and

$$\begin{bmatrix} s_{f,l} \\ \boldsymbol{z}_{f,l} \end{bmatrix} = \begin{bmatrix} \boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{x}_{f,l} \\ \boldsymbol{B}_{f,l}\boldsymbol{x}_{f,l} \end{bmatrix}. \tag{4}$$

B. CSV Mixing Model

In the CSV model, the signal after STFT is divided into T blocks, and the length of each block is defined as L_b. At this time, the index of each block is $t \in \{1, \ldots, T\}$. Thus, the microphone signal is divided into several blocks. We consider the signal in each block approximately stationary. Accordingly, the expressions of the corresponding mixing matrix $\boldsymbol{A}_{f,t}$ in (1) and separation matrix $\boldsymbol{W}_{f,t}$ in (2) will be rewrite as [12]

$$\boldsymbol{A}_{f,t} = [\boldsymbol{a}_{f,t}, \boldsymbol{D}_{f,t}] = \begin{bmatrix} \gamma_{f,t} & \boldsymbol{h}_f^{\mathsf{H}} \\ \boldsymbol{g}_{f,t} & \frac{1}{\gamma_{f,t}}(\boldsymbol{g}_{f,t}\boldsymbol{h}_f^{\mathsf{H}} - \boldsymbol{I}_{M-1}) \end{bmatrix}, \tag{5}$$

$$\boldsymbol{W}_{f,t} = \begin{bmatrix} \boldsymbol{w}_f^{\mathsf{H}} \\ \boldsymbol{B}_{f,t} \end{bmatrix} = \begin{bmatrix} \beta_f^* & \boldsymbol{h}_f^{\mathsf{H}} \\ \boldsymbol{g}_{f,t} & -\gamma_{f,t}\boldsymbol{I}_{M-1} \end{bmatrix}. \tag{6}$$

Here $(\cdot)^*$ denotes the complex conjugate, and $\boldsymbol{I}_M$ denotes to $M \times M$ identity matrix. In the remaining sections of this paper, we omit the frame index $l = \{1, \ldots, L\}$. Given that the mixing matrix and separation matrix are inverse to each other, we can obtain $\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{a}_{f,t} = 1$, which is called distortionless constraint. Similarly, we can get $\boldsymbol{B}_{f,t}\boldsymbol{a}_{f,t} = 0$, where $\boldsymbol{B}_{f,t}$ represents the block matrix. Using the assumption above, we can rewrite (1) and (2) as follows:

$$\boldsymbol{x}_{f,t} = \begin{bmatrix} \gamma_{f,t} & \boldsymbol{h}_f^{\mathsf{H}} \\ \boldsymbol{g}_{f,t} & \frac{1}{\gamma_{f,t}}(\boldsymbol{g}_{f,t}\boldsymbol{h}_f^{\mathsf{H}} - \boldsymbol{I}_{M-1}) \end{bmatrix}\begin{bmatrix} s_{f,t} \\ \boldsymbol{z}_{f,t} \end{bmatrix}, \tag{7}$$

and

$$\begin{bmatrix} s_{f,t} \\ \boldsymbol{z}_{f,t} \end{bmatrix} = \begin{bmatrix} \beta_f^* & \boldsymbol{h}_f^{\mathsf{H}} \\ \boldsymbol{g}_{f,t} & -\gamma_{f,t}\boldsymbol{I}_{M-1} \end{bmatrix}\boldsymbol{x}_{f,t}. \tag{8}$$

We assume that $\boldsymbol{s}_{f,t}$ and $\boldsymbol{z}_{f,t}$ are mutually independent across all time frequency bins. Based on this assumption, we can express the joint pdf of them as follows:

$$p(\{\boldsymbol{s}_t, \boldsymbol{z}_{f,t}\}_{f,t}) = \prod_t p(\boldsymbol{s}_t)\prod_{f,t} p(\boldsymbol{z}_{f,t}), \tag{9}$$

here $p(\boldsymbol{s}_t)$ denote the joint pdf of the SOI vector component $\boldsymbol{s}_t = [s_{1,t}, \ldots, s_{F,t}] \in \mathbb{C}^F$ and $p(\boldsymbol{z}_{f,t})$ denote the pdf of $\boldsymbol{z}_{f,t}$, respectively.

We consider the block-dependent variance of SOI, which can vary from block to block. We introduce pdf, denoted as $p(\boldsymbol{s}_t)$, that captures this block-dependent variance and accurately represents the characteristics of the source signal. Specifically, the pdf $p(\boldsymbol{s}_t)$ is defined as follows:

$$p(\boldsymbol{s}_t) = h\left(\left\{\frac{s_{f,t}}{\hat{\sigma}_{f,t}}\right\}_f\right)\left(\prod_{f=1}^{F}\hat{\sigma}_{f,t}\right)^{-2}, \tag{10}$$

where $\hat{\sigma}_{f,t} = \sqrt{\boldsymbol{w}_f^{\mathsf{H}}\hat{\boldsymbol{C}}_{f,t}\boldsymbol{w}_f}$ and $\hat{\boldsymbol{C}}_{f,t} = \mathbb{E}\left[\boldsymbol{x}_{f,t}\boldsymbol{x}_{f,t}^{\mathsf{H}}\right]$. $h(\cdot)$ is a pdf corresponding to a normalized non-Gaussian random variable:

$$h\left(\left\{\frac{s_{f,t}}{\hat{\sigma}_{f,t}}\right\}_f\right) = C\exp(-G_R(r_t)), \tag{11}$$

where C is a coefficient and G_R is a continuous and differentiable function of a real variable r satisfying that $\psi(r) = \frac{G_R'(r)}{r}$ is continuous and monotonically decreasing in $r \geq 0$. The background noise $\boldsymbol{z}_{f,t}$ is assumed to follow a circular Gaussian distribution with zero mean and a variance matrix $\hat{\boldsymbol{C}}_{\boldsymbol{z}_{f,t}} = \mathbb{E}\left[\boldsymbol{z}_{f,t}\boldsymbol{z}_{f,t}^{\mathsf{H}}\right]$.

After applying the auxiliary function method described in [8], we can obtain

$$\hat{\mathbb{E}}\left[-\log h\left(\left\{\frac{s_{f,t}}{\hat{\sigma}_{f,t}}\right\}_f\right)\right] \leq \frac{1}{2}\frac{1}{\hat{\sigma}_{f,t}^2}\boldsymbol{w}_f^{\mathsf{H}}\mathbb{E}\left[\psi(r_t)\boldsymbol{x}_{f,t}\boldsymbol{x}_{f,t}^{\mathsf{H}}\right]\boldsymbol{w}_f + R_t, \tag{12}$$

where r_t is an auxiliary variable and R_t depends purely on r_t. Based on the above assumptions, we proceed to apply the auxiliary function method for updating the objective function. Consequently, we obtain the auxiliary function for CSV as follows:

$$\mathcal{L}_{\text{Aux}} = \frac{1}{T}\sum_{t=1}^{T}\sum_{f=1}^{F}\left\{\frac{1}{2}\frac{\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{V}_{f,t}\boldsymbol{w}_f}{\hat{\sigma}_{f,t}^2} + \log\hat{\sigma}_{f,t}^2 + \mathbb{E}\left[\boldsymbol{z}_{f,t}^{\mathsf{H}}\boldsymbol{C}_{\boldsymbol{z}_{f,t}}^{-1}\boldsymbol{z}_{f,t}\right] - (M-2)\log|\gamma_{f,t}|^2\right\} + R_t, \tag{13}$$

where

$$\boldsymbol{V}_{f,t} = \mathbb{E}\left[\psi(r_t)\boldsymbol{x}_{f,t}\boldsymbol{x}_{f,t}^{\mathsf{H}}\right]. \tag{14}$$

To minimize the auxiliary function with respect to the normal variables, we calculate the partial derivative with respect

to $\boldsymbol{w}_f$. In order to minimize the auxiliary function (13), we derivate it and get

$$\frac{\partial \mathcal{L}_{\text{Aux}}}{\partial \boldsymbol{w}_f^*} = \frac{1}{2T}\sum_{t=1}^{T}\left\{\frac{\boldsymbol{V}_{f,t}}{\hat{\sigma}_{f,t}^2}\boldsymbol{w}_f - \frac{\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{V}_{f,t}\boldsymbol{w}_f}{\hat{\sigma}_{f,t}^2}\boldsymbol{a}_{f,t}\right\}, \quad (15)$$

where we used the same technique as the previous researches [12], [16] to replace the derivative of the third and fourth term in (13) as $\sum_{f=1}^{F}\boldsymbol{a}_{f,t}$. Using conventional technique [16], we get an update rule for the separation filter $\boldsymbol{w}_f$ by taking linearized solution by fixing $\frac{\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{V}_{f,t}\boldsymbol{w}_f}{\hat{\sigma}_{f,t}^2}$ and $\hat{\sigma}_{f,t}^2$ as constant terms. Then the update rule of $\boldsymbol{w}_f$ can be written as

$$\boldsymbol{w}_f = \left(\sum_{t=1}^{T}\frac{\boldsymbol{V}_{f,t}}{\hat{\sigma}_{f,t}^2}\right)^{-1}\sum_{t=1}^{T}\frac{\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{V}_{f,t}\boldsymbol{w}_f}{\hat{\sigma}_{f,t}^2}\boldsymbol{a}_{f,t}. \quad (16)$$

III. Proposed Method

So far, the CSV-Aux-IVE in Section II-B still encounters the permutation problem. In other words, without prior information, it is not determined whether the separate output corresponds to the SOI or Interference (IR). Therefore, we introduce GC [17] to ensure the extraction of the SOI. Then, let us consider GC that restrict the far-field response of the seperation filter$\boldsymbol{w}_f$ at the direction θ, which is described as

$$\mathcal{L}_{\text{GC}} = \lambda_{\text{GC}}\sum_{f=1}^{F}\sum_{\theta\in\Theta}|\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{d}_{f\theta} - 1|^2, \quad (17)$$

where $\boldsymbol{d}_{f\theta}$ is the steering vector pointing to the direction θ, λ_{GC} is a parameter weighting the importance of GC in the objective function, and we can preserve the SOI by designing this constraint when θ is the DOA (Direction of Arrival) of the target, which we call Unit Response (UR) constraints. The set Θ represents the collection of angles that will be taken into account.

The target source we aim to extract is moving, while the filter $\boldsymbol{w}_f$ remains time-invariant. Thus, a challenge lies in how to provide the filter with information regarding the movement of SOI. In this study, we make the assumption that the range of movement for the signals is known. We divide this range into p equally spaced angles and subsequently apply UR constraints to the signals at each angle.

We combine two loss functions (13) and (17) to apply UR constraints to SOI by summing them together to create a composite objective function, denoted as

$$\mathcal{Q}_{\text{CSV+GC}} = \mathcal{L}_{\text{Aux}} + \mathcal{L}_{\text{GC}}. \quad (18)$$

Then we calculate the partial derivative of the objective function. Thus the resulting derivative is as follows:

$$\frac{\partial \mathcal{Q}_{\text{CSV+GC}}}{\partial \boldsymbol{w}_f^*} = \frac{1}{2T}\sum_{t=1}^{T}\left\{\frac{\boldsymbol{V}_{f,t}\boldsymbol{w}_f}{\hat{\sigma}_{f,t}^2} - \frac{\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{V}_{f,t}\boldsymbol{w}_f}{\hat{\sigma}_{f,t}^2}\boldsymbol{a}_{f,t}\right\} + \lambda_{\text{GC}}\sum_{\theta\in\Theta}\boldsymbol{d}_{f\theta}\boldsymbol{d}_{f\theta}^{\mathsf{H}}\boldsymbol{w}_f - \lambda_{\text{GC}}\sum_{\theta\in\Theta}\boldsymbol{d}_{f\theta}. \quad (19)$$

Subsequently, we take the linearized solution of $\boldsymbol{w}_f$:

$$\boldsymbol{w}_f = \left(\lambda_{\text{GC}}\sum_{\theta\in\Theta}\boldsymbol{d}_{f\theta}\boldsymbol{d}_{f\theta}^{\mathsf{H}} + \frac{1}{2T}\sum_{t=1}^{T}\frac{\boldsymbol{V}_{f,t}}{\hat{\sigma}_{f,t}^2}\right)^{-1}\left(\lambda_{\text{GC}}\sum_{\theta\in\Theta}\boldsymbol{d}_{f\theta} + \frac{1}{2T}\sum_{t=1}^{T}\frac{\boldsymbol{w}_f^{\mathsf{H}}\boldsymbol{V}_{f,t}\boldsymbol{w}_f}{\hat{\sigma}_{f,t}^2}\boldsymbol{a}_{f,t}\right). \quad (20)$$

IV. Experiment

To evaluate the effectiveness of GC-CSV-Aux-IVE, we conducted a speech separation experiments. The evaluation criteria included extraction performance and order of the output signal, which we calculate its average as its accuracy. We compared our proposed method, GC-CSV-Aux-IVE, with the existing CSV-Aux-IVE method without being supervised.

A. Setup

In this experiment, we utilized a subset of the ATR Japanese Speech Database [22], consisting of recordings from three male speakers and three female speakers. We randomly selected two distinct speeches from this dataset to create mixtures. The indoor impulse response is generated through image method [23], with the observation signal generated using signal generator[1]. The layout of the simulated room is illustrated in Fig. 1. In total, we generated 100 pairs of original signals and mixed signals. The length of each signal is about 20 seconds. Among these, the first 50 signals had the SOI moving from 90° to 150°, while the remaining 50 signals had the SOI moving from 150° to 90°. Here SOI was set to move at a speed of 3° per second, while the IR is fixed at 45°. We have 6 microphones, 1 moving target source, and 1 fixed interference source.

To make this experiment more convincing, we added a white noise signal to the mixing signal. We adjusted the SNR to input SNR $= 10\log\frac{\lambda_1}{\lambda_2}$ as specified value, where λ_1 corresponds to the sample variance of mixing signal and λ_2 corresponds to that of noises. The other experiment conditions are shown in Table I.

In this experiment, we assumed that the movement range of SOI is known. We divided this movement range into p equal parts to set the collection of angles Θ. Then we applied UR constraints to SOI at each angle. Here is an example of how the Θ can be set:

- when p = 4, Θ = {90°, 110°, 130°, 150°},
- when p = 6, Θ = {90°, 102°, 114°, 126°, 138°, 150°},
- when p = 16, Θ = {90°, 94°, 98°, ..., 142° , 146°, 150°}.

For GC-CSV-Aux-IVE, we updated $\boldsymbol{w}_f$ 50 times while for CSV-Aux-IVE, we updated $\boldsymbol{w}_f$ 100 times. After applying GC, the convergence speed of the iterations is greatly improved, which results in the reduction of the number of convergence iterations required for convergence, compared to CSV-Aux-IVE. As a result, the convergence can be achieved in significantly fewer iterations.

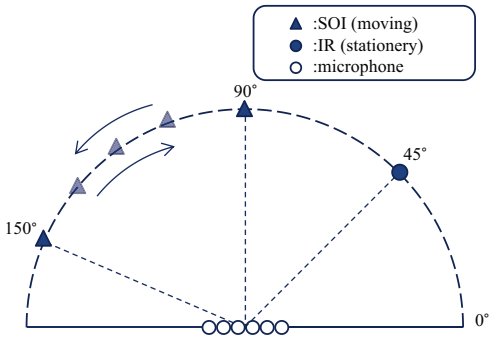

Fig. 1. Configurations of sources and microphones

TABLE I
EXPERIMENTAL CONDITIONS

Sampling rate	16 kHz
STFT window function	Hann
STFT window length	512 samples
STFT shift size	128 samples
Reverberation time	100 ms
Microphone spacing	2 cm
Input SNR	15 dB
L_b	100
λ_{GC}	0.2

TABLE II
AVERAGE SDR, SIR, AND ACCURACY OF EXTRACTING SOI (M=6)

method	SDR [dB]	SIR [dB]	Accuracy.
CSV-Aux-IVE	7.89	10.53	40.4%
GC-CSV-Aux-IVE (p=4)	11.42	15.73	97.4%
GC-CSV-Aux-IVE (p=6)	11.79	16.50	98.2%
GC-CSV-Aux-IVE (p=16)	**12.36**	**17.87**	**99.6%**

We exhibited the source extraction performance using the average source-to-distortion ratio (SDR), the source-to-interference ratio (SIR), and the accuracy of target source extraction. These evaluations were calculated by using BSS-eval [24] and setting the dry source as a reference. In order to obtain a more accurate extraction accuracy, we divided the signals into 20 blocks for comparison purposes. Hence we applied the BSS-eval to each block individually and calculated the average of the results from the 20 blocks. And we evaluated the accuracy of the extraction by assessing the output signal order.

B. Result

Table II shows the average SDR, SIR, and accuracy of the output signal. After applying GC, the accuracy of extracting SOI significantly improved from the initial 40% to over 98%. Additionally, the SDR experienced an improvement of approximately 4 dB, while the SIR showed an improvement of around 6 dB. Furthermore, we examined the performance of the extraction method in the different cases of p: $p > M$, $p = M$, and $p < M$ in Table II. Then we evaluated the extraction results under these three scenarios. Interestingly,

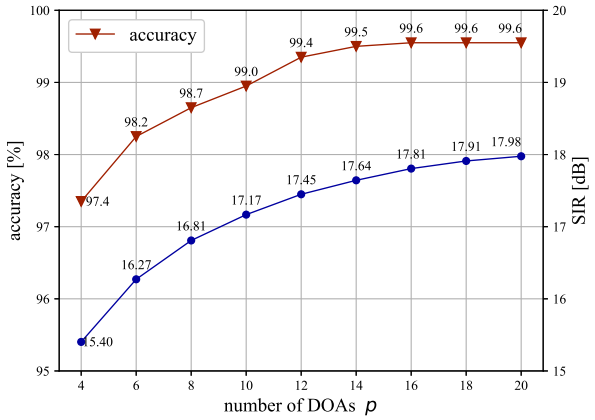

Fig. 2. Effect of increasing p on extraction performance

as the number of UR constraints p was increased, a notable improvement in the extraction performance was observed. The trend of this improvement is depicted in Fig. 2. The increasing trend of both the accuracy and SIR were observed with the increment of p.

V. CONCLUSION

This paper discovered a novel and effective BSE method for moving source. We apply a GC-based approach to address the permutation problem inherent in BSE. Our approach utilizes prior spatial information to aid in the filter updates. We extract the moving SOI by constraining multiple angles within the known range. Then we explore the effect of the changing number of constraint angles on the results. When the number of DOAs p is increased, the extraction effect is also improved. The results also demonstrated that, under similar conditions to the moving target source, GC-CSV-Aux-IVE algorithm achieved an average improvement of approximately 7dB in terms of SIR compared to the original algorithm and achieved an accuracy rate of nearly 100%.

Universal Sound Separation Using Replay-based Data Sampling in Incremental Learning

Kanta Shimonishi*, Takahiro Fukumori* and Yoichi Yamashita*
* Ritsumeikan University, Japan

***Abstract*—In this paper, we investigate an incremental learning method in universal sound separation (USS). USS uses deep learning methods, which require learning large numbers of data. In most real-world situations, the number of available data increases, and it is necessary to learn additional data incrementally. One of the challenges of incremental learning is mitigating catastrophic forgetting, which is a performance degradation on past data. We used the replay-based method to reduce catastrophic forgetting in USS. We proposed three sampling methods for the replay-based method and compared their effectiveness for different properties of the reused data. We also compared the three proposed sampling methods with regularization-based and fine-tuning-based methods to investigate the effects of catastrophic forgetting. Experimental results show that many proposed methods reduce the performance degradation and improve the average separation performance by up to 0.36 dB compared with the fine-tuning-based method. The replay-based method is also found to be more effective than regularization-based methods.**

I. Introduction

In the society in which we live, we hear a mixture of various types of sound. Humans can selectively hear multiple sounds simultaneously occurring. This phenomenon is called the cocktail party effect. Sound separation (SS) is a technique that allows a machine to perform the cocktail party effect. SS makes it possible to separate each sound source from the mixture and listen to them separately, making it easier to recognize the sounds heard compared with the mixture. This technique is applied to noise-robust speech recognition systems and intelligible voice communication. Various methods have been used for sound source separation, such as independent component analysis (ICA) [1] and non-negative matrix factorization (NMF) [2]. In recent years, deep learning methods have been widely used to achieve high accuracy. Moreover, there has been a growing interest in SS for various sounds, not limited to speech [3], [4] and music [5], [6]. This universal sound separation (USS) [7], [8], [9] technique can separate environmental sounds around us. In this paper, USS means sound source separation for environmental sounds, and SS means sound source separation technology in general, including voice separation and music separation in addition to USS. USS is expected to enable listening to universal sounds individually, improve the accuracy of environmental sound recognition [10] and anomalous sound detection [11], [12], and assist people who are hard of hearing with difficulty distinguishing sounds.

The widespread use of smartphones and smartwatches has made data acquisition from various locations possible, and the number of available sound data may gradually increase. When training additional data, building a general-purpose model without performance degradation is possible if the previously trained data and the new data are trained together. Still, increased training costs associated with increased data number become a problem. On the other hand, if only new data are used for training, the training cost can be reduced, but overfitting to new data may cause performance degradation on past data, called catastrophic forgetting. Therefore, a low-cost training method and minimal performance degradation on past training data are needed.

In this paper, we propose three data sampling methods in the replay-based method that reuses parts of previously training data to reduce the degradation of separation performance due to catastrophic forgetting. We also compare our methods with a regularization-based method, which is widely used in incremental learning, and a fine-tuning-based method, in which only new data are trained sequentially. Our work will contribute to the realization of USS systems that take into account domain shifts caused by changes in the location of sound recordings (acoustic scenes). For the replay-based method, we compare three methods: random sampling, difficulty-based sampling, and clustering-based sampling. By comparing the three methods, we will verify what type of data can be reused to enable incremental learning with minimal performance degradation.

II. Related Works

A. USS

Most of the SS research that has been conducted so far has focused on speech and music. USS [7] is a sound separation technique for various sounds, not limited to speech and music. Previous reports on USS have proposed methods for conditioning acoustic event classification results [8] and pre-training feature extractors for each acoustic event class [9]. Defining the characteristics of sound is difficult for USS because there are many different types of sound compared with speech and music. The aforementioned previous reports have proposed methods to solve these problems.

USS mainly uses mask-based separation models based on deep learning [7], [13], [14], [15]. In mask-based SS, a mixed sound $\boldsymbol{x} \in \mathbb{R}^T$ of signal length T is first converted by an encoder into a feature representation $\boldsymbol{x'} \in \mathbb{R}^{D \times L}$, where the feature dimension is D and the time frame length is L. Using the mask $\mathcal{M}_n \in \mathbb{R}^{D \times L}$ predicted by the mask prediction network, we perform mask processing on $\boldsymbol{x'}$ to obtain a

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

feature representation of the separated sound $\boldsymbol{y}'_n \in \mathbb{R}^{D\times L}$. $n(=1,2,\cdots,N)$ is the index of the sound source, and N is the number of sound sources. The masking process is performed by solving equation (1), where $\odot$ is the element-wise multiplication.

$$\boldsymbol{y}'_n = \boldsymbol{x}' \odot \mathcal{M}_n. \tag{1}$$

$\boldsymbol{y}'_n$ is resynthesized to $\boldsymbol{y}_n \in \mathbb{R}^T$ with the decoder.

Research has also been conducted to separate particular sounds from a mixture of sounds. By embedding information about the sound to be separated into the SS model, we can isolate only particular sounds. Expressly, the model is conditioned on acoustic event labels [16], onomatopoeia [17], and descriptions of the sounds (captions) [18]. Note that the tasks in this research differ from these tasks because all sounds in the sound mixture are separated.

B. Incremental learning

Incremental learning is a framework in which a deep neural network (DNN) learns sequentially from multiple different data, also known as continuous learning or lifelong learning. Incremental learning aims to build a model that can handle newly added data while maintaining performance on previously learned data when a single DNN learns multiple data. When a DNN learns new data, it overfits the given data, which can degrade performance on previously known data. Performance degradation on past data is called catastrophic forgetting. Reusing and training all previously trained data minimize catastrophic forgetting but increases the cost and requires more time for training. In actual operation, the time required for re-training is a serious problem. Therefore, a training method using new data without reusing all previous data is necessary.

We focused on the replay-based method [19] because of the simplicity and the need to vary the conditions depending on the task. A previous study [20] has shown that the replay-based method produce different results depending on the reused data. The replay-based method reuses part of the previous training data and train the previous training data together with the new data. The regularization-based method called elastic weight consolidation (EWC) [21] adds information on previously trained model parameters to the loss function as a regularization term. Therefore, it is possible to learn without using previously trained data. The loss function $\mathcal{L}_{EWC}$ used in EWC is obtained as

$$\mathcal{L}_{EWC} = \mathcal{L}_{new} + \frac{\lambda}{2}F(\theta_{new} - \theta_{past})^2, \tag{2}$$

where $\mathcal{L}_{new}$ is the loss associated with the new task, F is the fisher information matrix of the previously learned task, θ_{new} is the parameter related to the new task, and θ_{past} is the parameter associated with the past task. Moreover, λ is the importance of the new task relative to the past tasks. The second term of equation (2) restricts the training on new data so as not to depart from the parameters related to the past tasks, thereby suppressing overfitting to new tasks.

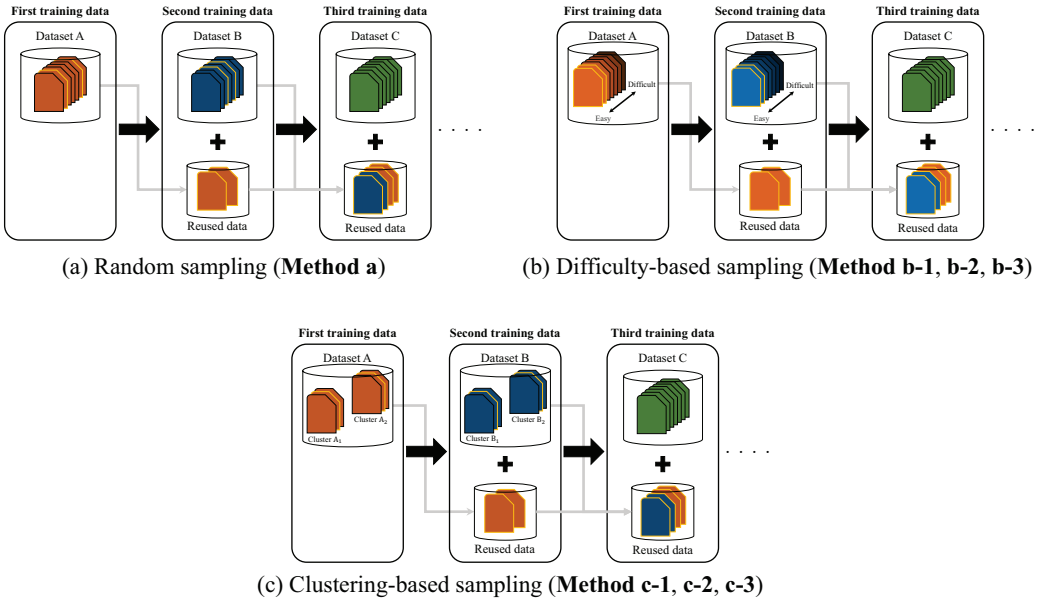
In sound and speech, incremental learning methods have been proposed to suppress catastrophic forgetting [20], [22], [23]. In [20] and [22], a replay-based method has been proposed for multilingual speech synthesis and automatic speech recognition (ASR). In particular, in [20], multiple sampling methods are proposed on the basis of the appearance of each language. In [23], a method is proposed to reduce catastrophic forgetting in ASR by updating only a part of the ASR model.

III. Proposed data sampling methods in the replay-based method

In this section, we propose and describe in detail three methods of sampling reused data in the replay-based method.

A. Random sampling

The first proposed sampling method is random sampling. It randomly selects data to be reused from past training data. The data selection is based on uniformly distributed random numbers within the range of the numbers of training data. As shown in Fig. 1(a), the data are randomly selected from past training data, and it is difficult to determine the characteristics of the reused data compared with the other two methods. However, it is the simplest of the three proposed methods. In this paper, we define random sampling as **Method a**.



B. Difficulty-based sampling

The second method is difficulty-based sampling, which selects data according to the training difficulty of the training data. As shown in Fig. 1(b), the data are arranged in order of decreasing or increasing difficulty score and selected according to the degree of difficulty. A detailed description of difficulty-based sampling is given on the basis of Fig. 1(b). When training Dataset B newly, we prepare a difficulty-determining SS (DDSS) model trained only on Dataset A. The DDSS model is used to calculate the difficulty scores for the training data in Dataset A. In this work, difficulty scores are calculated by scale-invariant signal-to-distortion ratio improvement (SI-SDRi), which is a measure of separation performance. The details of SI-SDRi are described in Section IV-A3. The data with low separation performance are considered hard to learn. Conversely, the data with high separation performance are considered easy to learn, and the effectiveness of reused data selection is evaluated on the basis of the difference in learning difficulty. In difficulty-based sampling, the following three selection methods are compared in terms of the difference in separation performance due to the difference in learning difficulty.

Method b-1
: Reuse data with a low learning difficulty

Method b-2
: Reuse data with a moderate learning difficulty

Method b-3
: Reuse data with a high learning difficulty

(a) Random sampling (**Method a**)

(b) Difficulty-based sampling (**Method b-1**, **b-2**, **b-3**)

(c) Clustering-based sampling (**Method c-1**, **c-2**, **c-3**)

Fig. 1. Overview of reused data selection in the replay-based method

C. Clustering-based sampling

The third method is clustering-based sampling, which uses clustering to select data. The clustering is performed using the k-means method to obtain cluster centers. Using the obtained cluster centers, we select M data from the previous dataset. At this time, the reused data are selected in order of nearest to the cluster center of each class so that the total number of data is M. An overview of clustering-based sampling is shown in Fig. 1(c). The effectiveness of clustering-based sampling is verified on the basis of the degree of scatter of the reused data from the past training data, depending on the number of classes in the clustering. In this paper, we compare the following three patterns of separation performance for different numbers of classes.

Method c-1
: Clustering the training data into 1 class

Method c-2
: Clustering the training data into 4 classes

Method c-3
: Clustering the training data into M classes (the same number as that of reused data)

IV. Experiments

In this experiment, we investigate the effect of three proposed sampling methods in the replay-based method and compare them with the fine-tuning-based method and EWC.

A. Experimental setup

1) Datasets: USS with incremental learning requires multiple datasets with different characteristics. However, currently available corpora do not allow us to experiment with the problem set up in this study. Therefore, we generate multiple datasets by dividing the currently available corpora and train them sequentially. We use data from FUSS [24], a corpus for USS. FUSS contains a mixture of sounds and corresponding ground truths, each containing one background sound and 0 to 3 foreground sounds. Since the FUSS is not assigned any acoustic event labels indicating the type of sound, the data were segmented as follows.

1) Mel-frequency cepstrum coefficients (MFCC) of 20 dimensions are extracted from the background sound waveforms and averaged in the time direction. The waveforms are normalized to have a maximum amplitude of 1 and a minimum amplitude of -1.
2) The k-means clustering clusters the extracted MFCC to obtain three clusters. The number of clusters is determined by the elbow method [25].
3) Generate three datasets from the clustering results: Datasets A, B, and C.

The scatter plots of the first and second principal components extracted by principal component analysis (PCA) for the created datasets are shown in Fig. 2, and the number of training, validation, and evaluation data for the created data set is shown in Table I.

2) Separation model: We use Conv-TasNet [13] as our separation model. Conv-TasNet has high performance in the field of speech separation. Convolutional layers are used in the encoder, decoder, and mask prediction networks. The mask prediction network comprises convolutional blocks serially connected to multiple convolutional and linear layers. The outputs of the last convolutional block and the skip-connection of each convolutional block are summed, and the mask is predicted after passing through the activation function. The structure of Conv-TasNet is shown in Table II.

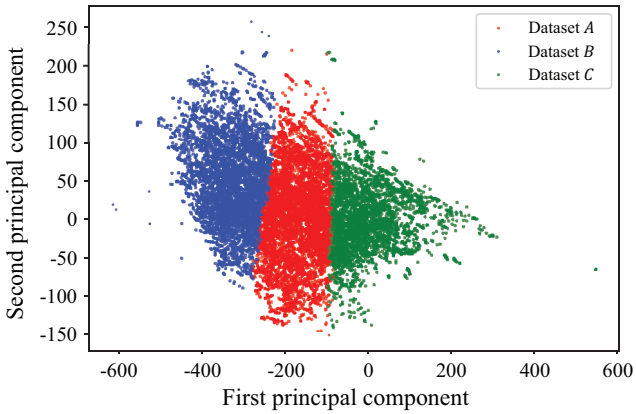


Fig. 2. PCA scatter plots of the created datasets

TABLE I
CONFIGURE OF THE CREATED DATASETS

Dataset	Train	Valid	Eval	Sum
A	7,759	435	391	8,585
B	7,683	384	306	8,373
C	4,558	181	303	5,042

TABLE II

# convolutional blocks in each repeat	8
# repeats	3
# output sources	4

3) Training and evaluation details: The training order of the datasets in incremental learning is $A \rightarrow B \rightarrow C$, and 80 epochs are trained in each training phase. The batch size is 4, Adam [26] is used as the optimizer, and the learning rate is 0.0001. SI-SDR loss [27] is used as the loss function. The SI-SDR is the distortion ratio of the separated sound to the ground truth and SI-SDR loss ($\mathcal{L}_{\text{SI-SDR}}$) is calculated as follows:

$$\text{SI-SDR}(\boldsymbol{s}, \hat{\boldsymbol{s}}) = 10 \log_{10} \frac{\|\alpha \boldsymbol{s}\|^2}{\|\alpha \boldsymbol{s} - \hat{\boldsymbol{s}}\|^2} \quad (3)$$

$$\mathcal{L}_{\text{SI-SDR}} = -\text{SI-SDR}(\boldsymbol{s}, \hat{\boldsymbol{s}}), \quad (4)$$

where $\boldsymbol{s}$ is the ground truth and $\hat{\boldsymbol{s}}$ is the separated sound. Moreover, $\alpha = \langle \boldsymbol{s}, \hat{\boldsymbol{s}} \rangle / \|\boldsymbol{s}\|^2$ and $\langle \boldsymbol{s}, \hat{\boldsymbol{s}} \rangle$ are the inner products of $\boldsymbol{s}$ and $\hat{\boldsymbol{s}}$, respectively. Let M be 2% of the number of data in each dataset, and we compare the three sampling methods proposed in Section III. The M values for Datasets A and B are 155 and 154, respectively. In difficulty-based sampling, DDSS models of Datasets A and B have also trained 80 epochs, respectively. λ in EWC was set to 1000 by preliminary experiments.

Separation performance is evaluated on the basis of SI-SDRi. SI-SDRi is the difference between SI-SDR for separated sounds and ground truth and that for mixed sounds and ground truth. If the SI-SDRi is high, the signal can be separated with less distortion than the mixture, indicating high separation performance. In this experiment, we constructed five models on the basis of **Method a**. The average of SI-SDRi values for the five models was then employed as the result of Method a. This is because **Method a** cannot uniquely determine the sampling data compared with the other two sampling methods, and bias may occur. Therefore, to reduce the bias, we use the average of SI-SDRi values for the five models.

B. Results

The experimental results are shown in Tables III to VII. Table III shows the results of incremental learning without replay/regularization-based methods, A_L, B_L, and C_L are the training data, and A_E, B_E, and C_E are the evaluation data in Datasets A, B, and C, respectively.

Table III shows that the separation performance for A_E decreased from 6.64 dB to 6.37 dB without the replay-based and regularization-based methods, and the same is true for B_E. This indicates that catastrophic forgetting reduces the separation performance for past data sets. Tables IV to VI are the results of data selection by the proposed random sampling, difficulty-based sampling, and clustering-based sampling methods in the replay-based method, respectively. Looking at each proposed method, the separation performance for A_E and B_E is degraded, indicating that catastrophic forgetting has occurred. However, when compared with Table III, it can be seen that the separation performance for each evaluated data is reduced for most of the methods. Table VII also shows that even when EWC is used, a slight reduction in catastrophic forgetting is observed for each evaluation data. Still, the overall performance is lower than that of the replay-based method. This indicates that the replay and regularization-based methods are effective in USS with incremental learning.

Next, we analyze the three proposed data sampling methods in the replay-based method. In difficulty-based sampling, the best performance is achieved by **Method b-3** after $A_L \rightarrow B_L$ training, the best performance is achieved by **Method b-1** after $A_L \rightarrow B_L \rightarrow C_L$ training, and **Method b-2** has the lowest performance in all training phases. From the SI-SDRi histograms of the previous training data in Fig. 3, the SI-SDRi of the data selected by **Method b-2** is locally concentrated, and there is a slight variation in the SI-SDRi, whereas **Methods b-1** and **b-3** show the lowest separation performance. **Methods b-1** and **b-3** show some variation. Therefore, the variation of SI-SDRi of the reused data in difficulty-based sampling may affect the separation performance during continuous learning.

Clustering-based sampling shows that the highest separation performance is achieved using **Method c-1** at all training

phases. By changing the number of clusters in clustering, we tested the effectiveness of selecting groups evenly or biasedly from the past training data. Table VI shows that selecting data biased toward a single location is practical. This may be because clustering was carried out using k-means when the datasets were generated. The cluster centers obtained by **Method c-1** are the average features of each dataset. These cluster centers are the same as those obtained when FUSS was clustered at the time of datasets generation. This is likely because data with average characteristics of each dataset were selected.

The separation performance of the seven data selection methods, **Method a**, **Methods b-1** to **b-3**, and **Methods c-1** to **c-3**, differed, and it was also found that the separation performance after incremental learning varied depending on the reused data. The separation performance after incremental learning also varied depending on the reused data. Among the seven methods, the difficulty-based sampling method

(**Methods b-1** and **b-3**) performed the best in each training phase. From the discussion of difficulty-based sampling mentioned above, it is clear that the method of selecting data with a variation in the SI-SDRi of the past training data is the best at each training phase. It is necessary to consider a method to select data with variations in the SI-SDRi of the past training data.

V. Conclusions

In this paper, we investigated USS methods using incremental learning and proposed sampling methods for reusing data in the replay-based method. We also compared our proposed methods with the fine-tuning-based method and regularization-based method. For the replay-based method, we proposed three reused data selection methods: random sampling, difficulty-based sampling, and clustering-based sampling, and verified what type of data is adequate for relearning. The experimental results showed that most of the methods could reduce catastrophic forgetting. Difficulty-based sampling, which was the most effective method, was even more effective when the data were sampled evenly without any bias in learning difficulty. In this study, we divided publicly available data on the basis of acoustic features to generate multiple datasets. The same experiments should be conducted with semantic data such as acoustic event and scene labels.

***Abstract*—This paper addresses the problem of tracking the positions of multiple sound sources using a compact-sized microphone array. Based on a generative model of the spatial gradient spectra of acoustic point sources, we propose incorporating the temporal continuity of source positions into the sequential posterior inference under a recursive Bayesian filter formulation. Simulation experiments with data generated by the image source model confirmed that the proposed idea had a certain effect on improving the accuracy of tracking moving sources.**

I. Introduction

This paper addresses the problem of tracking the positions of multiple "moving" sound sources using a compact array of microphones locally placed. Although the source is assumed to be moving in the present study, let us start by reviewing the sound source localization (SSL) methods which rely on the assumption that the source positions are "fixed". Indeed, many powerful SSL methods have already been proposed, representing the well-known multiple signal classification (MUSIC) algorithm [1] and generalized cross-correlation methods with phase transform (GCC-PHAT) [2] and their variants. Other methods have also been proposed, such as probabilistic generative model-based [3]–[7], deep neural network (DNN)-based [8], [9], and partial differential equation (PDE)-based [7], [10] methods.

Since most SSL methods enable SSL by means of information on the time-difference-of-arrival of each sound source measured by multiple microphones, it is generally preferable to use a large array with many microphones arranged in a spatially wide area. In contrast, the PDE-based methods, which utilize the PDE governing the propagation of the acoustic waves emitted by each sound source, are attractive because they can achieve SSL through a short-term observation of the sound pressure and its spatial gradient at a certain location, which can measured by a relatively compact array of locally placed microphones. This is an important feature, especially when it comes to realizing an SSL functionality on mobile objects such as robots and drones.

Although the DNN-based methods have proven to be very accurate under certain conditions, a potential drawback is the unpredictability of model behavior when used in acoustic environments that do not match the training conditions. In contrast, generative model-based methods are appealing in that they can be designed to flexibly adapt their models to various acoustic environments through model adaptation.

Focusing on the advantages of the PDE-based and generative model-based methods, an attempt to combine these ideas has already been made [7]. The idea is based on the assumption that only one source is dominant in each time-frequency (TF) bin of the observed signal and that its component is generated according to the PDE corresponding to the dominant source. Through simulation experiments, this method has been shown to work well with a compact microphone array even in reverberant environments. However, this method was designed to operate independently for each short-term frame, and the continuity of the location of each source was not considered in the inference. In order to enhance the accuracy and robustness of this method, this paper proposes an improvement that takes into account the continuity of the location of each sound source under the recursive Bayesian filter framework [11].[1]

II. Method

A. Sound Source Constraint PDE [10]

First, we briefly review the theory of the generative modeling of the spatial gradient spectra of a single acoustic point source. Let $\mathbf{r}_0 \in \mathbb{R}^3$ be the position of the point source of interest. By assuming the free-field (spherical-wave) propagation from that source, the sound pressure $f(\mathbf{r}, t)$ at an observation position $\mathbf{r} \in \mathbb{R}^3$ and time $t \in \mathbb{R}$ is given by

$$f(\mathbf{r}, t) = \frac{1}{\|\mathbf{r} - \mathbf{r}_0\|} g\left(t - \frac{\|\mathbf{r} - \mathbf{r}_0\|}{c}\right), \tag{1}$$

where g is the source signal, c is the speed of sound, and $\|\cdot\|$ denotes the Euclidean norm. From Eq. (1), the spatial gradient ∇f is given as

$$\nabla f(\mathbf{r}, t) = \rho^2 g\left(t - \frac{1}{\rho c}\right)\mathbf{n} + \frac{\rho}{c}\dot{g}\left(t - \frac{1}{\rho c}\right)\mathbf{n}, \tag{2}$$

[1]Temporal continuity of moving sources has been exploited in some other areas such as robotics [12].

