENV2, incorporates the TFE module for spectrogram enhancement and the ENV2 module for classification.

Fig. 2(a) illustrates the architecture of the original ENV2 while Fig. 2(b) illustrates the architecture of the proposed TFE-ENV2. The original ENV2 consists of a 2D convolutional layer (with a kernel size of 3×3), Fused-MBConv blocks, MBConv blocks, and a classifier, which is the same as that employed for image domain [16].

The proposed TFE-ENV2 structure utilizes a Log Mel Spectrogram as input. The TFE module serves as the front end, while the ENV2 module functions as the backbone for audio classification. This combination is chosen based on specific advantages and expected improvements. By incorporating the TFE module, we aim to enhance the feature extraction process, leading to improved classification performance compared to the original ENV2.

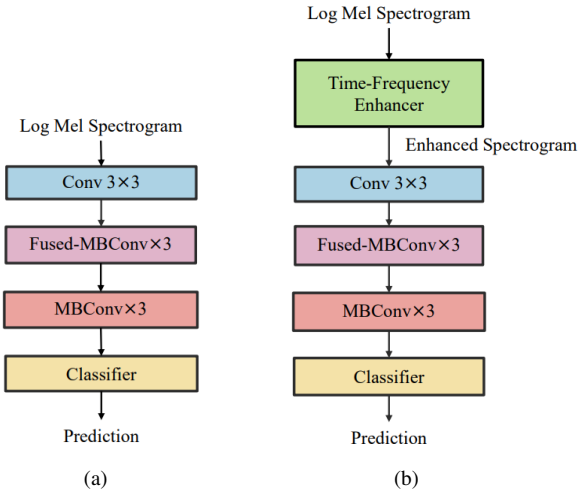

Fig. 2. Illustration for architectures of (a) the original ENV2 and (b) the proposed TFE-ENV2.

IV. Experiment

We validated the proposed method on ESC-50 [26] dataset and Speech Commands V2 [27] dataset.

To enhance audio classification performance, we employed the CMKD method to transfer knowledge from the AST model to the TFE-ENV2. And to ensure consistency in our approach, we reused the experimental settings of CMKD as described in the previous work [13] as shown in Table I.

A. Datasets

The experiments were conducted on two labeled datasets: ESC-50 and Speech Commands V2. The ESC-50 dataset is made up of 2,000 5-second environmental sounds organized into 50 classes. We followed the 5-fold cross-validation and recorded the mean accuracy. The speech Commands V2 dataset contains 105,829 different 1-second recordings divided into 35 classes. It is divided into a training set, a validation set, and an evaluation set, made up of 84,843, 9,981, and 11,005 samples, respectively. We followed the 35-class classification task and recorded the accuracy of the evaluation set.

B. Experimental Setup

To confirm the effectiveness of the proposed TFE, we conducted ablation experiments to compare the original ENV2 with the proposed TFE(**n**)-ENV2. We assessed three TFE models with varying numbers of Enhancer Blocks. **n** was adjusted to 1, 2, and 4 in our experiments. The objective was to evaluate the impact of different TFE configurations. TFE(1)-ENV2 is made up of Enhancer Block(1,1), TFE(2)-ENV2 is made up of Enhancer Block(1,32), and Enhancer Block(32,1). For a fair comparison, all student models were trained with the same training settings and learned from the same AST model. All experiments were repeated 5 times and the mean accuracy was reported.

Model settings: On the ESC-50 dataset, AST, the teacher model, was initialized by the weights pretrained on two

datasets (ImageNet and AudioSet) and then fine-tuned for 5 epochs. While on the Speech Commands V2 dataset, it was only pretrained on ImageNet and also fine-tuned for 5 epochs. Then, the fine-tuned models were used for knowledge distillation. The ENV2 was initialized with weights pretrained on ImageNet, serving as the backbone for audio classification. In contrast, the proposed TFE(**n**) module did not undergo any pretraining.

Data processing and data augmentation: For the ESC-50 dataset, to keep consistency, we followed the same data processing and data augmentation recipes as described in the CMKD method in previous work [13]. The teacher model was fine-tuned with SpecAugment [28] (frequency and time masking). After that, student models were trained using SpecAugment, random time-shift (rolling spectrograms in the time axis), random noise (generating distribution to spectrograms), and label smoothing (smoothing one hot label) [29]. For the Speech Commands V2 dataset, we followed the same data augmentation recipes as those used for the original AST in previous work [8]. The teacher model was trained with SpecAugment and mix-up (randomly mixing up two spectrograms and labels) [30]. After that, student models were trained using the same method. Input for the teacher model and student models were spectrograms with the same data augmentations during training, while there was no data augmentation during testing.

Training settings: All the details for implementation in experiments are shown in Table I. For ESC-50, to keep consistency, student models were trained with the same training settings used for the AST model in previous work [8], except for the initial learning rate, learning scheduler, and epochs. For ESC-50, the learning rate decreased by a factor of 0.85 every 5 epochs. For Speech Commands V2, the learning rate decreased by a factor of 0.85 for every epoch after the first 5 epochs. The Adam optimizer was used for both datasets.

TABLE I
TRAINING SETTINGS ON ESC-50 AND SPEECH COMMANDS V2

Settings	ESC-50	Speech Commands V2
Spectrogram size (Time frames/Frequency bins)	512/128	128/128
Initial learning rate	1e-4	5e-4
Batch size	48	128
Epochs	100	30
Loss for ground truth	Cross Entropy	Brainy Cross Entropy
SpecAugment (Time/Frequency)	(96/24)	(48/48)
Random noise on spectrogram	U(0,0.05)	U(0,0.1)
Random time-shift	±10 time frames	±10 time frames
Mix-up ratio	0	0.6
Label smoothing factor	0.1	0

Knowledge distillation: Distillation loss used in training can be written as

$$\mathcal{L} = \lambda \mathcal{L}_g(\delta(Z_S), y) + (1-\lambda)\mathcal{L}_d(\delta(Z_S), \delta(Z_T/\tau)), \quad (3)$$

where Z_S and Z_T present the logits from the student model and teacher model, respectively. $\mathcal{L}_g$ and $\mathcal{L}_d$ are losses for ground truth and distillation, respectively. y represents ground-truth labels. λ represents the balancing coefficient. δ is the activation function. τ is KD temperature. Cross-entropy (CE) loss and Kullback-Leibler divergence loss were used for $\mathcal{L}_g$ and $\mathcal{L}_d$, respectively. We fixed balancing coefficient $\lambda = 0.5$ and KD temperature $\tau = 5$. Soft-max was used as the activation function δ.

C. Results

TABLE II
RESULTS FOR ABLATION EXPERIMENTS ON THREE TFE-ENV2 MODELS

Model Name	Parameters	Accuracy	
		ESC-50	Speech Commands V2
TFE(1)-ENV2	8.75M	89.42% (±0.43)	97.78% (±0.04)
TFE(2)-ENV2	8.77M	89.23% (±0.27)	97.79% (±0.09)
TFE(4)-ENV2	8.82M	**89.67%** (±0.46)	**97.85%** (±0.04)

Table II shows the results of ablation experiments for TFE(**n**)-ENV2 models. According to results in Table II, for the Speech Commands V2 dataset, the accuracy increased as the number of Enhancer Blocks in TFE(**n**)-ENV2 increased. Compared with TFE(1)-ENV2, the accuracy of TFE(**n**)-ENV2 increased by 0.01% and 0.07% when **n** is set to 2 and 4, respectively. While for ESC-50, TFE(1)-ENV2 performed better than TFE(2)-ENV2. One possible reason might be that there was no pretraining for the TFE(**n**) module, so the increasing number of Enhancer Blocks caused the increase in unpretrained parameters, which need more data for training. As a result, TFE(**n**)-ENV2 models might overfit on the ESC-50 dataset, which has a smaller data size than Speech Commands V2. Thus, we believe that the trend of the accuracy of TFE(**n**)-ENV2 on the Speech Commands V2 is more deserving of reference.

TABLE III
COMPARISONS FOR THE PERFORMANCE BETWEEN AST, ENV2, AND THE BEST TFE-ENV2

Model Name	Parameters	Accuracy	
		ESC-50	Speech Commands V2
AST	85.70M	95.85%	97.46%
ENV2	8.74M	88.63% (±0.34)	97.74% (±0.07)
TFE(4)-ENV2	8.82M	**89.67%** (±0.46)	**97.85%** (±0.04)

Table III shows the comparison of the performance of AST, ENV2, and the best TFE-ENV2. According to the results, the accuracy of TFE(4)-ENV2, which is the best of all, increased by 1.04% and 0.11% compared with the original ENV2 on ESC-50 dataset and Speech Commands V2 dataset, respectively. Besides, all the proposed TFE(**n**)-ENV2 models outperformed the original ENV2 model. What's more, on Speech Commands V2, the accuracy of TFE(4)-ENV2 got almost 0.4% higher than AST with only 10.29% of its parameters. All these results demonstrated the effectiveness of the proposed TFE.

TABLE IV
PERFORMANCE OF ENV2 AND TFE(4)-ENV2 WHEN CMKD WAS SKIPPED FOR TRAINING

Model Name	Parameters	Accuracy	
		ESC-50	Speech Commands V2
ENV2	8.74M	86.74% (±0.29)	97.10% (±0.06)
TFE(4)-ENV2	8.82M	**87.13%** (±0.43)	**97.19%** (±0.09)

We also explored the impact of knowledge distillation on training models. In the experiment, by fixing the balancing coefficient $\lambda = 1$, the CMKD method was not performed to train the original ENV2 and the proposed TFE(4)-ENV2. Table IV shows the performance of ENV2 and TFE(4)-ENV2 when the CMKD was skipped. According to the results, the proposed TFE(4)-ENV2 still had better performance than the original ENV2 on both two datasets. However, compared to training with knowledge distillation, the accuracy of both ENV2 and TFE(4)-ENV2 dropped. For datasets ESC-50 and Speech Commands V2, the accuracy of the original ENV2 dropped from 88.63% to 86.74% and from 97.74% to 97.10%, respectively; the accuracy of the proposed TFE(4)-ENV2 dropped from 89.67% to 87.13% and from 97.85% to 97.19%, respectively. These findings demonstrate the importance of knowledge distillation for training the image-based model in the audio classification, and they also confirm that the proposed TFE module can still help improve the performance of the original ENV2 for speech classification even when knowledge distillation is not performed for training.