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

where $\rho := 1/\|\mathbf{r}-\mathbf{r}_0\|$, $\mathbf{n} := (\mathbf{r}-\mathbf{r}_0)/\|\mathbf{r}-\mathbf{r}_0\|$, and $\dot{g}$ denotes the time derivative of g. Namely, $\mathbf{n}$ and ρ correspond to the direction and reciprocal distance of the sound source from point $\mathbf{r}$, respectively. The time derivative $\dot{f}$ is given as

$$\dot{f}(\mathbf{r},t) = \rho \dot{g}\left(t - \frac{1}{\rho c}\right). \tag{3}$$

Substituting Eqs. (1) and (3) into Eq. (2), we obtain an equation governing the relationship between the sound pressure of the source signal observed at $(\mathbf{r},t)$, its spatial gradient, and its time-derivative

$$\nabla f(\mathbf{r},t) = \left(\rho f(\mathbf{r},t) + \frac{1}{c}\dot{f}(\mathbf{r},t)\right)\mathbf{n}. \tag{4}$$

Thus, if the sound pressure of the source signal, its spatial gradient, and its time-derivative can be measured at a certain position, the location of the sound source can be estimated by finding $\mathbf{n}$ and ρ that are as consistent as possible with Eq. (4). This equation is called the sound source constraint PDE (SSC-PDE) [10].

B. SSC-PDE-based Generaive Modeling [7]

Eq. (4) can be written in the frequency domain as

$$-\nabla F(\mathbf{r},\omega) + \left(\rho + \mathrm{j}\frac{\omega}{c}\right)F(\mathbf{r},\omega)\mathbf{n} = \mathbf{0}, \tag{5}$$

where $\mathbf{0}$ is a three-dimensional zero vector, F is the temporal Fourier transform of f, ω is the angular frequency, and j is the imaginary unit. ∇F is the spatial gradient spectrum of f. Let us use $\{\omega_m\}_m$ to denote the set of discrete frequencies, $F_{0,m}$ to denote $F(\mathbf{r},\omega_m)$, and $F_m^{(x)}$, $F_m^{(y)}$, and $F_m^{(z)}$ to denote the (x,y,z)-elements of $\nabla F(\mathbf{r},\omega_m)$. When $F_m^{(x)}$, $F_m^{(y)}$, and $F_m^{(z)}$ are approximated by the spatial differences measured using, for example, a microphone array shown in Fig. 1, Eq. (5) holds only approximately and the right-hand side of Eq. (5) can slightly deviate from $\mathbf{0}$. Here, we assume this deviation to be complex Gaussian noise. Namely, we replace the right-hand side of Eq. (5) with a random vector $\boldsymbol{\epsilon}_m = [\epsilon_m^{(x)}, \epsilon_m^{(y)}, \epsilon_m^{(z)}]^\mathsf{T}$ that follows a zero-mean complex normal distribution

$$\boldsymbol{\epsilon}_m \sim \mathcal{N}_\mathbb{C}(\boldsymbol{\epsilon}_m; \mathbf{0}, \mathbf{I}/\lambda_m), \tag{6}$$

where $\mathbf{I}$ denotes a 3×3 identity matrix and λ_m denotes the precision of each element of $\boldsymbol{\epsilon}_m$. For simplicity, we will henceforth assume that λ_m is an experimentally fixed constant. We further assume $F_{0,m}$ to follow a zero-mean complex normal distribution with source-dependent precision ζ_m:

$$F_{0,m} \sim \mathcal{N}_\mathbb{C}(F_{0,m}; 0, 1/\zeta_m). \tag{7}$$

Namely, $1/\zeta_m$ corresponds to the power spectral density of the source signal observed at point $\mathbf{r}$. Now, if we use $\mathbf{y}_m$ and $\mathbf{C}_m(\theta)$ to denote

$$\mathbf{y}_m = \left[F_m^{(x)}, F_m^{(y)}, F_m^{(z)}, F_{0,m}\right]^\mathsf{T}, \tag{8}$$

$$\mathbf{C}_m(\theta) = \begin{bmatrix} -1 & & & \left(\rho + \mathrm{j}\frac{\omega_m}{c}\right)n_x \\ & -1 & & \left(\rho + \mathrm{j}\frac{\omega_m}{c}\right)n_y \\ & & -1 & \left(\rho + \mathrm{j}\frac{\omega_m}{c}\right)n_z \\ & & & 1 \end{bmatrix}, \tag{9}$$

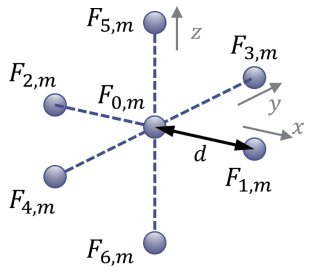

Fig. 1. Example of microphone placement. $F_m^{(x)}$, $F_m^{(y)}$, $F_m^{(z)}$ can be approximated by $(F_{1,m}-F_{2,m})/2d$, $(F_{3,m}-F_{4,m})/2d$, and $(F_{5,m}-F_{6,m})/2d$, respectively.

respectively, where $\theta = \{\mathbf{n}, \rho\}$, Eq. (5) can be rewritten as

$$\mathbf{C}_m(\theta)\mathbf{y}_m = [\boldsymbol{\epsilon}_m^\mathsf{T}, F_{0,m}]^\mathsf{T}. \tag{10}$$

Since $\mathbf{C}_m(\theta)$ is invertible and $\det \mathbf{C}_m(\theta) = -1$, from Eqs. (6), (7), and (10), the probability density function (PDF) of $\mathbf{y}_m$ given θ is obtained as

$$p(\mathbf{y}_m|\theta) = \mathcal{N}_\mathbb{C}(\mathbf{y}_m; \mathbf{0}, \mathbf{C}_m(\theta)^{-1}\boldsymbol{\Sigma}_m\mathbf{C}_m(\theta)^{-\mathsf{H}}), \tag{11}$$

where $\boldsymbol{\Sigma}_m = \mathrm{diag}(1/\lambda_m, 1/\lambda_m, 1/\lambda_m, 1/\zeta_m)$. Thus, given the observation $Y = \{\mathbf{y}_m\}_m$, $p(Y|\theta) = \prod_m p(\mathbf{y}_m|\theta)$ implies the likelihood of the source position θ [7].

C. Formulation of Multi-Source Case [7]

In the following, we will extend the above model to the case where there are multiple sound sources. Let $k \in \mathbb{N}$ denote the sound source index, where $k \neq 0$ corresponds to one of the point sources present and $k = 0$ corresponds to a mixture of all noise sources, including the reverberant components of the point sources.

Many real-world sound sources, such as speech and instrumental sounds, tend to have sparse TF representations. Hence, in many cases, each TF element of a mixture of multiple sources can be assumed to be dominated by at most one source. Recall that Eq. (11) describes a generative model that is justified in the frequency domain. We use it here as the generative model for each short-time frame signal, with frame index l. Assuming that the $z_{m,l}$-th source is active at the (m,l)-th TF bin, the PDF of the observed signal is given as

$$p(\mathbf{y}_{m,l}|z_{m,l}=k, \vartheta_l) = \mathcal{N}_\mathbb{C}(\mathbf{y}_{m,l}; \mathbf{0}, \boldsymbol{\Lambda}_{m,l}^{(k)}), \tag{12}$$

where

$$\boldsymbol{\Lambda}_{m,l}^{(k)} = \begin{cases} \mathbf{C}_{m,l}(\theta_l^{(k)})^{-1}\boldsymbol{\Sigma}_{m,l}^{(k)}\mathbf{C}_{m,l}(\theta_l^{(k)})^{-\mathsf{H}}, & (k \neq 0), \\ \mathbf{W}_m/\gamma_{m,l}, & (k = 0), \end{cases} \tag{13}$$

$$\boldsymbol{\Sigma}_{m,l}^{(k)} = \mathrm{diag}(1/\lambda_m, 1/\lambda_m, 1/\lambda_m, 1/\zeta_{m,l}^{(k)}). \tag{14}$$

Here, ϑ_l is used to denote the set of all the unknown parameters, $\{\theta_l^{(k)}\}_k$, $\{\zeta_{m,l}^{(k)}\}_{k,m}$, and $\{\gamma_{m,l}\}_m$, where $\theta_l^{(k)} = \{\mathbf{n}_l^{(k)}, \rho_l^{(k)}\}$. It should be noted here that the source position parameter $\theta_l^{(k)}$ is indexed also by time l, assuming that each source can move from moment to moment. As described above, the covariance matrix for the noise mixture is factorized

into channel-invariant and time-invariant factors, $1/\gamma_{m,l}$ and $\mathbf{W}_m$. The former and latter correspond to the power spectral density and normalized spatial covariance of the noise mixture, respectively. Note that if we assume a diffuse noise field, $\mathbf{W}_m$ can be set fixed using the diffuse model introduced in [13].

Modeling the prior distribution $p(z_{m,l})$ using a Dirichlet process allows us to handle an unknown number of sources [14]. The point is to first assume the existence of an infinite number of sound sources, one of which is drawn from a categorical distribution with infinite categories

$$p(z_{m,l} = k) = \pi_k \quad (k = 0, \ldots, \infty) \tag{15}$$

for each TF bin. The probability π_0, corresponding to the noise mixture, is assumed to be drawn according to a Beta distribution with hyperparameters α_{n} and β_{n}. The remaining probabilities $\pi_1, \ldots, \pi_\infty$, corresponding to the point sources, are assumed to be drawn according to a stick-breaking process with hyperparameter β_{s}:

$$\pi_k = v_k \prod_{j=0}^{k-1} (1 - v_j) \quad (k \geq 1), \tag{16}$$

$$v_k \sim \mathrm{Beta}(1, \beta_{\mathrm{s}}). \tag{17}$$

D. Posterior Inference

Let Θ_l denote the set consisting of $N_l = \{\mathbf{n}_l^{(k)}\}_k$, $\rho_l = \{\rho_l^{(k)}\}_k$, $\zeta_l = \{\zeta_{m,l}^{(k)}\}_{k,m}$, $\gamma_l = \{\gamma_{m,l}\}_m$, $V = \{v_k\}_k$, and $Z_l = \{z_{m,l}\}_m$. Given an observed signal $Y_l = \{\mathbf{y}_{m,l}\}_m$, the best approximating distribution $q(\Theta_l)$ that minimizes the Kullback-Leibler (KL) divergence between $q(\Theta_l)$ and the true posterior distribution $p(\Theta_l|Y_l)$ can be searched for using the variational Bayes inference (VB) algorithm [15]. By using an approximating distribution $q(\Theta_l)$ that factors as

$$q(\Theta_l) = q(N_l)q(\rho_l)q(\zeta_l)q(\gamma_l)q(V)q(Z_l), \tag{18}$$

each distribution becomes a parametric distribution of a particular form. For example, $q(N_l)$ is given in the form [7]

$$q(N_l) = \prod_k \mathrm{VMF}(\mathbf{n}_l^{(k)}; \bar{\mathbf{n}}_l^{(k)}, \kappa_l^{(k)}), \tag{19}$$

where $\mathrm{VMF}(\mathbf{x}; \mathbf{a}, b)$ denotes a von Mises-Fisher distribution with the mean direction $\mathbf{a}$ and the concentration parameter b. If we assume $p(N_l) = \prod_k \mathrm{VMF}(\mathbf{n}_l^{(k)}; \boldsymbol{\xi}_l^{(k)}, \tau_l^{(k)})$ to be the prior distribution of N_l (which becomes a uniform distribution when $\tau_l^{(k)} = 0$), the update equations of the VB algorithm for $\bar{\mathbf{n}}_l^{(k)}$ and $\kappa_l^{(k)}$ will be given as

$$\bar{\mathbf{n}}_l^{(k)} \leftarrow (\boldsymbol{\phi}_l^{(k)} + \tau_l^{(k)}\boldsymbol{\xi}_l^{(k)})/\|\boldsymbol{\phi}_l^{(k)} + \tau_l^{(k)}\boldsymbol{\xi}_l^{(k)}\|, \tag{20}$$

$$\kappa_l^{(k)} \leftarrow \|\boldsymbol{\phi}_l^{(k)} + \tau_l^{(k)}\boldsymbol{\xi}_l^{(k)}\|, \tag{21}$$

where

$$\boldsymbol{\phi}_l^{(k)} = \sum_m \bar{\varphi}_{m,l}^{(k)} \lambda_m \begin{bmatrix} \mathrm{Re}[(\bar{\rho}_l^{(k)} + \mathrm{j}\frac{\omega_m}{c}) F_{0,m,l} F_{m,l}^{(x)*}] \\ \mathrm{Re}[(\bar{\rho}_l^{(k)} + \mathrm{j}\frac{\omega_m}{c}) F_{0,m,l} F_{m,l}^{(y)*}] \\ \mathrm{Re}[(\bar{\rho}_l^{(k)} + \mathrm{j}\frac{\omega_m}{c}) F_{0,m,l} F_{m,l}^{(z)*}] \end{bmatrix}. \tag{22}$$

Here, $\bar{\varphi}_{m,l}^{(k)}$ and $\bar{\rho}_l^{(k)}$ represent $q(z_{m,l} = k)$ and the mean of $q(\rho_l{}^{(k)})$ obtained at the previous iteration, respectively. x^* denotes the complex conjugate of x. See [7] for the details of the derivation and the distribution form and update formula for each of the remaining parameters.

E. Recursive Bayesian Filter Formulation

The formulation up to this point did not consider the temporal continuity of the location of each sound source. In the following, we formulate the generative model of a mixture of moving sound sources under the recursive Bayesian filter framework [11], known as a generalization of the Kalman filter.

Let $x_{l_0:l_1}$ denote the abbreviation of the set $\{x_{l_0}, \ldots, x_{l_1}\}$. The main focus here is to infer the posterior $p(\Theta_l|Y_{1:l})$ under the assumption that $p(\Theta_{l-1}|Y_{1:l-1})$ is already given. First, we assume that $p(\Theta_{1:l})$ follows a Markov process such that

$$p(\Theta_l|\Theta_{1:l-1}) = p(\Theta_l|\Theta_{l-1}). \tag{23}$$

The assumption of the temporal continuity of the source positions can be imposed through the design of the transition probability $p(\Theta_l|\Theta_{l-1})$. By using $p(\Theta_{l-1}|Y_{1:l-1})$ and $p(\Theta_l|\Theta_{l-1})$, $p(\Theta_l|Y_{1:l-1})$ can be computed via

$$p(\Theta_l|Y_{1:l-1}) = \int p(\Theta_l|\Theta_{l-1}) p(\Theta_{l-1}|Y_{1:l-1}) \mathrm{d}\Theta_{l-1}. \tag{24}$$

This process corresponds to the prediction step in the Kalman filter. If we assume that Θ_l varies gradually over time, then it is reasonable to assume that $p(\Theta_l|\Theta_{l-1})$ is a unimodal distribution with a peak at Θ_{l-1}. In this case, Eq. (24) can be viewed as a convolution of $p(\Theta_l|\Theta_{l-1})$ and $p(\Theta_{l-1}|Y_{1:l-1})$, with $p(\Theta_l|\Theta_{l-1})$ serving to broaden $p(\Theta_{l-1}|Y_{1:l-1})$ around the peak.

Once $p(\Theta_l|Y_{1:l-1})$ is obtained, $p(\Theta_l|Y_{1:l})$ is finally obtained using the Bayes rule as

$$p(\Theta_l|Y_{1:l}) = \frac{p(Y_l|\Theta_l) p(\Theta_l|Y_{1:l-1})}{\int p(Y_l|\Theta_l) p(\Theta_l|Y_{1:l-1}) \mathrm{d}\Theta_l}, \tag{25}$$

with $p(\Theta_l|Y_{1:l-1})$ serving as the prior distribution. This process corresponds to the update step in the Kalman filter. Eqs. (24) and (25) imply that performing these two steps recursively allows us to infer the posterior distributions from $p(\Theta_1|Y_1)$ to $p(\Theta_l|Y_{1:l})$ sequentially. Note that the computation of Eq. (25) is analytically intractable, but as we saw in the previous section, a distribution that approximates it can be obtained with the VB algorithm.

In this study, we assume that only N_l follows a Markov process, and the remaining parameters are uniformly distributed and independent for each frame. Hence, $p(\Theta_l|\Theta_{l-1}) \propto \prod_k p(\mathbf{n}_l^{(k)}|\mathbf{n}_{l-1}^{(k)})$. Assuming that an approximation $q(\Theta_{l-1})$ of the posterior $p(\Theta_{l-1}|Y_{1:l-1})$ is already obtained using the VB algorithm, we define $p(\mathbf{n}_l^{(k)}|\mathbf{n}_{l-1}^{(k)})$ so that Eq. (24) can be written as

$$p(\Theta_l|Y_{1:l-1}) \propto \prod_k \mathrm{VMF}\left(\mathbf{n}_l^{(k)}; \bar{\mathbf{n}}_{l-1}^{(k)}, \delta\kappa_{l-1}^{(k)}\right), \tag{26}$$

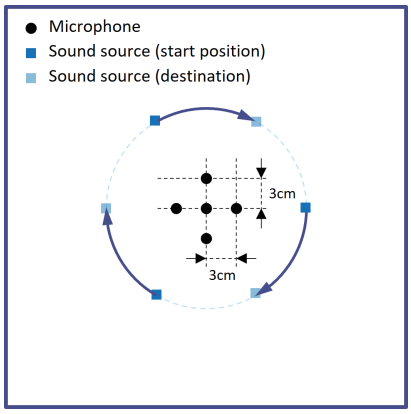

Fig. 2. Microphone and sound source arrangement

where $\bar{\mathbf{n}}_{l-1}^{(k)}$ and $\kappa_{l-1}^{(k)}$ are the mean direction and concentration parameter of $q(\mathbf{n}_{l-1}^{(k)})$, and δ is a non-negative hyperparameter that is responsible for sharpening or widening $q(\mathbf{n}_{l-1}^{(k)})$ around the peak. When $\delta = 0$, $p(\mathbf{n}_l^{(k)}|Y_{1:l-1})$ always becomes a uniform distribution, independent of the shape of $q(\mathbf{n}_{l-1}^{(k)})$.

As described in Subsection II-D, as long as the prior distribution of $\mathbf{n}_l^{(k)}$ is given in the form of a von Mises-Fisher distribution, the approximating distribution $q(\mathbf{n}_l^{(k)})$ in VB will be given in the same form. From Eq. (26), the update equations for $\bar{\mathbf{n}}_l^{(k)}$ and $\kappa_l^{(k)}$ in the VB algorithm for approximating Eq. (25) are given as

$$\bar{\mathbf{n}}_l^{(k)} \leftarrow (\boldsymbol{\phi}_l^{(k)} + \delta\hat{\kappa}_{l-1}^{(k)}\hat{\mathbf{n}}_{l-1}^{(k)})/\|\boldsymbol{\phi}_l^{(k)} + \delta\hat{\kappa}_{l-1}^{(k)}\hat{\mathbf{n}}_{l-1}^{(k)}\|, \quad (27)$$

$$\kappa_l^{(k)} \leftarrow \|\boldsymbol{\phi}_l^{(k)} + \delta\hat{\kappa}_{l-1}^{(k)}\hat{\mathbf{n}}_{l-1}^{(k)}\|, \quad (28)$$

where $\hat{\mathbf{n}}_{l-1}^{(k)}$ and $\hat{\kappa}_{l-1}^{(k)}$ represent the convergent values of $\bar{\mathbf{n}}_{l-1}^{(k)}$ and $\kappa_{l-1}^{(k)}$ in the VB algorithm performed at frame $l-1$, respectively. The update equations for the remaining parameters are the same as in the previous section. Note that when $\delta = 0$, the prior distribution will have no effect on inference at the current frame, and thus the above algorithm reduces to the frame-independent version described in Subsection II-D.

III. Simulation Experiments

A. Experimental Conditions

Simulation experiments were conducted to verify the effectiveness of the proposed method. Note here that the existing SSL methods cannot be applied to the present case because the source is unfixed and is moving over time. Experimental data were generated using the image source model under the microphone and sound source arrangement shown in Fig. 2. Each sound source was moved clockwise around the reference point of the microphone array at a speed of 6 degrees per second for 10s, with Fig. 2 as the initial and final placement. Each source was initially placed at 120 degree intervals. All the signals were sampled at 32kHz. See [7] for other experimental conditions.

In the experiment, several values of δ were tested to verify the effect of incorporating the temporal continuity of the source location into the inference.

B. Results

Figure 3 shows the estimated and true source positions for (a) $\delta = 0$, (b) $\delta = 1.0$, (c) $\delta = 6.4$, and (d) $\delta = 7.0$, respectively. As can be seen from Fig. 3(a), when the baseline method (frame-by-frame independent inference) was applied, the estimated source positions were temporally discontinuous and tended to deviate from the true positions. In contrast, Fig. 3(c) shows that the accuracy of inference was improved by incorporating the temporal continuity of the sound source location into the inference using the recursive Bayesian filtering approach. However, we also found, as shown in Fig. 3(d), that inference could instead deteriorate if δ is set too large. Therefore, finding an appropriate value for δ is an issue for future study.

IV. Conclusions

This paper addressed the problem of tracking the positions of multiple sound sources using a compact-sized microphone array. As a solution, we focused on the generative modeling formulation of the SSC-PDE-based SSL approach and proposed incorporating the temporal continuity of source positions into the inference based on a recursive Bayesian filter formulation. Simulation experiments with data generated by the image source model confirmed that the proposed idea had a certain effect on improving the accuracy of tracking moving sources.

Spatially-Regularized Switching Independent Vector Analysis

Tetsuya Ueda*, Tomohiro Nakatani†, Rintaro Ikeshita†, Shoko Araki†, and Shoji Makino*
* Waseda University, Japan and † NTT Coporation, Japan

***Abstract*—This paper proposes a novel algorithm that uses spatial regularization and a switching filter to enhance the separation accuracy of Independent Vector Analysis (IVA) with specified source permutation based on prior knowledge of sources' Directions-of-Arrival (DOAs). We call this algorithm Spatially-Regularized Switching Independent Vector Analysis (SR-SwIVA). Switching IVA (SwIVA) is a blind source separation (BSS) algorithm that builds on IVA and improves its separation accuracy with a switching filter. However, SwIVA requires relatively reliable estimates of acoustic transfer functions (ATFs) from sources to microphones for its initialization, which are difficult to obtain from DOAs in real reverberant environments. To overcome this limitation, we introduce spatial regularization to SwIVA, which has been shown to be effective for conventional BSS techniques to align permutation (or order) of separated sources with given DOAs. We conduct simulation experiments to show that our proposed SR-SwIVA can significantly improve the source separation accuracy using ATFs estimated from DOAs while completely eliminating the source permutation alignment errors. The achieved source separation accuracy is comparable to that of SwIVA with oracle ATFs.**

I. Introduction

Multichannel audio source separation has been actively studied as preprocessing of various speech applications to improve their performance. To develop effective source separation techniques, researchers often assume that speech signals' Directions of Arrival (DOAs) are available or can be estimated, e.g., from human look directions or using a camera. A promising source separation method for such a situation is Spatially-Regularized Source Separation (SRSS) that utilizes Blind Source Separation (BSS) techniques under regularization by DOA information [1], [2], [3], [4], [5], [6].

Independent Component Analysis (ICA) [7] is a BSS algorithm that estimates separation filters as ones that maximize the independence between the separated signals. To apply ICA to time-frequency domain audio signals, Independent Vector Analysis (IVA) [8], [9], [10], [11] has been proposed; it can group sources separated in different frequencies into individual sources using frequency-independent probabilistic source models. Several algorithms based on IVA have also been developed, including Independent Vector Extraction (IVE) [12], [13] and Convolutional beamformer extension of IVA (CIVA) [14], [15]. IVE can extract signals under the situations where microphones outnumber sources of interest in a computationally efficient way.

While BSS does not aim to determine the sources' order (or permutation) in the separated outputs, SRSS uses DOAs of sources as auxiliary information to align the separated source signals [1], [2], [3], [4], [5], [6]. We call this process source permutation alignment. In concrete, SRSS introduces to the BSS cost function a spatial regularization (also known as a geometric constraint [1]) using Acoustic Transfer Functions (ATFs) from sources to microphones estimated using DOAs (hereafter denoted as DOA-based ATFs). Note that DOA-based ATFs contain substantial estimation errors, e.g., due to reverberation in a real environment. Thus it is hard for classical beamformers like a Minimum Power Distortionless Response (MPDR) beamformer to extract speech signals accurately. In contrast, SRSS (e.g., Spatially-Regularized IVA (SR-IVA) [3], [4], [5], [6]) can estimate filters much more accurately by combining the BSS cost function with spatial regularization.

Although the above-mentioned multichannel audio source separation can separate signals effectively, the separation accuracy is limited, especially when the number of available microphones is small. A switching filter has recently been proposed to overcome this limitation [16], [17], [18], [19], [20]. With a switching filter, we cluster time frames of the microphone signals at each frequency so that each cluster contains relatively a small number of sources. Then, we estimate and apply different separation filters to respective clusters separately. It can achieve more accurate separation in noisy environments than simply applying a single separation filter to a whole captured signal because each cluster contains a smaller number of sources than a whole signal. The switching filter was initially introduced into a beamformer [16], [17] to enable it to handle underdetermined situations. It was then successfully introduced to IVA/CIVA [19] and IVE/CIVE [20] to improve their source separation accuracy. We denote IVA with switching filters as SwIVA, IVE with switching filters as SwIVE, and CIVA with switching filters as SwCIVA hereafter.

Despite the accurate source separation using a switching filter, SwIVA and algorithms based on SwIVA have a problem in that they are often trapped by a bad local optimum unless we carefully initialize their parameters at appropriate values. A reason for the problem to occur is that the permutation of separated sources can differ over different clusters. This problem is called inter-state permutation. To avoid the problem, previous research has proposed Blind Single-State initialization (*BSS init*) and SPatially-Guided initialization (*SPG init*) techniques [19]. Especially, *SPG init* avoids the inter-state permutation problem and aligns the source permutation when using relatively reliable ATFs estimated by a neural network. However, our preliminary experiments showed that using DOA-based ATFs was insufficient for *SPG init* in achieving

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

that.

This paper newly introduces spatial regularization to SwIVA to solve the above-mentioned inter-state permutation problem as well as to align the source permutation only using DOA-based ATFs. We call the algorithm Spatially-Regularized SwIVA (SR-SwIVA)[1]. In this algorithm, we use spatial regularization to align the source permutation in each cluster, thus the algorithm avoids the inter-state permutation problem during its filter optimization. Furthermore, we propose an initialization technique using SR-IVA with no switching mechanism. Because SR-IVA is free from the inter-state permutation problem, we can effectively avoid the problem at the filter initialization of SR-SwIVA. Our experiment shows that when using DOA-based ATFs, SR-SwIVA can perform as accurate source permutation alignment as SR-IVA and as much separation accuracy as SwIVA. In addition, the separation accuracy obtained by SR-SwIVA based on DOA-based ATFs is comparable to that obtained by SwIVA using accurately estimated ATFs.

In the remainder of this paper, we describe the problem formulation in Section II and the baseline algorithms in Section III. Our proposed algorithm is presented in Section IV. Experiment and conclusion are given in Sections V and VI.

II. Problem formulation

Suppose that N source signals are mixed and captured by M ($\geq N$) microphones. We represent observed signals $\boldsymbol{x}(f,t)$ and source signals $\boldsymbol{s}(f,t)$ at each time $t = 1,\ldots,T$ and frequency $f = 1,\ldots,F$ in the Short-Time Fourier Transform (STFT) domain as

$$\boldsymbol{x}(f,t) = [x_1(f,t),\ldots,x_M(f,t)]^{\mathsf{T}} \in \mathbb{C}^M, \tag{1}$$

$$\boldsymbol{s}(f,t) = [s_1(f,t),\ldots,s_N(f,t)]^{\mathsf{T}} \in \mathbb{C}^N, \tag{2}$$

where $(\cdot)^{\mathsf{T}}$ denotes the transpose. We model the observed signals $\boldsymbol{x}(f,t)$ as a mixture of signals defined by

$$\boldsymbol{x}(f,t) = \sum_{n=1}^{N} \boldsymbol{d}_n(f,t) + \boldsymbol{r}(f,t), \tag{3}$$

$$\boldsymbol{d}_n(f,t) = \boldsymbol{h}_n(f)s_n(f,t), \tag{4}$$

where $\boldsymbol{d}_n(f,t) = [d_{n,1}(f,t),\ldots,d_{n,M}(f,t)] \in \mathbb{C}^M$ is the microphone image of the nth source and $\boldsymbol{h}_n(f)$ is the transfer function of the nth source. $\boldsymbol{r}(f,t)$ is the diffuse noise composed of the background noise.

We also suppose that we have an estimate of the transfer functions (hereafter called a steering vector). Assuming that the DOAs of the sources and the locations of microphones are given or estimated, we obtain a steering vector $\boldsymbol{a}_n(f)$ based on the plane wave assumption and the relative time-delay-of-arrival (TDOA) $\boldsymbol{\tau}_n \in \mathbb{R}^M$ from the nth source to M microphones:

$$\begin{aligned}\boldsymbol{a}_n(f) &= [a_{n,1}(f),\ldots,a_{n,M}(f)]^{\mathsf{T}} \in \mathbb{C}^M \\ &= \frac{1}{\sqrt{M}} \exp\left(-2\pi \frac{f}{N_{\mathrm{F}}} \boldsymbol{\tau}_n \sqrt{-1}\right) \text{ for } 1 \leq n \leq N. \end{aligned} \tag{5}$$

[1]Because it is straightforward to incorporate spatial regularization into SwIVE and SwCIVA, this paper omits this explanation for conciseness.

where each element $a_{n,m}(f)$ is an estimate of a transfer function from the nth source to the mth microphone and N_{F} is the length of Fourier transform. Note that $\boldsymbol{a}_n(f)$ contains substantial errors from the true transfer function $\boldsymbol{h}_n(f)$ in (4) because $\boldsymbol{a}_n(f)$ only contains a direct path component but does not include reflection paths.

The aim of this paper is to develop an effective algorithm to estimate a microphone image of each source at the first microphone as $[\hat{s}_1(f,t),\ldots,\hat{s}_N(f,t)]^{\mathsf{T}}$ given $\boldsymbol{x}(f,t)$ and $\{\boldsymbol{a}_n(f)\}_{n=1}^N$. It is important to note that we need to align the estimated sources with the same permutation as the sources in (2) during the estimation. We call this process source permutation alignment.

III. Baseline algorithms

This section briefly describes two of our baseline algorithms, SR-IVA and SwIVA.

A. Spatially-Regularized IVA (SR-IVA) [3], [4], [5], [6]

SR-IVA is an algorithm to estimate signals $[\hat{s}_1(f,t),\ldots,\hat{s}_N(f,t)]^{\mathsf{T}}$ with the same source permutation as in (2) by applying separation matrices $\{\boldsymbol{W}(f)\}_f$ to the observed signal:

$$\hat{\boldsymbol{s}}(f,t) = \boldsymbol{W}^{\mathsf{H}}(f)\boldsymbol{x}(f,t), \tag{6}$$

where

$$\boldsymbol{W}(f) = [\boldsymbol{w}_1(f),\ldots,\boldsymbol{w}_M(f)] \in \mathbb{C}^{M\times M}, \tag{7}$$

$$\hat{\boldsymbol{s}}(f,t) = [\hat{s}_1(f,t),\ldots,\hat{s}_M(f,t)]^{\mathsf{T}} \in \mathbb{C}^M. \tag{8}$$

Note that $\hat{s}_{N+1}(f,t),\ldots,\hat{s}_M(f,t)$ correspond to noise components. With BSS techniques such as IVA, we can obtain $\boldsymbol{W}(f)$ based on the maximum likelihood estimation assuming the statistical independence between each source $\hat{s}_n(f,t)$. However, we cannot determine the source permutation uniquely based only on the independence between sources. Thus, SR-IVA introduces a spatial regularization term to force each separation filter $\boldsymbol{w}_n(f)$ to extract a signal corresponding to $\boldsymbol{a}_n(f)$. The following is an example of a regularization term [5], which we use throughout this paper.

$$\mathcal{L}_{\text{regl}}(\{\boldsymbol{W}(f)\}_f) = \sum_{f=1}^{F}\sum_{n=1}^{N} \|\boldsymbol{w}_n(f) - \boldsymbol{a}_n(f)\|_2^2, \tag{9}$$

where $\|\cdot\|_2$ stands for l-2 norm. This regularization term enforces the nth separation filter $\boldsymbol{w}_n(f)$ to have a value close to the nth steering vector $\boldsymbol{a}_n(f)$. SR-IVA estimates signals $\hat{s}_n(f,t)$ by combining the likelihood function of BSS with the spatial regularization, thus simultaneously realizing source separation and source permutation alignment.

B. Switching IVA (SwIVA) [19]

Switching filter has recently been proposed to improve source separation accuracy. This section gives an overview of switching IVA (SwIVA). Fig. 1 shows the processing flow of SwIVA.

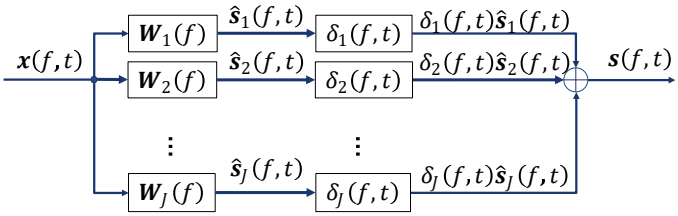

Fig. 1: Processing flow of switching IVA

SwIVA uses a multi-state separation model. It applies $J \geq 2$ separation matrices, $\boldsymbol{W}_j(f)$ for $1 \leq j \leq J$, to the observed signal to yield J different sets of separated sources $\hat{\boldsymbol{s}}_j(f,t) \in \mathbb{C}^M$:

$$\hat{\boldsymbol{s}}_j(f,t) = \boldsymbol{W}_j^{\mathsf{H}}(f)\boldsymbol{x}(f,t) \text{ for } 1 \leq j \leq J, \tag{10}$$

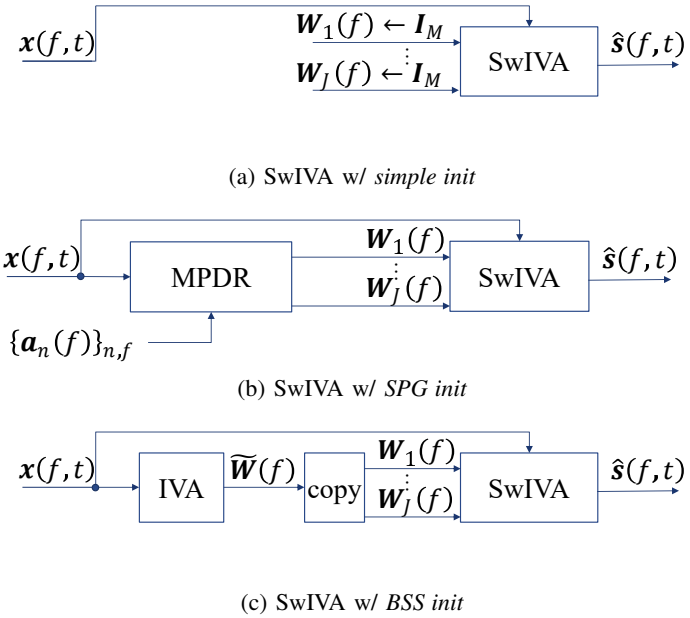
$$\boldsymbol{W}_j(f) = [\boldsymbol{w}_{j,1}(f), \ldots, \boldsymbol{w}_{j,M}(f)] \in \mathbb{C}^{M \times M}. \tag{11}$$

Here j is an index of a switching state and J is the number of the switching states (or the number of separation matrices). Then, it uses a switch to select one of J separated sources at each time frequency and yields its final output:

$$\hat{\boldsymbol{s}}(f,t) = \sum_{j=1}^{J} \delta_j(f,t)\hat{\boldsymbol{s}}_j(f,t), \tag{12}$$

$$\sum_{j=1}^{J} \delta_j(f,t) = 1 \quad \text{and} \quad \delta_j(f,t) \in \{0,1\}. \tag{13}$$

The switch mechanism is implemented using a time-frequency dependent switching weight $\{\delta_j(f,t)\}_{j,f,t}$ in (12). In this paper, we only consider hard switches and allow $\delta_j(f,t)$ to take only binary values, 0 or 1. It has been reported that SwIVA achieved more accurate source separation than IVA that applies a single set of separation matrix in (6).



One important issue with SwIVA is that the separation matrices $\{\boldsymbol{W}_j(f)\}_j$ are often trapped by a bad local optimum that yields relatively less accurate source separation. This problem occurs because the permutations of separated sources can differ over different states. Thus, the order of sources changes when the switching state changes, resulting in large estimation errors. We call this problem inter-state permutation problem.

Previous research has proposed several initialization techniques for SwIVA to avoid the inter-state permutation problem [19]. We explain three of them in the following using Fig. 2.

1) Simple initialization (simple init): In this initialization, we set each separation matrix $\boldsymbol{W}_j(f)$ as an $M \times M$ identity matrix $\boldsymbol{I}_M$ as shown in Fig. 2a:

$$\boldsymbol{W}_j(f) \leftarrow \boldsymbol{I}_M \text{ for } 1 \leq j \leq J \text{ and } 1 \leq f \leq F. \tag{14}$$

It is reported that *simple init* does not avoid the inter-state permutation problem well for SwIVA.

(a) SwIVA w/ *simple init*

(b) SwIVA w/ *SPG init*

(c) SwIVA w/ *BSS init*

Fig. 2: Flow of SwIVA with three different initialization techniques

2) Spatially-guided initialization (SPG init): In this initialization, we employ the conventional MPDR beamformer to initialize the separation matrices $\boldsymbol{W}_j(f)$ as shown in Fig. 2b. In concrete, after randomly initializing $\delta_j(f,t)$, each filter $\boldsymbol{w}_{j,n}(f)$ is initialized:

$$\boldsymbol{w}_{j,n}(f) = \begin{cases} \frac{a^*_{n,1}(f)\boldsymbol{\Xi}_j^{-1}(f)\boldsymbol{a}_n(f)}{\boldsymbol{a}_n^{\mathsf{H}}(f)\boldsymbol{\Xi}_j^{-1}(f)\boldsymbol{a}_n(f)} & \text{for } 1 \leq n \leq N, \\ \boldsymbol{e}_n, & \text{for } N+1 \leq n \leq M, \end{cases} \tag{15}$$

where

$$\boldsymbol{\Xi}_j(f) = \frac{\sum_t \delta_j(f,t)\boldsymbol{x}(f,t)\boldsymbol{x}^{\mathsf{H}}(f,t)}{\sum_t \delta_j(f,t)}, \tag{16}$$

is a sample covariance matrix using time-frequency bins specified by the jth switch $\delta_j(f,t)$. $(\cdot)^*$ denotes complex conjugate, and $\boldsymbol{e}_n$ denotes the nth column of $\boldsymbol{I}_M$. The effectiveness of *SPG init* has been shown when we can obtain relatively accurate ATFs using a neural network.

3) Blind single-state initialization (BSS init): In this initialization, we use IVA to initialize the separation matrices $\boldsymbol{W}_j(f)$ as shown in Fig. 2c. Let $\tilde{\boldsymbol{W}}(f) \in \mathbb{C}^{M \times M}$ be a separation matrix estimated by IVA (or SwIVA with $J = 1$), then we initialize $\boldsymbol{W}_j(f)$ by $\tilde{\boldsymbol{W}}(f)$:

$$\boldsymbol{W}_j(f) \leftarrow \tilde{\boldsymbol{W}}(f) \text{ for } 1 \leq j \leq J \text{ and } 1 \leq f \leq F, \tag{17}$$

and randomly initialize $\delta_j(f,t)$. *BSS init* can avoid the inter-state permutation but is not intended to align the source permutation.

C. Drawbacks of SwIVA

Although using *SPG init* for SwIVA has been shown effective in avoiding the inter-state permutation problem when accurately estimated ATFs are available, it is not certain whether we can correctly align the source permutation based on only the initialization. In addition, our preliminary experiments showed that *SPG init* was insufficient when ATFs are estimated based on DOAs. This is probably because DOA-based ATFs contain substantial errors when estimated in real reverberant environments.

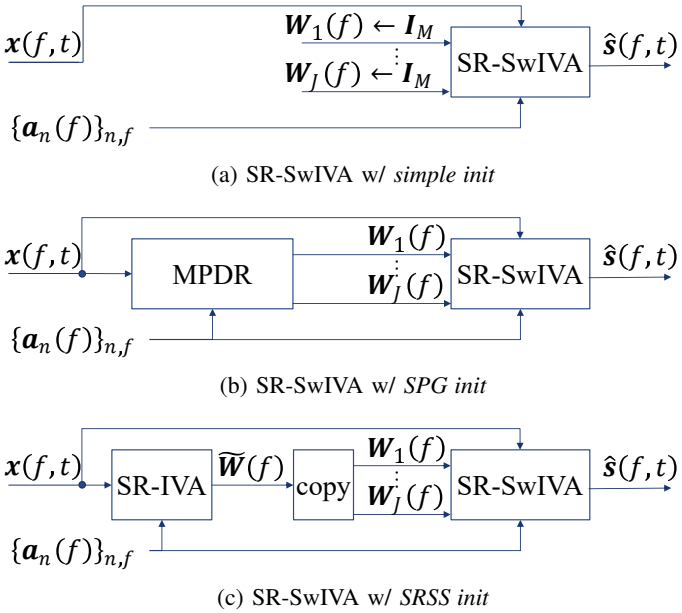
IV. Proposed algorithm: Spatially-Regularized SwIVA (SR-SwIVA)

This section proposes Spatially-Regularized SwIVA (SR-SwIVA) that controls SwIVA using DOA-based ATFs. To solve the problem discussed in Section III-C, we utilize DOA-based spatial regularization, which was shown effective for SR-IVA to align the source permutation. We first explain the estimation model and parameter optimization of SR-SwIVA in Section IV-A, and then present a new initialization technique for SR-SwIVA in Section IV-B. We expect that the algorithm effectively avoids the inter-state permutation problem and aligns the source permutation at the same time.

A. Estimation model and parameter optimization

First, we explain the estimation model and develop the parameter optimization of SR-SwIVA. SR-SwIVA uses the same separation model as SwIVA in (10). Then, similar to SR-IVA, we define the cost function as the sum of the negative log likelihood function $\mathcal{L}_{\text{NL}}(\mathcal{X};\Theta)$ used for SwIVA [19] and a spatial regularization term $\mathcal{L}_{\text{regl}}(\mathcal{W})$ that we design for SR-SwIVA:

$$\mathcal{L}(\Theta) = \mathcal{L}_{\text{NL}}(\mathcal{X};\Theta) + \lambda_{\text{regl}}\mathcal{L}_{\text{regl}}(\mathcal{W}). \tag{18}$$



$$\mathcal{L}_{\text{NL}}(\mathcal{X};\Theta) = \sum_{j,f,t}\delta_j(f,t)\left\{\sum_{n=1}^{M}\left(\log v_n(f,t) + \frac{|\hat{s}_{j,n}(f,t)|^2}{v_n(f,t)}\right) - 2\log\left|\det \boldsymbol{W}_j(f)\right|\right\} \tag{19}$$

where $\hat{s}_{j,n}(f,t)$ is the nth element of $\hat{\boldsymbol{s}}_j(f,t)$ in (10), $\mathcal{X} = \{\boldsymbol{x}(f,t)\}_{f,t}$ is the set of observed signals, and $\Theta = \{\mathcal{D},\mathcal{W},\mathcal{V}\}$ is a set of model parameters composed of switching weights $\mathcal{D} = \{\delta_j(f,t)\}_{j,f,t}$, separation matrices $\mathcal{W} = \{\boldsymbol{W}_j(f)\}_{j,f}$, and the time-frequency dependent variance of the sources[2] $\mathcal{V} = \{v_n(f,t)\}_{n,f,t}$.

As for the spatial regularization term, $\mathcal{L}_{\text{regl}}(\mathcal{W})$, this paper adopts almost the same definition as that introduced for SR-IVA in (9). A major difference from SR-IVA is that we duplicate the same term to regularize the separation filters in all states. In concrete, the regularization term is formulated:

$$\mathcal{L}_{\text{regl}}(\mathcal{W}) = \sum_{f=1}^{F}\sum_{j=1}^{J}\sum_{n=1}^{N}\|\boldsymbol{w}_{j,n}(f) - \boldsymbol{a}_n(f)\|_2^2. \tag{20}$$

[2]Following the previous work for SwIVA [19], we use the frequency-independent source model only for updating the separation matrices as a practical technique to group the separated sources over different frequencies.

(a) SR-SwIVA w/ *simple init*

(b) SR-SwIVA w/ *SPG init*

(c) SR-SwIVA w/ *SRSS init*

Fig. 3: Flow of SR-SwIVA with three different initialization techniques

This term forces separation filters $\boldsymbol{w}_{j,n}(f)$ that share the same source index n at different states $1 \le j \le J$ to be close to the same steering vector of the nth source $\boldsymbol{a}_n(f)$. Therefore, as long as the spatial regularization successfully aligns the source permutation in the same way as SR-IVA, all the filters $\boldsymbol{w}_{j,n}(f)$ are expected to extract the same nth source for $1 \le j \le J$. As a consequence, we can also solve the inter-state permutation problem and align the source permutation.

The parameter optimization of SR-SwIVA can be straightforwardly derived by combining the existing algorithms (i.e., SR-IVA [5] and SwIVA [19]). We describe the derivation in Appendix A.

B. Spatially-Regularized single-state initialization (SRSS init)

Next, we introduce the DOA-based spatial regularization to the initialization for SR-SwIVA, referred to as Spatially-Regularized Single-State initialization (*SRSS init*). The aim of using *SRSS init* is to improve the estimation accuracy of SR-SwIVA better than *SPG init* that was used for SwIVA.

Fig. 3 shows flows of SR-SwIVA with three different initialization techniques that we compare in our experiments. In Figs. 3a and 3b, we use the same initialization techniques used in Figs. 2a and 2b. Fig. 3c shows our proposed *SRSS init*, which is a modification of *BSS init* in Fig. 2c for SwIVA. In *SRSS init*, we use SR-IVA (or SR-SwIVA with $J = 1$) instead of IVA to initialize all the parameters of SR-SwIVA. Because SR-IVA aligns the source permutation effectively, it can be a desirable initialization for SR-SwIVA using DOA-based ATFs.

V. Experiment

In this section, we compare the source separation and alignment accuracy of IVA, SwIVA, and SR-SwIVA combined with various initialization techniques, including *SPG init* and *SRSS init*. Our experiment shows the effectiveness of SR-SwIVA when using DOA-based ATFs.

A. Conditions of experiment

We conducted an experiment using TIMIT-ConvMix, which is composed of simulated noisy reverberant mixtures. To generate the mixtures, we first concatenated utterances extracted from the TIMIT corpus [21] to obtain a set of single-speaker clean utterance sequences, each of which is 30 s long. Then we mixed three utterance sequences and five different additive noise signals extracted from the CHiME-3 dataset [22] after individually reverberating them. We randomly selected 8 Room Impulse Responses (RIRs) out of 9 RIRs from the RWCP E2A dataset [23], corresponding to the azimuths of $10^\circ, 30^\circ, 50^\circ, \ldots, 170^\circ$. We then performed the convolution by assigning the RIRs to the utterances and noises. Here, we set the minimum angle difference between each utterance at 40°. RT60 of the RIRs was 0.3 s. We used four microphones labeled in the dataset: the 21st, 22nd, 23rd, and 24th. All four types of noise signals were used, BUS, STR, PED, and CAF, although each mixture contained only a single type. We set the power ratio of each reverberant utterance sequence to the sum of the additive noise signals to 10 dB.

We used a Hann window for a short-time analysis, where frame length N_{F} and shift size were set to 64 ms and 32 ms, respectively. The sampling frequency f_{s} was set to 16 kHz. We initialized switching weights $\delta_j(f,t)$ at a random value in a range of 1 ± 10^{-3}, and normalized it to satisfy $\sum_{j=1}^{J} \delta_j(f,t) = 1$. Note that after initialization, the weights $\delta_j(f,t)$ are updated to binary values during the parameter optimization. For all algorithms, including IVA, SR-IVA, SwIVA, and SR-SwIVA, we updated the separation filters 50 times and applied projection back [24] post-processing to solve the scale ambiguity.

Because we used linear arrays, we set relative TDOA $\boldsymbol{\tau}_n = [\tau_{n1}, \ldots, \tau_{nM}]$ in (5) for the DOA-based steering vectors:

$$\tau_{nm} = f_{\mathrm{s}} \frac{d(m-1)}{c} \cos\left(2\pi \frac{\theta_n}{360^\circ}\right), \tag{21}$$

where $c = 343$ m/s is the speed of sound and $d = 0.0281$ meter is the distance between adjacent microphones. We used the angle labels for RIRs in the RWCP dataset as the speakers' directions θ_n. Note that even using the angle labeled at the dataset, the steering vector in (5) should contain substantial errors because it does not include the effects of reflection paths. To confirm the performance using oracle information, we also evaluated the source separation accuracy of SRSS algorithms when replacing DOA-based ATFs $\boldsymbol{a}_n(f)$ with oracle steering vectors $\boldsymbol{h}_n(f)$ in (4). We created $\boldsymbol{h}_n(f)$ as the primary eigenvector of the spatial covariance matrix of the noiseless reverberant source image of $s_n(f,t)$.

In this evaluation, we adopted signal-to-distortion ratio (SDR) and signal-to-interference ratio (SIR) as the metrics of source separation accuracy [25], which is widely used in source separation research. We used the MUSEVAL V4 toolkit [26] with its bss_eval_images configuration. As reference signals, we used clean utterance sequences that were convolved with the RIRs for generating the corresponding mixtures. We evaluated SDRs and SIRs using a correct permutation of estimated sources, not depending on the actual permutation estimated by each separation algorithm. We determined the correct permutation as the order of estimated sources that gave the best SIR score with the reference signals in their original order. In addition to SDR and SIR, we evaluated the correctness of the estimated source permutation alignment using the permutation error (permE) defined.

$$\text{permE} = \frac{\text{\# of mixtures separated with incorrect permutation}}{\text{Total \# of mixtures (=100)}}. \tag{22}$$

The estimated source permutation alignment was determined to be incorrect when it was not identical to the correct source permutation.

B. Result

We compared the SDR improvement, SIR improvement, and permE for each source separation algorithm in Table I. We conducted two experiments, one with three microphones and the other with four microphones, and show the results in Tables Ia and Ib. For each experiment, we set the regularization weight λ_{regl} as a value, with which SR-SwIVA achieved the highest SDRs while reducing permE to zero.

We first show the result of the baseline algorithms, SR-IVA and SwIVA. In both Tables Ia and Ib, although SR-IVA ($J = 1$) reduced permE to zero and achieved comparable SDRs and SIRs as IVA, SwIVA with *SPG init* showed 5 % permE when $M = 3$. Moreover, SwIVA with *SPG init* showed 100 % permE when $M = 4$. This is because DOA-based ATFs contained a lot of errors, as shown by the low source separation accuracy (3.83 dB SIR improvement) by MPDR beamformer. The above results show that when using DOA-based ATFs, SwIVA with *SPG init* cannot correctly align separated sources.

Next, we show the result of SR-SwIVA with several initialization techniques presented in Fig. 3 using the same tables. From the tables, SR-SwIVA could not achieve 0 % permE when using *simple init* or *SPG init* except for using *simple init* with $M = 4$. Also, their SDRs are comparable to or even worse than the baseline algorithms. On the other hand, SR-SwIVA with *SRSS init* achieved the highest SDR and 0 % permE when using DOA-based ATFs. Thus, we conclude that SR-SwIVA with *SRSS init* can separate signals and align the source permutation more effectively than the baseline algorithms.

Finally, we show the results using oracle ATFs. In both tables, the MPDR beamformer worked much better using oracle ATFs than using DOA-based ATFs, and SwIVA with *SPG init* attained high SDR and SIR and reduced permE to 0 %. It means that *SPG init* is effective for SwIVA only when

TABLE I: The improvements of SDR (SDRi), SIR (SIRi) [dB], and permutation error (permE) [%]. SDRs and SIRs were calculated using a correct source permutation that achieved the highest SIRs among all possible source permutations.

we have relatively accurate ATFs. In contrast, SR-SwIVA with *SRSS init* can achieve the same high scores regardless of using oracle ATFs or DOA-based ATFs. Thus we showed that SR-SwIVA could achieve as much accurate source separation and source permutation alignment as SwIVA based on relatively accurate ATFs.

VI. Conclusions

In this paper, we have proposed a novel algorithm called SR-SwIVA that uses spatial regularization to enhance SwIVA for accurate source separation and permutation alignment based on DOA-based ATFs. We have shown that DOA-based ATFs have significant estimation errors in real reverberant environments, which prevent conventional SwIVA from achieving high separation accuracy and correct permutation alignment. To address this challenge, we have developed SR-SwIVA by incorporating spatial regularization into SwIVA and presented a new effective initialization technique called *SRSS init* that uses DOA-based ATFs. We have conducted an experiment using noisy reverberant sound mixtures and demonstrated that our proposed SR-SwIVA can significantly improve the SDRs and SIRs compared to our baseline algorithms, SR-IVA and SwIVA, with DOA-based ATFs, and eliminate the source permutation alignment errors completely. Moreover, we have shown that the source separation accuracy achieved by SR-SwIVA is similar to that of SwIVA with oracle ATFs.

Appendix A. parameter optimization of SR-SwIVA

We optimize the parameters Θ for SR-swIVA by minimizing the cost function in (18). Because no closed form solution has been obtained, we use iterative estimation based on a coordinate descent method. It alternately updates one of $\mathcal{W}$, $\mathcal{D}$, and $\mathcal{V}$ by fixing the other parameters, and iterates the update until convergence is obtained.

Because the update of $\mathcal{D}$ and $\mathcal{V}$ is not related with the regularization term, we can update $\mathcal{D}$ and $\mathcal{V}$ using the same update rules written in [19]. Hereafter we only explain the update of $\mathcal{W}$. For the update of the separation matrices $\mathcal{W}$, we adopt a frequency-independent source model following a practical technique proposed in [19] to group separated sources over different frequencies. In concrete, instead of using the frequency-dependent variance $v_n(f,t)$, we use a frequency-independent variance $v_n(t)$ for the update, which is obtained by $v_n(t) \leftarrow \frac{1}{F}\sum_{f=1}^{F} v_n(f,t)$. Then, fixing $\delta_j(f,t)$ and $v_n(t)$, we can rewrite the function $\mathcal{L}(\Theta)$ in (18) as

$$\begin{aligned}\mathcal{L}(\boldsymbol{W}_j(f)) \overset{c}{=} &-2\log\left|\det \boldsymbol{W}_j(f)\right| \\ &+ \sum_{n=1}^{M}\big(\boldsymbol{w}_{j,n}^{\mathsf{H}}(f)\boldsymbol{\Pi}_{j,n}(f)\boldsymbol{w}_{j,n}(f) \\ &- \boldsymbol{w}_{j,n}^{\mathsf{H}}(f)\boldsymbol{p}_n(f) - \boldsymbol{p}_n^{\mathsf{H}}(f)\boldsymbol{w}_{j,n}(f)\big), \end{aligned} \tag{23}$$

where

$$\boldsymbol{\Pi}_{j,n}(f) = \begin{cases} \boldsymbol{\Sigma}_{j,n}(f) + \lambda_{\text{regl}}\boldsymbol{I}_M & \text{for } 1 \le n \le N, \\ \boldsymbol{\Sigma}_{j,n}(f) & \text{for } N+1 \le n \le M, \end{cases} \tag{24}$$

$$\boldsymbol{p}_n(f) = \begin{cases} \lambda_{\text{regl}}\boldsymbol{a}_n(f) & \text{for } 1 \le n \le N, \\ \boldsymbol{0}_M & \text{for } N+1 \le n \le M, \end{cases} \tag{25}$$

$$\boldsymbol{\Sigma}_{j,n}(f) = \frac{1}{T_j(f)}\sum_{t=1}^{T}\frac{\delta_j(f,t)}{v_n(t)}\boldsymbol{x}(f,t)\boldsymbol{x}^{\mathsf{H}}(f,t), \tag{26}$$

$$T_j(f) = \sum_{t=1}^{T}\delta_j(f,t), \tag{27}$$

and $\boldsymbol{0}_M \in \mathbb{C}^M$ is a zero vector. Because the above objective has the same form as SR-IVA [4], [5], we can apply iterative optimization techniques proposed for it, such as Vectorwise Coordinate Decent (VCD) [2], and Iterative Source Steering [11], [6]. This paper employs VCD that updates $\boldsymbol{W}_j(f)$ with a sequence of $\boldsymbol{w}_{j,1}(f) \rightarrow \boldsymbol{w}_{j,2}(f), \ldots, \rightarrow \boldsymbol{w}_{j,M}(f)$ for $j =$

$1, \ldots, J$:

$$\boldsymbol{u}_{j,n}(f) = (\boldsymbol{W}_j^{\mathsf{H}}(f)\boldsymbol{\Pi}_{j,n}(f))^{-1}\boldsymbol{e}_n, \tag{28}$$

$$\tilde{\boldsymbol{u}}_{j,n}(f) = \boldsymbol{\Pi}_{j,n}^{-1}(f)\boldsymbol{p}_n(f), \tag{29}$$

$$h_{j,n}(f) = \boldsymbol{u}_{j,n}^{\mathsf{H}}(f)\boldsymbol{\Pi}_{j,n}(f)\boldsymbol{u}_{j,n}(f), \tag{30}$$

$$\hat{h}_{j,n}(f) = \boldsymbol{u}_{j,n}^{\mathsf{H}}(f)\boldsymbol{\Pi}_{j,n}(f)\tilde{\boldsymbol{u}}_{j,n}(f), \tag{31}$$

$$\tilde{h}_{j,n}(f) = \frac{\hat{h}_{j,n}(f)}{2h_{j,n}(f)}\left[-1 + \sqrt{1 + \frac{4h_{j,n}(f)}{|\hat{h}_{j,n}(f)|^2}}\right], \tag{32}$$

$$\boldsymbol{w}_{j,n}(f) = \begin{cases} \frac{1}{\sqrt{h_{j,n}(f)}}\boldsymbol{u}_{j,n}(f) + \tilde{\boldsymbol{u}}_{j,n}(f) & \text{if } \hat{h}_{j,n}(f) = 0, \\ h_{j,n}(f)\boldsymbol{u}_{j,n}(f) + \tilde{\boldsymbol{u}}_{j,n}(f) & \text{otherwise.} \end{cases} \tag{33}$$

***Abstract*—Face recognition is a crucial task in numerous applications, but it has difficulties because of the high-dimensional nature of facial photos, limited sample sizes, variations in illumination, and facial expressions. This paper presents a novel face recognition approach to overcome these challenges by combining the advantages of the Approximately Symmetrical Face (ASF) preprocessing strategy and the Locality-regulated Linear Regression Discriminant Analysis (LLRDA) method. The proposed method, called ASF-LLRDA, makes use of ASF to generate axis-symmetric face images for reducing the impact of illumination and variations in facial expressions, followed by LLRDA to extract discriminative features and project the data into a lower dimensional space. Locality-regulated Linear Regression (LLRC) is further utilized as the classifier. Experimental results on the Yale-B face dataset demonstrated the superiority of the proposed method compared to the baselines.**

I. Introduction

Face recognition has many applications in a variety of fields, such as biometric identification [1], action detection [2], marketing [3], and personalization [4], [5]. In real-world scenarios, face recognition systems often encounter challenges related to limited storage space and time constraints for capturing training samples [6], [7]. This is primarily due to the high-dimensional nature of facial images, which necessitates a larger storage capacity [8]. Additionally, when the available sample size is restricted, variations in illumination and facial expressions can lead to greater intra-subject variability compared to inter-subject variability [9]. Consequently, different faces may exhibit similar patterns, resulting in the incorrect recognition of individuals as the same person.

In order to deal with high-dimensional data effectively, dimension reduction has become a vital preprocessing step. The primary objective of dimensionality reduction is to concurrently solve two major problems: reducing intra-subject variability and enhancing inter-subject variability. This is achieved by eliminating irrelevant, redundant, and noisy data samples in extracting the underlying features inherent in high-dimensional data. As a result, dimensionality reduction has also been extensively explored to overcome the limitations encountered in real-world facial recognition applications, as previously discussed [10].

Among the various dimensionality reduction techniques utilized in face recognition algorithms, Principal Component Analysis (PCA) [11] and Latent Dirichlet Allocation (LDA) [12] are widely employed due to their effectiveness in extracting low-dimensional and discriminative features [13]. PCA is an unsupervised approach that aims to maximize the variance of the data by projecting it onto a new subspace. However, it does not incorporate any prior class information, thus ignoring potentially useful discriminative information [14]. Meanwhile, LDA is a supervised method that takes into account the prior class information. By considering class information, LDA can potentially enhance the separability of the data [14]. Nevertheless, both PCA and LDA primarily capture the global Euclidean structure of the data, disregarding the underlying manifold structure that may exist in the data [15]. Moreover, they do not explicitly consider the decision rule of the classifier, which can lead to subspaces with distinct characteristics that are not fully exploited by the classifiers, resulting in suboptimal classification performance.

To retain the local manifold structures of the data, several nonlinear-based techniques have been developed, including isometric mapping [16], [17], locally-linear embedding [18], [19], and multi-dimensional scaling [20]. However, these methods often exhibit poor performance when applied to new and unseen data [21]. Some existing approaches leverage representation-based classifiers to improve pattern recognition within dimensionality reduction. Examples include the sparse representation-based classifier (SRC) [22], collaborative representation-based classification (CRC) [23], and linear regression classification (LRC) [24]. Among these methods, LRC offers reasonable accuracy while maintaining lower complexity.

In [14], Huang *et al.* have proposed the locality-regularized linear regression discriminant analysis (LLRDA) designed according to the decision rule of the expanded LRC using a locality-regularized procedure. LLRDA exhibits promising potential in capturing the most discriminant information from the data by leveraging the characteristics of the learned subspace. However, it should be noted that the original feature space may not guarantee high classification accuracy, particularly when faced with variations in illumination and limited training samples, which are common challenges in face recognition tasks.

Various preprocessing methods have been proposed to mitigate the effects of illumination on face images. Lambertian reflection-based methods have gained significant attention lately due to their effectiveness in handling unbalanced illumination conditions. Developing a robust model that can handle general real-world scenes, however, remains a challenge. One of the main difficulties lies in reliably estimating the surface orientations and light directions, which are crucial for accurate illumination compensation. The complexity of real scenes, with diverse lighting conditions and surface properties, adds to the complexity of this task.

A study proposed by Xu *et al.* [25] has introduced a non-Lambertian reflectance, called Axis-Symmetrical Face (ASF), to address the challenges of varying face appearances and their negative effects on face recognition. ASF leverages the symmetrical geometric structure of the face to generate an axis-symmetrical virtual face image by equalizing the illumination between the right and left sides of the face. In addition to its impact on face recognition accuracy, ASF also has the potential to produce more visually appealing face images. It is worth noting that ASF is a face image preprocessing method. Further research might open the possibility of using ASF to optimize the performance and computational efficiency of face recognition tasks.

Motivated by the promising properties of ASF and LLRDA, we propose a novel approach for dimensionality reduction designed to improve face recognition performance. The proposed method, called ASF-LLRDA, combines the advantages of the ASF method in handling varying illuminations and facial expressions of face images with the abilities of LLRDA to capture dominant trends in the data and project them to a lower-dimensional space. We further employ the locality-regularized linear regression classification (LLRC) classifier, known for its promising performance in face recognition, to enhance classification accuracy. As we demonstrate in the following discussions, the proposed method significantly enhances face recognition performance in small sample-size data with face images of varying illumination. We also conduct comprehensive experiments to show the outstanding performance of the method in recognizing face images.

The rest of this paper is organized as follows. Section II describes the details of our face recognition framework. The performance of the algorithm is thoroughly investigated in Section III. Finally, Section IV concludes our work with potential directions for future work.

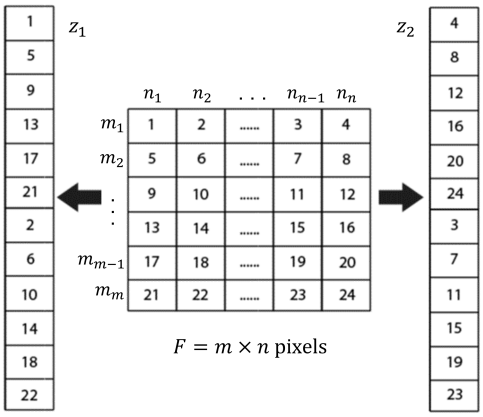

Fig. 1: An illustration of how to obtain the column vectors of z_1 and z_2.

II. Methodology

Our approach comprises three primary steps, namely: (1) facial image synthesis, (2) subspace construction, and (3) face recognition, as described below.

A. Facial Image Synthesis

To generate an approximate axis-symmetric model of a grayscale face image F with the size of $m \times n$ pixels, we first create the left column vector (z_1) and right column vector (z_2) of F. As illustrated in Figure 1, z_1 is formed by concatenating the first column of n, denoted by n_1, to the $n_{\frac{n}{2}}$-th column of F one by one. Similarly, z_2 is obtained by concatenating the last column of n, denoted by n_n, to the $n_{\frac{n}{2}+1}$-th column of F one by one.

In the following step, an axis-symmetric face image is generated to reduce the effect of varying illumination and facial expression. This involves iteratively updating each pixel value in the z_1 and z_2 using gradient descent:

$$x^{t+1} = x^t - \eta \triangle f(x^t), \tag{1}$$

where η represents the learning rate and x^t represents the pixel value at iteration t. Two types of f functions are used to minimize the difference in value between z_1 and z_2, which are defined as:

$$f_{z_1} = \|z_1 - z_2\|^2, \tag{2}$$

$$f_{z_2} = \|z_2 - z_1\|^2. \tag{3}$$

Then, the iterative update for the values of both z_1 and z_2 at each iteration t are as follows:

$$z_1^{t+1} = z_1^t - \eta(z_1^t - z_2^t), \text{and} \tag{4}$$

$$z_2^{t+1} = z_2^t - \eta(z_2^t - z_1^t). \tag{5}$$

As t increases, the learning rate η decreases. Thus, to facilitate easier convergence of the solution, the learning rate is adjusted using the following formula:

$$\eta = \alpha / t, \tag{6}$$

where α is a positive constant. The iteration continues until the following conditions are satisfied:

$$\|z_1^{t+1} - z_1^t\| < \epsilon(z_1^t), \text{and} \tag{7}$$

$$\|z_2^{t+1} - z_2^t\| < \epsilon(z_2^t). \tag{8}$$

Here, ϵ is a small positive constant.

B. Subspace Construction

This step is designed to highlight the distinctiveness of samples from different classes. To achieve this, the data is projected onto a subspace that minimizes the intra-class local reconstruction scatter, indicating the proximity of samples within the same class, while maximizing the inter-class local reconstruction scatter. The representation of the data in the new subspace is defined by:

$$y = \mathbf{A}^T F', \tag{9}$$

where F' represents the preprocessed F using the strategy described in Section II-A, and $\mathbf{A}$ denotes a matrix projection.

Specifically, the matrix projection $\mathbf{A}$ that describes how to perform the mapping from original space to lower dimensional space is formed by:

$$\mathbf{A} = \mathbf{A}_P \mathbf{A}_L. \tag{10}$$

Here, $\mathbf{A}_P$ is the result of PCA projection, and $\mathbf{A}_L$ is constructed by utilizing the intra-class local reconstruction scatter matrix S_w and the inter-class local reconstruction scatter matrix S_b. It is important to note that the dimension of the subspace for $\mathbf{A}_P$ does not exceed the number of samples N.

To obtain S_w and S_b, we first determine the nearest neighbors of F' within each class. The k-nearest neighbors of F belonging to class i can be expressed as

$$\tilde{F}_i = [\ F_i^1, F_i^2, ..., F_i^k]\ \in \mathbb{R}^{N \times k}, \tag{11}$$

where F_i^j represent the j-th sample of class i and F_l^j represent the j-th sample of class l, with l being a class different from i. Subsequently, S_w and S_b are calculated using

$$S_w = \sum_{i,j} (\ F_i^j - \tilde{F}_i^j \beta_i^j)\ (\ F_i^j - \tilde{F}_i^j \beta_i^j)\ ^T, \tag{12}$$

$$S_b = \sum_{i,j,l} (\ F_i^j - \tilde{F}_l^j \beta_l^j)\ (\ F_i^j - \tilde{F}_l^j \beta_l^j)\ ^T. \tag{13}$$

In these equations, β_i^j and β_l^j represent the reconstruction coefficient vectors for class i and class l, respectively. The linear reconstruction of y for class i is defined as

$$\tilde{\beta}_i = (\ \tilde{F}_i^T \tilde{F})\ ^{-1} \tilde{F}_i^T y. \tag{14}$$

By solving the following eigenvalue problem,

$$S_w^{-1} S_b^a = \lambda a, \tag{15}$$

we obtain $\mathbf{A}_L \in \mathbb{R}^{N \times d} (d < N)$, which is constructed from the eigenvectors of $S_w^{-1} S_b^a$ associated with the largest eigenvalues of $S_w^{-1} S_b^a$.

Fig. 2: Examples of images from a single subject within the Yale B dataset.

C. Face Recognition

In face recognition, it is commonly observed that samples within a class demonstrate local linearity rather than global linearity. This implies that neighboring samples within a class, rather than all samples, tend to lie in a linear subspace [14]. Consequently, in LLRC, only the k-nearest neighbors of the testing sample from each class are considered when performing the linear reconstruction. To generate a discriminant subspace for LLRC, the decision rule is formulated as:

$$class(y) = \min_i \|y - \tilde{X}_i (\ \tilde{X}_i^T \tilde{X}_i)\ ^{-1} \tilde{X}_i^T y\|^2. \tag{16}$$

III. Experiments

In this section, we provide a detailed description of the dataset utilized in the experiments, outline the parameters employed, baseline method for comparison, and subsequently present a comprehensive analysis of the experimental results.

A. Dataset

The primary objective of this study is to evaluate the performance of the proposed method in handling small sample-size datasets with variations in illumination and facial expressions. To achieve this, we utilize the Yale B dataset [26] as the dataset for our experiments. The Yale B dataset comprises a total of 16,128 grayscale face images captured from 28 distinct subjects. Each subject exhibits 9 different facial expressions, while the images are captured under 64 distinct illumination conditions. Figure 2 presents a visual representation of sample images from a single subject, illustrating the variations in facial expression and illumination within the dataset.

B. Experimental Setup

Three parameters were employed in the experiment. The first parameter, denoted by n_{tr}, represents the number of training samples utilized for each class or subject. Because our focus is on evaluating the performance of methods with small-sample sizes, a limited number of samples ranging from 3 to 6 were employed as training data. The second parameter relates to the number of nearest neighbors for each sample, denoted by *k*. To ensure a balanced consideration of neighboring samples, *k* was set to $\frac{n_{tr}}{2}$ in the case of an even n_{tr} and *k* was set to $\lfloor \frac{n_{tr}}{2} \rfloor + 1$ for an odd n_{tr}. Lastly, the third parameter corresponds to the number of features extracted from the data, denoted by d. For this study, d was consistently set to 20, allowing for a concise representation of the data while retaining relevant discriminatory information.

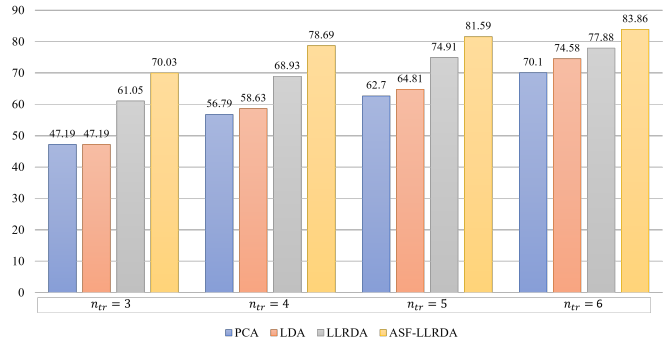

Fig. 3: The average accuracy of each method with different number of training samples n_{tr}.

C. Baselines

To assess the classification performance of the proposed method, we conducted a comparative analysis by evaluating its average classification accuracy against dimensionality reduction-based methods, namely PCA [11], LDA [12], and LLRDA [14]. The LLRC classifier was employed for each method to classify the testing samples. To ensure reliability, we performed five experiments for each n_{tr} and calculated the average classification accuracy. In each experiment, the training samples were randomly selected to assess the robustness of each method against variations in illumination and facial expressions depicted in the face images.

D. Experimental Results and Discussion

Table I summarizes the classification performance of baseline methods and the proposed ASF-LLRDA method. The average computational time for PCA, LDA, LLRDA, and ASF-LLRDA is 4.59, 4.42, 4.69, and 4.78 seconds, respectively. Note that, for a fair comparison across methods, we used the same data partition.

As shown in Table I and the bar chart in Figure 3, for $n_{tr} = 3$, the average classification accuracy of PCA and LDA was very low (less than 50%). However, as the number of training samples increased, the classification accuracy of both PCA and LDA markedly improved. For example, for $n_{tr} = 6$, the average classification accuracy exceeded 70%. We suggest this lack of accuracy is related to the extreme variations in illumination and facial expressions present in the images. Particularly, in PCA, this limitation arises because the focus is only on maximizing the variance of the data, without considering the previous class information and the geometric structure of the data. Therefore, in the generated new subspace, the samples from different classes tend to overlap, posing challenges in distinguishing between samples of different classes. On the other hand, LDA takes into account the prior class information, enabling it to capture the discriminant structure of the data and achieve a slightly improved average classification accuracy. However, even with this consideration, the variations in illumination and facial expression prove substantial, resulting in insufficient separability of samples from different classes within the new subspace generated by LDA. Similar to PCA, LDA disregards the geometric structure of the data, further contributing to lower classification accuracy compared to other methods.

In contrast to PCA and LDA, LLRDA demonstrated the ability to reveal the discriminant and local geometric structure of the data. Consequently, the generated new subspaces possess enhanced separability among samples from different classes, surpassing the subspaces produced by PCA and LDA. For $n_{tr} = 3, 4$, and 5, the average classification accuracy achieved by LLRDA was 61.05%, 68.93%, and 74.91% respectively, surpassing the average classification accuracy of PCA and LDA by a notable margin of 10%. For $n_{tr} = 6$, the difference in average classification accuracy between LLRDA and LDA decreases significantly to slightly over 3%. These results indicate that LLRDA performance is still affected by extreme variations in illumination and facial expressions present in images, although to a lesser degree compared to PCA and LDA.

Evidently, the experimental results demonstrate the superiority of ASF-LLRDA, which consistently outperformed PCA, LDA, and LLRDA by substantial margins with an average computation time that does not exceed 9%. Remarkably, even with a limited number of training samples, the average classification accuracy of ASF-LLRDA remained consistently above 70%. These results validate ASF-LLRDA as an effective face recognition technique when combined with the LLRC classifier, especially in scenarios with small sample sizes and face images characterized by extreme variations in illumination and facial expression. Nevertheless, it is worth noting that ASF-LLRDA still exhibits limitations in extracting meaningful information to comprehensively elucidate data characteristics. Consequently, promising directions for future research may entail exploring the application of Autoencoders to capture intricate data relationships, as demonstrated in [27]

IV. Conclusion

This paper has presented a novel method called ASF-LLRDA to address the challenges encountered in face recognition applications. By integrating the Approximately Symmetrical Faces (ASF) preprocessing technique with the Locality-regularized Linear Regression Discriminant Analysis (LLRDA) approach, ASF-LLRDA offers a robust solution for handling high-dimensional face images, limited sample sizes, and variations in illumination and facial expressions. The generation of axis-symmetric face images through ASF alleviated the impact of illumination and facial expression variations, while LLRDA extracted discriminative features and projected the data into a lower-dimensional space. Leveraging the locality-regularized linear regression classification (LLRC) classifier further enhanced the classification accuracy. Experimental evaluations conducted on the Yale-B face dataset confirmed the superiority of ASF-LLRDA over baselines, as it achieved significantly higher average classification accuracy.

***Abstract*—Versatile Video Coding (VVC) standard further improves the video compression ratio. Despite inter prediction and intra prediction effectively eliminating temporal and spatial residual information, there is still room for further improvement in rate control (RC) accuracy and rate distortion (R-D) performance. In view of the above issues, the joint optimization RC algorithm for adaptive bit allocation for VVC is proposed. In this paper, the proposed algorithm utilizes a specific pre-analysis mechanism so that the Temporal-Spatial Information (TSI) is obtained. And then the TSI is integrated into the RC model so as to optimize adaptive bit allocations for frame-level and coding tree unit level (CTU-level). Experimental results have shown that compared to the default RC under common test conditions (CTC), the proposed RC algorithm achieves obvious 2.26% Bjøntegaard Delta rate (BD-rate) saving, and the RC accuracy can be improved in the Random Access (RA) configuration.**

I. Introduction

Versatile Video Coding (VVC) [1] [2] is the latest internationally developed video coding standard to meet the growing demands of video services, improve video compression quality, and support today's diverse media content and emerging applications. Rate control (RC) [3] is widely used in the coding and transmission of video and is a significant module for controlling the bits output by encoder. It plays a role in allocating bitrate and adjusting the source output bit stream. In actual video coding, the generated bitrate also fluctuates due to differences in frame type, scene complexity, and coding configurations. The actual video transmission channel needs to introduce RC to ensure smooth transmission of the bit stream and full utilization of channel bandwidth. How to transmit various high-quality videos in different network environments and with limited bandwidth resources has put forward higher requirements for video coding technology. Therefore, the RC technology of general video coding has always been a problem worth studying.

B. Li et al. [4] [5] first proposed R-λ Model in High Efficiency Video Coding (HEVC) [6]. The Lagrange multiplier is directly related to the actual distortion and bitrate of the coding unit (CU). The R-λ model has also been further utilized and integrated into the VVC Test Model (VTM) [7]. The VTM encoder implements a single-pass RC algorithm that provides a constant bitrate (CBR) mode. Many scholars have optimized the RC model. Y. Chen et al. [8] jointly considered the content complexity and temporal dependence based on the CU Tree pre-analysis outputs and performed effective bit allocation. M. Zhou et al. [9] designed a decision tree based on a multiclass classification scheme by fully considering visual features for Ultra High Definition (UHD) videos. C. R. Helmrich et al. [10] proposed a scene change and noise-aware RC method for Versatile Video Encoder (VVenC). H. Liu et al. [11] developed two rate destruction solutions by determining the bit allocation factors for video frames based on their dependence. L. He et al. [12] proposed an adaptive parameter updating and bit allocation algorithm to control the bitrate of frames based on the Quasi-Newton algorithm. Besides the traditional rate distortion (R-D) models, this paper also summarizes schemes based on deep learning. Y. Li et al. [13] trained convolutional neural networks to estimate λ domain model parameters. Y. Mao et al. [14] adopted a pre-analysis framework to obtain the prediction residuals and derived the R-Q and D-Q model parameters by inferring from the prediction residuals with deep neural networks.

However, the RC algorithm in the VVC is not accurate enough at the frame-level and coding tree unit level (CTU-level) bit allocation for videos with some complex local textures, significant edge contours, and motion relationships, which can lead to a loss in coding quality. In the hierarchical coding of VVC, the frame-level bit allocation algorithm doesn't consider the texture complexity difference between frames at the same temporal level. In fact, different frame quality dependencies at the same temporal level also vary, and the consumed bits also vary. In the default CTU-level bit allocation algorithm of VVC, in order to reduce the computational complexity, each bit allocation weight directly follows each current frame-level Lagrange multiplier calculation without considering the difference in temporal importance. Due to the fact that bit allocation using the same Lagrange multiplier is not accurate enough, there is still room for further improvement in the RC accuracy and R-D performance.

In this paper, to address the above issues, a two-stage adaptive bit allocation joint optimization algorithm is proposed based on Temporal-Spatial Information (TSI) through pre-analysis. The contributions of this paper can be summarized as follows: We propose a frame-level bit allocation algorithm based on spatial information at the same temporal level. By

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

considering the impact of intra-frame texture complexity on bit allocation, the bit allocation weights between different frames at the same temporal level are adjusted. And we propose a CTU-level bit allocation algorithm based on temporal and spatial information. By considering the impact of motion and texture information of the CTUs on bit allocation, the CTU-level bit allocation weights are adjusted.

The rest of the paper is organized as follows: Section II briefly explains the workflow of the current integrated RC of VVC. Section III proposes the joint optimization algorithm for adaptive bit allocation based on TSI. Section IV provides the results and analysis of the experiments to verify the effectiveness of the proposed RC. Finally, Section V summarizes the conclusion.

II. Related Work

In this section, the workflow of the current integrated RC model of VVC is summarized [15].

A. Bit Allocation

Bit allocation is sequentially performed at the GOP-level, frame-level, and CTU-level. As the level deepens, the accuracy of RC is also improving. Initially, the encoder calculates the average bits per frame as follows,

$$R_{PicAvg} = \frac{R_{tar}}{f} \tag{1}$$

where R_{tar} is the target bitrate and f is the frame rate.

1) GOP-level: The value of target bits allocated for the current GOP is given as:

$$T_{GOP} = \frac{R_{PicAvg} \cdot (N_{coded} + SW) - R_{coded}}{SW} \cdot N_{GOP} \tag{2}$$

$$SW = \alpha * N_{GOP} / \max(32, IP) + \beta \tag{3}$$

where N_{coded} is the sum of frames already coded and R_{coded} is the bits consumed on these frames. *SW* and *IP* represent an adaptive smoothing window and $IntraPeriod$, respectively. N_{GOP} represents the current GOP size. α and β are set as 20 and 60, respectively.

2) Frame-level: The value of target bits allocated for the current frame is given as:

$$T_{CurrPic} = \frac{T_{GOP} - CODED_{GOP}}{\sum_{i \in \{non-coded\ frames\}} \omega_i} \cdot \omega_{CurrPic} \tag{4}$$

where $CODED_{GOP}$ represents the bits already coded inside the current GOP. $\omega_{CurrPic}$ and ω_i represent the weight of the current frame and the non-coded frames, respectively.