V. CONCLUSIONS

Unlike the general field of image processing, where the vertical and horizontal axes typically have similar physical meanings, the audio spectrogram exhibits distinct interpretations for these axes. This unique characteristic poses a challenge when utilizing spectrograms for image-based classifier models. To address this issue and obtain a more suitable spectrogram for the image-based classifier model, we proposed a new TFE module for spectrogram enhancement. The proposed model, TFE, consists of multiple Enhancer Blocks to extract time-frequency features in high dimensions, providing enhanced spectrograms to ENV2 for classification. In our experiments, compared with the original ENV2, the accuracy of the proposed TFE-ENV2 increased by 1.04% and 0.11% on ESC-50 and Speech Commands V2 respectively. All of these results demonstrated the effectiveness of the proposed TFE for ENV2 on audio classification tasks. Moreover, the evidence supports the idea that enhancing spectrograms through the extraction of high-dimensional time-frequency features based on energy distributions can be beneficial for audio classification. These findings not only contribute to the current understanding of audio classification but also provide a potential direction for future research in this area.

Evaluating Methods for Ground-Truth-Free Foreign Accent Conversion

Wen-Chin Huang and Tomoki Toda
Nagoya University, Japan
E-mail: wen.chinhuang@g.sp.m.is.nagoya-u.ac.jp

***Abstract*—Foreign accent conversion (FAC) is a special application of voice conversion (VC) which aims to convert the accented speech of a non-native speaker to a native-sounding speech with the same speaker identity. FAC is difficult since the native speech from the desired non-native speaker to be used as the training target is impossible to collect. In this work, we evaluate three recently proposed methods for ground-truth-free FAC, where all of them aim to harness the power of sequence-to-sequence (seq2seq) and non-parallel VC models to properly convert the accent and control the speaker identity. Our experimental evaluation results show that no single method was significantly better than the others in all evaluation axes, which is in contrast to conclusions drawn in previous studies. We also explain the effectiveness of these methods with the training input and output of the seq2seq model and examine the design choice of the non-parallel VC model, and show that intelligibility measures such as word error rates do not correlate well with subjective accentedness. Finally, our implementation is open-sourced to promote reproducible research and help future researchers improve upon the compared systems.**

I. Introduction

Voice conversion (VC) is the task of converting between two types of speech without changing the linguistic content [1], [2]. While speaker conversion has been the main focus of previous VC research, in this paper we aim to tackle a special application: foreign accent conversion (FAC)[1] [3]. As illustrated in the right side of Figure 1, given an accented speech utterance spoken by a non-native source speaker, FAC aims to generate a native-sounding version with the same speaker identity as the source speaker. Applications of FAC include computer-aided language learning [3]–[5] and entertainment such as movie dubbing [6].

At first sight, one might try to apply existing state-of-the-art deep learning-based VC methods, such as sequence-to-sequence (seq2seq) modeling [7], [8] or non-parallel recognition-synthesis-based models [9], to FAC. However, such direct application is considered infeasible because of the absence of the ground-truth training target: it is impossible to collect native speech from a non-native speaker. In fact, there are many other VC applications that face the same problem, such as dysarthric speech conversion [10], [11], which aims to convert from disordered speech to healthy speech while preserving the speaker identity.

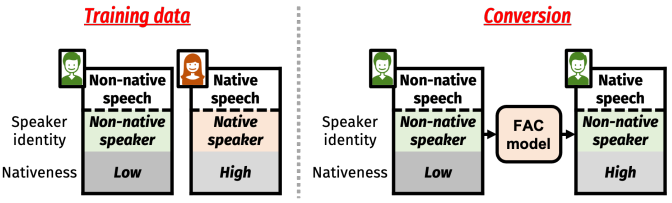

Fig. 1: Left: the training data, which is a parallel corpus between the source non-native speaker and a reference native speaker. Right: the goal in the conversion phase of FAC. The nativeness is expected to be increased while maintaining the speaker identity.

Researchers have proposed several methods for such a type of ground-truth-free[2] VC task. They all share a main idea, which is to first collect a training corpus from the source non-native speaker and then collect the native counterpart from a native reference speaker with the same prompt set, as depicted in the left side of Figure 1. Then, state-of-the-art VC methods for disentangling the speaker and content are designed to achieve FAC. However, these works were developed in parallel, and comparisons were often conducted on a system-to-system basis, leading to a lack of comparison and understanding of each method.

In this work, we aim to systematically evaluate three methods [10], [12], [13] for FAC. Experiments were conducted in a unified setting using a shared database, model architecture, and vocoder. We conducted a subjective evaluation test assessing three different aspects (naturalness, speaker similarity, accentedness) of the synthesized samples, allowing us to compare the methods. As we will show in our experimental evaluation section, we found that **no single method was significantly better than the others in all evaluation axes**, which is in contrast to conclusions drawn in previous studies [13]. We also present results of an objective intelligibility measure which was used in previous studies [12], and show that it might not correlate well to subjective accentedness. Finally, to promote reproducible FAC research, we open-source our implementation to help future researchers improve upon our system[3].

[1]Readers should note that the term "accent conversion" can be referred to many different tasks in the literature. While many have used this term to refer to the conversion between different accents or from native to accented speech, in this work we focus on the task of "de-accenting".

[2][12] used the term 'reference-free', but we found it confusing since a reference speaker is needed for training. Therefore we use "ground-truth-free" in the rest of the paper, where "ground-truth" refers to the ground-truth used as the training target.

II. Related works and background knowledge

A. Non-native to native foreign accent conversion

In the FAC literature, most works tried to utilize accent-independent features to decompose accent from voice identity. For instance, early attempts made use of articulatory trajectories (e.g., lips and tongue movements) [14]–[16] and vocal tract length normalization [17]. More recently, more simplified features such as phonetic posteriorgrams (PPGs) [18], [19] and text [20] are combined with advanced deep neural network architectures, especially seq2seq VC models, whose ability to model segmental and prosody features simultaneously play a crucial role in FAC. However, only very few works have tried to address ground-truth-free FAC [12], [13]. We believe this difficult yet practical setting is worth further investigation.

B. Seq2seq VC modeling

Seq2seq modeling learns the alignment between the source and target data sequences in a data-driven manner, equipping the model with the ability to generate outputs of various lengths and capture long-term dependencies. This is considered particularly important in FAC, as duration and supra-segmental characteristics like f_0 play an important role in prosody conversion, which strongly affects the perception of foreign accents. In addition, in this work, we apply the text-to-speech (TTS) pre-training technique proposed in [7], [8] to increase the performance. However, a major drawback of seq2seq models is the requirement of parallel data, which is impractical to collect in FAC. Therefore, we resort to the help of another family of VC models.

C. Non-parallel frame-based VC modeling

Non-parallel VC relaxes the requirement of a parallel corpus, and one of the mainstream methods is autoencoder-style training. An encoder first extracts latent features to filter out certain attributes (e.g. speaker identity in speaker conversion), and then a decoder tries to generate the input speech by reconstructing the missing information. In contrast with seq2seq models, non-parallel models are frame-based, i.e. the duration and other supra-segmental attributes are not converted. It is therefore assumed that non-parallel frame-based models convert only global characteristics such as the speaker identity while maintaining local characteristics, such as pronunciation.

Although the extractor and the decoder can be jointly trained, as reported in [21], it is more effective to first train the extractor and then used the extracted features to train the decoder. The extractor is usually pre-trained using a large, multi-speaker dataset, and as a result an any-to-one (A2O) VC model is obtained as it generalizes well to unseen speakers. Among the many choices, the most widely used latent feature is the PPG [9] extracted from a supervisedly trained automatic speech recognition (ASR) model, as it preserves strong linguistic clues and serves as a strong speaker information bottleneck. Recently, self-supervised speech representations (S3Rs) are attractive in that they can be trained without labeled data and thus benefit from training on larger scales. Many have applied them to VC as an alternative [22], [23], and the best performing one is vq-wav2vec [24]. In this work, we evaluate the effectiveness of PPG and vq-wav2vec in the context of FAC.

III. Evaluated methods

In all three methods we evaluate, we assume two materials are prepared beforehand. First, as shown in Figure 1, access to a parallel dataset between the non-native speaker and a reference native speaker is assumed. Second, the dataset of the native speaker is used to train a non-parallel frame-based model, which will then be fixed in all three methods. This process is illustrated in the top of Figure 2. In the following subsections, the detailed procedures of all three methods are described. Figure 2 shows a complete illustration.

A. Method 1: cascade

The cascade method was originally proposed for dysarthric VC [10], but as mentioned in Section I, since dysarthric VC and FAC share a common problem of lacking ground-truth training target, here we examine whether it could be applied to FAC.

In the cascade method, a seq2seq model is trained to map from the source non-native speech to that of the reference native speaker. During conversion, the source speech is first sent into the seq2seq model to get the first stage converted speech. Although the nativeness is improved, the speaker identity is unwantedly changed into that of the reference speaker. Therefore, the non-parallel VC model is then used to change the identity back to that of the native speaker, while maintaining the pronunciation.

B. Method 2: synthetic target generation (STG)

In STG [12], the non-parallel VC model converts the training dataset of the native speaker such that the generated speech has the same nativeness of the input but with the speaker identity of the non-native speaker. We refer to this step as synthetic target generation. Then, the seq2seq model is trained using the non-native training set as the source and the synthetic native speech with the speaker identity of the same non-native speaker as the target. The conversion process is then as simple as using the seq2seq model to generate the de-accented speech with the identity of the non-native speaker.

C. Method 3: latent space conversion (LSC)

The LSC method [13] first uses the latent feature extractor module of the non-parallel VC model to transfer the training datasets of the source non-native and target native speakers from the speech space to the latent space. Then, the seq2seq model is trained to map the source latent features to the target latent features. During conversion, the latent features of the source non-native speech are first extracted and transformed to their native counterpart using the seq2seq model. Finally, the decoder of the non-parallel VC model is used to inject the identity of the non-native speaker into the converted latent features in order to generate the final converted speech.