Frames at different temporal levels have quality dependent characteristics and risk of distortion propagation during the coding. In the Random Access (RA) configuration, those lower-level frames will consume more bits because they will be used as references for subsequent higher-level frames of the hierarchical GOP structure. On the contrary, those higher-level frames will consume fewer bits.

3) CTU-level: The value of target bits allocated for the current CTU is given as:

$$T_{CurrCTU} = \frac{\omega_{CurrCTU} - \left(\sum_{i \in \{non\text{-}coded\ CTUs\}} \omega_i - CODED_{CTU}\right)}{SW_{CTU}} \tag{5}$$

where $CODED_{CTU}$ represents the bits consumed while encoding previous CTUs. $\omega_{CurrCTU}$ and ω_i represent the weight of the current CTU and the non-coded CTUs, respectively. $SW_{CTU} = min\,(4, non\ coded\ CTUs)$ and represents a smoothing window used to spread the allocated bits over the next SW_{CTU} CTUs.

B. QP Derivation Based on the R-λ Model

After the available bits are allocated for the current CTU, it is possible to derive the Lagrange multiplier based on the *R-λ* model as follows,

$$\lambda = \alpha \cdot (bpp)^{\beta} \tag{6}$$

where *bpp* represents the bits per pixel in the current CTU. λ represents the slope of the line tangential to the R-D curve as follows,

$$D = CR^{-K} \tag{7}$$

$$\lambda = -\frac{\partial D}{\partial R} = CK \cdot R^{-K-1} \tag{8}$$

where λ, R, D are derived after encoding a frame and the value of C, K are estimated with (7) and (8). And then, the updated C and K can be utilized as the new R-D parameters.

Finally, QP can be derived as:

$$QP = \lfloor 4.2005 \cdot \ln(\lambda) + 13.7122 \rfloor \tag{9}$$

III. Proposed Algorithm

Under the constraints of GOP-level bit allocation and from the perspective of global rate distortion optimization (RDO), this paper improves the R-D performance by pre-analyzing TSI, and utilizing motion and texture based on TSI to jointly optimize the frame-level and CTU-level bit allocation for the reconstructed video more satisfies attention mechanism of human visual system (HVS).

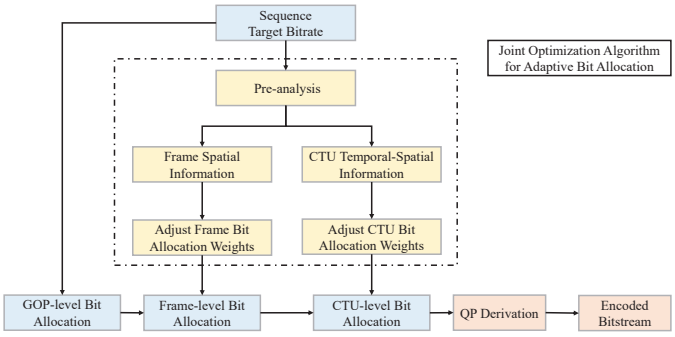

Fig. 1. The workflow of the proposed RC algorithm based on TSI.

Fig. 1 shows the workflow of the proposed joint frame-level and CTU-level bit allocation optimization algorithm. Add a pre-analysis mechanism before encoding to obtain the content information of the frame to be encoded. Specifically, the frames are first stored in the pre-analysis queue to calculate the TSI of the frames and CTUs. After the pre-analysis, the frame is sent to the encoder to complete the bit allocation and QP Derivation.

A. Frame-level Bit Allocation Algorithm

Before encoding, the pre-analysis mechanism for texture complexity is added to the temporal hierarchical structure. By considering the impact of intra-frame texture complexity on bit allocation, the bit allocation weights between different frames at the same temporal levels are adjusted and become more reasonable. Typically, compared with the chroma components (U and V), the luma component (Y) contains more texture features. As a result, the texture features of Y component are pre-analyzed for representing frame's spatial information.

Gradient is used to reflect the fluctuation range of intra-frame pixels, so it can be calculated to characterize the texture complexity of each frame. Take the calculation of Sobel operator with a 3×3 convolutional kernel as an example, convoluting the luma component of a frame with G_x and G_y, as shown in Fig. 2. And then calculate the Gradient of frame (G_{Pic}).

-1	0	1
-2	0	2
-1	0	1

G_x

1	2	1
0	0	0
-1	-2	-1

G_y

Fig. 2. The illustration of Sobel operator.

$$G_{Pic} = \sum_{I \in Pic} |I \odot G_x + I \odot G_y| \tag{10}$$

The bit allocation weight of the current frame is proportionally to each frame's Gradient as follows,

$$\omega_{CurrPic} = \frac{1}{\sum_{i=1}^{S_{Temp}} G_{Pic}\ (i)} G_{CurrPic} \tag{11}$$

$$T_{CurrPic} = \omega_{CurrPic} \cdot \left(\sum_{i=1}^{S_{Temp}} \omega(i) \cdot T_{GOP} - CODED_{Temp} \right) \tag{12}$$

where $\omega(i)$ and $\omega_{CurrPic}$ represent the default bit allocation weight of frames and the adjusted weight of the current frame, respectively. S_{Temp} and $CODED_{Temp}$ represent the sum of frames and the number of bits consumed at the same temporal level, respectively. $T_{currPic}$ represents the target bits of the current frame.

The bit allocation relationship between different temporal layers is still used according to the default algorithm.

B. CTU-level Bit Allocation Algorithm

The motion and texture information of each CTU are pre-analyzed in the current frame as its TSI. If the current frame is non-I frame, temporal information threshold is calculated and all the CTUs of the current frame are divided into important temporal CTUs (CTU_{imp}) and non-important temporal CTUs ($\text{CTU}_{non-imp}$). And then, according to these CTUs' respectively spatial information, the CTU-level bit allocation is performed. On the contrary, if the current frame is I frame, only the spatial information need to be pre-analyzed for CTU-level bit allocation.

1) Temporal-Spatial Information: In this paper, for optimizing CTU-level bit allocation of non-I frame, motion compensated temporary pre filtering (MCTF) is enabled.

Before temporal filtering, motion search will be conducted in multiple frames before and after to obtain the optimal matching block and the motion compensated frame. In the final motion search, each 8×8 block corresponding motion compensation (MC) distortions will be obtained. Based on MC distortion, the similarity between the current frame and the subsequent frames can be estimated, so the motion information in MCTF can be used to estimate the importance of CTUs within the current frame.

After performing MC on the 8×8 blocks, the last step of MCTF is to perform. The sum of the square differences (SSD) between the original block within the current frame and the best MC block within the search frame will be calculated. Based on above, the error (E) will be further calculated as follows,

$$E = 20 \cdot \frac{SSD + 5}{V + 5} + \frac{SSD}{3200} \tag{13}$$

where V is the original Variance within 8×8 blocks.

The E reflects the similarity between the original block within the current frame and the best MC block within the search frame. The more similar it is, the more likely the current block is to be referenced in subsequent encoding. Therefore, the E can be used to estimate the importance of the block, and a lower E value indicates a higher importance. $E1$ can be calculated for each CTU from frames with a distance of 1, and $E2$ can be calculated from frames with a distance of 2. Combining $E1$ and $E2$ can obtain the importance $\hat{E}$. As a result, the importance is pre-analyzed for representing CTU's temporal information as follows:

$$\hat{E} = 1/(\max(E1, E2) + abs(E2 - E1) * 3) \tag{14}$$

If both $E1$ and $E2$ values are small, it indicates that the importance duration is longer, and the current block is important for subsequent references, requiring allocating more bits to encode with the same coding quality or distortion. Due to the fact that the process of pre-analyzing the temporal information of CTU relies on motion information in MCTF,

this algorithm of non-I frame only adjusts the weight of CTU-level bit allocation for the filtered frames in temporal filtering, that is, the POC can only be divided by 8.

The average of temporal information is calculated to represent the temporal threshold (ξ) of this frame as follows,

$$\xi = \frac{1}{S_{CTU}} \sum_{i=1}^{S_{CTU}} \hat{E}(i) \tag{15}$$

Furtherly, according to the temporal threshold, these CTUs of the current frame are divided into two types such as CTU_{imp} and $\text{CTU}_{non-imp}$.

$$\text{CTU}(i) = \begin{cases} \text{CTU}_{imp}, & \hat{E}(i) > \xi \\ \text{CTU}_{non-imp}, & \hat{E}(i) \leq \xi \end{cases} \tag{16}$$

Specifically, if the current CTU's temporal information is less than ξ, it is classified as CTU_{imp}. Otherwise, the CTU is classified as $\text{CTU}_{non-imp}$. In the subsequent bit allocation, CTU_{imp} and $\text{CTU}_{non-imp}$ will be allocated different bits based on TSI.

For the non-I frames, due to the inter relationship, temporal information has a greater impact than spatial information. From this, the CTU-level bit allocation can be divided into two regions: T_{imp} and $T_{non-imp}$ represent important temporal and non-important temporal bits, respectively, as follows,

$$T_{imp} = T_{currPic} \cdot \frac{\sum_{j=x+1}^{S_{imp}} \hat{E}_{impCTU}(j)}{\sum_{i=coded+1}^{S_{CTU}} \hat{E}_{CTU}(i)} \tag{17}$$

$$T_{non-imp} = T_{currPic} \cdot \frac{\sum_{j=y+1}^{S_{non-imp}} \hat{E}_{non-impCTU}(j)}{\sum_{i=coded+1}^{S_{CTU}} \hat{E}_{CTU}(i)} \tag{18}$$

where S_{imp} and $S_{non-imp}$ are the sum of CTU_{imp} and $\text{CTU}_{non-imp}$ within the current frame, respectively. $\hat{E}_{impCTU}$ and $\hat{E}_{non-impCTU}$ are the importance of CTU_{imp} and $\text{CTU}_{non-imp}$, respectively. $coded$ represents the sum of all the CTUs that have been coded. x and y are the sum of coded CTU_{imp} and $\text{CTU}_{non-imp}$, respectively.

$T_{impCTU}(i)$ and $T_{non-impCTU}(i)$ represent the bits allocated to the CTU_{imp} and $\text{CTU}_{non-imp}$, respectively. As a result, furtherly, $T_{impCTU}(i)$ and $T_{non-impCTU}(i)$ can be calculated based on the proportion of the current CTU's Gradient in the sum of Gradient of remaining CTUs.

$$T_{impCTU}(i) = T_{imp} \cdot \frac{G_{impCTU}(i)}{\sum_{n=i}^{S_{imp}} G_{impCTU}(n)} \tag{19}$$

$$T_{non-impCTU}(i) = T_{non-imp} \cdot \frac{G_{non-impCTU}(i)}{\sum_{n=i}^{S_{non-imp}} G_{non-impCTU}(n)} \tag{20}$$

Algorithm 1 The Proposed RC Based on TSI.

Input:
Original video sequence and Target bitrate.
Output:
The TSI of frames and CTUs.
QPs of frames and CTUs.

```
Perform GOP-level model parameter initialization, using (1) to calculate R_PicAvg for each frame;
for i=1 to S_Pic do
  if the current frame is non-I frame and POC%8=0 then
    Allocate frame-level bits with (12);
    Calculate the each CTU's temporal information and the temporal threshold (ξ);
    if Ê(i) > ξ then
      The current CTU is classified as CTU_imp;
      Allocate CTU-level bits with (17) and (19);
    else
      Allocate CTU-level bits with (18) and (20);
    end if
  else
    Allocate frame-level bits with (12);
    for i=1 to S_CTU do
      Calculate G_CTU and allocate CTU-level bits with (21) and (5);
    end for
  end if
  Perform CTU-level and frame-level default QP Derivation and model parameter updating, respectively;
end for
```

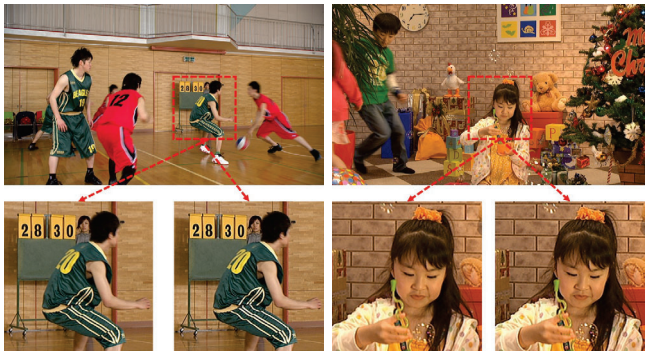
where $G_{impCTU}(i)$ and $G_{non-impCTU}(i)$ represent the spatial information of CTU_{imp} and $\text{CTU}_{non-imp}$, respectively.

2) Spatial Information: For I frame, it doesn't have reference frame, so optimizing CTU-level bit allocation based on spatial information by calculating the Gradient of the CTU (G_{CTU}) according to the frame-level mentioned above (10) and (11).

$$\omega_{CurrCTU} = \frac{1}{\sum_{i=1}^{S_{CTU}} G_{CTU}(i)} G_{CurrCTU} \tag{21}$$

where S_{CTU} represents the sum of CTUs. $\omega_{CurrCTU}$ represents the adjusted bit allocation weight of the current CTU.

The target bits of the current CTU can be calculated with (5).



The whole proposed joint optimization algorithm for adaptive bit allocation based on TSI is summarized in Algorithm 1.

IV. Experimental Results and Analysis

Experiments are conducted on the VTM 18.0 under common test conditions (CTC) [16] for verifying the performance of the proposed RC algorithm based on TSI. The target bitrate of each test sequence can be obtained through encoding it in the RA configuration where QPs are set as $\{22,\ 27,\ 32,\ 37\}$.

TABLE I
PERFORMANCE COMPARISON BETWEEN THE PROPOSED RC ALGORITHM AND THE VTM 18.0 DEFAULT RC ALGORITHM

Classes	Sequences	Bitrate Error		BD-rate	$\Delta EncT$
		VTM RC	*Proposed RC*		
A1	Tango2	0.18%	0.10%	-3.15%	101.3%

	Campfire	0.27%	0.37%	-3.81%	103.8%
A2	CatRobot	0.23%	0.11%	-2.77%	101.2%
	DaylightRoad2	1.31%	1.22%	-4.14%	99.5%
	ParkRunning3	0.85%	0.87%	-1.80%	102.4%
B	MarketPlace	0.76%	0.85%	-2.87%	98.9%
	RitualDance	0.35%	0.35%	-1.54%	101.8%
	Cactus	0.37%	0.30%	-2.89%	104.9%
	BasketballDrive	0.11%	0.10%	-3.42%	107.1%
	BQTerrace	0.97%	0.94%	-2.49%	106.5%
C	BasketballDrill	0.60%	0.41%	-1.52%	107.8%
	BQMall	0.94%	0.63%	-1.96%	104.3%
	PartyScene	0.25%	0.23%	-2.27%	106.8%
	RaceHorses	0.28%	0.23%	-2.13%	104.7%
D	BasketballPass	0.56%	0.76%	-1.18%	108.2%
	BQSquare	1.08%	0.80%	-1.28%	111.5%
	BlowingBubbles	1.89%	0.96%	-0.83%	109.6%
	RaceHorses	0.19%	0.52%	-1.19%	107.7%
AVERAGE		0.61%	0.54%	-2.26%	104.7%

(a) (b)

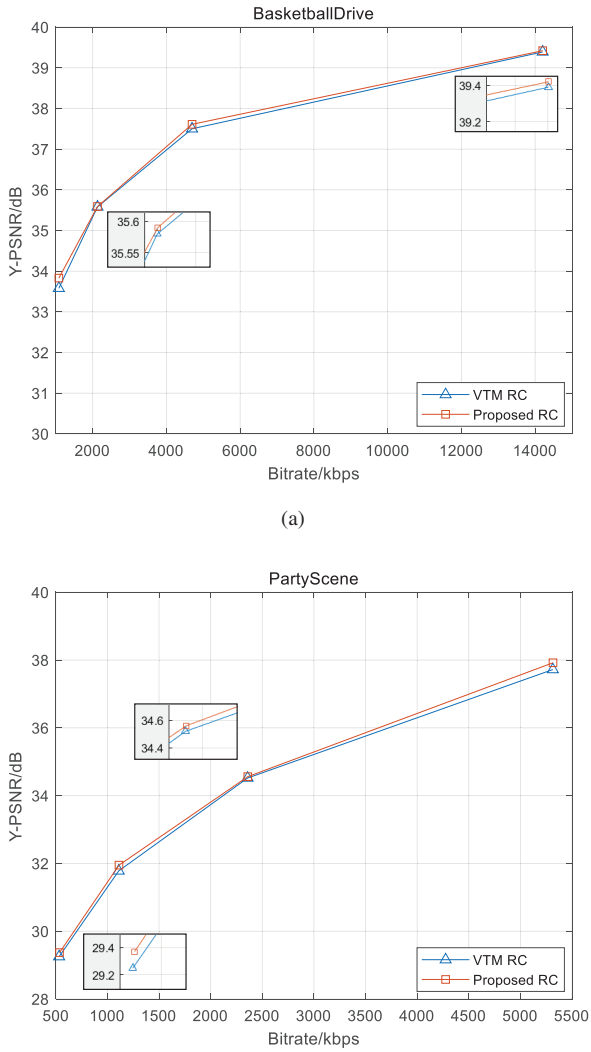

Fig. 3. The subjective quality comparison with the VTM 18.0 default RC and proposed RC of "BasketballDrive" for POC 201 (a) and of "PartyScene" for POC 51 (b). In (a) and (b), the left and right images are reconstructed with the VTM 18.0 default RC and Proposed RC, respectively.

Bitrate error is measured by $Error$. If the $Error$ is smaller, it indicates higher RC accuracy. Coding time complexity is measured by $\Delta EncT$.

$$Error = \frac{|R_{tar} - R_{act}|}{R_{tar}} \times 100\% \tag{22}$$

$$\Delta EncT = \frac{EncT_{proposedRC}}{EncT_{VTMRC}} \times 100\% \tag{23}$$

According to the experimental results shown in TABLE I, the average Bjøntegaard Delta rate (BD-rate) and the average bitrate error of classes A1, A2, B, C, D are reduced by 2.26% and 0.07%, respectively, while only increasing coding time complexity by 4.7% with the proposed RC based on STI in the RA configuration. The majority of the sequences have gained better R-D performance and higher RC accuracy. From the Fig. 3, it can be seen that the subjective quality using the proposed RC is better. As shown in Fig. 4, the "BasketballDrive" and "PartyScene" have obtained 3.42% and 2.27% R-D performance improvement, respectively.

(a)

(b)

Fig. 4. The R-D curves of sequence "BasketballDrive" (a) and "PartyScene" (b).

From above, this proposed algorithm can be verified and analyzed that it is effective in VVC and achieves a trade-off between bitrate and distortion. In addition, the increasing of coding time complexity is moderate, indicating its high practicality, and this algorithm can also be applied to other video coding standards.

V. Conclusions

In this paper, we proposed a frame-level and CTU-level adaptive bit allocation joint optimization algorithm based on TSI which is different from previous studies on the temporal-spatial domain. Our proposed algorithm is performed based on the pre-analysis information and more satisfies attention mechanism of HVS while improving the objective and subjective video coding quality. Specifically, texture complexity and temporal dependence are comprehensively considered to improve the compression performance of video coding in the RA configuration which can dynamically control and adjust local and global bit allocation.

Maximization of 2D Cross-Correlation Based on Auxiliary Function Method for Image Alignment

Yuma Kinoshita*, Kouei Yamaoka†, and Hitoshi Kiya†
* Tokai University, Kanagawa, Japan
† Tokyo Metropolitan University, Tokyo, Japan

***Abstract*—In this paper, we propose an algorithm to maximize the generalized 2D cross-correlation function for image alignment, a cornerstone task in image signal processing and computer vision. As a fast image alignment method, 2D cross-correlation-based methods are often used in real-time applications. These approaches aim to optimize the 2D cross-correlation function between two images, inferring the displacement between them. Nevertheless, image misalignment commonly necessitates a maximization of the continuous cross-correlation function, and existing iterative and approximation-based approaches exhibit limited computational speed or accuracy. In response to this challenge, this paper proposes a novel algorithm to maximize the generalized 2D cross-correlation function. Inspired by Yamaoka et al.'s work for the 1D case, our approach maximizes a quadratic auxiliary function that bounds the 2D cross-correlation from below, instead of directly maximizing the cross-correlation. The accuracy and computational speed of our method, in comparison to three existing techniques, were assessed via a simulation experiment. Our findings confirm the superiority of the proposed method over a quadratic curve fitting approach in terms of image shift estimation accuracy. Remarkably, our proposed method proved approximately 6.8 and 4 times faster than gradient ascent and golden section search per iteration, respectively, competing with the speed of the non-iterative curve fitting.**

I. Introduction

Image alignment or matching is a fundamental problem in image signal processing and computer vision. Pre-alignment of images are required in many tasks: creating panoramas [1], medical imaging [2], image-based 3D modeling [3], high dynamic range imaging [4], [5], and more. Owing to the necessity, various image alignment methods have been proposed.

There are two main approaches to image alignment: homography-based methods and intensity-based methods. The former method endeavors to estimate a homography matrix between two images utilizing features such as SIFT [6], SURF [7], and A-KAZE [8]. RANSAC [9] is frequently employed to estimate the homography matrix. Contemporary research has explored the use of deep learning for estimating the homography matrix [10], [11]. The latter method typically focuses on estimating optical flow [12]–[15]. Nonetheless, these approaches require a significant amount of time for the estimation of either a homography matrix or optical flow.

Given these limitations, two-dimensional (2D) cross-correlation-based methods [16], [17] are often used for image alignment in real-time applications [5]. These strategies seek to maximize the 2D cross-correlation function between two images to deduce the displacement amongst them. The cross-correlation function for discrete pixel shifts can be computed expeditiously using the fast Fourier transform (FFT), and its maximum is easily found.

However, image misalignment usually manifests sub-pixel-wise necessitating maximization of the continuous cross-correlation function. Regrettably, a closed-form solution to this problem remains undiscovered. Although iterative algorithms and approximation-based solutions have been designed to tackle this challenge, these suffer from limited computational speed or accuracy, respectively. For example, the burst photography showcased in [5] adopts an alignment approach that maximizes the 2D cross-correlation function with subpixel accuracy by using a quadratic curve fitting method. It ensures rapid calculation on smartphones, but the limited accuracy of its estimations necessitates more resolution levels used for alignment in a progressive, coarse-to-fine strategy.

Because of such a situation, we aim to develop a fast and accurate maximization algorithm for the 2D cross-correlation function. For maximizing the generalized 1D cross-correlation function considering not only the standard correlation but also the phase-only correlation [18], Yamaoka et al. have proposed a fast and accurate algorithm based on an auxiliary function method which is also known as the majorization-minimization (MM) algorithm [19]. Following the approach, we derive an algorithm to maximize the generalized 2D cross-correlation function. The proposed method can find a (local) maximizer of the objective function by iteratively maximizing a quadratic auxiliary function that bounds the objective function from below. Since the maximizer of quadratic function can be obtained analytically, the proposed method can efficiently maximize the 2D cross-correlation.

We evaluate the accuracy and computational speed of the proposed method and other three methods, by a simulation experiment. Experimental results demonstrate the superior estimation accuracy of the gradient ascent method (GA) with backtracking, the golden section search (GSS), and the proposed method over a quadratic curve fitting approach for image shift estimation, corroborating the effectiveness of iterative methods including our one. Notably, the proposed method is approximately 6.8 and 4 times faster than GA and GSS per iteration, respectively, and could compete with the non-iterative curve fitting.

II. Problem Statement

In this paper, the focus is on the issue of aligning 2D discrete signals, essentially images, denoted as x and y. Their pixel

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

values at a position $\boldsymbol{p} = (p_1, p_2)^\top$, are represented as $x[\boldsymbol{p}]$ and $y[\boldsymbol{p}]$, respectively, where the superscript $\top$ indicates the transpose of a vector or a matrix. We denote the 2D discrete Fourier transforms of x and y, which are $N \times M$ in size, as $\hat{x}$ and $\hat{y}$, respectively. We assume that $\hat{x}$ and $\hat{y}$ are strictly band-limited, i.e., $\hat{x}(\boldsymbol{\omega}) = \hat{y}(\boldsymbol{\omega}) = 0$ for angular frequency $\boldsymbol{\omega}$ such that at least one element is equal to π. By using the 2D cross-spectrum $\hat{\Phi}_2^{(xy)}(\boldsymbol{\omega}_{kl}) = \hat{x}^*(\boldsymbol{\omega}_{kl})\hat{y}(\boldsymbol{\omega}_{kl})$, the 2D cross-correlation function of x and y can be written as

$$\check{\Phi}_2^{(xy)}[\boldsymbol{p}] = \frac{1}{NM} \sum_{k \in K} \sum_{l \in L} \hat{\Phi}_2^{(xy)}(\boldsymbol{\omega}_{kl}) \exp\left(j \boldsymbol{\omega}_{kl}^\top \boldsymbol{p}\right), \quad (1)$$

where j represents the imaginary unit and $\boldsymbol{\omega}_{kl} = (\omega_k, \omega_l)^\top = (\frac{2\pi k}{N}, \frac{2\pi l}{M})^\top$. The summation range for K and L is given as $K = \{-N/2+1, -N/2+2, \cdots N/2\}$ and $L = \{-M/2+1, -M/2+2, \cdots M/2\}$, respectively.

In applications like image matching, the peak of the cross-correlation function may be sharpened by applying weights to each term in (1). For this reason, we consider the 2D generalized cross-correlation function given as

$$\check{\Phi}_2^{(xy)}[\boldsymbol{p}] = \frac{1}{NM} \sum_{k \in K} \sum_{l \in L} w_{kl} \hat{\Phi}_2^{(xy)}(\boldsymbol{\omega}_{kl}) \exp\left(j \boldsymbol{\omega}_{kl}^\top \boldsymbol{p}\right), \quad (2)$$

where $w_{kl} \in \mathbb{R}^+$ is an arbitrary weight. If the weight w_{kl} is set to 1, it is the same as the standard cross-correlation in (1). If $w_{kl} = |\hat{\Phi}_2^{(xy)}(\boldsymbol{\omega}_{kl})|^{-1}$, it coincides with the phase-only correlation [18], also known as GCC-PHAT [16] in acoustic signal processing.

Usually, (2) is a discrete function calculated with each element of $\boldsymbol{p}$ being an integer. On the other hand, if $\boldsymbol{p}$ is a real vector, $\check{\Phi}_2^{(xy)}$ can be considered as a continuous function. The purpose of this paper is to estimate a real vector $\boldsymbol{p} \in \mathbb{R}^2$ that maximizes the continuous 2D generalized cross-correlation function, that is, to solve the following optimization problem:

$$\tilde{\boldsymbol{p}} = \underset{\boldsymbol{p} \in \mathbb{R}^2}{\arg\max}\, \check{\Phi}_2^{(xy)}(\boldsymbol{p}). \quad (3)$$

III. Maximizing 2D Cross-Corrlation based on Auxiliary Function Method

Yamaoka et al. have already proposed an algorithm to maximize the 1D generalized cross-correlation using an auxiliary function method [19]. In this paper, following Yamaoka's work, we derive an algorithm that maximizes the 2D generalized cross-correlation.

A. Auxiliary Function Method

The auxiliary function method is an iterative algorithm designed for maximizing an objective function [20]–[22]. It maximizes an auxiliary function corresponding to a lower bound of the objective function, rather than directly maximizing the objective function itself.

To employ the auxiliary function method for solving the optimization problem shown in (3), it is necessary to design an auxiliary function $Q(\boldsymbol{p}, \boldsymbol{\theta})$ that satisfies the following conditions:

- For any given vectors $\boldsymbol{p}$ and $\boldsymbol{\theta}$, the inequality $\check{\Phi}_2^{(xy)}(\boldsymbol{p}) \geq Q(\boldsymbol{p}, \boldsymbol{\theta})$ holds true.
- There exist a $\boldsymbol{\theta} = f(\boldsymbol{p})$ satisfying $\check{\Phi}_2^{(xy)}(\boldsymbol{p}) = Q(\boldsymbol{p}, \boldsymbol{\theta})$ for any $\boldsymbol{p}$.

In this context, $\boldsymbol{\theta} \in \mathbb{R}^2$ is referred to as an auxiliary variable. Given the presence of such a $Q(\boldsymbol{p}, \boldsymbol{\theta})$ and an initial estimate $\tilde{\boldsymbol{p}}^{(0)}$, we can assure the subsequent sequence of updates to converge towards a local maximum:

$$\boldsymbol{\theta}^{(i)} = f(\boldsymbol{p}^{(i)}),\ \boldsymbol{p}^{(i+1)} = \underset{\boldsymbol{p} \in \mathbb{R}}{\arg\max}\, Q(\boldsymbol{p}, \boldsymbol{\theta}^{(i)}). \quad (4)$$

Here, i stands for the iteration index.

B. Deriving Auxiliary Function for 2D Correlation

From the conjugate symmetry of $\hat{\Phi}_2^{(xy)}$, we can rewrite $\check{\Phi}_2^{(xy)}$ as a sum of cosines as

$$\check{\Phi}_2^{(xy)}[\boldsymbol{p}] = \frac{1}{NM} \sum_{k \in K^+} \sum_{l \in L} \alpha_{kl} \cos\left(\boldsymbol{\omega}_{kl}^\top \boldsymbol{p} + \varphi_{kl}\right), \quad (5)$$

where $K^+ = \{0, 1, \cdots, N/2\}$,

$$\alpha_{kl} = w_{kl} \beta_{kl} \left|\hat{\Phi}_2^{(xy)}(\boldsymbol{\omega}_{kl})\right|, \quad (6)$$

$$\beta_{kl} = \begin{cases} 0 & \text{if } k = 0 \text{ and } l < 0 \\ 1 & \text{if } k \in \{0, N/2\} \text{ and } l \in \{0, M/2\} \\ 2 & \text{otherwise} \end{cases}, \quad (7)$$

$$\varphi_{kl} = \angle \hat{\Phi}_2^{(xy)}(\boldsymbol{\omega}_{kl}). \quad (8)$$

As shown in Proposition 1 in [19], for any real number θ, the following inequality holds

$$\cos\theta \geq -\frac{1}{2}\frac{\sin\theta_0}{\theta_0}\theta^2 + \left(\cos\theta_0 + \frac{1}{2}\theta_0 \sin\theta_0\right), \quad (9)$$

where $\|\theta_0\| \leq \pi$. Equality holds if and only if $|\theta| = |\theta_0|$ for $\theta_0 < \pi$ and $\theta = (2n+1)\pi, n \in \mathbb{Z}$ for $\theta_0 = \pi$.

Using (9) and the periodicity of $\cos\theta$, we obtain

$$\begin{aligned} &\alpha_{kl} \cos(\boldsymbol{\omega}_{kl}^\top \boldsymbol{p} + \varphi_{kl}) \\ &\geq -\frac{\alpha_{kl}}{2}\frac{\sin\theta_{kl}}{\theta_{kl}} \left(\boldsymbol{\omega}_{kl}^\top \boldsymbol{p} + \varphi_{kl} + 2n_{kl}\pi\right)^2 + C, \end{aligned} \quad (10)$$

where $n_{kl} \in \mathbb{Z}$ is such that $|\boldsymbol{\omega}_{kl}^\top \boldsymbol{p} + \varphi_{kl} + 2n_{kl}\pi| \leq \pi$, and C is a constant term that does not include $\boldsymbol{p}$. Equality holds when

$$\theta_{kl} = \boldsymbol{\omega}_{kl}^\top \boldsymbol{p} + \varphi_{kl} + 2n_{kl}\pi. \quad (11)$$

By applying (10) to each term of (5), an auxiliary function $Q(\boldsymbol{p}, \boldsymbol{\theta})$ of the objective function (5) is derived as follows:

$$\begin{aligned} &\check{\Phi}_2^{(xy)}[\boldsymbol{p}] \geq Q(\boldsymbol{p}, \boldsymbol{\theta}) \\ &= \sum_{k \in K^+} \sum_{l \in L} -\frac{\alpha_{kl}}{2NM}\frac{\sin\theta_{kl}}{\theta_{kl}} \left(\boldsymbol{\omega}_{kl}^\top \boldsymbol{p} + \varphi_{kl} + 2n_{kl}\pi\right)^2 \\ &+ C. \end{aligned} \quad (12)$$

C. Update Rules

Since $Q(\boldsymbol{p}, \boldsymbol{\theta})$ is a quadratic function in terms of $\boldsymbol{p}$, the maximizer of Q is easily obtained by solving an equation

$$\begin{aligned}&\nabla Q(\boldsymbol{p}, \boldsymbol{\theta})\\ &= \sum_{k\in K^+}\sum_{l\in L} -s_{kl}\left(\boldsymbol{\omega}_{kl}^\top \boldsymbol{p} + \varphi_{kl} + 2n_{kl}\pi\right)\boldsymbol{\omega}_{kl}\\ &= \mathbf{0}. \end{aligned} \tag{13}$$

In the above, ∇ indicates the gradient for $\boldsymbol{p}$ and $s_{kl} = \alpha_{kl}\frac{\sin\theta_{kl}}{\theta_{kl}}$. This equation yields, $\mathbf{A}\boldsymbol{p} = \boldsymbol{b}$, defined as:

$$\mathbf{A} = \sum_{k\in K^+}\sum_{l\in L} s_{kl}\boldsymbol{\omega}_{kl}\boldsymbol{\omega}_{kl}^\top, \tag{14}$$

$$\boldsymbol{b} = \sum_{k\in K^+}\sum_{l\in L} s_{kl}\left(-\varphi_{kl} - 2n_{kl}\pi\right)\boldsymbol{\omega}_{kl}. \tag{15}$$

Considering the condition for equality (11), we can substitute $-\varphi_{kl} - 2n_{kl}\pi = \boldsymbol{\omega}_{kl}^\top \boldsymbol{p} - \theta_{kl}$, and obtain the following update rules:

$$n_{kl}^{(i)} \leftarrow \arg\min_{n\in\mathbb{Z}} \left|\boldsymbol{\omega}_{kl}^\top \boldsymbol{p}^{(i)} + \varphi_{kl} + 2n\pi\right|, \tag{16}$$

$$\theta_{kl}^{(i)} \leftarrow \boldsymbol{\omega}_{kl}^\top \boldsymbol{p}^{(i)} + \varphi_{kl} + 2n_{kl}^{(i)}\pi, \tag{17}$$

$$\boldsymbol{p}^{(i+1)} \leftarrow \left(\mathbf{A}^{(i)}\right)^{-1}\boldsymbol{b}^{(i)} = \boldsymbol{p}^{(i)} - \left(\mathbf{A}^{(i)}\right)^{-1}\boldsymbol{v}^{(i)}, \tag{18}$$

where

$$s_{kl}^{(i)} = \alpha_{kl}\frac{\sin\theta_{kl}^{(i)}}{\theta_{kl}^{(i)}}, \tag{19}$$

$$\mathbf{A}^{(i)} = \sum_{k\in K^+}\sum_{l\in L} s_{kl}^{(i)}\boldsymbol{\omega}_{kl}\boldsymbol{\omega}_{kl}^\top, \tag{20}$$

$$\boldsymbol{v}^{(i)} = \sum_{k\in K^+}\sum_{l\in L} s_{kl}^{(i)}\theta_{kl}^{(i)}\boldsymbol{\omega}_{kl}. \tag{21}$$

IV. Simulation

To evaluate the performance of the proposed method in terms of the estimation accuracy and computational cost, we conducted a simulation.

A. Experimental Conditions

In this simulation, we numerically prepared misaligned image pairs from 20 well-known standard test images such as *airplane, barbara, cameraman, mandrill*, and so on[1]. An example of the misaligned image pair is shown in Fig. 1. The size of the original images was 256×256 pixels. To generate shifted images, the original images were shifted both vertically and horizontally, with the cubic interpolation. Each shift amount $\boldsymbol{p}^*$ was randomly selected from the uniform distribution with a range of $[-10, 10]$ pixels. Areas that the image shift causes to fall outside the original image boundaries were cropped. Finally, we added Gaussian noise with a standard deviation of 0.1 to both original and shifted images, independently.

[1]They can be downloaded from https://sipi.usc.edu/database/ and http://www.ess.ic.kanagawa-it.ac.jp/app_images_j.html

Language	Python 3.9.11
Library	PyTorch 2.0.1

The proposed auxiliary function-based method (Aux.) was compared with three methods: the gradient ascent (GA), the 2D golden section search (GSS) in [23], and a quadratic curve fitting in [5]. GA iteratively updates the maximizer $\tilde{\boldsymbol{p}}$ as $\tilde{\boldsymbol{p}}^{(i+1)} = \tilde{\boldsymbol{p}}^{(i)} + \eta\nabla\check{\Phi}_2^{(xy)}(\tilde{\boldsymbol{p}}^{(i)})$, where the step size η is determined by the backtracking line search following the Armijo rule [24]. GSS is also an iterative algorithm, but it does not require the gradient of the objective function. For GA, GSS, and the proposed method, we set the number of iterations to 50 and the initial estimation $\boldsymbol{p}^{(0)}$ was set to the maximizer of the discrete cross-correlation $\check{\Phi}_2^{(xy)}[\boldsymbol{p}]$ with $w_{kl} = 1$.

The curve fitting can be found an approximate solution by fitting a quadratic curve to the discrete function and finding the maximum of the fitted curve. Although a quadratic curve is fit to the $L2$ distance in [5], we used $\check{\Phi}_2^{(xy)}[\boldsymbol{p}]$ with $w_{kl} = 1$ for the curve fitting similarly to the other methods.

We implemented all methods in Python with PyTorch. The estimation error between $\tilde{\boldsymbol{p}}$ estimated by methods above mentioned and true shift $\boldsymbol{p}^*$ was measured by the root mean square error (RMSE).

The simulation was run on a PC, with a 3.8 GHz processor and a main memory of 64 Gbytes (see Table I). For measuring the executing time, *time.perf_counter()* function in the Python standard library was used, and GPUs were not used in the simulation

B. Results

Table II shows the RMSE between the estimated and true shifts for five images in the test set and the average and standard deviation of the RMSE for all 20 images. From the result, we can see that GA, GSS, and the proposed method achieved the higher estimation accuracy than the curve fitting. For this reason, it is confirmed that the iterative methods are more effective to obtain the accurate shift estimation than the curve fitting.

TABLE II
RMSE BETWEEN ESTIMATED AND TRUE SHIFTS

Image	GA	GSS [23]	Curve fitting [5]	Aux. (ours)
Airplane	0.0158	0.0158	0.0489	0.0158
Barbara	0.0453	0.0453	0.1900	0.0453
Cameraman	0.0139	0.0140	0.0157	0.0140

Std. (20 images)	0.0391	0.0391	0.0612	0.0391

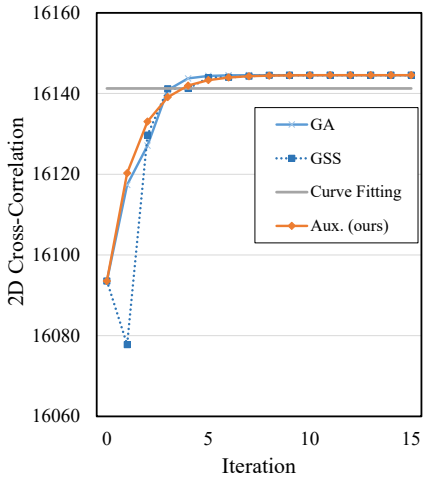

Fig. 2. Values of objective function during iterations for *Pepper*. Since curve fitting is not an iterative method, objective function value is drawn as line

TABLE III
ELAPSED TIME (MS) PER ONE ITERATION FOR ITERATIVE METHODS

Statistic	GA	GSS [23]	Curve fitting [5]	Aux. (ours)
Average	4.793	2.801	4.428	0.705
Std.	1.103	0.097	0.144	0.017

The values of the objective function during iteration are shown in Fig. 2. Here, the input image pair was *Pepper* shown in Fig. 1. From the figure, the objective values for GA and GSS converged mostly to the local maximum after six iterations and eight iterations for the proposed method. The trajectory of the estimated shift $\tilde{\boldsymbol{p}}^{(i)}$ for each method is shown in Figs. 3 to 5. Note that the maximizer of the 2D cross-correlation function $\check{\Phi}_2^{(xy)}(\boldsymbol{p})$ was slightly different from the true shift $\boldsymbol{p}^*$. A reason for this is that the input images were cropped after shifting.

Average elapsed times of the four methods for the 20 images are shown in Table III, where, for the iterative methods, the elapsed time for 50 iterations was measured and the elapsed time per iteration was calculated. As shown in the table, the proposed method is about 6.8 times faster than GA and about 4 times faster than GSS, and if the proposed method converges in about 8 iterations, as shown in Fig. 2, it is competitive with the non-iterative curve fitting.

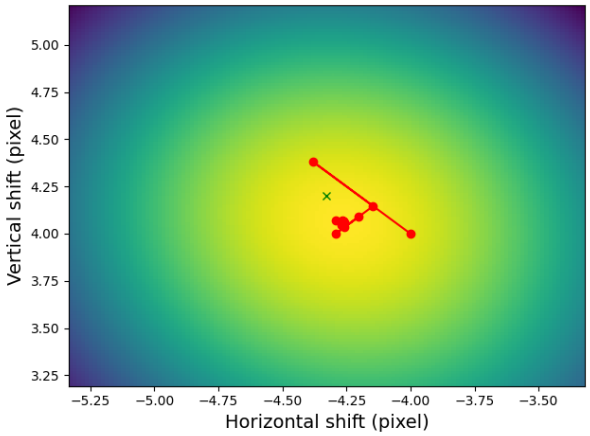

Fig. 4. Trajectories of estimated shifts by GSS [23] for image *Pepper* , where red points indicate estimations $\boldsymbol{p}^{(i)}$ and cross indicates true shift $\boldsymbol{p}^*$.