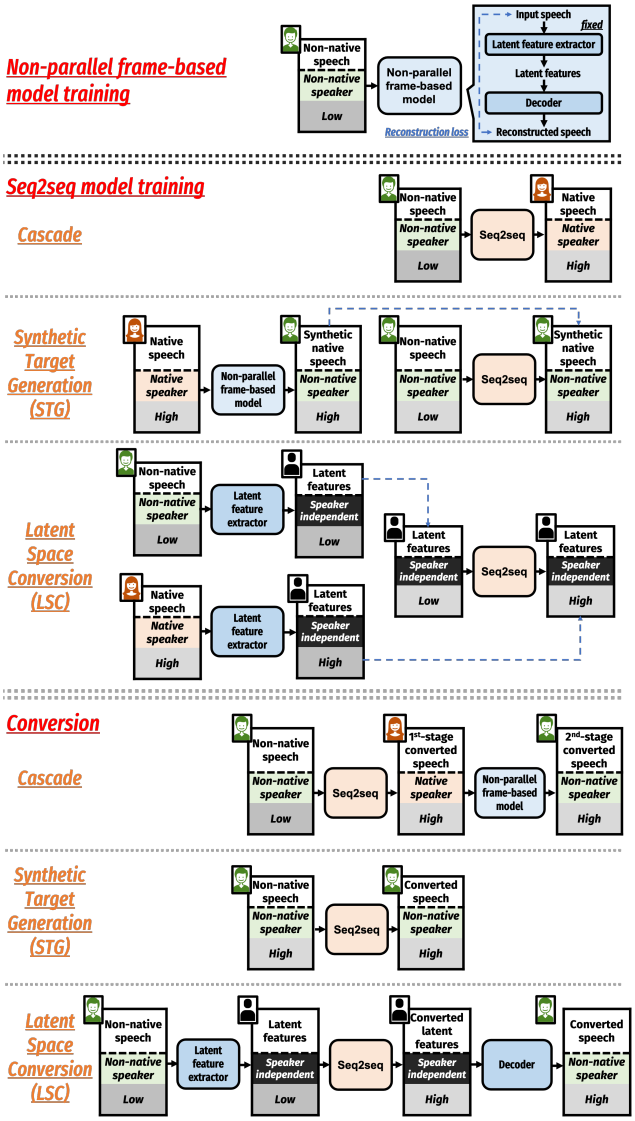

Fig. 2: Illustration of the training and conversion processes of the three evaluated methods (cascade, STG, LSC). Top: non-parallel frame-based VC model training using the data from the source non-native speaker. Middle: seq2seq model training. All the components from the non-parallel frame-based VC model (marked in blue), including the latent feature extractor and the decoder, are fixed in this phase. Bottom: the conversion phases.

D. What is the difference between these three methods?

As these methods might be seemingly complicated in their individual ways, the difference lies in the training input and output of the seq2seq model. This can be clearly observed in the right column of the middle part in Figure 2. First, in the cascade method, the seq2seq model needs to simultaneously convert the speaker identity and the nativeness, which is considered to be the most difficult. In contrast, STG first changes the speaker identity of the native training set, such that the seq2seq model only needs to model the pronunciation pattern. Finally, to further ease the job of the seq2seq model, LSC projects the training datasets onto the latent space, which is speaker-independent, and this is easier to model than the speech space. Based on this observation, we may hypothesize that the performance of each method should correlate with the difficulty of the mapping function that the seq2seq model needs to find. We will discuss this hypothesis in the results section.

These three methods also have their own weakness. For instance, during the conversion phase, not only cascade but also LSC does the input speech pass through a pipeline consisting of multiple modules, suffering from potential error propagation. STG, on the other hand, requires only the seq2seq module during conversion and thus does not suffer from error propagation, but the synthetic target data inevitably contains artifacts. The performance of the seq2seq model is then bounded by how imperfect the synthetic data is. With these unique limitations, we note to the readers that it is difficult to fairly compare these methods.

IV. Experimental Evaluation and Discussion

A. Experimental setting

The non-native and reference native speakers are THXC (Chinese male) and bdl (English male) from the L2-ARCTIC [25] and ARCTIC datasets, respectively. There are 1032/50/50 training/development/testing parallel utterances respectively, and the total duration of the training set is around one hour. All samples are in 16 kHz. The downsampled LJSpeech dataset [26] was used for the seq2seq model pretraining. The LibriSpeech (960 hours) [27] and LibriLight [28] (60k hours) datasets were used to train the PPG and vq-wav2vec models, respectively.

Mel-spectrograms were used as the acoustic features with a hop size of 256. ParallelWaveGAN [29] was used as the neural vocoder, trained with only the training set of the source non-native speaker. The seq2seq model is based on the Transformer [7], [30] and the decoder of the non-parallel frame-based VC model resembles Tacotron2 [31], following [22]. The implementation is open-sourced[4], so we refer readers to the source code for detailed hyperparameters due to space limits. An NVIDIA V100 GPU was used to train all the models, and the seq2seq model and non-parallel VC model in total took 6 hours to train.

B. Evaluation protocols

We conducted subjective evaluation tests on three axes, following previous works [12], [13]. In the naturalness and accentedness tests, listeners were asked to rate the samples on a 5-point and a 9-point scale, respectively. Samples of the source non-native and target native speech were also included. In the similarity test, a source non-native sample and a converted sample were presented, and listeners were asked to judge whether the two samples were uttered by the same speaker on a four-point scale, following the same convention in voice conversion challenges [21]. The naturalness and similarity tests were conducted using Amazon Mechanical Turk, and each of

[4]See footnote 3

TABLE I: Objective and subjective evaluation results with 95% confidence interval of samples from the evaluated methods, source and target.

Method	Extractor	CER/WER	Naturalness ↑ (1-5)	Similarity ↑ (0% -100%)	Accentedness ↓ (1-9)
Source (non-native)		5.3/12.3	4.18±0.19	–	6.06±0.38
Cascade	vq-wav2vec	29.1/52.5	3.17±0.23	28.7%±6.7%	5.41±0.32
	PPG	30.4/52.7	3.50±0.22	45.7%±7.3%	4.18±0.30
STG	vq-wav2vec	25.3/45.0	3.23±0.21	37.0%±7.0%	5.27±0.31
	PPG	17.7/40.9	3.66±0.20	57.3%±7.8%	4.36±0.32
LSC	vq-wav2vec	33.4/52.5	3.65±0.25	36.0%±7.0%	4.61±0.32
	PPG	9.8/19.5	3.64±0.22	43.8%±7.5%	3.95±0.31
Target (native)		1.3/4.3	4.42±0.18	–	1.49±0.21

the 65 workers we recruited rated 20 samples (or sample pairs). As for the accentedness, due to the difficulty of the task itself, we conducted an in-lab study by recruiting 19 listeners to each listen to 40 samples. Audio samples are available for readers[5].

Finally, we consider one objective measure for calculating speech intelligibility: character/word error rates (CER/WER) obtained by running an ASR model on the speech samples. We used a pretrained ASR model based on wav2vec 2.0[6] [32].

C. Design choice of the non-parallel frame-based model

In Secion II-C, we mentioned we experimented with two types of latent features in the non-parallel frame-based model: PPG and vq-wav2vec. As shown in Table I, in all three subjective evaluation axes (naturalness, similarity, and accentedness) and all three evaluated methods, using PPG was almost always significantly better than using vq-wav2vec. The only exception was that the naturalness scores were nearly identical when using vq-wav2vec and PPG in the LSC scenario.

Although previous works [22], [23] have already shown that PPG outperforms vq-wav2vec in terms of naturalness and similarity, the superiority of PPG in accentedness implies the importance of linguistic supervision in the training of the latent extractor. In the rest of the section, we focus on the results of the three methods using PPG.

D. Effectiveness of the three evaluated methods

In this subsection, we try to compare the performance tendency with the hypothesis described in Section III-D. We first look at the naturalness scores of the three methods in Table I. As the confidence intervals overlap, there is no statistically significant difference between the three methods. This suggests that naturalness is not affected by the difficulty of the seq2seq mapping.

Next, for similarity, STG is significantly better than cascade and LSC, which again violates the above-mentioned hypothesis. Nonetheless, this result leads to two implications. First, as the seq2seq model in STG operates in the speech domain, the model prioritizes the learning of speaker identity generation over accent removal. Second, the relatively low similarity of LSC implies that the assumption of speaker independence of the latent features may be invalid in the context of FAC.

Finally, in terms of accentedness, the only significant difference that can be observed is the superiority of LSC over STG. Although this does not match the hypothesis, we note that the accentedness score of LSC is significantly better than cascade and STG when using vq-wav2vec. This suggests that LSC is more robust to the choice of the latent feature.

E. Is character/word error rate a proper objective measure for FAC?

The feasibility of using objective measures to predict subjective results is a long-standing problem in VC research [33], [34]. Developing such a measure allows us to inspect the performance during system development without the expensive subjective evaluation process. Some previous works on FAC reported CER/WER as an indirect measure of accentedness, with the expectation that reducing accentedness can also reduce the error rates. Nonetheless, we try to investigate whether such a hypothesis is valid.

With the 8 data points in Table I, the linear correlation coefficients between accentedness and CER/WER are 0.413 and 0.442, respectively. It can be then inferred that there is a weak yet insignificant correlation between accentedness and CER/WER. We thus conclude that there are other factors than intelligibility when it comes to accentedness, thus using CER/WER solely as an objective measure for FAC is unreliable.

V. Conclusion and Future Works

In this work, we systematically compared three methods for ground-truth-free FAC. Experiments were carried out in a unified setting, and subjective tests were conducted in terms of naturalness, speaker similarity, and accentedness. In addition to the detailed discussion of each method and evaluation axis presented in Section IV, the most important message that the evaluation results show is that **no single method was significantly better than the other two in all evaluation axes**. While this may arise from the insufficiency of the evaluated methods, we also doubt if the evaluation protocols which we follow are proper. Below we list two directions that we wish to improve upon in the future.

A. Adopting non-autoregressive (non-AR) seq2seq modeling

We observed that the seq2seq VC models suffer from intelligibility issues, evidenced by the high error rates in Table I. This mainly comes from the autoregressive (AR) design of the seq2seq models we adopted. With the advance of non-AR seq2seq modeling [35], [36] which is known for its robustness compared to AR models, it can be expected that adopting non-AR models in the FAC methods can further improve the performance.

B. Better subjective evaluation protocols

Although we adopted the absolute rating evaluation protocol following previous works [12], [13], the large confidence intervals observed in the naturalness and accentedness axes in Table I suggest that a more reliable protocol needs to be developed. Listener feedback suggests that a 9-point scale test as used in [12], [13], [37] is too fine-grained to give precise ratings. Also, while it is easy to tell whether a sample is native or not, rating the degree of accentedness is rather difficult. Comparative measurements such as preference tests might be more suitable, as advised in [38].