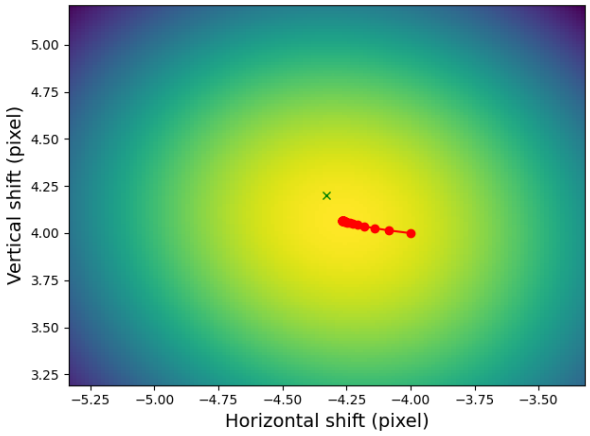

Fig. 5. Trajectories of estimated shifts by Aux. (ours) for image *Pepper* , where red points indicate estimations $\boldsymbol{p}^{(i)}$ and cross indicates true shift $\boldsymbol{p}^*$.

V. CONCLUSIONS

In this paper, we derived a maximization algorithm for the 2D generalized cross-correlation function, on the basis of the

auxiliary function based 1D cross-correlation maximization. The proposed method find the maximizer of the 2D cross-correlation function by iteratively maximizing a quadratic auxiliary function that bounds the 2D cross-correlation function from below. Experimental results showed that the proposed method can estimate the displacement between two images more accurately than a quadratic curve fitting method. In addition, the proposed method is faster than the gradient ascent method the golden section search, and the executing time is competitive with that of the curve fitting method.

Abstract— A framework simplifies a novel multi-task for badminton, automating detection in tournament videos and game information prediction. The model combines EfficientNetv2 with distinct module networks for different tasks. This approach achieves a balance between efficiency and precision via a streamlined model architecture.

I. Introduction

Sports event analysis poses challenges in image analysis and machine learning. This task involves a sequential multi-task problem. While Transformer[1] and Multi-Level MTL[2] models are common choices, we've abstained due to suboptimal computational efficiency, which doesn't align with our speed requirements. Moreover, MTL encounters challenges with tasks of low interdependence, such as estimating ball coordinates and shot postures, leading to interference during training and performance decline. Given these constraints and task demands, we've adopted alternative approaches for an effective and efficient solution.

II. Related Work

EfficientNetV2[3] is an efficient neural network design aimed at enhancing model performance while maintaining efficiency. It offers variants of varying sizes to accommodate diverse applications. It employs the MBConv module, which decomposes convolutional operations into depth-wise and point-wise convolutions, reducing computation and parameters. To enhance the efficiency of representation learning, the authors introduce the Fused-MBConv module in shallower layers, combining depth-wise separable convolution and a linear bottleneck mechanism. EfficientNetV2 is acclaimed for its efficiency and robust performance, achieved through depth-wise separable convolution, linear bottleneck, and feature pyramid networks

III. Datasets

The dataset comprises competition videos and associated analysis data, denoted as L. These contest videos are sourced from prominent international badminton matches endorsed by the Badminton World Federation (BWF). The analysis data L encompasses various categories, as detailed in Table 1. The training dataset encompasses around 5,000 shots, while the testing dataset comprises approximately 1,000 shots.

Table 1. categories of $\mathcal{L}$

Categories	Meaning
HitFrame	The frame number when the *Hit* occurs in the video.
Hitter	Which player hit the current shot.
RoundHead	Whether the hitting player executed a round-the-head stroke.
Backhand	Whether the hitting player executed a backhand stroke
BallHeight	Whether the hitting point is above the net.
LandingX *LandingY*	The coordinates of the trajectory endpoint, projected onto the court plane.
HitterLocationX *HitterLocationY*	The coordinates of the hitter's dominant foot's tiptoe in the frame.
DefenderLocationX *DefenderLocationY*	The coordinates of the defender's dominant foot's tiptoe in the frame.
BallType	The type of shot played in each Hit. The ball types are sorted as follows: Shot serve, long serve, Clear, Drive, Smash, Net shot, Slice, Drop shot, Push or block shot.

The training dataset consists of approximately 5,000 shots, while the testing dataset consists of approximately 1,000 shots.

IV. Method

A. Processing

This section clips videos into *Tubes* and packages with the corresponding *Label*. *Tubes* are synthesized by a range of frames. based on the *Side*, which determines the number of frames extracted around the *Hit* frames. The options for *Side* are {1, 2, 3}. During the Training stage, the *HitFrame* is obtained from the $\mathcal{L}$ dataset, and 6 frames around the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

HitFrame are preserved. The required frames, $F_{require}$, are randomly selected while ensuring include the *Hit* frame using (1), shown in Fig. 1.

$$\mathcal{F}_{require} = random.choise(range(6 - Side, 6))) \quad (1)$$

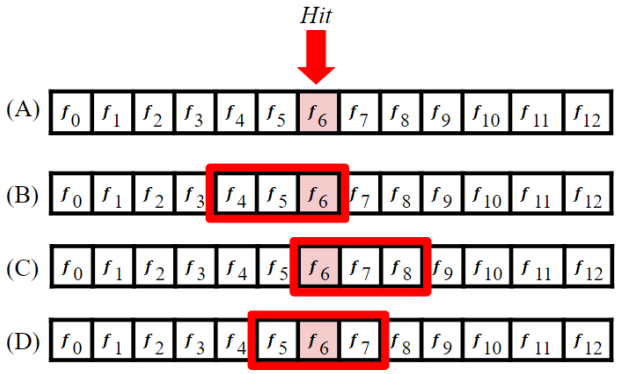

Fig. 1. (A) f_6 containing the detected Hit. (B), (C), and (D) depict the randomly selected 3 frames (*Side* = 1).

The *Labels* are categorized into two types: Regression and Classification [4]. For Regression, only consider six *X* and *Y* coordinates and normalize them into 0 to 1. Others belong to Classification and are converted into corresponding 0 and 1. Also, choose Classification for *HitFrame* because the given value represents which frame the *Hit* occurs, but the model only receives a few frames, lacking the information to predict. Therefore, the model is provided with several options and determines the probability P_t of each frame to be the *HitFrame*.

The index with the highest probability is selected, denoted as $P_{HitIndex}$, as in (2). By adding the starting frame number t, the *HitFrame* probability $P_{HitFrame}$ can be reconstructed using (3).

$$P_{HitIndex} = argmax(P_t, P_{t+1}, P_{t+2}) \quad (2)$$

$$P_{HitFrame} = t + P_{HitIndex} \quad (3)$$

During the Testing stage, a sliding window technique is employed to sequentially select frames, create *Tubes*, and predict, until the entire video is predicted.

B. Data Augmentation

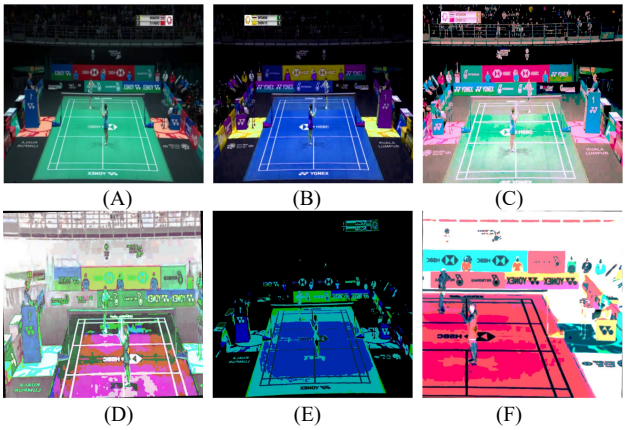

Fig. 1. (A) Original frame. (B) and (C) chosen augmentation parameter result. (D), (E) and (F) other parameter result.

Several algorithms including *Gaussian Blur*[5], *Color Jitter*[6], *Random Equalize*[7], *Random Horizontal Flip*, *Random Rotation*, and *Random Resized Crop* have been employed to enhance the dataset. Also, *Elastic Transform* has been applied to imitate the shacking of the net or the camera.

The augmentation parameters are specially designed so that the transformed image doesn't lose its feature, shown in Fig. 2.

C. Model

1. Architecture

As shown in the Fig. 2, the structure of the model is as follows:

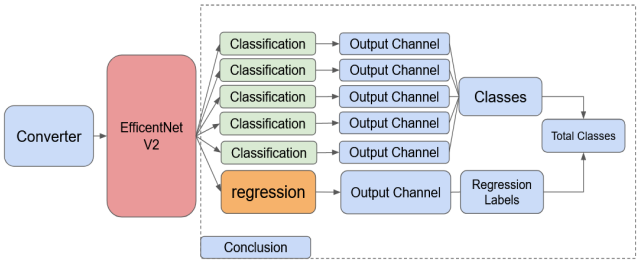

Fig. 2. The structure of the model established by Converter, EfficientNetV2 and Linear module.

1) Converter

The *Converter* comprises two components, each featuring a Conv3D[8] layer with ReLU activation. The distinction arises from an additional BN[9] layer in the first component, absent in the second. The primary function of the first component is to reduce the depth of input data to 3, followed by a further reduction to 1 in the second component. These convolutional operations perform dimensionality reduction and non-linear transformations on the input data, thereby endowing the model with the capability to comprehend sequential concepts while simultaneously achieving dimensionality reduction.

2) EfficientNetV2

EfficientNetV2 is chosen because of its ability to deliver better performance with fewer parameters. It adopts a non-uniform expansion strategy, gradually adding more layers in the later stages. The Fuse-MB Conv layer solves the problem of lightweight models not utilizing the GPU/CPU fully. The authors use NAS to search for the optimal combination of fused and regular MB Conv layers. Smaller models achieve better performance when some early MB Conv layers are replaced with fused layers. EfficientNetV2 provides a flexible network architecture that balances training speed and accuracy.

3) Linear module

The extracted outputs are propagated through a linear neural network module comprising three linear layers and two ReLU[10] activation functions. Within this module, Softmax

activation is employed for the classification task, while it is not utilized for regression task.

2. Backpropagation

According to the concept of backpropagation[11], the gradient vectors computed by each Cost Function are independent. When a network architecture is shared by different Cost Functions, the weights and biases within the network are independently calculated by each Cost Function, resulting in a weighted gradient.

3. Loss

Cross-Entropy is utilized as the loss function for the classification module, while MSE serves as the loss function for the regression module. As the labels in the regression module are normalized within the range of 0 to 1, the MSE-calculated gradient does not overpower the overall loss. This ensures a balanced weighting and similar significance between MSE and Cross-Entropy.

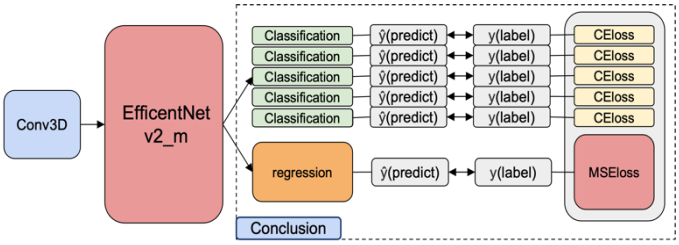

Fig. 4. The loss function design structure.

4. Optimizer

Various optimizers were employed, and a comparison of the differences in loss was conducted.

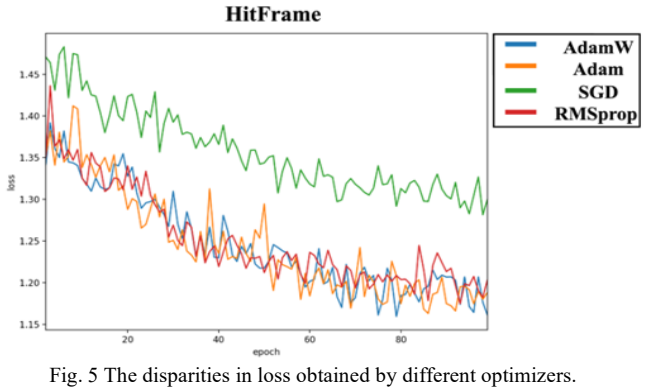

Fig. 5 The disparities in loss obtained by different optimizers.

In Figure 5, it is evident that AdamW[12] exhibited the best performance.AdamW[12] is employed as the optimizer, which receives gradients computed by all the loss functions. As each Linear module possesses its own specific loss function, the optimizer updates the parameters based on the corresponding loss function of each Linear module. However, in EfficientNetV2, the parameters are updated by aggregating a weighted combination of gradients all the loss functions.

V. Experiments

A. Category

Training: Our models are trained in PyTorch using the standard AdamW optimizer. We set a Side value of 1 per epoch and maintain a batch size of 15. We employ EfficientNetV2-M with either Fused-MBConv or MBConv at each stage of our architecture. To expedite training, we converted the data to pickle files.

Testing: Data is resized to 512x512 and normalized for testing.

Table 2. Accuracy of the original model, *Side*=1 and AdamW

Type	Accuracy	Type	Accuracy
Hitframe	56.6%	**LandingX**	89.1%
Hitter	99.9%	**LandingY**	88.1%
RoundHead	96.9%	**HitterLocationX**	93.0%
Backhand	97.2%	**HitterLocationY**	88.5%
BallHeight	96.1%	**DefenderLocationX**	95.0%
BallType	51.1%	**DefenderLocationY**	87.5%

Results in Table 2 presents data for nine categories, including *HitFrame* and *Hitter*. Among these, *Landing*, *DefenderLocation*, and *HitterLocation* predict coordinates individually. *HitFrame* and *BallType* exhibit relatively lower accuracy due to limited data for successful hits and the complexity of nine ball types. Increasing model depth might improve *BallType* classification. However, other categories demonstrate effective classification, affirming our use of distinct loss functions and optimizers. Accuracy and loss curves are in Figs. 6 and 7.

B. Ablation Studies

1. Side

In the Method section, we comprehensively described the Tube generation process using Side=1 as an example. We also examined Tubes for *Side*=2 and *Side*=3. We selected different frame configurations because they provide varying levels of information. However, we considered the model's overall learning and convergence capabilities. Increasing information doesn't guarantee improved performance. Our primary focus in the ablation experiments was to find the optimal data mixing ratio for each *Side*, aiming for the lowest loss and highest accuracy. Evaluation results in Fig. 8 and 9 showed that *Side*=1 had the highest recognition ability among all *HitFrames*.

VI. Conclusion

This article presents a study on badminton recognition using EfficientNetV2 as the training model. The focus is on efficiently and effectively categorizing each hit in a video. The model performs multi-task detection, encompassing regression

and classification of each Hit. We found that the label unbalanced caused the model unstable, it will be one of the main focuses in the future. This article is the first publication based on the dataset, contributing to the dissemination of the data and laying the foundation for the future development of a comprehensive badminton recognition system.

Abstract—An effective approach to solve the ill-posed problem of Inverse Halftoning is presented in this study using a combination of deep residual neural network and variance classification. The proposed method involves a two-stage process that utilizes the concept of progressive learning. In the first stage, the proposed deep neural network extracts intrinsic features from the image and eliminates halftone patterns. In the second stage, the network incorporates multiple deep residual blocks to restore fine details with high accuracy. The model employs various neural nets trained over different statistical ranges, taking into account the statistics of halftone patches. The proposed approach outperforms other methods and achieves superior reconstruction quality.

Keywords: Inverse halftoning, progressive learning, residual neural networks, variance classification, convolutional neural network

I. INTRODUCTION

Digital halftoning [1] is used to obtain the two-tone or binary equivalent of the continuous tone image. The technique is predominantly used in the printing industry specifically to obtain black and white printouts. When the printed image is viewed from a certain distance, it is perceived as a continuous tone image due to the low pass nature of the human eyes. This conversion helps us to create the illusion of the continuous tone image (various gray shades) using a single black cartridge ink. Briefly, the objective of halftoning is to convert a high bit-depth image (0-255) into a low bit-depth image (0-1). Many image rendering schemes have been developed in the past, likely ordered dithering (OD) [2] [3], error diffusion (ED) [4] [5], dot diffusion (DD) [6] [7], and direct binary search (DBS) [8] [9].

Inverse halftoning is a reverse process of halftoning that reconstructs a continuous-tone image of grayscale image (0-255) from its halftone version (0-1). Besides image restoration, inverse halftoning is also useful for printed image processing, image compression, and image enhancement.

For example, printed photos from old books or magazines can be scanned and recovered into the original grayscale image, which is extremely important for historical photos restoration.

Moreover, continuous-tone images are required to reconstruct in many applications, such as image sharpening, size adjustment, image rotation, or even color correction to o favorable results. Nevertheless, inverse halftoning is an ill-posed problem since there would be numerous feasible solutions.

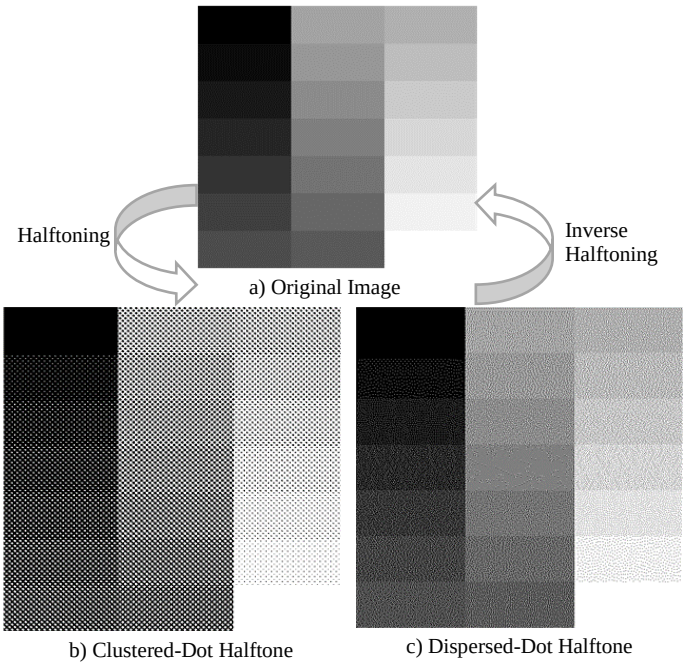

Fig. 1. Types of halftones

In this paper, we take the advantages of deep Convolutional Neural Network (CNN), which has been widely used for many computer vision problem [10] [11]. The training based on CNN can learn corresponding pairs of continuous-tone and halftone images efficiently. In general, the proposed scheme includes two steps: first removing the halftone effects to obtain the raw approximation of the image and then enhance the fine details using progressive learning. This is an end-to-end mapping solution to recover not only the gray-scale version but also the color halftone image. The experimental results show that the proposed deep learning approach is superior to the inverse halftoning benchmarks and achieves a new state-of-the-art performance.

We also show that statistical analysis on the dataset is an important factor to optimize the deep learning task. The halftone patterns are classified according to their variance values and then is used to train the model sets. We consider variance as a major factor because it has a close relationship with edge reconstruction.

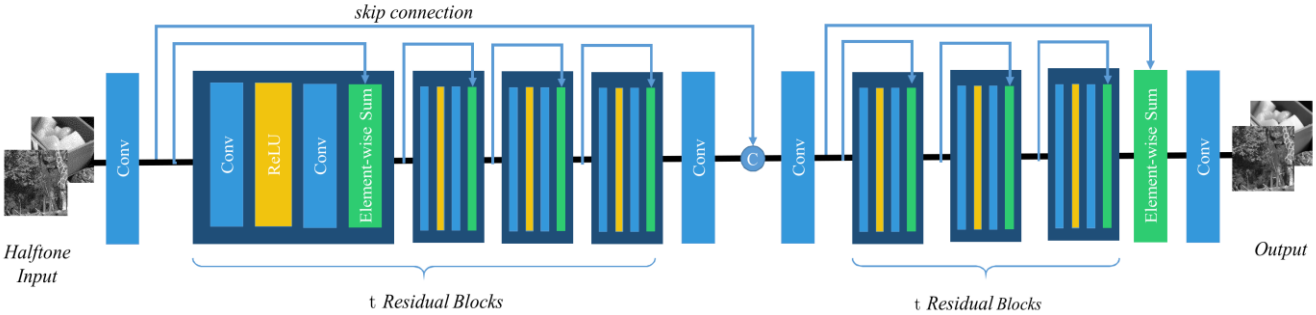

Fig. 2. Proposed deep neural network architechture

Section II briefly introduces different inverse halftoning approaches including conventional methods and new deep learning techniques. Section III explains the proposed method and the highlights of our proposed architecture. Section IV focuses on the experimental results and comparison to conventional techniques and deep learning-based methods as well.

II. PROPOSED WORK

A. *Conventional Inverse Halftoning*

The simplest approach to perform inverse halftoning is to use a simple gaussian low-pass kernel that can remove the halftone patterns. The approximation results in elimination of high frequency information and textures, and hence the resultant image is often blurry and shows poor reconstruction result. Chang et. al. [12] proposed a method based on the least-mean-square adaptive filtering algorithm which attempts to estimate the optimal mask shapes and filter weights. The method achieves better image quality with reduced image artifacts. Further, Mese et. al. [13] utilize a look up table (LUT) strategy to which approximates the halftone image to its closest gray scale equivalent image. The reconstruction performance completely relies on LUT construction and has severe performance limitations. Chung-Wu et. al [14] proposed an improved version of the Mese [13] method incorporating the classified edge features to achieve a sharper edge which slightly improve the visual quality. The main problem associated with the LUT methods is it memory requirement and time consumption to search and obtain the optimal gray-scale image. Guo. et. al [15] solved the memory issue using the LUT based on the multi-classifier optimized inverse halftone approach. The approach also uses the edge-based LUT which results in better reconstruction, but it is trained on a set of 30 image which resulted in limited performance.

B. *Deep Learning-Based Methods*

Deep convolutional neural networks have become the state-of-the-art method for numerous computer visions tasks including image segmentation [16], image classification [11], image denoising [17], super resolution [18], image restoration [19], and image-to-image transformation [20]. Especially, the inverse halftoning task is almost identical to the image-to-image transformation issue that transforms a halftone into the desired continuous-tone image. Qiu et. al [21] successfully deployed the deep learning-based solution to inverse halftoning. The method trained a deep convolutional neural network inspired by U-Net architecture [22] and leveraged another pre-trained deep CNN as a feature extractor. The U-Net network is similar to encoder-decoder that primarily used in biomedical semantic segmentation. In latest, Xia et. al [27] also proposed an encoder-decoder approach similar to U-Net architechture containing up- and down-sampling. Along with this progressive learning approach is also adopted for inverse halftoning. However, a lot of important features are lost due to the spatial dimension reduction of feature maps to obtain the latent representation. Therefore, edges and textures information cannot be recovered very accurately.

In contrast to this, the proposed model is straightforward method that doesn't affect the spatial dimension of inputs. Furthermore, our network is deeper, we immensely investigate the efficient residual blocks in the network design. To summarize, a novel residual neural network inspired by the progressive learning concept to enhance the subtle information such as textures, edges, and shape of objects is proposed. Our deep CNN is considered as a nonlinear mapping function that approximate the relationship between halftone images and their continuous-tone version. The model architecture and loss function are presented in section A and B respectively.

C. *Model Architectures*

At present, the existing CNN architectures are found to be very effective in solving many image processing tasks. Among different CNN models, the proposed model is constructed based on the combination of VGG16 [10] and SR-ResNet [18] model. As the primary VGG model is proposed for the image classification problem, it has been modified optimally to perform for the inverse halftoning problem. As shown in Fig. 2, the proposed network comprises of two stages: the first part of DRCNN starts with a normal convolutional layer and followed by t residual blocks. From our experiment results, it has been verified that at $t = 18$, our model has best performance. Besides, the concatenation is also provided to extract the contextual semantic information to the network. The first stage extracts a variety of features and simply remove the halftone patterns.

After the first step, essential information such as shapes, colors, tones, and contextual information are extracted. In the next stage, consecutive *t* residual blocks are integrated network to extract the subtle information by learning a residual image in order to restore the fine details similar to the concept of SR-ResNet [18]. The addition of *t* residual blocks into the first part has two benefits. Firstly, increasing the number of residual blocks can boost the performance of the model significantly as reported in [23]. Secondly, the concept of progressive learning is applied to synthesize subtle details by the leveraging prior knowledge from the first stage.

The proposed progressive framework gradually exploits the intrinsic features from the first part of the network and those are then fed into the next part to synthesize subtle structures incrementally. This process is progressive so that that numerous essential information extracted from the first part network can have an impact on later enhancement process. In such a progressive manner, our approach utilizes the features learned in the first progressive step to benefit the detail enhancement stage.

D. Loss Functions

Our goal is to reconstruct the continuous-tone images I_r from a given halftone images I_h that looks like the ground truth image I_{gt} with good perceptual quality. The halftone image of size $W \times H \times C$ can be transformed by the residual neural network into the continuous-tone image of size $W \times H \times C$ where W, H, and C are the width, height, and the number of channels of the image respectively. The proposed network can learn directly features from halftone without downsizing spatial dimension in U-Net architecture.

To recover I_{gt} from I_h , the network firstly trained to reduce the pixel-wise difference between I_r and I_{gt}. Pixel-wise loss reproduces I_{gt} in terms of PSNR. The $\mathcal{L}_1$ loss is a pixel-based reconstruction loss function which is widely used for many optimization problems. Optimizing $\mathcal{L}_1$ loss is the cheapest way to offer high PSNR performance. However, in the absence of high frequency information, images are usually blurry and noisy. We employ the $\mathcal{L}_1$ by computing the pixel-wise value between the ground-truth image I^{gt} and reconstructed image I^r.

$$\mathcal{L}_1 = \frac{1}{W \times H \times C} \sum_{i}^{W} \sum_{j}^{H} \sum_{k}^{C} \left| I^r_{i,j,k} - I^{gt}_{i,j,k} \right| \qquad (1)$$

Furthermore, we adopt the ideas of Gats et al. [24], Bruna et al. [25] and Johnson et al. [26] to integrate the VGG based perceptual loss $\mathcal{L}_{VGG}$, that is defined as

$$\mathcal{L}_{VGG/i,j} = \frac{1}{W_{i,j} \times H_{i,j}} \sum_{x=1}^{W_{i,j}} \sum_{y=1}^{H_{i,j}} (\phi_{i,j}(I^{gt})_{x,y} - \phi_{i,j}(I^r)_{x,y})^2 \qquad (2)$$

This loss encourages the network to generate a realistic result and enhance visual quality by optimizing the difference between high-level features. In Eq. 2, the $W_{i,j}$ and $H_{i,j}$ represent the dimensions of the corresponding feature maps. $\mathcal{L}_{VGG}$ loss measures the Euclidean distance between the feature representations of a ground truth image I_{gt} and a recovered image I_r. Moreover, $\phi_{i,j}$ indicates the feature map obtained by the j^{th} convolution (after activation) before the i^{th} max-pooling layer. Similar to [27], we choose $\phi_{i,j} = \phi_{4,4}$ that means the feature map obtained by the fourth convolution before the fourth max-pooling layer within the VGG19 network.

Structural similarity index (SSIM) is one of the popular full reference quality indexes which evaluates image quality based on the structural similarity. It can be used as an assessment of the perceptual similarity between two images with respect to a human viewer. We adopt SSIM to be a loss function that helps network learn the local structures in the image. μ and σ are means and standard deviations that are computed with a Gaussian filter kernel size of 7x7. According to [28], the SSIM loss function can be written by:

$$\mathcal{L}_{SSIM} = 1 - \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\sigma_x^2 + \sigma_y^2 + c_2)} \qquad (3)$$

To sum up, the final loss of our network is the weighted sum of pixel-wise $\mathcal{L}_1$, perceptual loss, $\mathcal{L}_{VGG}$ and $\mathcal{L}_{SSIM}$:

$$\mathcal{L}_{total} = \alpha_1 \times \mathcal{L}_1 + \alpha_2 \times \mathcal{L}_{VGG} + \alpha_3 \times \mathcal{L}_{SSIM} \qquad (4)$$

Here $\alpha_1 = 1, \alpha_2 = 4 \times 10^{-4}$ and $\alpha_3 = 1.5$

The α_2 is set in reference with the paper [27]. The $\mathcal{L}_{VGG/i,j}$ is calculated based on the difference between two feature maps of I^{gt} and I^r from pre-trained VGG19 network on another dataset. Therefore, the $\mathcal{L}_{VGG}$ from our experiments are extremely large. The weight α_2 will scale down the impact of $\mathcal{L}_{VGG}$ since $\mathcal{L}_1$ and $\mathcal{L}_{SSIM}$ are our objective for optimization. The final value α_2 is 4×10^{-4}. $\mathcal{L}_1$ and $\mathcal{L}_{SSIM}$ have correlated weights and are chosen based on practical experiments.

In this study, we select three popular datasets including MSCOCO [29], VOC2012 [30] and Place365 [31]. Due to a large number of images in each dataset, we select the small portion of images to do the variance analysis. MSCOCO [29] subset contains 20,000 image while VOC2012 [30] and Place365 [31] subset consist of 17,000 and 36,500 images respectively. For each subset, we randomly select 5 million patches with size 33x33 and attempt to sketch the histogram of variances for all subsets as in Fig. 3.

III. RESULTS AND DISCUSSION

In this part, the proposed DRCNN is applied for quantitative and qualitative performance evaluation. Firstly, we compare our proposed DRCNN with many state of the art methods and the results are provided in Fig. 4 and Table I. From the reconstruction quality assessment using SSIM and PSNR it can been seen that the proposed work has achieved a better results in terms of better edge reconstruction and achieved better perceptual quality than the existing works.

(a) Low Variance 0 – $2x10^3$ (b) Medium Variance $2x10^3$ – $4x10^3$ (c) High Variance Above $4x10^3$

SSIM	0.8820	0.8835	0.8689	0.8826	0.8816	0.8767	**0.8787**

IV. CONCLUSION

In this paper, a deep residual and classified neural network (DRCNN) is proposed to perform inverse halftoning.

The proposed architecture is comprising of the CNN network integrated with residual learning blocks to perform the optimal reconstruction. For training, various databases such as VOC2012, Place365 and DHD are used, and this helps to

improve the reliability and robustness of the proposed scheme. From initial experiments, it has been inferred that the statistical properties of the halftones have a substantial influence over the reconstruction accuracy. Consequently, the proposed method is an integration of many sub-models each of which performs for the halftone pattern with specific variance. In addition, various loss function such as PSNR, SSIM, and VGG loss are integrated to accurately reconstruct the average and structural information effectively. From our comprehensive results, it has been concluded that the proposed architecture performs superior over the existing models in terms of image quality and achieves good generalization to images of various types.

***Abstract*—This paper describes sound event localization and detection (SELD) for spatial audio recordings captured by first-order ambisonics (FOA) microphones. In this task, one may train a deep neural network (DNN) using FOA data annotated with the classes and directions of arrival (DOAs) of sound events. However, the performance of this approach is severely bounded by the amount of annotated data. To overcome this limitation, we propose a novel method of pretraining the feature extraction part of the DNN in a self-supervised manner. We use spatial audio-visual recordings abundantly available as virtual reality contents. Assuming that sound objects are concurrently observed by the FOA microphones and the omni-directional camera, we jointly train audio and visual encoders with contrastive learning such that the audio and visual embeddings of the same recording and DOA are made close. A key feature of our method is that the DOA-wise audio embeddings are *jointly* extracted from the raw audio data, while the DOA-wise visual embeddings are *separately* extracted from the local visual crops centered on the corresponding DOA. This encourages the latent features of the audio encoder to represent both the classes and DOAs of sound events. The experiment using the DCASE2022 Task 3 dataset of 20 hours shows non-annotated audio-visual recordings of 100 hours reduced the error score of SELD from 36.4 pts to 34.9 pts.**

***Index Terms*—Sound event localization and detection, audio-visual contrastive learning, self-supervised learning**

I. Introduction

Sound event localization and detection (SELD) is a task that aims to estimate the activations, classes, and directions of arrival (DOAs) of sound events from multichannel audio recordings [1]. It is one of the foundations of computational intelligence for understanding acoustic environments. The current standard approach to this task is to train a deep neural network (DNN) in a supervised manner using pairs of audio recordings with ground-truth annotations [2]–[4]. In general, it is difficult to collect a sufficient amount of annotated audio data covering a wide range of acoustic environments.

A popular solution to this problem is data augmentation [5], [6]. Specifically, one can synthesize multichannel audio data by convolving source signals of various classes with room impulse responses (RIRs) that simulate various acoustic environments and DOA conditions. This approach is known to effectively improve the performance of SELD for many common sound events (e.g., music and speech). However, SELD for some complex sound events (e.g., wildlife sound) remains an open problem because it is difficult to isolate and capture their individual sound source signals.

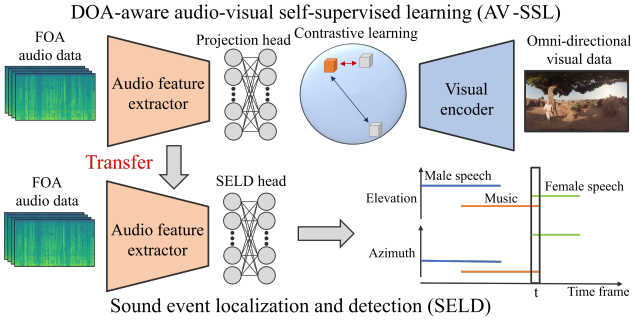

Fig. 1. AV-SSL of an audio feature extractor for SELD.

Another solution is to pretrain an audio feature extractor that constitutes the front end of a DNN used for SELD with audio-visual self-supervised learning (AV-SSL) (Fig. 1) [7]. This approach can make effective use of abundant virtual reality (VR) contents, each of which consists of multichannel audio data recorded by first-order ambisonics (FOA) microphones and 360° equirectangular visual data recorded by an omni-directional camera. Considering the cross-modal co-occurrence between the sounds and appearances of the same objects, one can jointly train audio and visual encoders in a contrastive fashion such that the audio and visual embeddings are made close to each other if they correspond to the same DOA and recording (positive sample) and far apart otherwise (negative sample). The front end of the trained audio encoder is then used for initializing the audio feature extractor for SELD.

Audio-visual spatial alignment (AVSA) [7] is one of the latest AV-SSL methods. It takes advantage of the FOA format, in which the single-channel audio signal with an arbitrary DOA can be computed from the observed FOA data. The audio embedding extracted from this enhanced signal are made close to the visual embedding extracted from the visual crop centered on the same DOA in the equirectangular visual data. However, the audio feature extractor trained in this way is insufficient for SELD because the DOA features of sound events cannot be extracted from the enhanced signal. On the other hand, the features useful for DOA estimation of sound events are not learnable with such non-DOA-aware contrastive learning equivalent in principle to AVC [8].

In this paper, we propose a DOA-aware extension of AVSA. Our method differs from the conventional AVSA [7] in that it jointly extracts audio embeddings over a DOA grid from raw

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

FOA audio data without DOA-wise signal enhancement. This encourages the latent features of the audio encoder to represent both the classes and DOAs of sound events. In addition, this paper also tackles one of the remaining challenges in AVSA that the cross-modal co-occurrence between sound and appearance does not hold for visible silent objects and occluded sound objects. In general, meaningful sound events exist only in a small number of DOAs, which limits this *local* contrastive learning based on the DOA-wise similarity between audio and visual embeddings.

To mitigate this problem, we also propose *global* contrastive learning based on recording-wise audio-visual similarity obtained by averaging the DOA-wise similarities over all the DOAs. Our goal is to maximize the similarity when the audio and visual embeddings correspond to the same recording (positive) and minimize it otherwise (negative). To encourage the audio encoder to extract DOA information as the latent features, we introduce a data augmentation technique that randomly spatially rotates only the equirectangular visual data to generate negative samples from the same recording.

II. Related Work

This section reviews existing SELD and AV-SSL methods.

A. Sound event localization and detection (SELD)

The modern approach to SELD is to train a DNN in a supervised manner. For instance, the activations of sound events are estimated with a DNN, while the DOAs are estimated geometrically [2]. Both the activations and DOAs can be estimated using a DNN [3]. Recently, an end-to-end approach to SELD has been proposed for directly estimating a DOA vector whose length corresponds to the duration of sound events in the Cartesian coordinate system [4].

To improve the robustness of SELD with a limited amount of annotated audio data, data augmentation tequniques such as SpecAugment [9] and Mixup [10] can be employed. Particularly for audio data provided in the FOA format, rotation-based augmentation is known to be effective [11]. Multichannel audio data with ground-truth annotations can be synthesized by convolving audio samples of various classes with arbitrary transfer functions [5], [12]. Alternatively, a general-purpose audio model [13] pretrained with a large dataset of audio signals called AudioSet [14] in an unsupervised manner can be used for sound event detection [15].

B. Audio-visual self-supervised learning (AV-SSL)

At the heart of AV-SSL is contrastive learning, which aims to train audio and visual encoders based on the cross-modal co-occurrence between the sounds and appearances of objects. The information encoded in the audio and visual embeddings may vary depending on the design of positive and negative samples. AVC [8], for example, uses standard video recordings and considers a pair of audio and visual data from the same recording as a positive sample and a pair of those from different recordings as a negative pair. The audio and visual embeddings are thus encouraged to represent the features of sound event classes. AVSA [7] uses spatial video recordings, which are originally made for VR application that requires DOA-based audio-visual rendering. AVSA, however, is essentially identical to AVC because it can be regarded as AVC for *non-spatial* video standard recordings obtained by decomposing *spatial* video recordings in a DOA-wise manner.

Audio-visual temporal synchronization (AVTS) [16] is another AVC-like self-supervised method. A key feature of AVTS is that it incorporates audio and visual data in the same recording, but at different moments in time, to negative pairs. The embeddings are thus encouraged to represent both the classes and activations of sound events.

III. Proposed Method

This section describes two variants of DOA-aware AV-SSL to improve SELD. The first variant employs DOA-wise contrastive learning, and the other employs recording-wise contrastive learning (Fig. 2). In both variants, an audio feature extractor $\mathcal{A}$ is used to transform raw FOA data into the latent audio features that represent sound event classes and DOAs. In this study, K discrete points on the Fibonacci lattice [17] are considered as potential DOAs. Each DOA $k \in [1, K]$ is defined by an azimuth angle θ_k and an elevation angle ϕ_k. A projection head $\mathcal{H}$ is then used to *jointly* convert the latent features to the audio embeddings over the DOA grid. A visual encoder $\mathcal{V}$, in contrast, is used to *separately* convert visual crops of a 360° equirectangular visual data over the DOA grid to the visual embeddings. Let I be the total number of recordings.

In DOA-wise contrastive learning, we maximize the local similarity between DOA-wise audio and visual embeddings when they correspond to the same DOA (positive sample), and minimize it otherwise (negative sample). In recording-wise contrastive learning, in contrast, we maximize global similarity obtained by averaging the local similarities over the DOA grid when the audio and visual embeddings correspond to the same recording (positive), and minimize it otherwise (negative).

Once $\mathcal{A}$, $\mathcal{H}$, and $\mathcal{V}$ are trained jointly in a self-supervised manner, $\mathcal{A}$ is connected to another head $\mathcal{H}'$ for SELD and the entire network is fine-tuned in a supervised manner.

A. Audio encoding

Let $\mathbf{X}_i^{(a)} \in \mathbb{R}^{(4+3)\times F\times T_a}$ be the multichannel audio spectrogram of spatial recording $i \in [1, I]$ obtained by stacking the mel spectrograms of the four-channel audio signals of the FOA format and the three intensity spectrograms on the orthogonal axes, where F is the number of mel frequency bins, and T_a is the number of frames. A series of frame-wise audio latent features denoted by $\mathbf{Y}_i^{(a)} \triangleq \{\mathbf{y}_{it}^{(a)}\}_{t=1}^{T_a}$ is obtained with the audio feature extractor $\mathcal{A}$ as follows:

$$\mathbf{Y}_i^{(a)} \leftarrow \mathcal{A}\left(\mathbf{X}_i^{(a)}\right). \tag{1}$$

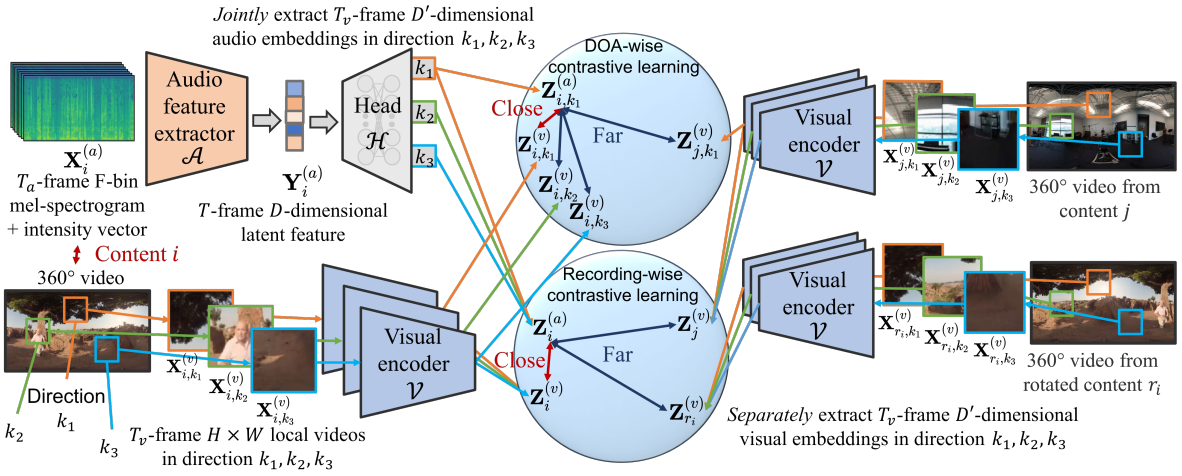

Fig. 2. The proposed DOA-wise and recording-wise DOA-aware contrastive learnings for pretraining the audio feature extractor.