C. More accurate accentedness evaluation

Listeners mentioned that even as native English speakers, it is difficult to confidently rate accentedness. One way to improve this is to provide a training section containing utterances with different levels of accentedness, as the one provided in [39]. Another alternative is to directly recruit linguistics or educators, as someone with in-depth professional knowledge may make judgments more confidently.

***Abstract*—Voice conversion is a task to convert a non-linguistic feature of a given utterance. Since nuance of speech strongly depends on its pitch pattern, in some applications, it would be desirable to keep the original rise/fall pitch pattern while changing the speaker identity. Some of the existing methods address this problem by either using a source-filter model or developing a neural network that takes an F_0 pattern as input to the model. Although the latter approach can achieve relatively high sound quality compared to the former one, there is no consideration for discrepancy between the target and generated F_0 patterns in its training process. In this paper, we propose a new variational-autoencoder-based voice conversion model accompanied by an auxiliary network, which ensures that the conversion result correctly reflects the specified F_0/timbre information. We show the effectiveness of the proposed method by objective and subjective evaluations.**

I. Introduction

Voice conversion (VC) is a task to convert a non-linguistic feature of a given utterance and it can be used for various applications [1] including personalizing or changing emotion of text-to-speech systems [2]–[4]. In this paper, we focus on the conversion of F_0 pattern and timbre (i.e., speaker identity).

A basic VC framework consists of feature extraction from a speech signal, feature conversion, and speech synthesis based on a converted feature. With regard to feature conversion, some of the existing methods require parallel data set (e.g., Gaussian-mixture-model-based [5]–[7], deep-neural-network-based [8], [9], and sequence-to-sequence-based [10], [11] methods), while others do not (e.g., recognition-synthesis-based [12]–[14], phonetic-posteriorgram-based [15], variational-autoencoder (VAE) [16]-based [17]–[19], generative-adversarial-network-based [20]–[22], flow-based [23], [24], and score-based [25], [26] methods). As for feature extraction and speech synthesis, the existing methods can be classified roughly into two approaches. One is the parametric-vocoder-based (PV) approach [6], [8], [17], where we first apply timbre conversion based on mel-cepstral coefficients (MCCs) and F_0 conversion (e.g., linear transformation) separately and then synthesize a waveform with a parametric vocoder such as WORLD [27]. The other is the neural-vocoder-based (NV) approach [18], [28], [29], where we use a neural network for speech synthesis. While early neural vocoders have required spectral envelope- and excitation-related features as input [30], [31], the recent mainstream is to synthesize a waveform from a mel-spectrogram [32], [33].

In some applications such as online communication, it would be desirable to keep the original rise/fall pitch pattern, since it strongly affects the nuance of speech. Inappropriate modification of the relative pitch pattern would cause miscommunication in regard to the speaker's intent and/or emotion. One way to securely keep the relative pitch pattern of input speech would be to take the PV approach, which allows us to explicitly specify the F_0 pattern of the converted speech. However, one disadvantage is that it cannot generally achieve as high sound quality as the NV approach. Recently, some F_0-controllable NV methods have been proposed, with which we can specify both F_0 and timbre conditionings explicitly [34]–[36]. However, even with these models, a generated speech does not necessarily have the same F_0 pattern as the input conditioning. This is because the relationship between the specified F_0 pattern and the conversion result has not been considered in the training criteria, and thus the decoder may disregard the specified F_0 pattern and not reproduce it faithfully in the reconstruction process.

In this paper, we develop a disentangled and F_0-controllable neural VC (DisC-VC). DisC consists of the VAE-based generator and auxiliary network. The auxiliary network, which is composed of F_0 extractor and speaker classifier, ensures that the conversion result correctly reflects the specified F_0/timbre information. We show the effectiveness of DisC by both objective and subjective evaluations.

II. Proposed Method

A. Preprocessing of training samples

Fig. 1 shows the architecture of the DisC model. During the training phase, we use the standardized log mel-spectrogram $\boldsymbol{x} \in \mathbb{R}^{F \times T}$, the log F_0 pattern $\boldsymbol{\lambda} \in \mathbb{R}^{T}$, and the speaker index $s \in \{1, 2, \ldots, S\}$ as the input features, where T, F, and S indicate the numbers of time and frequency bins and speakers, respectively. To define $\boldsymbol{x}$, we first compute the log mel-spectrogram $\boldsymbol{x}^{(0)}$. Then, each entry of the column vectors of $\boldsymbol{x}^{(0)}$ is standardized according to the mean and standard deviation for all the time bins and training samples. To compute $\boldsymbol{\lambda}$, we extract the F_0 pattern from an input

speech signal with the WORLD F_0 estimator [27] and apply logarithmic transformation to its non-zero entries.

B. Generator

The generator consists of content encoder $\mathrm{ENC_C}$ and decoder DEC. To reflect the discrete nature of the phonemic units of speech, we adopt the encoder of Vector Quantised-Variational AutoEncoder or VQ-VAE [40] as $\mathrm{ENC_C}$. In the generator, we first extract the content feature $\boldsymbol{c} = \mathrm{ENC_C}(\boldsymbol{x}) \in \mathbb{R}^{N_\mathrm{C} \times T}$ from $\boldsymbol{x}$, where we set $N_\mathrm{C} = 16$ in the experiment. Then, the decoder reconstructs the mean and variance of the log mel-spectrogram $(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\sigma}}) = \mathrm{DEC}(\boldsymbol{c}, \boldsymbol{\lambda}, s)$, where $\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\sigma}} \in \mathbb{R}^{F \times T}$.