A series of DOA- and frame-wise audio embeddings $\mathbf{Z}_i^{(a)} \triangleq \{\mathbf{z}_{ikt}^{(a)}\}_{k=1,t=1}^{K,T_v}$ is then obtained with the projection head $\mathcal{H}$:

$$\{\mathbf{z}_{ikt}^{(a)}\}_{k=1}^{K} \leftarrow \mathcal{H}\left(\mathbf{y}_{it}^{(a)}\right), \tag{2}$$

where the features $\mathbf{y}_{it}^{(a)}$ at each frame t are independently transformed for temporally localizing information, followed by an adaptive average pooling to match the visual data of T_v frames.

B. Visual encoding

Let $\mathbf{X}_i^{(v)} \triangleq \{\mathbf{x}_{ikt}^{(v)}\}_{k=1,t=1}^{K,T_v}$ be the series of DOA-wise local images cropped from the 360° equirectangular visual data of recording $i \in [1, I]$, where $\mathbf{x}_{ikt}^{(v)} \in \mathbb{R}^{H \times W}$ is a local image that corresponds to DOA $k \in [1, K]$ at time $t \in [1, T]$, H and W are the height and width of each image (cropping size), and T_v is the number of frames. Note that $\mathbf{x}_{ikt}^{(v)}$ is centered on DOA k on the Gnomonic projection [18] of the original spatial visual data. A series of DOA- and frame-wise visual embeddings $\mathbf{Z}_i^{(v)} \triangleq \{\mathbf{z}_{ikt}^{(v)}\}_{k=1,t=1}^{K,T_v}$ is obtained with the visual encoder $\mathcal{V}$ as follows:

$$\{\mathbf{z}_{ikt}^{(v)}\}_{t=1}^{T_v} \leftarrow \mathcal{V}\left(\{\mathbf{x}_{ikt}^{(v)}\}_{t=1}^{T_v}\right), \tag{3}$$

where the same visual encoding is independently applied to each DOA k to obtain the embeddings that represent the classes of visible sound objects.

C. Self-supervised learning (pretraining)

We describe the two variants of contrastive learning.

1) Similarity measures: Since the audio and visual data of the same spatial recording usually have the DOA-wise correspondence, we define the similarity between recordings i and j for each DOA k as the cosine similarity as follows:

$$\mathcal{S}_{\mathrm{DOA}}(\mathbf{Z}_{ik}^{(a)}, \mathbf{Z}_{jk}^{(v)}) = \frac{1}{T_v} \sum_{t=1}^{T_v} \frac{\mathbf{z}_{ikt}^{(a)\mathsf{T}} \mathbf{z}_{jkt}^{(v)}}{\|\mathbf{z}_{ikt}^{(a)}\| \|\mathbf{z}_{jkt}^{(v)}\|}, \tag{4}$$

where $\mathbf{Z}_{ik}^{(a)} \triangleq \{\mathbf{z}_{ikt}^{(a)}\}_{t=1}^{T_v}$ and $\mathbf{Z}_{ik}^{(v)} \triangleq \{\mathbf{z}_{ikt}^{(v)}\}_{t=1}^{T_v}$.

We here focus on the InfoNCE loss [19] defined as follows:

$$\mathcal{I}(\mathbf{Z}, \mathbf{Z}_p, \mathbf{U}_n) = -\frac{\exp(\mathcal{S}(\mathbf{Z}, \mathbf{Z}_p)/\tau)}{\sum_{\mathbf{Z}_n \in \mathbf{U}_n} \exp(\mathcal{S}(\mathbf{Z}, \mathbf{Z}_n)/\tau)}, \tag{5}$$

where $\mathbf{Z}$ is an anchor, $\mathbf{Z}_p$ is a positive sample, $\mathbf{U}_n$ is a set of negative samples, and τ is a temperature hyperparameter. Minimizing $\mathcal{I}$ encourages the similarity of $\mathbf{Z}$ to $\mathbf{Z}_p$ to be larger than to $\mathbf{U}_n$ in a contrastive manner.

2) DOA-wise contrastive learning: The loss $\mathcal{L}_{\mathrm{DOA}}$ used in this variant is calculated as follows:

$$\mathcal{L}_{\mathrm{DOA}} = \sum_{i,k=1}^{I,K} \mathcal{I}\left(\mathbf{Z}_{ik}^{(a)}, \mathbf{Z}_{ik}^{(v)}, \{\mathbf{Z}_{jk}^{(v)}\}_{j=1}^{I} \cup \{\mathbf{Z}_{ik'}^{(v)}\}_{k'=1}^{K}\right), \tag{6}$$

where the similarity between the audio and visual embeddings is maximized when they correspond to the same DOA.

3) Recording-wise contrastive learning: The loss $\mathcal{L}_{\mathrm{REC}}$ used in this variant is calculated as follows:

$$\mathcal{L}_{\mathrm{REC}} = \sum_{i=1}^{I} \mathcal{I}\left(\mathbf{Z}_i^{(a)}, \mathbf{Z}_i^{(v)}, \{\mathbf{Z}_j^{(v)}\}_{j=1}^{I} \cup \{\mathbf{Z}_{r_i}^{(v)}\}\right), \tag{7}$$

where $\mathbf{Z}_{r_i}^{(v)}$ is a series of visual embeddings that corresponds to the visual data from the rotated recording r_i, which is obtained by rotating the spatial information of the recording i. The recording-wise similarity used in $\mathcal{L}_{\mathrm{REC}}$ is obtained by averaging the DOA-wise similarities over all the directions:

$$\mathcal{S}_{\mathrm{REC}}(\mathbf{Z}_i^{(a)}, \mathbf{Z}_j^{(v)}) = \frac{1}{K} \sum_{k=1}^{K} \mathcal{S}_{\mathrm{DOA}}(\mathbf{Z}_{ik}^{(a)}, \mathbf{Z}_{jk}^{(v)}). \tag{8}$$

D. Supervised learning (fine-tuning)

Using annotated data, the audio feature extractor $\mathcal{A}$ is fine-tuned for SELD based on activity-coupled Cartesian DOA representation (ACCDOA) [20]. Specifically, multiple sound

events of the same class can be separately assigned to different tracks. Let $\hat{\mathbf{P}} \in \mathbb{R}^{T' \times C \times N \times 3}$ be a multi-ACCDOA vector of T' frames, C classes, N tracks given by

$$\hat{\mathbf{P}} \leftarrow \mathcal{H}'\left(\mathcal{A}\left(\mathbf{X}\right)\right), \tag{9}$$

where $\mathbf{X} \in \mathbb{R}^{(4+3)\times F \times T'_a}$ is the multichannel spectrogram computed in the same way as $\mathbf{X}_i^{(a)}$, where T_a is the number of frames. The projection head $\mathcal{H}'$ consists of several fully-connected layers, followed by an adaptive average pooling to suit the target time resolution T'. Since the SELD label for frame t, class c, and track n is given as a pair of the activity $a^*_{tcn} \in \{0, 1\}$ and the Cartesian DOA vector $\mathbf{R}_{tcn}$, the target ACCDOA vector is given by

$$\mathbf{P}^*_{tcn} = a^*_{tcn}\mathbf{R}_{tcn}. \tag{10}$$

The overall network is trained to minimize:

$$\mathcal{L}^{\mathrm{PIT}} = \frac{1}{TC}\sum_{t,c=1}^{T',C} \min_{\alpha \in \mathrm{Perm}(ct)} \mathcal{L}^{\mathrm{ACCDOA}}_{\alpha,tc}, \tag{11}$$

$$\mathcal{L}^{\mathrm{ACCDOA}}_{\alpha,tc} = \frac{1}{N}\sum_{n=1}^{N} \mathrm{MSE}\left(\mathbf{P}^*_{\alpha,tcn}, \hat{\mathbf{P}}_{tcn}\right), \tag{12}$$

where $\alpha \in \mathrm{Perm}(t)$ is a possible frame-level permutation of M tracks at the frame t and $\mathrm{Perm}(t)$ is a set of all possible permutations. $\mathrm{MSE}(\cdot, \cdot)$ is the mean square error function.

IV. Evaluation

This section reports a comparative experiment conducted for evaluating the proposed AV-SSL methods with the two variants of contrastive learning.

A. Network configuration

The STFT spectrograms with a shifting interval of 480 samples and a window size of 1024 were converted to the mel spectrograms with $F = 64$ mel bins. The number of DOAs K was 220.

We used a ResNet-Conformer [12] for the audio feature extractor $\mathcal{A}$ as shown in Figs. 3 (a)–(c). The architecture of the projection head $\mathcal{H}$ consisted of two linear+SiLU layers followed a linear layer which output dimension was 220×128 as shown in Figs. 3 (d). The FOA audio data were resampled at a sampling rate of 24 kHz and split into 2-second clips in the training.

The visual encoder $\mathcal{V}$ consisted of 9-layer $R(2+1)D$ convolution layers [21] as shown in Fig. 4. The input equirectangular visual data were extracted at the time resolution T_v of 16 (8 Hz). The field of view ψ of visual crops for each direction was $40°$, and the resolution $H \times W$ was 16×16. The horizontal and vertical flipping was applied to the visual crops as data augmentation.

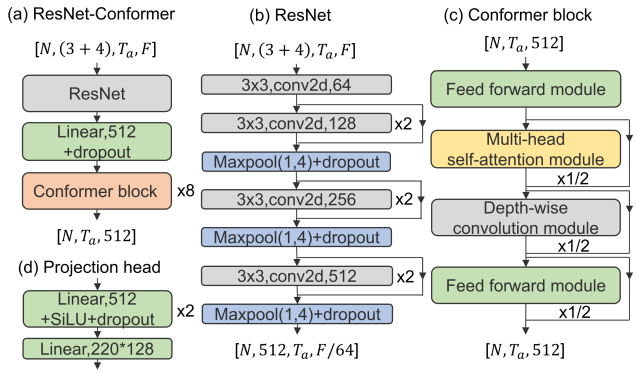

Fig. 3. The architecture of the audio encoder.

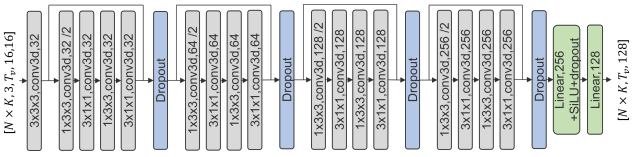

Fig. 4. The architecture of the visual encoder.

B. Pretraining

We used the YT-360 dataset [7] for pretraining. It contains VR contents collected from YouTube, each of which consists of a synchronized pair of FOA audio data and equirectangular visual data, including 246 hours of 10-second-long recordings on diverse genres including music and sports. After removing recordings with some missing channels, 104 hours of the training data and 20 hours of the validation data were used.

By the proposed AV-SSL methods, the ResNet-Conformer was trained for 100 epochs using AdamW optimizer [22] with a batch size of 4, a learning rate of 10^{-4}, a weight decay of 10^{-5}. Rotated recordings for the negative sample were obtained by randomly rotating the equirectangular visual data around the z-axis. The temperature hyper-parameter τ was 0.1. The SpecAugment [9] and the dropout with a rate of 0.1 were used. The model having the lowest validation loss was used for the downstream SELD task.

The conventional AV-SSL method called AVC [8] was also evaluated as a baseline for comparison. Specifically, the loss $\mathcal{L}_{\mathrm{AVC}}$ was calculated with the recording-wise similarity $\mathcal{H}(\{\mathbf{z}^{(a)}_{it}\}_{t=1}^{T_v}, \{\mathbf{z}^{(v)}_{it}\}_{t=1}^{T_v})$, where $\mathbf{z}^{(a)}_{it} \in \mathbb{R}^{128}$ was obtained by max-pooling the DOA-wise visual embeddings $\{\mathbf{z}^{(v)}_{ikt}\}_{k=1}^{K}$ and $\mathbf{z}^{(a)}_{it} \in \mathbb{R}^{128}$ was directly obtained from the output layer $\mathcal{H}$ with output dimension 128.

As in [7], curriculum learning was introduced for the proposed methods, where two audio feature extractors $\mathcal{A}$ were first trained with AVC for 50 epochs, then trained with the two different proposed AV-SSLs for 50 epochs.

C. Fine-tuning

The SELD performance was evaluated on the STARSS22 and Synth1 datasets [5]. The STARSS22 is a dataset of actual recorded FOA data annotated with the activations, classes, and

DOAs of 13 sound events every 0.1 seconds, where the class labels follow the Audioset ontology [14]. This dataset consists of 2.9 hours of training data and 2 hours of validation data. Note that some classes have very low frame coverages in STARSS22 as shown in Table I. The Synth1 is a dataset of synthesized FOAs annotated in the same way as STARSS22, obtained by remixing source signals from FSD50K [23] with room RIRs from TAU-SRIR database [24]. Two datasets of different sizes constructed from these datasets were used for fine-tuning. The first one was a dataset made up of all training data from STARSS22 and Synth1 (STARSS22+Synth1). The second one consisted only of all training data from STARSS22 (STARSS22). A dataset that consists of all validation data from STARSS22 and Synth1 was used as the validation dataset in both conditions. The original FOA data were split every 5 seconds, and they were sampled uniformly over all 13 classes to deal with the class imbalance in STARSS22.

Each pretrained model was fine-tuned with a head $\mathcal{H}'$ to output 3-track multi-ACCDOAs [20]. The architecture of $\mathcal{H}'$ was the same as the head $\mathcal{H}$ shown in the Sec. IV-A except that the output dimension was changed to $13 \times 3 \times 3$. AdamW with a learning rate of 10^{-4} and a weight decay of 10^{-5} was used for training. The models were trained for 1000 epochs. For data augmentation, the input FOA was randomly rotated. The dropout rate was 0.1 for ResNet-Conformer and 0.05 for $\mathcal{H}'$.

Models pretrained with our methods were compared with a non-pretrained model and a model pretrained with the conventional AVC method based on SELD score [1] on the vali-

dation dataset. The SELD score is obtained by averaging over four metrics as follows:

$$SELD = \frac{1}{4}\left(ER_{\leq 20^\circ} + (1 - F_{\leq 20^\circ}) + \frac{LE}{180} + (1 - LR)\right),$$

where the smaller score indicates better performance. $ER_{\leq 20^\circ}$ is the location-dependent error rate, where the prediction is counted as a true positive only if the estimated class activity is correct and the distance between the estimated and reference DOAs is smaller than 20°. $F_{\leq 20^\circ}$, LE and LR are the averages of class-wise metrics $F_{c,\leq 20^\circ}$, LE_c and LR_c, respectively. $F_{c,\leq 20^\circ}$ is the location-dependent F1-score for class c. LE_c is the average DOA estimation error over only the correctly detected events of class c. LR_c is the location-independent recall for class c. LE_c and LR_c can be considered to be the performance of detection and localization, respectively. The performance of each model was measured by averaging the metrics over the epochs with the first to tenth highest SELD scores.

D. Experimental results

Table II shows the overall SELD performances in terms of the five metrics, i.e., $ER_{\leq 20^\circ}$, $F_{\leq 20^\circ}$, LE, LR, and SELD score for each dataset and each pretraining method. In the STARSS22+Synth1 dataset, both the AV-SSL with DOA-wise contrastive learning and the AV-SSL with recording-wise contrastive learning improved the SELD scores by about 1.5 pts, while the conventional AVC improved only about 0.5 pts. This result indicates that our proposed approach is more suitable for the pretraining of SELD than AVC.

Table III shows the performance gaps in the class-wise metrics, $F_{c,\leq 20^\circ}$, LE_c and LR_c, between the non-pretrained model and each pretrained model, where all the metrics were transformed to the range of $[0, 1]$ for readability, and only some of the classes required for the following discussion were picked up due to the page limitation. The proposed AV-SSLs degraded the SELD scores more than AVC when only a few hours of imbalanced data were used for training (STARSS22). This would be partly due to the domain mismatch between YT-360 and STARSS22 and the class imbalance of STARSS22. As for the knock class, which was not included in the pretraining dataset (YT-360), for example, the detection performance LR_c got particularly worse. While in the classes related to home sounds (e.g., domestic sounds and door), which frequently appear in YT-360, the detection performance was improved.

Another reason for the degradation would be that a large amount of background music data independent from the visual data are included in YT-360. Background music was considered to have a negative impact on the localization of sound events related to music because it did not spatially correspond to the paired visual data. In fact, the localization performance LE_c was significantly degraded by the pretraining for the musical instruments and bell classes.

V. Conclusion

We proposed two variants of pretraining an audio feature extractor useful for SELD using spatial audio-visual recordings. To obtain the latent audio features representing not only the classes but also the DOAs of sound events, the audio encoder takes the FOA data as input, and outputs the audio embeddings over the DOA grid. The transfer learning with a sufficient amount of data showed the effectiveness of the proposed AV-SSLs as pretraining for SELD. For future work, one should deal with the deterioration in the SELD performance when sufficient labeled data is unavailable. One of the promising approaches would be to prepare the dataset of spatial audio-visual recordings covering various domains with good correspondence between audio and visual data.

***Abstract*—In this study, we propose a novel approach to sound event localization and detection (SELD) by using sound separation (SS) models to tackle key challenges of a high percentage of overlapped segments between sound events and imbalanced distributions of sound event classes in real-world scenarios. Specifically, we introduce class-dependent SS models to deal with overlapping mixtures and extract features from the SS model as prompts for SELD of a specific event class. The proposed SS-SELD method enhances the overall performance of the SELD system, resulting in improved accuracy and robustness in real-world scenarios. In contrast to many other classification methods that can be affected by the interference events, the proposed class-dependent SS framework enhances the overall performance of the SELD system, resulting in improved accuracies and robustness in real-world scenarios. When evaluated on the Sony-TAu Realistic Spatial Soundscapes 2023 (STARSS23) dataset, we demonstrate significant improvements in both sound event detection (SED) and direction-of-arrival (DOA) estimation. Our findings suggest that sound separation is a promising strategy to enhance the performance of SELD systems, particularly in scenarios with high overlaps between sound events and imbalanced distributions of event classes. In addition, our proposed framework had contributed building to our champion systems submitted to the Challenge of DCASE 2023 Task 3.**

I. Introduction

Sound event localization and detection (SELD) is an essential task in various audio processing applications, including surveillance systems [1]–[3], environmental monitoring [4], [5], and augmented reality [6], [7]. It was initially introduced as Task 3 in the Detection and Classification of Acoustic Scenes and Events (DCASE) 2019 Challenge [8], [9]. The goal of SELD is to accurately estimate the temporal onsets and offsets, spatial locations, as well as categories of sound events simultaneously within an audio recording. Over the past few years, significant advancements have been made in SELD techniques, driven by the increasing demand for robust and efficient sound analysis algorithms.

SELDnet was proposed to map the input to the sound event detection (SED) and the 3-D Cartesian coordinates of direction-of-arrival (DOA) with two separated branches [10], [11]. In this paper, we use SEDDOA to replace the two-branch network. Shimada et al. introduced an output format called Activity-coupled Cartesian DOA (ACCDOA) for SELD [12]. ACCDOA associates event activity with the length of the Cartesian DOA vector, enabling the solution of SELD task without the requirement of separate branches [13], [14]. However, ACCDOA assumes that each event occurs only once within a frame. When multiple sources of the same event class exist in different directions at the same time, ACCDOA becomes unreliable, leading to angular errors. To address this issue, multi-ACCDOA was proposed [15], which adds a track for concurrence of sources in the prediction results, thereby yielding more accurate localization results. Wang et al. employed data augmentation techniques and performed model fusion with the previous SELD methods, achieving the state-of-the-art performance and ranking the first place in the DCASE 2022 Task 3 Challenge [16]. While SELD models have achieved impressive performance in real-world scenarios, obtaining excellent results in the DCASE 2019-2022 Task 3 Challenge series [8], [9], [13], [17], they face challenges due to the unbalanced distribution of sound events and severe overlapping in real-world scenes. As a result, pure SELD classification systems struggle to effectively model all sound event classes. Therefore, we aim to explore a frontend approach to enable the SELD system to better model each individual class. It has been proven that the separation method is effective in weakly labeled sound event detection (SED) tasks [18]–[20]. However, the effectiveness of sound separation in SELD tasks has been less extensively studied. In DCASE 2022, Jin-Young and his team attempted to use separation as a branch to handle SED information, ultimately merging it with DOA information for further processing [21]. However, such an approach led to the waste of spatial information contained in the 4-channel recordings within the SED branch and resulted in SED information relying entirely on the performance of separation, which could easily lead to unstable results.

In this paper, we introduce a new framework that employs sound separation (SS) as the front-end of SELD model, named SS-SELD. By combining the separated sound with the original mixture, better results can be achieved compared to the traditional SELD methods which only use the mixture. We evaluate our approach on the Sony-TAu Realistic Spatial Soundscapes 2023 (STARSS23) dataset [22] and demonstrate significant

improvements in both SED and DOA estimation. Our findings suggest that sound separation is a promising strategy to enhance the performance of SELD systems. Besides, the newly proposed methods made a great contribution to our system ranking the first place in the DCASE 2023 Task3 Challenge.

II. Proposed Methods

In real-world scenarios, sound events often exhibit a high degree of overlap, as depicted in Table I. It can be observed that all sound events exhibit an overlap rate of over 50%, with certain classes such as clapping and laughter having overlap rates exceeding 80%. The Bell class, in particular, has a 100% overlap rate, indicating that all instances of this class overlap with other sound events in the dataset. Traditional SELD models focus on classification-based approaches, facing difficulties in adequately modeling these overlapping events. Building upon this foundation, we propose a novel SS-SELD method. Fig.1 illustrates this new framework.

A. Sound Separation

The newly proposed method consists of two main components. The first introduced component of SS-SELD is the SS method as depicted by the blue dashed box in Fig.1. SS illustrates the inference process of the separation model. As mentioned earlier, due to the uneven distribution of sound events, some events have short durations. Therefore, we sought to enhance the richness of the data by sourcing the required sound events from open-source datasets. Given a mixed audio signal $x(t)$, where t is the sample index in time domain. $x(t)$ contains target sound event $s(t)$ and multiple Interfering sound classes $x_1(t), \cdots, x_m(t)$:

$$x(t) = s(t) + \cdots + x_m(t), \quad m = 1, \ldots, n \tag{1}$$

where n represents the number of events in the mixed audio. The separation process is performed as follows:

$$f_\theta(x(t)) = \hat{s}(t) \tag{2}$$

Here, $f_\theta(\cdot)$ denotes the separation model, θ represents the model parameter set. $\hat{s}(t)$ is the extracted sound. In this process, we train a widely used time-domain model architecture, namely, Conv-TasNet [23] on the dataset simulated from both STARSS23 and Audioset. We first segment data into single-event segments based their labels, which are then added in the time domain to generate mix audios. Simulating training data for the sound separation model also considers the proportion of overlap in natural conditions. The separation model is capable of filtering out the mixed audios and providing separated event distributions, which can serve as guidance for further analysis and modeling. It is worth mentioning that due to significant differences between different event classes, we constructed a dedicated training set for each class with that class as the target. This allows us to achieve class-dependent sound separation. This approach effectively mitigates detection errors of low-intensity classes with significant overlap.

During the fusion process of SS-SELD, the mixture $x(t)$ will be first passed through Audio Channel Swapping (ACS) to obtain augmented signal $x'(t)$. Then for each class, $x'(t)$ will be sent into the separation model to obtain separated sound $\hat{s}(t)$ that only contains the specific class of interest. Afterward, audio signal $\hat{s}(t)$ and $x'(t)$ undergo feature extraction modules separately. $S_{\text{lm}}(k,l)$ denotes log Mel-spectrogram extracted from $\hat{s}(t)$, $X_{\text{lm}}(k,l)$ and $X_{\text{iv}}(k,l)$ denote log Mel-spectrogram and intensity vectors extracted from $x'(t)$, respectively. These features are concatenated to train the SS-SELD model, resulting in output O for detection and localization. We can represent the entire process using the following equations, corresponding representations in Fig.1:

$$x'(t) = \text{ACS}(x(t)) \tag{3}$$

$$\hat{s}(t) = \text{SS}(x'(t)) \tag{4}$$

$$S_{\text{lm}}(k,l) = \text{FE1}(\hat{s}(t)) \tag{5}$$

$$\{X_{\text{lm}}(k,l), X_{\text{iv}}(k,l)\} = \text{FE2}(x'(t)) \tag{6}$$

$$O = \text{SELD}(S_{\text{lm}}(k,l), X_{\text{lm}}(k,l), X_{\text{iv}}(k,l)) \tag{7}$$

where ACS$(\cdot)$, SS$(\cdot)$, FE1$(\cdot)$, FE2$(\cdot)$ and SELD$(\cdot)$ denote the audio channel swapping, sound separation, separated sound feature extraction, mixed sound features extraction and SELD predicting operations, respectively. The final output O contains both frame-level sound event labels and the angle information.

B. Sound Event Localization and Detection

Fig.1 (b) illustrates the training process of the traditional SELD model. Mixture from STARSS23 undergo the data augmentation technique ACS [24] to increase the data size by approximately 8 times. The augmented mixture are then fed into the feature extraction module, which extracts log Mel-spectrogram containing event label information and intensity vector features containing spatial location information. These features are used to train the SELD which follows a similar principle to the traditional SELD approach, consistent with the SELD methodology employed in our winning solution for DCASE 2022 TASK 3. For more detailed information, please refer to reference [16].

III. Experiment Setup

We evaluate SELD on the official development set of the DCASE 2023 Task 3, which is collected in realistic spatial soundscapes [22]. The set totals 168 recording clips (about 9 hours), which can be split into a training part (dev-train, 90 clips) and a testing part (dev-test, 78 clips) according to the official set. We have utilized labeled segments of individual sound events from Audioset [25], in addition to the DCASE 2023 Task 3 dev-train data, to construct training data for sound separation. The total duration of single-event segments amounts to approximately 39.42 hours. Out of this duration, 6.21 hours are obtained from the STARSS23 dev-train dataset, while the remaining 33.21 hours are sourced from the Audioset dataset. For each sound event class, we utilize its corresponding single-event segments as targets and treat the remaining sound events as noise. During the data simulation

TABLE I
OVERLAPPING PERCENTAGE (%).

	Woman speaking	Man speaking	Clap	Telephone	Laughter	Domestic sounds	Footsteps	Door	Music	Musical instrument	Water tap	Bell	Knock
Overlap	59.98	54.25	83.19	51.89	84.79	69.56	54.79	66.77	67.20	58.62	79.79	100.00	82.22

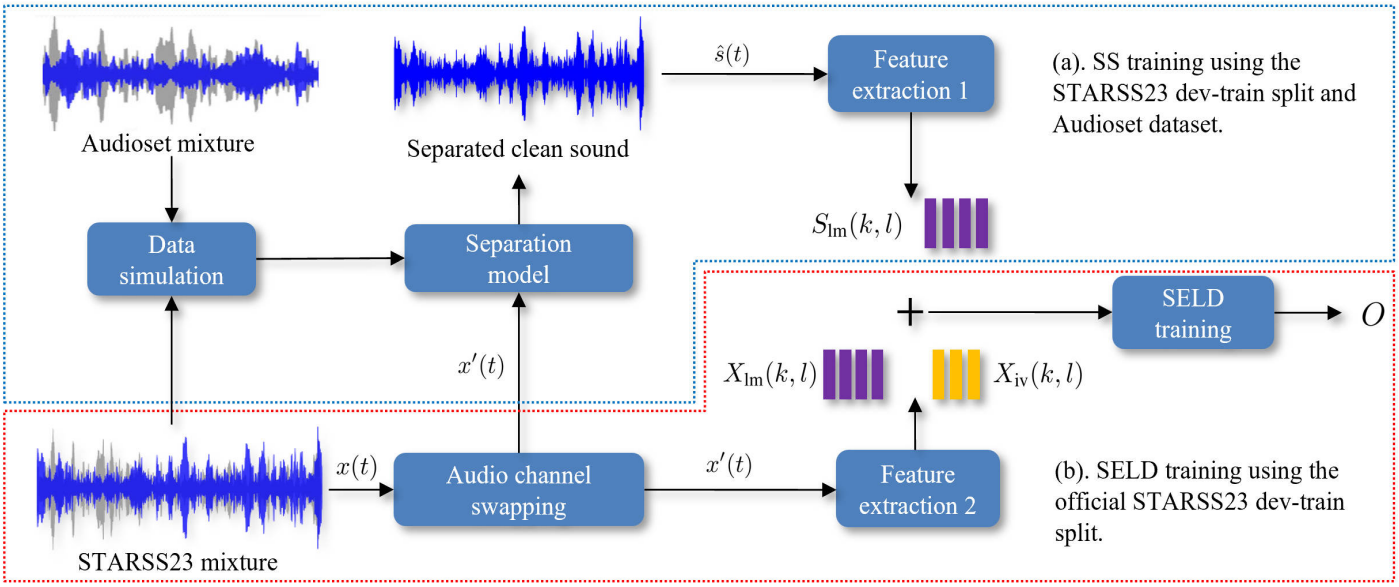

Fig. 1. Framework of the proposed SS-SELD system. Note that (a) in the blue dashed box represents the inference process of SS. while (b) in the red dashed box represents the inference process of the SELD model. In the data simulation part, the data from the dev-train set and open-source dataset are split into single-event segments based on their labels. Once the target class is determined, other classes are considered as interference, and simulation is carried out accordingly.

phase, we overlay the target sound event segments with other sound event segments in the time domain to create mixed audio. This allows us to simulate approximately 40 hours of data, which is used for training the corresponding separation model. All recordings from STARSS23 are 4-channel with a 24 kHz sampling rate. Similarly, single-channel speech from Audioset are also downsampled to 24 kHz. There are 13 sound classes in total. We apply the short-term Fourier transform (STFT) with 40 ms frame length and 20 ms frame hop on 4-channel first-order Ambisonics (FOA) [26] audios to extract log Mel-spectrogram. We concatenate them to get the 11-channel feature at each frame. Considering its outstanding performance in real-world scenarios in recent years, the separation models is trained on ConvTasNet architecture and the model parameter settings can be referenced in [23].

For the SS-SELD training, the data size can be augmented to 8 times by applying the ACS strategy, which results in about 192 hours of data. We use the ResNet-Conformer as our main model architecture [27]. The model employs 8 attention heads, with input, key, and value vectors having dimensions of 256, 32, and 32, respectively. It consists of 8 Conformer layers. The optimizer used is Adam, and a warm-up learning schedule is employed with a maximum learning rate of 0.001. Batch-size is set to 32. The training process is conducted for a maximum of 180,000 steps (which is around). All experiments are conducted on a NVIDIA Tesla V100 Graphic Card-32GB GPU.

All methods are evaluated using SELD_{score} [28], which is calculated as follows:

$$\text{SELD}_{score} = \frac{\text{ER}_{20^\circ} + (1 - \text{F}_{20^\circ}) + \text{LE}'_{\text{CD}} + (1 - \text{LR}_{\text{CD}})}{4} \tag{8}$$

$$\text{LE}'_{\text{CD}} = \frac{\text{LE}_{\text{CD}}}{\pi} \tag{9}$$

where ER_{20° and F_{20° are location-dependent error rate and F-score when the spatial error is within 20°. Note that the F_{20°, LE_{CD} and LR_{CD} are calculated through macro-averaging follow the official definition.

IV. RESULTS AND ANALYSIS

The dev-train split of the official development set of the DCASE 2023 Task 3 is used for training the SELD model as

TABLE II
EXPERIMENTAL RESULTS FOR DEVELOPMENT SET OF DCASE 2023 TASK 3 BASELINE AND SOME SELD METHODS, AS WELL AS THE PROPOSED SS-SELD METHOD. THE BEST RESULTS ARE HIGHLIGHTED IN BOLD.

	$ER_{20^\circ} \downarrow$	$F_{20^\circ} \uparrow$	$LE_{CD} \downarrow$	$LR_{CD} \uparrow$	$SELD_{score} \downarrow$
Baseline-FOA [22]	0.57	0.30	21.60	0.48	0.478
SEDDOA	0.41	0.59	14.05	0.70	0.304
Multi-ACCDOA	0.44	0.58	13.75	0.74	0.303
ACCDOA	0.42	0.59	13.72	0.72	0.300
SS-SELD	**0.40**	**0.64**	**13.40**	**0.74**	**0.279**

well as the newly proposed SS-SELD framework. The dev-test split is used to validate the performance of the models.

Table II shows the overall experimental results of the proposed method for development dataset. "ACCDOA", "SEDDOA" represent the ACCDOA- and SEDDOA-based modeling method, where SEDDOA adopts a two-branch (SED and DOA) approach for SELD modeling. "Multi-ACCDOA" represents the multi-ACCDOA-based method. SS-SELD denotes the proposed SELD model with SS front-end, with the same output format as SEDDOA. As shown in the table, each proposed single model outperforms the two baseline systems by a large margin. It can also be observed that compared to the baseline, traditional SELD models (SEDDOA, ACCDOA, Multi-ACCDOA) exhibit a decrease of approximately 0.18 in $SELD_{score}$, dropping from 0.478 to around 0.300. Despite attempting to use more data and iterative optimization, there was no significant improvement in the performance of the SELD models. However, with the assistance of the separation method, our SS-SELD system further reduces $SELD_{score}$ to 0.279, breaking through the bottleneck around 0.30 for SELD performance. Additionally, the results of the ER_{20° and F_{20° metrics demonstrate that the inclusion of the separation method significantly improves the model's performance in the detection aspect. As the localization results rely on the accuracy of the detection, the introduction of separation indirectly enhances the localization performance, leading to improvements in LE_{CD} and LR_{CD} as well.

Furthermore, we present the results for each individual class as shown in Table III. It can be observed that the separation method achieves significant improvements in the majority of classes, especially for classes like 'class11' (i.e., *Bell*). These classes have short durations within the entire test set but poss distinct features. The separation method effectively distinguishes them from other classes. However, for the class Water tap, the separation method is ineffective. Through specific analysis, we discovered that Water tap sounds are often low in volume, distant from the microphones (the official dataset provides auxiliary video information, but it is not allowed to be used during the testing process in the Audio-only track. Therefore, we only utilized the video information for analysis purposes.) More importantly, there exists interference noise in the test set that closely resembles the sound of Water tap. This makes it challenging for the separation model to accurately isolate the target Faucet sounds, thereby misleading

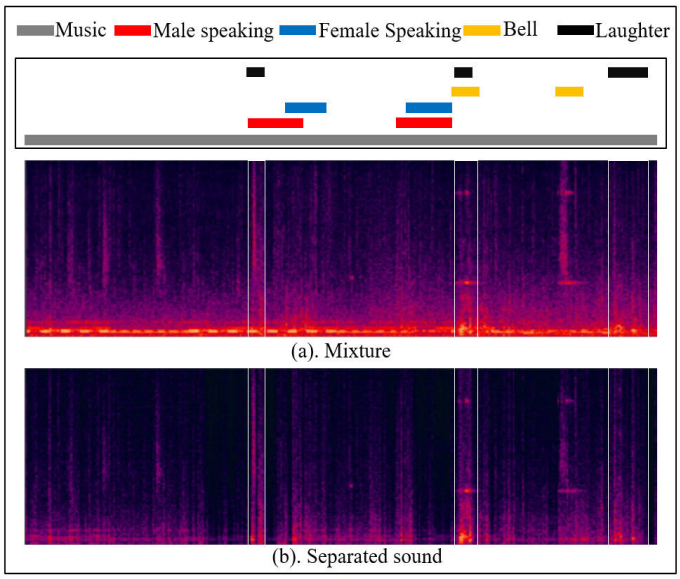

Fig. 2. Comparison of spectrograms before and after sound separation, where the colored rectangular bars at the top represent temporal event labels. The target class in this case is laughter. The model is able to preserve the laughter while effectively removing other sounds such as music.

the training of the subsequent SS-SELD model.

Fig.2 illustrates the spectrogram comparison of the input mixture before and after separation. The colored rectangular tags at the top represent different sound events, with laughter being the target class in this example. The white regions represent the target sound event, which is *Laughter*. It can be observed that the input mixture contains background 'class 8' (*Music*) with high energy in the low-frequency range throughout the entire audio segment, as well as overlapping conversations between different speakers ('class 0' and 'class 1', i.e., *Female speaking* and *Male speaking*), and occasional instances of bell sounds. After passing through the separation model, the target class, laughter, is preserved completely while effectively removing the background music and other interfering sound events. Additionally, in the first white rectangular region, 'class 4' (*Laughter*) in the original mixed audio is almost completely masked by 'class 8' (*Music*). This would cause significant interference for the laughter class in the SELD methods. However, after applying the separation process, it can be observed that the music sound is almost completely removed, allowing the laughter to be clearly revealed. This ensures 'class 4' can be detected more accurately. All of the above indicate that the application of the separation model can eliminate non-target classes with high energy, allowing the extraction of target classes that may have been masked by other sounds with lower energy. This provides a cleaner reference for the SELD model.

In order to analyze the performance of the model more comprehensively, we visualized the SED and DOA estimation, presented in Fig.3. The horizontal axis in all subplots

TABLE III
SELD$_{score}$ COMPARISON BETWEEN SELD SYSTEM AND THE PROPOSED SS-SELD METHOD OF ALL 13 CLASSES FOR DEVELOPMENT DATASET. THE BETTER RESULTS ARE HIGHLIGHTED IN BOLD.

	Woman speaking	Man speaking	Clap	Telephone	Laughter	Domestic sounds	Footsteps	Door	Music	Musical instrument	Water tap	Bell	Knock
SELD	0.243	0.231	0.254	0.345	0.377	0.341	0.458	0.318	0.241	0.257	**0.276**	0.338	0.278
SS-SELD	**0.227**	**0.217**	**0.231**	**0.313**	**0.359**	**0.303**	**0.421**	**0.282**	**0.236**	**0.254**	0.314	**0.248**	**0.244**

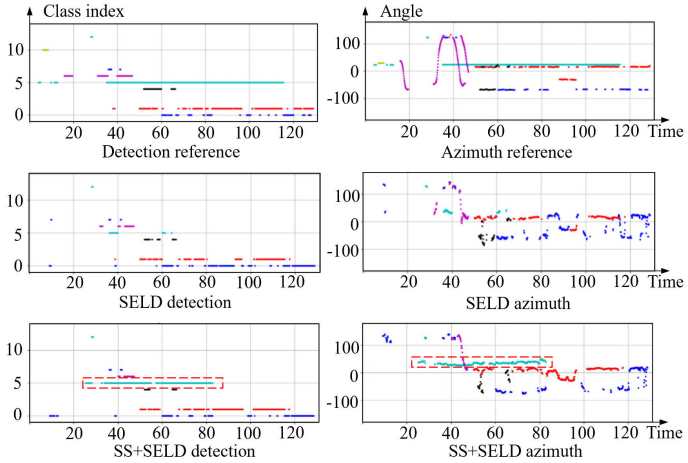

Fig. 3. The visualized results comparing SELD and SS-SELD, with the two columns representing the detection results and azimuth angle results, respectively. Different colors represent different events. The horizontal axis represents time (s) for all subplots. The vertical axis in the left column represents event class index, while the vertical axis in the right column represents angles in degrees (°).

represents time in seconds, while different colors represent different sound events. The first column represents the SED results, where the vertical axis represents 13 sound event classes. The occurrence of a color indicates the presence of the corresponding sound event at that time. The second column represents the DOA results. It is worth mentioning that the presented information pertains to the azimuth angle. The trend in the elevation angle is similar to that of the azimuth angle. To avoid clutter and congestion in the figure, the elevation angle information is not shown. The azimuth angle ranges from -180° to 180°, illustrating the relative angles of sound events with respect to the origin of the microphone array. The first row represents the ground truth results, while the second and third rows represent the results of SELD and SS-SELD, respectively. From the figure, it can be observed that SS-SELD exhibits a significant improvement over SELD in the 'class 5' (light blue line, *Domestic sounds*), as shown in the dashed boxes. SELD almost entirely missed the home-related sounds, thus failing to provide angle information for this class. In contrast, SS-SELD can detect the majority of these sounds and accurately provide angle information. This further demonstrates that our SS-SELD not only enhances the model's detection capability but also brings improvements in localization performance.

V. CONCLUSIONS

In this study, we explored the effectiveness of the sound separation method in sound event localization and detection task. By using a separation model as a front-end to obtain separated audio for each event class, we were able to extract the features of both the sound event mixtures and the separated sound. The combined SS-SELD model trained on these features effectively improved the performance of single SELD model. In future work, we will continue to explore more effective and universally applicable separation strategies to address the existing issues and enhance the performance of the SELD model.

***Abstract*—Considering that acoustic scenes and sound events are closely related to each other, their joint analysis in some previous studies has been explored utilizing multitask learning (MTL)-based neural networks. In conventional approaches, either strongly or weakly supervised schemes are applied to sound event detection in MTL models. However, annotating strong event labels is quite time-consuming or using only weak labels achieves low performance in sound event detection. In this paper, we thus propose a method for the joint analysis of acoustic scenes and sound events based on the MTL framework using both strong and weak labels of sound events. Our experimental results, which were obtained using subsets of the TUT Acoustic Scenes 2016/2017 and TUT Sound Events 2016/2017 datasets, show that the proposed method using both strong and weak labels achieves reasonable performance even with a small number of strongly labeled data and a large number of weakly labeled data.**

I. Introduction

In recent years, there has been great attention to research and development in the computational analysis of environmental sounds. The computational analysis of environmental sounds is applicable to a wide variety of applications including media retrieval, hearing assistance, machine condition monitoring, and biomonitoring systems [1], [2], [3].