C. Training objective

1) Reconstruction error: The first training objective is the reconstruction error of the generator. Let $q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x})$ be a probability density function (PDF) of content feature $\boldsymbol{c}$ conditioned on log mel-spectrogram $\boldsymbol{x}$, based on which the content encoder with parameter $\boldsymbol{\phi}$ generates the content feature. Let $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}, s)$ be a PDF of $\boldsymbol{x}$ conditioned on $(\boldsymbol{c}, \boldsymbol{\lambda}, s)$, based on which the decoder with parameter $\boldsymbol{\theta}$ generates the output mel-spectrogram. We assume the prior distribution of $\boldsymbol{c}$ to be a discrete uniform distribution independent of the F_0/timbre features (i.e., $p(\boldsymbol{c}|\boldsymbol{\lambda}, s) = p(\boldsymbol{c})$). By using Jensen's inequality, the negative log marginal distribution can be upper bounded by

$$
\begin{aligned}
&-\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{\lambda}, s) = -\log \int q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x}) \frac{p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}, s) p(\boldsymbol{c})}{q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x})} \mathrm{d}\boldsymbol{c} \\
&\leq -\int q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x}) \log \left(\frac{p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}, s) p(\boldsymbol{c})}{q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x})} \right) \mathrm{d}\boldsymbol{c} \\
&= D - \mathbb{E}_{\boldsymbol{c} \sim q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x})} [\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}, s)], \qquad (1)
\end{aligned}
$$

where $D \coloneqq D_\mathrm{KL}[q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x})||p(\boldsymbol{c})]$ and $D_\mathrm{KL}(q||p)$ indicates the KL divergence of q from p. It can be shown that the difference between the right- and left-hand sides of (1) is equal to $D_\mathrm{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x})||p_{\boldsymbol{\theta}}(\boldsymbol{c}|\boldsymbol{x}, \boldsymbol{\lambda}, s))$, which is minimized when $q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x}) = p_{\boldsymbol{\theta}}(\boldsymbol{c}|\boldsymbol{x}, \boldsymbol{\lambda}, s)$ (i.e., the content feature $\boldsymbol{c}$ extracted by the encoder is independent of $(\boldsymbol{\lambda}, s)$, given $\boldsymbol{x}$). When $p(\boldsymbol{c})$ is a discrete uniform distribution, D becomes constant [40]. By assuming $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}, s)$ to be a Gaussian distribution with mean $\hat{\boldsymbol{\mu}}$ and variance $\hat{\boldsymbol{\sigma}}$, where all the entries are mutually independent, the second term in (1) can be interpreted as the reconstruction error of $\boldsymbol{x}$ [16]. Given training samples of $(\boldsymbol{x}, \boldsymbol{\lambda}, s)$, the actual training criterion $\mathcal{L}_\mathrm{like}$ will be the expectation of the right-hand side of (1) over $(\boldsymbol{x}, \boldsymbol{\lambda}, s)$.

2) Negative mutual information: As we later show experimentally in Section III, even if the conversion model is conditioned on specified F_0/timbre information $(\boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R})$, the converted speech does not always reflect them sufficiently with a model trained only based on the reconstruction loss $\mathcal{L}_\mathrm{like}$, since the decoder may disregard $(\boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R})$ and only use $\boldsymbol{c}$ to reconstruct the log mel-spectrogram. Therefore, as the second training objective, given $\boldsymbol{c} \sim q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x})$ and s_R, we consider the negative mutual information $\mathcal{I}_\mathrm{P}(\boldsymbol{\theta})$ between output log mel-spectrogram $\boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R})$ and log F_0 pattern $\boldsymbol{\lambda}_\mathrm{R}$, which is given by

$$
\begin{aligned}
\mathcal{I}_\mathrm{P}(\boldsymbol{\theta}) &= -\mathbb{E}_{\boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R}), \boldsymbol{\lambda}'_\mathrm{R} \sim p(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})} \left[\log \frac{p(\boldsymbol{\lambda}'_\mathrm{R}, \boldsymbol{x})}{p(\boldsymbol{\lambda}'_\mathrm{R}) p(\boldsymbol{x})} \right] \\
&= -\mathbb{E}_{\boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R}), \boldsymbol{\lambda}'_\mathrm{R} \sim p(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})} [\log p(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})] + H_\mathrm{P}, \qquad (2)
\end{aligned}
$$

where $H_\mathrm{P} \coloneqq \mathbb{E}_{\boldsymbol{\lambda}_\mathrm{R} \sim p(\boldsymbol{\lambda}_\mathrm{R})} [\log p(\boldsymbol{\lambda}_\mathrm{R})]$ is a constant that does not depend on $\boldsymbol{\theta}$. By using the fact that a KL divergence is non-negative and the law of total expectation (i.e., Lemma 5.1 in [41]), the expectation of the first term in (2) over $\boldsymbol{\lambda}_\mathrm{R}$ can be upper bounded by

$$
\begin{aligned}
&-\mathbb{E}_{\boldsymbol{\lambda}_\mathrm{R} \sim p(\boldsymbol{\lambda}_\mathrm{R}), \boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R}), \boldsymbol{\lambda}'_\mathrm{R} \sim p(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})} [\log p(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})] \\