There are several significant tasks in the computational analysis of environmental sounds, such as acoustic scene classification (ASC) and sound event detection (SED). Among these tasks, ASC, which predicts a predefined acoustic scene label from an input audio signal, is one of the most major tasks. Moreover, sound event detection (SED), in which sound event labels and their corresponding time stamps within an audio signal are detected, is also a popular task in this area. Many neural-network-based methods have been recently employed in ASC and SED systems, leading to marked advancements in performance. For example, Valenti et al. [4] and Raveh and Amar [5] have proposed ASC methods based on the convolutional neural network (CNN) and ResNet, respectively. Çakır et al. have proposed a SED method using a convolutional recurrent neural network (CRNN) [6]. Kong et al. [7] and Miyazaki et al. [8] have recently proposed a SED method using the Transformer and Conformer encoders, respectively.

A majority of conventional methods analyze acoustic scenes and sound events separately. However, acoustic scenes and sound events are closely related, and it would be inefficient to analyze them separately. For example, in the acoustic scene "park," the sound events "bird singing" and "wind blowing" are likely to co-occur, whereas the sound events "cutlery" and "keyboard typing" rarely co-occur. Considering this relationship, Mesaros et al. [9] and Heittola et al. [10] proposed methods utilizing information on acoustic scenes for SED. Imoto and co-workers proposed ASC methods considering the relationship between sound events and acoustic scenes using Bayesian generative models [11], [12]. Moreover, Mesaros et al. [9], Heittola et al. [10], and Imoto et al. [11], [12] have proposed ASC or SED methods considering the relationship between sound events and acoustic scenes. More recently, Bear et al. [13], Tonami et al. [14], and Jung et al. [15] have proposed the joint analysis of acoustic scenes and sound events based on multitask learning-based neural networks of ASC and SED.

The neural network-based methods for the computational analysis of environmental sounds typically rely on models trained using large numbers of strongly annotated data, which has information of sound types and their time boundaries. However, especially in SED, the process of annotating time boundaries is very time-consuming. One way to alleviate this difficulty is to apply weakly supervised SED, which only utilizes weakly labeled data to train the SED model [16], [17], [18], where weak labels in SED only have information on whether sound events are active or inactive per sound clip. By applying a weakly supervised approach to the MTL framework, Tsubaki et al. [19] have proposed the joint analysis of acoustic scenes and sound events only with weak labels of sound events. This approach achieves a higher performance in ASC than a single-task ASC method, but it results in performance degradation in SED compared with the MTL method using strong labels of sound events.

To address the limitations of the conventional MTL framework using either strong or weak labels of sound events, in this paper, we propose a method of joint analysis of acoustic scenes and sound events in a situation where the strong labels of sound events are partially available, that is, in a semi-supervised scenario [20]. We then investigate ASC and SED experimental results in detail, including performance changes depending on the ratios of strong and weak labels of sound events.

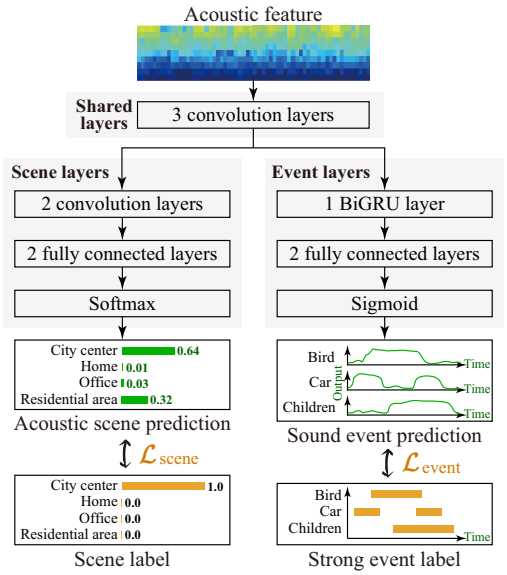

Fig. 1. Network structure of conventional MTL-based method [14]

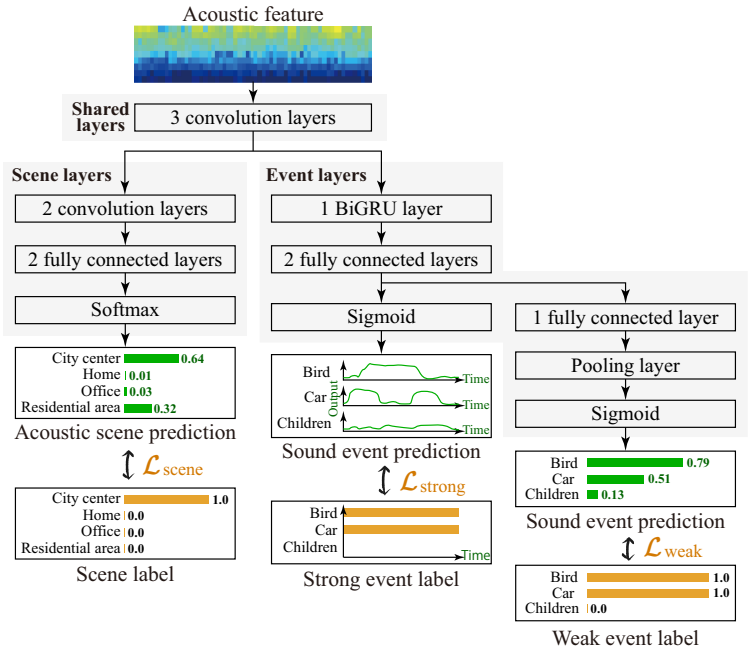

Fig. 2. Network structure of MTL-based method using weak labels of sound events

The remainder of this paper is organized as follows. In section 2, we introduce the conventional methods of ASC, SED, and the joint analysis of scenes and events based on multitask learning. In section 3, we propose a method for the joint analysis of acoustic scenes and sound events using both strong and weak labels of sound events. In section 4, we discuss the experiments conducted to evaluate the ASC and SED performance characteristics. Finally, we conclude our work in section 5.

II. Conventional Methods

A. Acoustic Scene Classification and Event Detection

In this section, we review conventional systems for ASC and SED based on neural networks, such as CNN [4], [21], CRNN [6], and the Transformer encoder [7]. Many ASC and SED systems calculate a time–frequency feature of the acoustic signal $\mathbf{X} \in \mathcal{R}^{D \times T}$, such as the log mel-band spectrogram or a time series of mel frequency cepstrum coefficients (MFCCs), as the acoustic feature. We here denote D and T as the numbers of frequency bins and time frames, respectively. The acoustic feature is fed to the ASC and SED networks, which calculate logits $\mathbf{y}$ for scene classification and event detection, respectively. The model parameters of the ASC network are trained using the logits and the cross-entropy (CE) loss function $\mathcal{L}_{\text{scene}}$ as

$$\mathcal{L}_{\text{scene}} = -\sum_{n=1}^{N} \Big\{ z_n \log\big(\sigma\left(y_n\right)\big) \Big\}, \tag{1}$$

where N, $z_n \in \{0, 1\}$, and σ are the number of acoustic scene classes, the target one-hot scene label, and softmax function, respectively.

The model parameters of the SED network are trained using the logits and the binary cross-entropy (BCE) loss function $\mathcal{L}_{\text{event}}$ as

$$\begin{aligned}\mathcal{L}_{\text{event}} &= -\sum_{t=1}^{T} \Big\{ \mathbf{z}_t \log(\mathbf{y}_t) + (1-\mathbf{z}_t) \log\big(1-s(\mathbf{y}_t)\big) \Big\} \\ &= -\sum_{t,m=1}^{T,\,M} \Big\{ z_{t,m} \log s(y_{t,m}) + (1-z_{t,m}) \log\big(1-s(y_{t,m})\big) \Big\},\end{aligned} \tag{2}$$

where T, M, $z_{t,m}$, and s are the number of time frames, the number of sound event classes, the target event label for sound event m in time frame t, and sigmoid function, respectively.

B. Joint Analysis of Acoustic Scenes and Sound Events Based on Multitask Learning

Many methods for environmental sound analysis handle scene classification and event detection as separate tasks. Moreover, some recent works employ methods that jointly analyze acoustic scenes and sound events, which are based on the idea that information on acoustic scenes and sound events is mutually beneficial for ASC and SED. In particular, several works apply a multitask (MTL)-based neural network for the joint analysis of ASC and SED [13], [14], [15], [22].

Figure 1 shows a typical implementation of the MTL-based method, which shares part of the network and information on acoustic scenes and sound events. In the shared layers, acoustic features are embedded in the feature space common to acoustic scenes and sound events. This acoustic embedding is then fed to the scene and event-specific layers that perform ASC and SED, respectively. As the scene and event-specific

layers, CNN, the recurrent neural network (RNN), and the Transformer encoder are often applied.

To train the model parameters, the following linear combination of Eqs. (1) and (2) is adopted as the loss function to train the MTL model:

$$\mathcal{L} = \alpha\mathcal{L}_{\text{scene}} + \beta\mathcal{L}_{\text{event}}, \tag{3}$$

where α and β are the constant weights of scene classification and event detection losses, respectively. In this paper, $\beta = 1.0$ without loss of generality.

C. Joint Analysis of Scenes and Events Based on Multitask Learning With Weak Labels of Sound Events

Annotating strong labels for sound events is very time-consuming. To alleviate this problem of annotation, many SED methods utilize a weakly supervised approach with weak labels of sound events.

In particular, Tsubaki *et al.* have proposed a method for the joint analysis of acoustic scenes and events [19] using weak labels of sound events. This method applies the multiple-instance learning (MIL) framework [23] to the weakly supervised training of SED. As shown in Fig. 2, the network of this method has two branches in the event layers. One event branch has the MIL-based pooling layer immediately before the sigmoid function, which enables the weakly supervised training of a SED model. The other branch holds temporal information to predict sound events and their timestamps as in conventional methods.

The model parameters of the weakly supervised method are trained using Eq. (3), whereas the loss function $\mathcal{L}_{\text{event}}$ is expressed as

$$\begin{aligned}\mathcal{L}_{\text{event}} &= \gamma\mathcal{L}_{\text{strong}} + \zeta\mathcal{L}_{\text{weak}} \\ &= -\gamma \sum_{m,t=1}^{M,T} \Big\{ z_{m,t} \log s(y_{m,t}) + (1 - z_{m,t}) \log\big(1 - s(y_{m,t})\big) \Big\} \\ &\quad - \zeta \sum_{m=1}^{M} \Big\{ z_m \log s(y_m) + (1 - z_m) \log\big(1 - s(y_m)\big) \Big\},\end{aligned} \tag{4}$$

where y_m and z_m are the bag (clip) level prediction of the sound event m and the weak label of the target event, respectively. γ and ζ are the constant weights of event detection losses. Here, the strong event label $z_{m,t}$ is generated from the weak label z_m as a pseudo-label as follows:

$$\mathbf{Z}_{\mathsf{pseudo_strong}} = \begin{pmatrix} \overbrace{\begin{matrix} z_1 & \cdots & z_1 & \cdots & z_1 \end{matrix}}^{T} \\ \begin{matrix} \vdots & \ddots & \vdots & & \vdots \end{matrix} \\ \begin{matrix} z_m & \cdots & z_m & \cdots & z_m \end{matrix} \\ \begin{matrix} \vdots & & \vdots & \ddots & \vdots \end{matrix} \\ \begin{matrix} z_M & \cdots & z_M & \cdots & z_M \end{matrix} \end{pmatrix} \tag{5}$$

III. PROPOSED METHOD

The conventional MTL-based method using weak labels of sound events [19] alleviates the problem of collecting strong labels of sound events. However, the joint analysis of ASC and SED using weak labels results in a lower SED performance than that using strongly labeled data [14]. In the proposed method, we then apply a semi-supervised approach to the joint analysis of ASC and SED. In general, a method that combines supervised and unsupervised training schemes is called semi-supervised learning. In this paper, however, we refer to the method that uses both strong and weak labels for the model training of SED as semi-supervised learning, following [20].

For the semi-supervised learning approach, we construct the following acoustic feature set $\mathcal{X}_{\mathsf{semi}}$ and label set $\mathcal{Z}_{\mathsf{semi}}$ from $\mathcal{X}_{\mathsf{strong}}$, $\mathcal{X}_{\mathsf{weak}}$, $\mathcal{Z}_{\mathsf{strong}}$, and $\mathcal{Z}_{\mathsf{weak}}$.

$$\mathcal{X}_{\mathsf{semi}} = \{\mathcal{X}_{\mathsf{strong}}, \mathcal{X}_{\mathsf{weak}}\}, \tag{6}$$

$$\mathcal{Z}_{\mathsf{semi}} = \{\mathcal{Z}_{\mathsf{strong}}, \mathcal{Z}_{\mathsf{weak}}\}, \tag{7}$$

where $\mathcal{X}_{\mathsf{strong}}$, $\mathcal{X}_{\mathsf{weak}}$, $\mathcal{Z}_{\mathsf{strong}}$, and $\mathcal{Z}_{\mathsf{weak}}$ indicates the acoustic feature set with strong labels, the acoustic feature set with weak labels, the string label set, and weak label set, respectively.

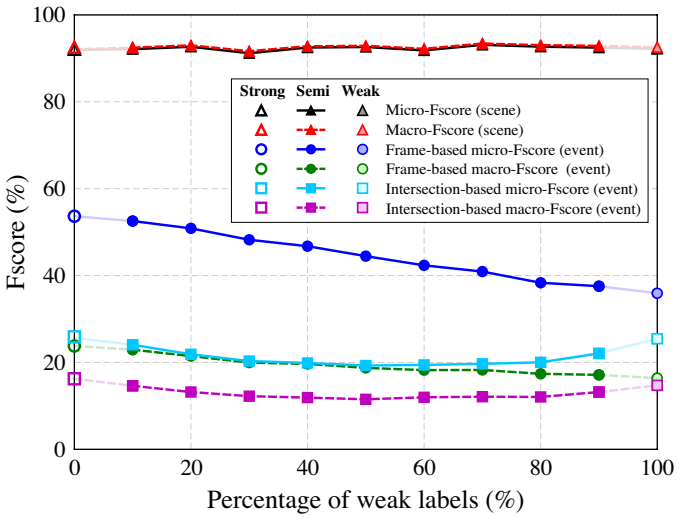

Fig. 3. ASC and SED performance characteristics for various ratios of weakly labeled data of sound events with constant weights γ and ζ

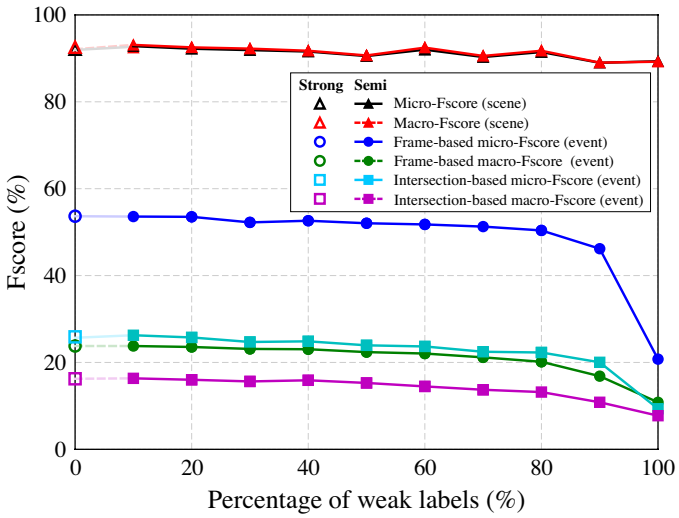

Fig. 4. ASC and SED performance characteristics for various ratios of weakly labeled data of sound events with Kronecker delta function δ_γ and δ_ζ

In the proposed method, we apply the same network architecture as that for the conventional weakly supervised MTL approach, as shown in Fig. 2. We then apply two strategies to train the MTL model. In the first one, we prepare both strong and weak labels for each training data using Eq. (5) if the acoustic feature has only weak labels. The model parameters are then trained using the same Eqs. (3) and (4) as in the conventional MTL-based method using weakly labeled data. In the second strategy, we respectively replace γ and ζ with the following Kronecker delta functions:

$$\delta_\gamma = \begin{cases} 1 & \text{if } \mathbf{z} \text{ is strong label} \\ 0 & \text{otherwise,} \end{cases} \tag{8}$$

$$\delta_\zeta = \begin{cases} 1 & \text{if } \mathbf{z} \text{ is weak label} \\ 0 & \text{otherwise.} \end{cases} \tag{9}$$

IV. EVALUATION EXPERIMENTS

A. Experimental Conditions

We conducted evaluation experiments to determinate how effective the proposed method can analyze environmental sounds using a limited number of strong labels. In our experiments, we used datasets composed of the TUT Acoustic Scenes 2016/2017 and TUT Sound Events 2016/2017 [25], [26]. Among these datasets, we selected four acoustic scenes, namely *city center*, *home*, *office*, and *residential area*, and 25 sound events, such as *bird singing*, *car*, and *keyboard typing*. These sounds comprised a total of 192 min of sounds for the training set and 74 min for the evaluation set. The weak labels for sound events were created using data from a part of the training set with strong labels, which were selected randomly. The details of the dataset used for the evaluation experiments are in [27]. We also evaluated the MTL-based method using only strong label data [14] and that using only weak label data [19] as comparison methods.

As an acoustic feature, we applied the 64-dimensional log mel-band spectrogram, which was calculated with a frame length of 40 ms and a hop size of 20 ms. The model architecture for this experiment is shown in Table I, which is originally proposed in [14]. We performed the evaluation experiments 10 times under each experimental condition with random initial values of model parameters. The detailed experimental conditions are listed in Table II, which were determined by referring to [19].

TABLE IV
NUMBERS OF TN, FP, AND FN FOR FRAME-BASED AND INTERSECTION-BASED METRICS (SEMI MTL WITH CONSTANT WEIGHTS γ AND ζ)

Percentage of weak label	Frame-based			Intersection-based		
	# TP	# FP	# FN	# TP	# FP	# FN
10%	90,216	86,220	78,388	578	2,753	900
30%	95,260	133,124	71,717	628	4,091	851
50%	97,662	175,527	69,315	622	4,338	872
70%	101,961	229,783	65,017	620	4,184	872
90%	105,319	289,086	61,658	576	3,138	924

B. Experimental Results

1) Overall Performance characteristics of ASC and SED: The average performance characteristics of ASC and SED in terms of Fscore are shown in Table III. Here, we refer to the MTL-based methods of joint analysis of acoustic scenes and sound events using only strong, only weak, and both strong and weak labels as strong MTL, weak MTL, and semi MTL, respectively. As the evaluation metrics for SED, we applied the frame-based and intersection-based metrics [28]. For the experimental results shown in this paper, except for Figs. 3 and 4, we conducted the experiments with half of the strongly labeled data and half of the weakly labeled data under the semi MTL condition. The results show that the proposed method based on semi MTL achieves micro- and macro-Fscores for ASC that are similar to those of the conventional strong and weak MTL methods. The performance of the proposed method in the frame-based SED metric is between those of the strong and weak MTL methods, whereas that using the constant weights in SED losses is lower than those of the strong and weak MTL method in the intersection-based SED metric.

To investigate the detailed behavior of the strong, weak, and semi MTL methods, we show the ASC and SED performance characteristics with various ratios of weakly labeled data of sound events in Figs. 3 and 4. The results show that the ASC performance does not degrade when we use more weak labels of sound events. This result indicates that ASC does not require temporal information on sound events, but requires only information on sound event tags in acoustic signals. In the proposed method with the constant weights γ and ζ, the frame-based Fscore decreases as the percentage of weak labels is increased. On the other hand, in the proposed method with the Kronecker delta functions δ_γ and δ_ζ, the Fscore does not decrease markedly until the percentage of weak labels reaches around 80%. This means that the semi MTL approach with the delta functions achieves reasonable performance even with a small number of strongly labeled data and a large number of weakly labeled data. Thus, the proposed method mitigates the problem of annotating sound event labels. Figure 3 also shows that the intersection-based Fscores of the proposed method with the constant weights decrease as the percentage of weak labels is increased, but gradually increase as the percentage of weak labels exceeds 50%.

We then investigate the numbers of total true positives (TPs), total false positives (FPs), and total false negatives (FNs) to explore why the intersection-based Fscores of semi MTL with the constant weights gradually increase as the percentage of weakly labels exceeds 50%, as shown in Table IV. The table shows that in the frame-based metric, the numbers of TPs and FPs increase with the percentage of weak labels. The large increase in the number of FPs compared with the number of TPs indicates that the model is trained to detect more false frames as the percentage of weak labels increases. On the other hand, in the intersection-based metric, the number of FPs increases with the percentage of weak labels; however, it decreases when the percentage of weak labels exceeds 50%. As shown in Fig. 5, this is because the number of FPs increases as the percentage of weak labels increases, and then it decreases as multiple FP instances are integrated. That is, the intersection-based Fscore tends to improve with increasing percentage of weak labels; however, a large number of FP frames may appear. Thus, the experimental results corollarily revealed that the intersection-based Fscore and polyphonic sound detection score (PSDS) [28] may not appropriatly evaluate the SED performance with many FPs.

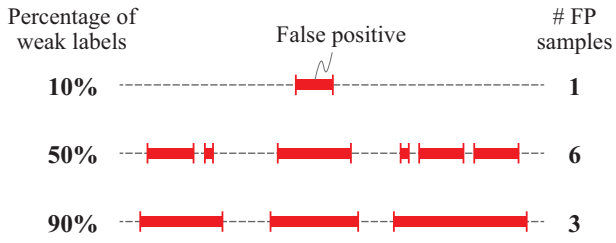

Fig. 5. Number of FPs for ratio of weakly labeled data of sound events

TABLE V
ASC PERFORMANCE FOR EACH SCENE IN TERMS OF FSCORE

Method	city center	home	office	residential area
Strong MTL	89.94% ±4.28	94.28% ±4.61	95.08% ±4.22	85.20% ±6.08
Weak MTL	89.60% ±3.50	95.41% ±1.45	95.50% ±3.46	84.53% ±3.03
Semi MTL w/ const. weights	**92.10%** **±1.44**	**96.66%** **±1.37**	96.67% ±1.43	**88.76%** **±2.47**
Semi MTL w/ delta func.	90.48% ±2.57	93.90% ±3.70	**96.69%** **±1.10**	81.59% ±10.68

2) Detailed performance evaluation for each acoustic scene and event: The ASC performance for each acoustic scene is shown in Table V. The results show that there is no significant difference in ASC performance among the strong, weak, and semi MTL methods. These results also indicate that the temporal information on sound events is not important for each scene classification and that information on sound event tags should be sufficient.

The SED performance for each sound event is shown in Table VI. The results show that the conventional and proposed methods exhibit similar trends. In particular, these methods

TABLE VI
SED PERFORMANCE FOR EACH SOUND EVENT IN TERMS OF FRAME-BASED FSCORE

Method	bird singing	brakes squeaking	car	cutlery	dishes	drawer	fan	keyboard typing	large vehicle	mouse clicking	people walking	washing dishes
Strong MTL	43.35% ±6.13	51.30% ±4.82	**52.03% ±1.62**	9.13% ±6.46	10.65% ±4.88	0.19% ±0.52	**96.82% ±1.08**	**57.61% ±3.02**	16.87% ±1.80	**70.78% ±1.83**	19.01% ±4.23	3.56% ±3.27
Weak MTL	43.13% ±5.93	**51.75% ±4.30**	50.86% ±3.56	**11.76% ±9.63**	12.56% ±6.64	0.07% ±0.20	96.53% ±1.70	56.26% ±4.78	18.04% ±2.41	70.32% ±3.46	20.19% ±4.13	6.07% ±4.78
Semi MTL w/ const. weights	**44.00% ±4.25**	38.14% ±6.23	50.30% ±1.25	4.46% ±5.37	**14.32% ±5.00**	**1.34% ±2.26**	95.44% ±2.01	25.83% ±3.51	16.34% ±2.21	13.41% ±3.96	15.68% ±4.42	**14.68% ±9.32**
Semi MTL w/ delta func.	39.95% ±8.08	40.75% ±12.45	50.22% ±2.92	8.70% ±7.13	12.75% ±4.31	0.06% ±0.21	96.46% ±1.71	54.01% ±4.46	**18.37% ±3.31**	69.81% ±3.21	**20.23% ±5.02**	7.93% ±5.81

show high SED performance for sound events with long durations, such as *bird singing* and *fan*, whereas they show low performance for instantaneous sounds, such as *cutlery* and *drawers*. For a detailed discussion on the reason for these results, refer to [29]. More investigation on SED performance needs to be conducted in a future work.

V. CONCLUSIONS

We proposed a method for the joint analysis of acoustic scenes and sound events using the semi-supervised approach for SED. In the proposed method, we applied the MTL-based framework including the shared layers with acoustic scenes and sound events, ASC layers, and strong and weak SED layers. The experiments using the TUT Acoustic Scenes 2016/2017 and TUT Sound Events 2016/2017 datasets show that the semi MTL approach with the Kronecker delta functions δ_γ and δ_ζ achieves reasonable performance even with a small number of strongly labeled data and a large number of weakly labeled data. The experimental results corollarily revealed that the intersection-based Fscore and the PSDS metric may not approximately evaluate the SED performance with many FPs.

***Abstract*—This paper presents a novel deep learning approach for analyzing massive underwater acoustic data by leveraging a model trained on a broad spectrum of non-underwater (aerial) sounds. Recognizing the challenge in labeling vast amounts of underwater data, we propose a two-fold methodology to accelerate this labor-intensive procedure.**

The first part of our approach involves PCA and UMAP visualization of the underwater data using the feature vectors of an aerial sound recognition model. This enables us to cluster the data in a two dimensional space and listen to points within these clusters to understand their defining characteristics. This innovative method simplifies the process of selecting candidate labels for further training.

In the second part, we train a neural network model using both the selected underwater data and the non-underwater dataset. We conducted a quantitative analysis to measure the precision, recall, and F1 score of our model for recognizing airgun sounds, a common type of underwater sound. The F1 score achieved by our model exceeded 84.3%, demonstrating the effectiveness of our approach in analyzing underwater acoustic data.

The methodology presented in this paper holds significant potential to reduce the amount of labor required in underwater data analysis and opens up new possibilities for further research in the field of cross-domain data analysis.

I. Introduction

Underwater acoustics is a complex and vast field with a wide range of applications, such as ocean survey, marine life monitoring, and submarine detection. In general, the underwater sound data is collected via Passive Acoustic Monitoring (PAM), which is a non-invasive technique aiming to record cetacean sounds. However, the analysis of underwater acoustic data is challenging due to the unique characteristics of underwater sound. The underwater sound propagating through the acoustic waveguide interacts with the boundaries (i.e., reflection and scattering) while also undergoing refraction due to variations in the sound speed in the water medium. Additionally, the kinds of animals that reside underwater and the kinds of artificial noise that humans make are different from the aerial noise. As a result, even if we have a massive sound dataset in advance of the underwater sound analysis, it can be difficult to reuse it directly to analyze the underwater data.

Hence, the studies concerning underwater acoustic data have been focusing on making a sound recognizer from the scratch. Many research efforts used conventional rule-based methods such as Erbe and King's method using information theory [1] and Baumgartner *et al.*'s spectrogram filtering-based method [2]. In Yack *et al.*'s study [3], six detection algorithms were tested and compared. In other studies including Halkias *et al.*'s [4] and Thomas *et al.*'s work [5], deep neural network architecture was used. Usman *et al.* summarized the recent research trends and their methods [6].

To train a neural network model that is capable of recognizing underwater sounds, we need an enormous amount of labeled data. However, labeling underwater acoustic data is a labor-intensive task due to the limited available labeled data and the complexity of the underwater environment. Additionally, the people who can distinguish the underwater sound events are very rare because they need to have expertise in the underwater environments and acoustics.

To overcome this problem, several studies tried to reduce the amount of data required to train a model. Both Shiu *et al.* [7] and Webber *et al.* [8] generalized a model trained on a small underwater data to analyze massive database consists of several years of recording. Thomas *et al.* utilized a transfer learning approach to generalize a neural network model to detect other sources [9]. However, none of the previous studies tried to utilize aerial sounds to analyze the underwater data even though they are easy to collect and guarantee diversity of the data.

In this paper, we propose a novel approach to address the challenges of underwater acoustic data analysis. Our methodology is a cross-domain approach, which is about applying state-of-the-art aerial sound recognition AI to underwater data to accelerate the entire analysis process. Our methodology is two-fold, involving the visualization of underwater data using the feature vectors of a sound recognition model trained on non-underwater sounds and quantitative analysis using this same model.

By using a deep learning model trained on a broad array of aerial sounds, we can navigate around the limited availability

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

of labeled underwater data. Furthermore, visualizing and listening to the clustered data allows for efficient labeling and selection of candidate labels for additional training.

Following this approach, we conducted an in-depth analysis of our model's performance with underwater acoustic data, specifically focusing on the recognition of airgun sounds. The results highlight the model's high precision, recall, and F1 score, demonstrating the effectiveness and robustness of our approach. Through this research, we aim to pave the way for more efficient underwater acoustic data analysis, reducing labor-intensive processes, and fostering further innovations in the field.

The rest of this paper is organized as follows. In Section II, we explain our underwater data and how we collected it. Section III covers our method for the visualization of the underwater data. Section IV provides the empirical measures that confirm the success of our model in detecting underwater sounds. In Section V, we conclude the paper with our final thoughts.

II. Underwater Dataset and Collection Method

A. Underwater sound data

The underwater dataset used in this study was collected in the East Siberian Sea, Arctic Ocean, using a hydrophone over one year [10]. The data collection period spanned from August 2017 to August 2018.

The hydrophone was programmed to record 600 seconds of sound every hour, with a sample rate of 32,768Hz, a common rate for high-quality underwater audio capture. Over the one-year period, this method provided a comprehensive audio snapshot of the underwater environment, capturing a broad range of underwater sound events.

B. Airgun labels

Among the various sound events in the dataset, specific labels for airgun sounds were included. Airguns, widely used in marine seismic surveys, produce unique acoustic signatures and are among the more recognizable sound events in underwater acoustic data. Unlike other sounds, such as mammal sounds, airgun sounds are steady in terms of the sound pattern. Hence, collecting labels for this sound is relatively straightforward with the help of automated algorithms.

In particular, we focused on the September 2017 data, since most of the airgun sounds occur in the summer season [11]. For the initial identification of airgun sounds in our dataset, we employed a matched filter algorithm as described in [10] and [12]. Following this semi-automated identification process, an expert in underwater acoustics reviewed the potential airgun events. This step ensured the accuracy of the labels, verifying that the sounds identified by the algorithm were indeed airgun sounds. Additionally, the expert examined if there were any missing airgun sounds.

As a result, the dataset we obtained covered a wide range of underwater sounds and also contained a verified set of labeled airgun sounds, serving as a valuable resource for our deep learning model training and evaluation.

III. Underwater Sound Visualization for Initial Identification

The manual labor involved in the categorization and identification of large, unlabeled underwater acoustic datasets can be overwhelming. This challenge calls for a method that can aid in the initial identification and selection of underwater sound characteristics without relying on extensive manual labeling. This section introduces our innovative approach to visualizing underwater sounds, which streamlines this process and provides a launching point for further analysis.

Our methodology relies on a deep learning model trained on a broad array of aerial sounds. The basis for this approach is the understanding that a variety of aerial sounds can capture a wide range of acoustic features, which can be extended to the underwater environment.

A. Principal component analysis

Our process begins by feeding the underwater acoustic data through our trained sound recognition model. The audio data is segmented into one-second snippets, with no overlap between adjacent snippets, to match our model's input requirement of a 22,050Hz audio snippet lasting one second. These segmented chunks are then fed into the model. For this experiment, we removed the final layer, which functions as the classifier, to obtain the feature vectors of 1,280 dimensions. These contain intricate information about the acoustic properties of the underwater sounds. These feature vectors serve as the coordinates in a high-dimensional space where similar sounds cluster together.

However, visualizing and interpreting high-dimensional data is neither intuitive nor straightforward. Therefore, we employ Principal Component Analysis (PCA), which is a dimensionality reduction technique, to project the high-dimensional feature vectors into a 2D space. In the visualized space, clusters of similar sounds emerge based on their acoustic features, making them discernible to the human eye and ear.

This visualization allows researchers to isolate and listen to individual points or clusters within the projected data. By doing so, we can qualitatively assess the sound characteristics of these clusters and choose suitable candidate labels for the sounds within them.

Fig. 1 shows various visualizations of the underwater sounds. Each subfigure represents the data of different dates and times. It can be seen that the data points spread in different locations on the plane. For example, the data points of **August 21, 2017, 22:00:00** are condensed around (0, 0), as in Fig. 1a. Meanwhile, those of **December 04, 2017, 09:00:00** in Fig. 1c have a higher $PrincipalComponent2$. In the **June 05, 2018, 05:00:00** data, we can observe that the data points are spread across various $PrincipalComponent1$ as in Fig. 1f.

This difference in distribution may be caused by the sound characteristics, which in turn are influenced by the environmental changes due to the changing seasons. Deeper investigation by an expert revealed that $PrincipalComponent1$ is related to the presence of animal sounds such as those of

TABLE I: Sound Types and Characteristics of the data with $PrincipalComponent1 > 40$.

Sound Type	Number of Data	Occurrence Date
Bearded Seal	1033	Mar. or May 2018
Walrus	9	Sept. or Oct. 2017
Airgun	275	Sept. 2017
Sea ice	1	Aug. 25 2017 00:00:00
Whales	12	Sept. 11 or 19 2017
Mammal	7	Sept. 23 2017 17:00:00

bearded seals. Besides, $PrincipalComponent2$ is associated with sea ice concentration and fluid velocity.

For further analysis, we extracted 84,499 one-second long sound data that had a $PrincipalComponent1$ larger than 40. Then, the underwater data expert screened out the ones that contain sound events from those which do not. As a result, we obtained the labeled dataset shown in Table I. It is interesting to observe that most of the sound events are either bearded seals or airguns. Also, each sound is concentrated in a certain season. For example, all the airgun sounds were detected in September 2017, and bearded seal sounds were detected in either March or May 2018.

B. Uniform Manifold Approximation and Projection

Uniform Manifold Approximation and Projection, often referred to as UMAP, is a technique to reduce data dimension [13]. It is often used for high-dimensional data visualization. Even though PCA is a simple approach to visualize data, we can further improve the visualization by applying UMAP and obtain further insights.

Fig. 2a and Fig. 2b show the visualizations using PCA and UMAP, respectively. To reduce computational complexity and enhance graph visibility, we used 25,650 randomly chosen data points, which constitute 0.5% of the entire data in quantity. It is interesting to see that the data points of a season are gathered together in both plots. In the PCA visualization, the sound cluster boundaries are relatively unclear and the data points are scattered. Based on the clear clusters of data points that represent specific types of sounds, we can argue that the UMAP algorithm better visualizes our data.

The sound visualization method drastically simplifies the process of labeling, offering an intuitive, visual, and auditory understanding of the characteristics and distribution of the underwater acoustic data. In the subsequent section, we will outline the process of training our new deep learning model with selected candidate labels and the aerial dataset, followed by a rigorous quantitative analysis of the model's performance.

IV. Quantitative Analysis of Underwater Sound Recognition

A. Model training

This section applies quantitative analysis to underwater data, focusing specifically on the recognition of airgun sounds. In the previous chapter, candidate labels for the underwater sounds were selected based on the results of our visualization and on listening to the clustered data. Bearded seal and airgun labels served as starting points for a more comprehensive training process. They were combined with the aerial sound dataset with the aim of creating a robust model capable of recognizing a variety of underwater sounds. Other underwater sound event labels, such as whales, were discarded due to the small quantity of data available for training.

The trained model employs a Convolutional Neural Network (CNN)-based architecture with an argmax classifier. An audio snippet with a sample rate of 22,050Hz and 22,050 samples in length is fed into the model as input and transformed into a melspectrogram. Because the original data has a sample rate of 32,768Hz, downsampling to 22,050Hz is necessary prior to training.

A significant advantage of our approach is its ability to work with relatively small amounts of labeled underwater data due to the use of the aerial sound dataset. This substantially reduces the burden of manual labeling and allows us to quickly move into the training phase. Cochl's aerial sound dataset, which consists of 586,343 labels across 242 classes, helps the new model learn the feature representation of the sounds. Both aerial and underwater sound data are split into train, validation, and test sets, with the validation and test sets each containing 10% of the data.

B. Internal evaluation

After training, a comprehensive quantitative analysis of the model's performance is conducted, focusing specifically on the recognition of airgun sounds. Precision, recall, and the F1 score are used as the primary metrics for evaluating the performance of our model.

Precision measures the model's ability to correctly identify positive instances out of all instances it classified as positive. Recall, on the other hand, determines the model's ability to identify all positive instances from the total actual positives. The F1 score harmonizes these two metrics, providing an overall assessment of the model's accuracy in recognizing airgun sounds.

In the first part of the evaluation, an internal evaluation is performed using the test split of the dataset. It consists of 28 labels of airgun, 103 labels of bearded seal, and 173,844 labels of the rest of the aerial sound data. Notably, the underwater ambient noise data is not included in the test set.

Interestingly, both the recall and precision of airgun and bearded seal sounds are estimated as 1.0, which in turn causes the F1 scores also to be 1.0. This high performance can be attributed to the fact that the training and test data share the same characteristics because they are randomly split. Also, the exclusion of ambient underwater sound from the dataset may have made the evaluation easier because it is closer to the target sounds than the aerial sounds.

C. External evaluation

The second part of the evaluation uses the airgun labels mentioned in Section II-B. Along with the labeled airgun sounds, the remaining underwater sounds are also used to check for false positives. Preliminarily, labels overlapping with

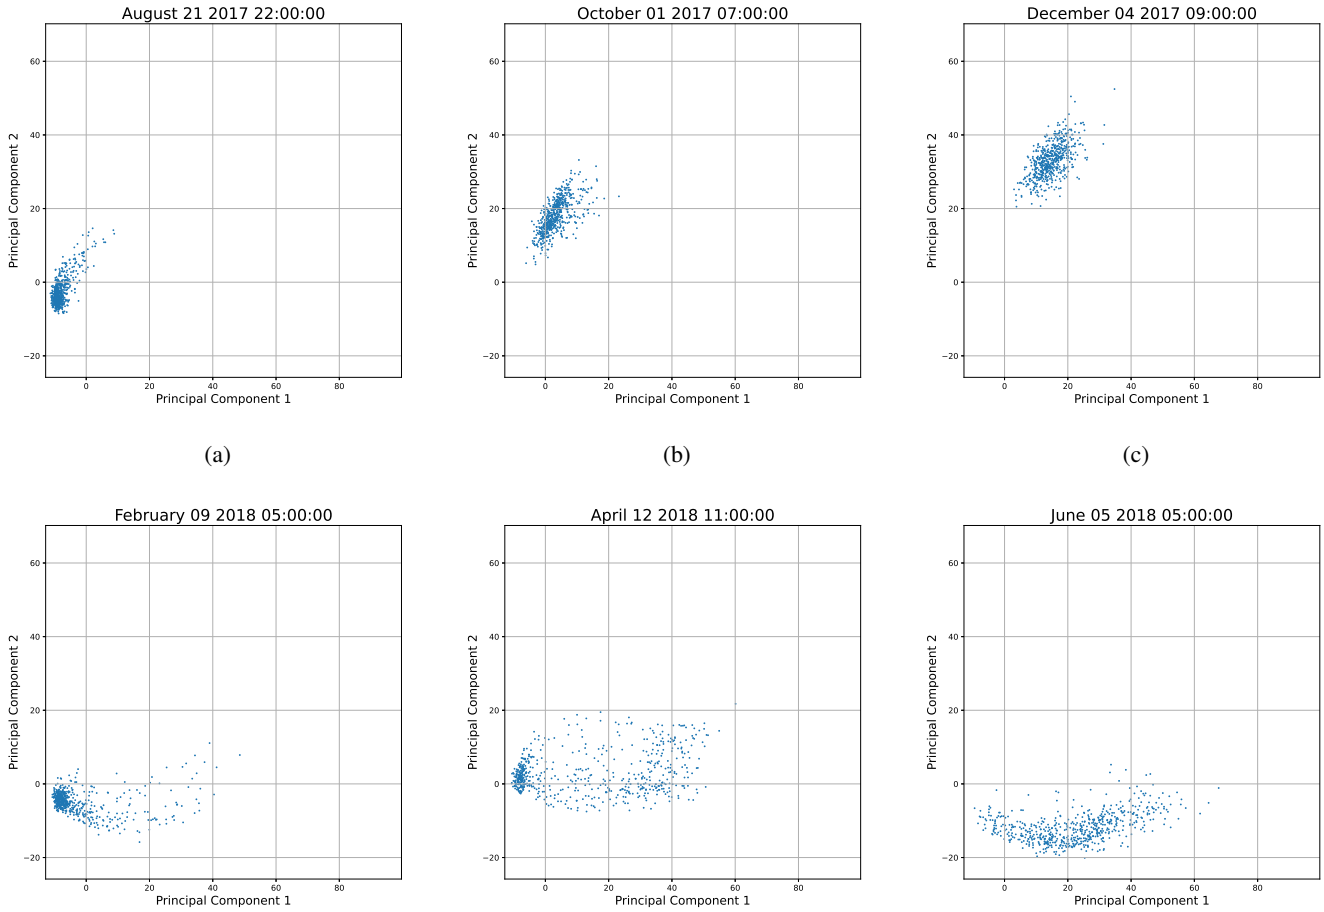

Fig. 1: Visualizing and analyzing the distributions of audio data based on seasonal sound characteristic variations.

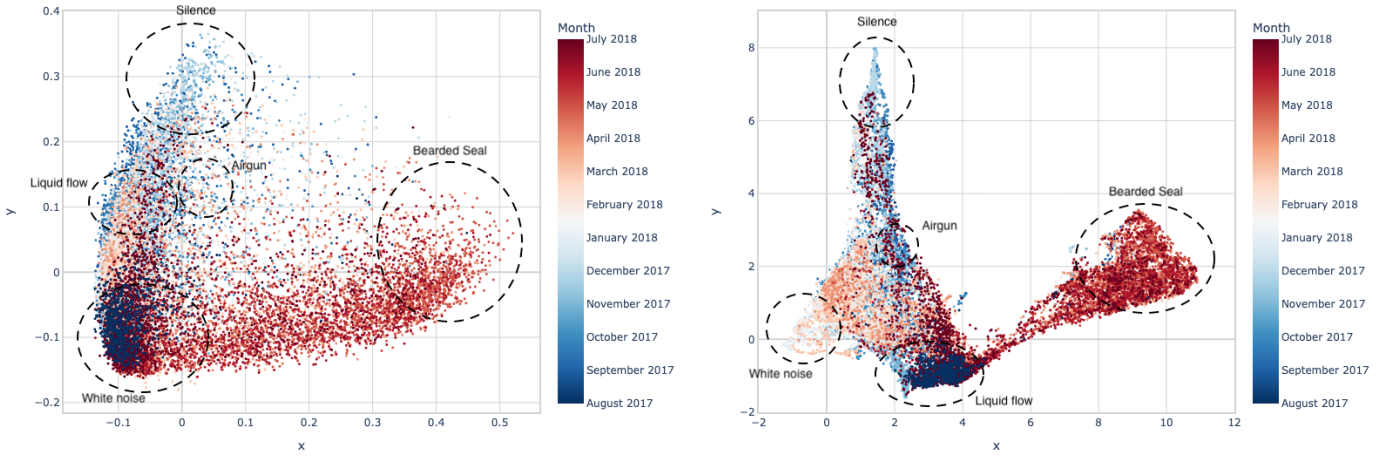

the training data are eliminated to avoid the influence of the training and internal test data on the performance. As a result, the total count of the airgun data is 20,397, whereas that of the ambient underwater data is 259,238. The sound snippets are cut into 1-second chunks without overlap with the neighboring chunk and fed into the model.

We initially used the argmax criteria, as in the training phase. However, we also observed changes in performance according to the threshold level. As the model returns the probability for three classes, the probability of the detected class has to exceed 0.3333. Hence, lowering the threshold with the threshold-based detection criteria increases the recall.

Fig. 3 shows the evaluation results. The precision under the argmax criteria is noticeably high, with the model only detecting 4 false positives out of a total of 259,238 snippets. These misidentified chunks were walrus moan sounds, which may be hard to distinguish from airgun sounds for non-experts. Nevertheless, the model struggled to achieve a high recall rate, potentially attributable to the constrained volume and diversity of the data. The lack of underwater ambient sound data in the training set might have also contributed to this issue. Moreover, the model's sensitivity to the start time of input audio chunks could have complicated results, as airgun sounds are short and can be challenging to identify if split between two consecutive chunks. Using the threshold-based detection criterion, the recall rate escalates as the threshold descends, thereby accommodating more false positives. The optimal F1-score can be achieved at a threshold value of 0.05.

Upon observing the threshold and probability values, we can infer that the large amount of aerial data might have influenced the probability of the airgun sounds. This is particularly relevant considering the argmax layer's characteristic that normalizes the sum of probabilities to 1.0, which could have magnified the effect.

In conclusion, our deep learning model showcases an effective and efficient method for recognizing underwater sounds. This quantitative analysis underscores the value of our approach in streamlining labor-intensive processes in underwater acoustic data analysis, and it emphasizes its potential for future improvements. However, some types of post-processing, such as threshold optimization, may be necessary to maintain a high recall rate.

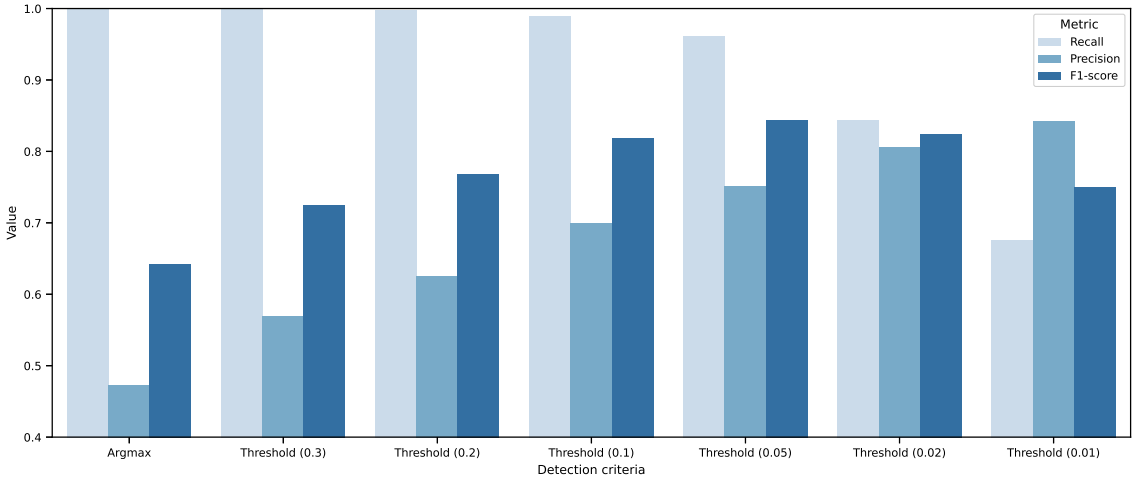

Fig. 3: Performance metrics for airgun detection: Precision, Recall, and F1-score. Optimal F1-score is achieved when the detection threshold is established at 0.05.

V. Conclusion

In this paper, we have presented a novel approach to accelerate underwater sound analysis by leveraging an aerial sound recognition model. Successful visualization and labeling of underwater sound data were achieved, and a sound recognition model that achieves F1 scores of 1.0 in internal evaluation was trained. In external evaluation, although the overall probability of airgun detection was low, we managed to obtain an F1 score of 84.3% when we set the threshold to a lower value. This study is the first to utilize an aerial sound recognition model to accelerate the process of underwater sound analysis. Our approach holds significant potential to improve the efficiency of underwater sound analysis substantially. This efficiency could be utilized to a variety of applications, such as monitoring marine life and detecting underwater threats.

***Abstract*—In this study, we present a data augmentation method for machine-learning-based acoustic traffic monitoring that estimates traffic speed from the running-vehicle sound observed by microphones. Acoustic traffic monitoring is superior to existing traffic detectors using loop coils in terms of installation and maintenance costs, and machine-learning-based acoustic traffic monitoring has demonstrated high performance with sufficient training data. However, it is often difficult or burdensome to collect a large amount of running-vehicle sound with the corresponding labels of traffic speed over many days as training data. In addition, the tendency of the traffic speed changes significantly from day to day, depending highly on the traffic situation, such as congested or free flowing. This may result in biased traffic speed in the training data, particularly the absence of low-speed data. To overcome this problem, we propose a data augmentation method for artificially generating training data with a sufficient range of traffic speed from data with a limited range of traffic speed by controlling frame overlap in the time-frequency domain. In the experimental evaluation, a deep neural network was trained using only high-speed real data with and without the proposed data augmentation method, and the estimation performance characteristics for high-speed and low-speed test data were compared. The results showed that the estimation accuracy for low-speed data was greatly improved with the proposed data augmentation method, while that for high-speed data was kept almost the same, compared with the condition without data augmentation.**

I. Introduction

The measurement of road traffic conditions, such as traffic volume, speed, and time occupancy, is essential to understand traffic situations and provide them to road traffic control systems and users. For this reason, traffic detectors are used for the real-time, automatic, and constant monitoring of traffic conditions [1], [2].

Loop-coil-based detectors are the most commonly used traffic detectors that detect the passage of vehicles electromagnetically. In spite of their high observation accuracy, they require high installation and maintenance costs because they use loop coils embedded in the roadway surface [3]. As a low-cost alternative to loop-coiled-based detectors, acoustic traffic monitoring, which uses the acoustic information obtained by microphones installed at the roadside, has been proposed and investigated in the literature. Unlike vision-based traffic monitoring, it can also cope with dark areas and overlapping vehicles. Approaches to acoustic traffic monitoring are classified roughly into two types: rule-based detection [4]–[8] and machine-learning-based detection [9]–[13]. In our previous study [13], it was demonstrated that our proposed machine-learning-based method using a deep neural network (DNN) with sufficient training data achieved a higher estimation accuracy than the rule-based method [8].

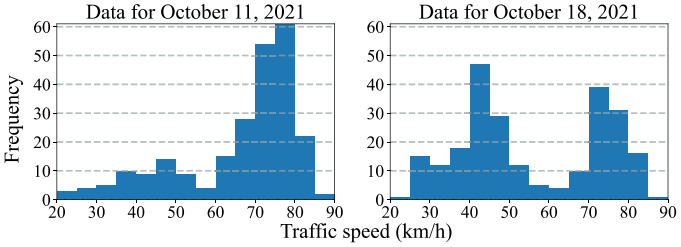

Fig. 1. Histogram of traffic speed for two different days

As in other general tasks in machine learning, a large amount of vehicle-running sound and corresponding labels of traffic conditions must be collected as training data in machine-learning-based acoustic traffic monitoring. In addition, the training data are desired to cover a sufficient variety of traffic situations, e.g., congested and free flowing conditions. However, the tendency of the traffic conditions varies significantly from day to day depending on the road and weather conditions. For example, Fig. 1 shows a histogram of the traffic speed for every minute during the same four hours but on two different days along a certain road. One can see that low-speed data below $60\,\mathrm{km/h}$, corresponding to traffic congestion, are rarely included in the left figure. As shown in this example, the absence of low-speed data is one of the typical difficulties that can occur in collecting training data, because they tend to appear only under somewhat rare weather or road conditions, such as heavy rain, traffic congestion, or regulated traffic. Such biases in the training data may degrade the estimation accuracy, which is indeed confirmed by our experiment described in Section IV.

In this study, we propose a data augmentation method for machine-learning-based acoustic monitoring to improve the estimation accuracy even when a sufficient variety of data are unavailable. To focus on the problem of the absence of low-speed data mentioned above, we here deal with speed estimation when only high-speed data are available as training data, leaving the esimation of other traffic conditions, such as traffic volume and time occupancy, for future work. Data augmentation is one typical strategy to widen the variety of training data, and various data augmentation methods have

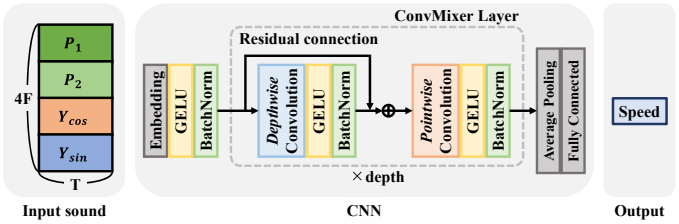

Fig. 3. Network architecture used in acoustic traffic monitoring

been proposed for acoustic data [14]–[22]. Note that these methods are designed mainly to prevent overfitting and are not applicable in the specific problem of our interest, i.e., the augmentation of various speed data in acoustic traffic monitoring. Instead, in the proposed method, low-speed data are generated artificially from high-speed data by controlling frame overlap in the time–frequency domain. The proposed method is evaluated by experiment, where a DNN was trained only on the basis of high-speed data under two conditions: with and without data augmentation. Then, the estimation performance characteristics for low-speed and high-speed data were compared. The experimental results indicate that the proposed data augmentation method improved the estimation accuracy significantly for low-speed test data that were not included in the training data, while maintaining good estimation accuracy for high-speed data.

II. Previous Work on Our Approach

In this section, we introduce our previous work on acoustic traffic monitoring by machine learning. Important points regarding input and output features and network architecture are summarized briefly below.

A. Input and Output Features

The objective of acoustic traffic monitoring is to estimate traffic conditions from acoustic signals. Our acoustic traffic monitoring method uses the stereo running-vehicle sound observed by two microphones aligned parallel to the direction of the road as the input acoustic signal because spatial acoustic information is expected to be useful in the detection of the passage of vehicles. Although four variables, i.e., the total number of vehicles passing, the number of large vehicles passing, traffic speed, and time occupancy, were defined as output features in our previous work [13], we use only traffic speed as the single output feature in this study.

The strict definitions of the input and output features are described below. First, the input acoustic signal is divided into one-minute segments in accordance with the specification of the loop-coil-based traffic detector used as a teacher. Then, the 2-channel power spectrograms $\mathbf{P}_1$ and $\mathbf{P}_2$ and the cosine and sine of the phase differences $\mathbf{Y}_{\cos}$ and $\mathbf{Y}_{\sin}$ (see Fig. 2) are used as input features, which are calculated using the following equations:

$$\mathbf{X}_i = \mathrm{STFT}(\mathbf{x}_i), \tag{1}$$

$$P_i(k,l) = |X_i(k,l)|^2, \tag{2}$$

$$\Delta\phi(k,l) = \arg(X_1(k,l)/X_2(k,l)), \tag{3}$$

$$Y_{\cos}(k,l) = \cos(\Delta\phi(k,l)), \tag{4}$$

$$Y_{\sin}(k,l) = \sin(\Delta\phi(k,l)). \tag{5}$$

Here, $\mathbf{x}_i$ is the ith-channel acoustic signal ($i = 1, 2$), and $\mathrm{STFT} : \mathbb{C}^N \to \mathbb{C}^{F\times T}$ in (1) represents the short-time Fourier transform that transforms an N-sample time signal into a complex-valued spectrogram with F frequency bins and T time frames, where redundant components for negative frequencies are omitted. k and l are indices in the frequency and time directions, respectively, and $X_i(k,l)$ denotes the (k,l) element of $\mathbf{X}_i$ (the same notation applies to other matrices). Finally, the arrays $(\mathbf{P}_1^\top, \mathbf{P}_2^\top, \mathbf{Y}_{\cos}^\top, \mathbf{Y}_{\sin}^\top)^\top$, which are concatenated along the frequency index direction, are used as an input feature. The output feature, i.e., traffic speed, is defined as the space-mean speed for every minute, which corresponds to the harmonic mean of the speed of individual vehicles.

B. Network Architecture

We use ConvMixer [23], [24] as a network architecture of the estimator in our approach. ConvMixer has a repeating network structure consisting of a pointwise convolution, which mixes the features for each time frame using a fully connected layer, and a depthwise convolution, which mixes the features by convolving in the direction of the time frame (see Fig. 3). Patch embedding is applied to input features by handling short time frames in the input as patches. The output of the ConvMixer layer is finally aggregated in the time-frame direction by the average pooling layer and then transformed into a one-dimensional vector representing the traffic speed label by the fully connected layer.

III. Proposed Data Augmentation Method

As mentioned in Section I, it is often difficult to collect training data with a sufficient variety of traffic speed, especially low-speed data, within a limited amount of time. To compensate the lack of data variety, we propose a data augmentation method based on the control of the frame overlap in the time–frequency domain. As previously mentioned, the inputs to our DNN are the power spectrum and phase difference of the stereo-recorded signal. Our idea is to virtually generate their

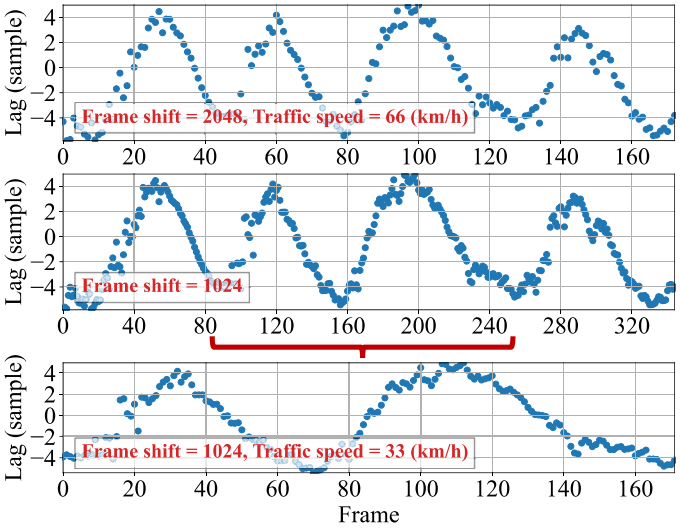

Fig. 4. Conceptual diagram of the proposed data augmentation method

features of slowly-moving vehicles from the original high-speed data by changing the frame shift of STFT.

Let W and M respectively denote the frame length and frameshift of the short-time Fourier transform in (1) for unaugmented data, e.g., $M = W/2$ in the case of half-overlap. Then, the proposed data augmentation algorithm is described as follows. First, a positive integer $M' \leq M$ is determined randomly. Next, a complex-valued spectrogram is obtained from the original acoustic signals $\mathbf{x}_1$ and $\mathbf{x}_2$ via the short-time Fourier transform with M'-sample frameshift instead of M-sample frameshift, and the central T frames, denoted by $\mathbf{X}'_1$ and $\mathbf{X}'_2$, are extracted so that the size of augmented data becomes equal to that of unaugmented data. Finally, input features, i.e., the 2-channel power spectrograms and the cosine and sine of the phase differences, $\mathbf{P}'_1, \mathbf{P}'_2, \mathbf{Y}'_{\cos}, \mathbf{Y}'_{\sin}$ are obtained from $\mathbf{X}'_1$ and $\mathbf{X}'_2$ by (2), (3), (4), and (5). For these input features, the label of the traffic speed is obtained by multiplying M'/M to the original label.

Figure 4 shows the concept of the proposed data augmentation, where the time difference of arrival (TDOA) is plotted for the original data (top), augmented data before T-frame extraction (center), and augmented data after T-frame extraction (bottom). In this example, W, M, and M' are 4096, 2048, and 1024, respectively, and the original label of the traffic speed is $66\,\mathrm{km/h}$; therefore, the artificial label for the augmented data is $33\,\mathrm{km/h}$. One can see that the change in TDOA for the augmented data is stretched twice in the horizontal direction from the original data, as would be expected to occur also for actual vehicles traveling at $33\,\mathrm{km/h}$.

IV. Experiments

To evaluate the proposed method, we investigated the traffic speed estimation performance using a DNN with and without the proposed data augmentation method.

A. Experimental Conditions

The dataset used in this experiment was composed of $48\,\mathrm{h}$ of vehicle-running sound recorded by an IC recorder and

Fig. 5. Recording scenery. A traffic detector is embedded in road pavement in the direction of travel and is not shown in the picture.

corresponding traffic speed labels collected by a loop-coil-based traffic detector near the $6.7\,\mathrm{km}$ post on the Yokohama Shindo in Yokohama City, Kanagawa Prefecture, Japan, which was also used in our previous work [13]. The acoustic signals were recorded with a Panasonic RR-XS470 IC recorder located near the traffic detector (see Fig. 5). The sampling frequency of the IC recorder was $44.1\,\mathrm{kHz}$, and the high-pass filter equipped in the IC recorder was activated during the recording to reduce the effect of wind noise. Four-hour data from 6:00 am to 10:00 am per day were collected over eleven weekdays. The data for the eleven days were first split into seven days for training, two days for validation, and two days for test. Furthermore, the data were split into high-speed data above $60\,\mathrm{km/h}$ and low-speed data below the low-speed data were omitted from the training and validation data to simulate an extreme case in which any low-speed data were not available in training.

We compared the estimation performance characteristics under the following two conditions: (1) without and (2) with proposed data augmentation method. In the absence of data augmenation, only high-speed data were used in the training and validation. For the proposed augmentation method, high-speed data were used with data augmentation in the training and validation, where the frameshift M' was determined independently of each one-minute data and each epoch in the optimization as follows. First, data augmentation was performed with a probability of $1/2$ so that the original data were kept in the training data while the total number of iterations was equal to that in the case without data augmentation to ensure a fair comparison. In the case of performing data augmentation, a random integer p between 10 and 100 was generated from the uniform distribution. Then, the frameshift M' was defined as $M' = \mathrm{round}(pM/100)$, where round denotes rounding to the nearest integer.

Parameters for the ConvMixer and its training were determined as follows. The number of embeddings was set to $T = 1029$. The dimension of feature vectors in the ConvMixer layer was 529, and the kernel size of the depthwise convolution was 5. The number of iterations of the ConvMixer layer was set to 5. The mean absolute error was used for the loss function, and Adam [25] was used for the optimizer. Training was performed for 100 epochs with an initial learning rate of

TABLE I
AVERAGE RMSE ± STD. (km/h) FOR 5 TRIALS

	High speed (Above 60 km/h)	Low speed (Below 60 km/h)
Without data augmentation	3.13±0.13	26±3.85
Proposed	4.12±0.2	**14.7**±1.39
All	3.42±0.11	7.42±0.62

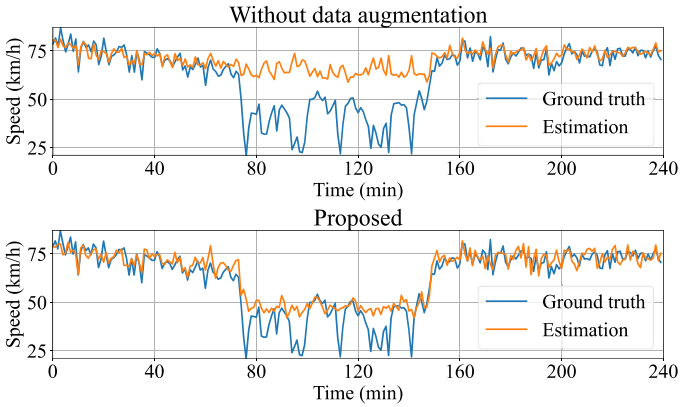

Fig. 6. Temporal changes in true and estimated traffic speeds with and without data augmentation

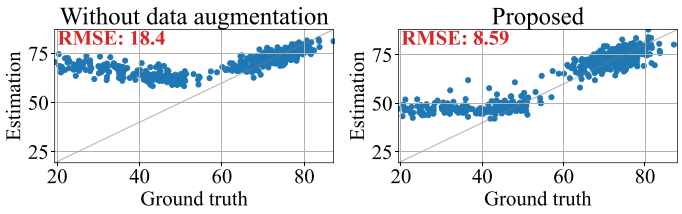

Fig. 7. Scatter plots of true and estimated traffic speeds with and without data augmentation

0.0005.

The estimation performance was evaluated for the test data including both high-speed and low-speed data. The evaluation criterion was the root mean square error (RMSE) between the estimated and true traffic speeds. We additionally evaluated binary classification of low- and high-speed because the characteristics of traffic monitoring do not require perfect estimation for, e.g., detecting congestion.

B. Experimental Results

Table I shows the estimation accuracies obtained with and without the proposed data augmentation method. We also evaluated the estimation accuracy in the case where all data, including both high-speed and low-speed data, were used in the training and validation (without data augmentation) as a reference, denoted by All. The obtained results indicate that the proposed data augmentation method significantly improves the estimation performance for low-speed data compared with the case where no data augmentation is applied. Although the estimation accuracy became slightly degraded for high-speed data, the amount of degradation was much smaller than that of improvement for low-speed data. We also provide the temporal changes in the estimated and true traffic speeds within the designated four hours in Fig. 6 and the scatter plot for all test

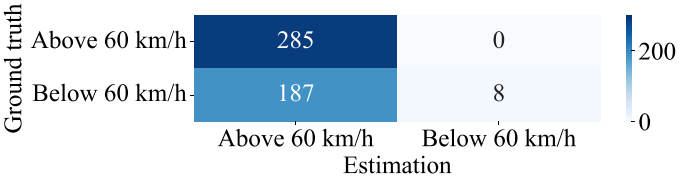

Fig. 8. Confusion matrix in discrimination of high-speed and low-speed data without data augmentation

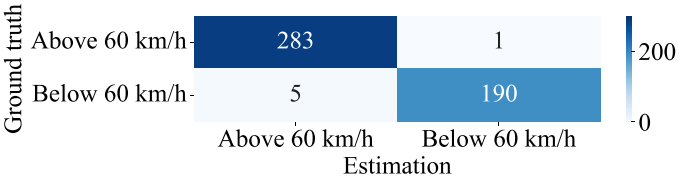

Fig. 9. Confusion matrix in discrimination of high-speed and low-speed data with data augmentation

TABLE II
DISCRIMINATION ACCURACIES FOR HIGH-SPEED AND LOW-SPEED DATA

	Accuracy	**Precision**	**Recall**	**F1-score**
Without data augmentation	61.0 %	100 %	4.1 %	7.9 %
Proposed	98.7 %	99.5 %	97.4 %	98.4 %

data in Fig. 7. From the results in these figures, it is confirmed that the proposed data augmentation method did not simply induce bias on all data toward low speed but indeed improved the estimation accuracy to some extent for the low-speed range while maintaining good accuracy for the high-speed range.

Figures 8 and 9 show the confusion matrices for high-speed (above 60 km/h) and low-speed (below 60 km/h) test data, which represent the total number of data whose true/estimated traffic speed was above/below 60 km/h. In addition, Table II shows the accuracy, precision, recall, and F1-score values calculated from the confusion matrices in Figs. 8 and 9. As shown in these results, the DNN was seriously affected by the bias of traffic speed in the training data without data augmentation; the estimated traffic speed was almost always above 60 km/h for the test data. On the other hand, the proposed data augmentation method enabled the DNN to discriminate high-speed and low-speed data.

V. CONCLUSIONS

We proposed a data augmentation method for machine-learning-based acoustic traffic monitoring, which widens the variety of traffic speed in the training data by controlling frame overlap in the time-frequency domain. The experimental evaluation revealed that the proposed data augmentation method improved the accuracy of traffic speed estimation in the low-speed range, which was not included in the original training data, compared with the case without data augmentation.

Future work includes data augmentation for other features of the traffic condition, such as the number of vehicles.

Abstract— **Heat kernel smoothing (HKS) is one of important methods to reduce noise corrupted in the irregular data collected from various complex network. In this paper, the distributed computation of HKS method using series expansion is studied. First, the relation between HKS computation and matrix exponential is presented and the centralized computation of HKS method is derived. Then, two series expansion methods are used to implement the HKS operator in a distributed manner. They include Taylor series expansion (TSE) and Laguerre series expansion (LSE). The TSE method corresponds to a maximally-flat graph filter method, and LSE method corresponds to the weighted-least-squares graph filter method. Next, the realization structures of two series expansion methods are described by choosing the Laplacian matrix as graph shift operator. Finally, the denoising experiments of data collected from sensor network and social network are used to demonstrate the effectiveness of HKS methods in terms of the improvement of signal to noise ratio.**

I. INTRODUCTION

Heat kernel smoothing (HKS) is a mathematical technique that is commonly used in data analysis and signal processing to reduce the noise in a dataset. The technique is based on the idea of heat diffusion, where heat is allowed to flow from hotter areas to cooler areas. HKS method has applications in various fields such as image processing, computer vision, signal processing and brain network etc. In [1], the graph spectral image smoothing using heat kernel is presented. In [2], heat kernels of generalized Laplacians and its application to color image smoothing are studied. In [3], discrete heat kernel smoothing in irregular image domains is investigated and used to filter out noisy data in the lung blood vessel trees obtained from computed tomography. In [4], the investigating heritability across resting state brain networks via heat kernel smoothing on persistence diagrams is provided. In [5], the denoising method of temperature data collected from sensor network is derived by using directed Laplacian matrix and heat kernel smoothing. In [6], the distributed implementation of heat kernel smoothing for graph signal denoising is described. Owing to the success of HKS method in the denoising of irregular dataset, this paper aims to study the efficient distributed computation method of HKS.

On the other hand, series expansion is a method used in mathematics and physics to represent a function as a sum of terms in a series. This is often done to simplify the function or to approximate it with a simpler function. Moreover, series expansion and filters are often used together in signal processing and control systems. Series expansions can be used to approximate the transfer function of a system, which describes the relationship between the input and output signals. In [7], evaluation and design of filters using a Taylor series expansion is presented. In [8], the closed-form design of maximally flat FIR Hilbert transformer, differentiators, and fractional delays by power series expansions is studied. In [9], the series expansion design of variable fractional order integrator and differentiator using logarithm is investigated. In [10], the series expansions in Hermite polynomials and Laguerre polynomials have been studied in science and engineering. In [11], a simple design of fractional delay FIR filter based on Binomial series expansion theory is described. In [12], the Fourier series expansion based on filter parametrization for equivariant convolutions is investigated. Due to the success of series expansion methods in the signal processing area, the purpose of this paper is to use series expansion to develop the distributed computation methods of heat kernel smoothing.

This paper is organized as follows. In section II, the relation between HKS computation and matrix exponential is presented and the centralized computation of HKS method is derived. In section III and IV, two series expansion methods are used to implement the HKS operator including Taylor series expansion

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

and Laguerre series expansion. The realization structures of two series expansion methods are described by choosing the Laplacian matrix as graph shift operator. In section V, the denoising experiments of irregular data collected from sensor network and social network are used to show the effectiveness of HKS methods. Finally, a conclusion is made.

II. HEAT KERNEL SMOOTHING

In this section, the basics of heat kernel smoothing (HKS) which is based on graph signal processing (GSP) theory in [13]-[15] are described. Let $G=(V,E,\boldsymbol{A})$ be an undirected weighted graph, where $V=\{v_1,v_2,\cdots,v_N\}$ is a set of vertices, $E\subseteq V\times V$ is a set of edge and matrix $\boldsymbol{A}$ is the weighted adjacency matrix. If we denote $\overline{v_nv_m}$ as the edge between vertices v_n and v_m, then elements of matrix $\boldsymbol{A}$ is defined by

$$A(n,m)=\begin{cases}a_{n,m} & \overline{v_nv_m}\in E\\ 0 & \text{otherwise}\end{cases} \tag{1}$$

where $a_{n,m}>0$, i.e., vertices are connected with positive edge weights. For an undirected graph, the $\boldsymbol{A}$ is a symmetric matrix. Moreover, let the degree of vertex v_n is defined as

$$d_n=\sum_{m=1}^{N}a_{n,m} \tag{2}$$

then degree matrix $\boldsymbol{D}$ of graph is given by the diagonal matrix $\boldsymbol{D}=diag[d_1,d_2,\cdots,d_N]$. Based on the above definitions, the Laplacian matrix of graph G is defined as $\boldsymbol{L}=\boldsymbol{D}-\boldsymbol{A}$ which is a positive semi-definite operator. Let the eigen-decomposition of $\boldsymbol{L}$ be given by $\boldsymbol{L}=\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^T$, where $\boldsymbol{\Lambda}$ is an diagonal matrix containing the eigenvalues $\lambda_1\le\lambda_2\le\cdots\le\lambda_N$ and orthonomal matrix $\boldsymbol{U}$ is composed of the eigenvectors $\boldsymbol{u}_1,\boldsymbol{u}_2,\cdots,\boldsymbol{u}_N$. If $z(n)$ is the signal value associated with the vertex v_n, the graph signal is the vector $\boldsymbol{z}=[z(1),z(2),\cdots,z(N)]^T$ defined on the vertices V. The graph Fourier transform (GFT) of signal $\boldsymbol{z}$ is defined as $\hat{\boldsymbol{z}}=\boldsymbol{U}^T\boldsymbol{z}$ and its corresponding inverse graph Fourier transform (IGFT) is given by $\boldsymbol{z}=\boldsymbol{U}\hat{\boldsymbol{z}}$, where spectrum $\hat{\boldsymbol{z}}=[\hat{z}(\lambda_1),\hat{z}(\lambda_2),\cdots,\hat{z}(\lambda_N)]^T$. After reviewing the GSP basics, the heat kernel smoothing (HKS) method is described below. The well-known heat equation is given by

$$\frac{\partial\phi}{\partial t}=\nabla^2\phi \tag{3}$$

where ϕ is the temperature function. Replacing operator ∇^2 by $-\boldsymbol{L}$ and function ϕ by graph signal $\boldsymbol{z}$, the discrete heat equation over a graph is then given by

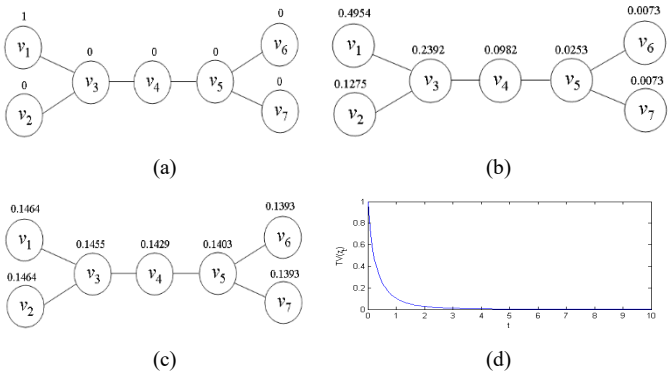

Fig.1 An example of heat kernel smoothing or diffusion. (a) The topology of a simple graph with 7 nodes. The initial signal is $\boldsymbol{z}_0=[1,0,0,0,0,0,0]^T$. (b) The graph signal $\boldsymbol{z}_t$ at $t=1$. (c) The graph signal $\boldsymbol{z}_t$ at $t=15$. (d) The relation between total variation $TV(\boldsymbol{z}_t)$ and t.

$$\frac{\partial\boldsymbol{z}}{\partial t}=-\boldsymbol{L}\boldsymbol{z}\quad\text{with initial}\quad\boldsymbol{z}_0 \tag{4}$$

The solution of this differential equation is given by

$$\boldsymbol{z}_t=e^{-t\boldsymbol{L}}\boldsymbol{z}_0=\boldsymbol{H}_d\boldsymbol{z}_0 \tag{5}$$

where $\boldsymbol{H}_d=e^{-t\boldsymbol{L}}$ is matrix exponential. Clearly, the diffusion process of heat energy is determined completely by the initial value $\boldsymbol{z}_0$. The matrix exponential $\boldsymbol{H}_d=e^{-t\boldsymbol{L}}$ can be computed by using the eigen-decomposition of $\boldsymbol{L}$, that is, substituting $\boldsymbol{L}=\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^T$ into $\boldsymbol{H}_d$, we have

$$\boldsymbol{H}_d=\boldsymbol{U}\boldsymbol{\Lambda}_d\boldsymbol{U}^T \tag{6}$$

where $\boldsymbol{\Lambda}_d=diag[h_d(\lambda_1),h_d(\lambda_2),\cdots,h_d(\lambda_N)]$ with ideal spectral response $h_d(\lambda)=e^{-t\lambda}$. Now, one example is illustrated. Fig.1(a) shows the graph topology with $N=7$ vertices. The edge weights are all equal to unity. The initial graph signal is chosen as $\boldsymbol{z}_0=[1,0,0,0,0,0,0]^T$. Fig.1(b) and (c) depicts the graph signals $\boldsymbol{z}_t$ for $t=1$ and $t=15$. Clearly, the heat energy flows from vertex v_1 to all other vertices $v_2,v_3,\cdots,v_7$ gradually until signal values at all vertices are the same. Moreover, the total variation (TV) that measures the smoothness of signal $\boldsymbol{z}_t$ is defined by

$$TV(\boldsymbol{z}_t)=\boldsymbol{z}_t^T\boldsymbol{L}\boldsymbol{z}_t \tag{7}$$

Fig.1(d) shows the relation between $TV(\boldsymbol{z}_t)$ and t. It can be seen that the larger t is, the smaller TV signal has. That is, the larger t is, the smoother signal $\boldsymbol{z}_t$ is.

Finally, two remarks are made. First, if $\boldsymbol{z}_t=\boldsymbol{H}_d\boldsymbol{z}_0$ in (5) is used to compute smoothed signal $\boldsymbol{z}_t$, the matrix-vector multiplication is needed. Thus, this method is only suitable for

centralized computation and has high communication cost in the computation process. Second, the eigen-decomposition of $\boldsymbol{L}$ is needed to compute the matrix exponential $\boldsymbol{H}_d = e^{-t\boldsymbol{L}}$. Because the computation load of eigen-decomposition of a matrix is high, the eigen-decomposition free method is wanted. In next sections, the series expansion methods are presented to compute $\boldsymbol{z}_t$ from the initial $\boldsymbol{z}_0$ such that the distributed computation can be achieved and the computation of eigen-decomposition of matrix $\boldsymbol{L}$ can be also avoided.

III. TAYLOR SERIES EXPANSION METHOD

The Taylor series expansion (TSE) of exponential function is given by

$$e^x = \sum_{k=0}^{\infty} \frac{x^k}{k!} \tag{8}$$

Replacing x with $-t\boldsymbol{L}$, the matrix exponential $\boldsymbol{H}_d = e^{-t\boldsymbol{L}}$ can be expressed as

$$\boldsymbol{H}_d = e^{-t\boldsymbol{L}} = \sum_{k=0}^{\infty} \frac{(-t)^k}{k!} \boldsymbol{L}^k \tag{9}$$

Truncating this infinite series to a finite series with truncation order M, it yields the result

$$\boldsymbol{H}_d \approx \sum_{k=0}^{M} \frac{(-t)^k}{k!} \boldsymbol{L}^k \tag{10}$$

Let the coefficients $b_k = \frac{(-t)^k}{k!}$ be chosen, then the following polynomial graph filter $\boldsymbol{H}_1$ will approximate $\boldsymbol{H}_d$ well:

$$\boldsymbol{H}_1 = \sum_{k=0}^{M} b_k \boldsymbol{L}^k \tag{11}$$

Substituting the eigen-decomposition $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^T$ into filter $\boldsymbol{H}_1$ in (11), we have

$$\boldsymbol{H}_1 = \sum_{k=0}^{M} b_k (\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^T)^k = \boldsymbol{U}\boldsymbol{\Lambda}_1\boldsymbol{U}^T \tag{12}$$

where diagonal matrix $\boldsymbol{\Lambda}_1 = diag[h_1(\lambda_1), h_1(\lambda_2), \cdots, h_1(\lambda_N)]$ with filter spectral response

$$h_1(\lambda) = \sum_{k=0}^{M} b_k \lambda^k \tag{13}$$

Now, let us show that the filter spectral response $h_1(\lambda)$ satisfies the following property:

Fact 1: The spectral responses $h_1(\lambda)$ and $h_d(\lambda) = e^{-t\lambda}$ have the same m-th order derivatives at $\lambda = 0$ for $m = 0,1,\cdots,M$, that is, the following equalities hold:

$$\left.\frac{d^m h_1(\lambda)}{d\lambda^m}\right|_{\lambda=0} = \left.\frac{d^m h_d(\lambda)}{d\lambda^m}\right|_{\lambda=0} \qquad m = 0,1,\cdots,M \tag{14}$$

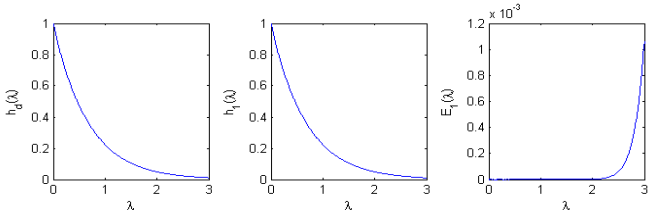
Proof: Because $h_d(\lambda) = e^{-t\lambda}$, the derivatives of $h_d(\lambda)$ at $\lambda = 0$ can be computed as

$$\left.\frac{d^m h_d(\lambda)}{d\lambda^m}\right|_{\lambda=0} = (-t)^m e^{-t\lambda}\Big|_{\lambda=0} = (-t)^m \tag{15}$$

Moreover, the derivatives of $h_1(\lambda)$ can be calculated as

$$\left.\frac{d^m h_1(\lambda)}{d\lambda^m}\right|_{\lambda=0} = m!b_m = m!\frac{(-t)^m}{m!} = (-t)^m \tag{16}$$

From the above results in (15) and (16), it can be seen that equation (14) is valid. The proof is completed.



Based on the fact 1, it is clear that the larger order M is, the responses $h_1(\lambda)$ and $h_d(\lambda)$ have more same derivatives at frequency $\lambda = 0$. Therefore, the approximation error $E_1(\lambda) = |h_d(\lambda) - h_1(\lambda)|$ decreases when order M increases. Moreover, fact 1 tells us that polynomial graph filter $\boldsymbol{H}_1$ is a maximally flat approximation of HKS filter $\boldsymbol{H}_d = e^{-t\boldsymbol{L}}$ at $\lambda = 0$. When $t = 1.5$ and $M = 15$ are chosen, Fig.2(a)-(c) show the spectral responses $h_d(\lambda)$, $h_1(\lambda)$ and error $E_1(\lambda)$. Clearly, the errors around $\lambda = 0$ are very small, so the Taylor series expansion method corresponds to a maximally flat graph filter design.

Next, the distributed computation of HKS using TSE is investigated. Because $\boldsymbol{H}_d \approx \boldsymbol{H}_1$ holds, the HKS equation in (5) can be rewritten as

$$\boldsymbol{z}_t \approx \boldsymbol{H}_1\boldsymbol{z}_0 = \left(\sum_{k=0}^{M} b_k \boldsymbol{L}^k\right)\boldsymbol{z}_0 \tag{17}$$

Let us define $\boldsymbol{z}_k = \boldsymbol{L}^k\boldsymbol{z}_0$, then $\boldsymbol{z}_k$ satisfies the recursive equation $\boldsymbol{z}_{k+1} = \boldsymbol{L}\boldsymbol{z}_k$ and (17) reduces to

$$\boldsymbol{z}_t = \sum_{k=0}^{M} b_k \boldsymbol{z}_k \tag{18}$$

(a) (b) (c)

Fig.2 The spectral responses and error of TSE method. (a) Ideal response $h_d(\lambda)$. (b) The actual response $h_1(\lambda)$. (c) The error $E_1(\lambda)$.

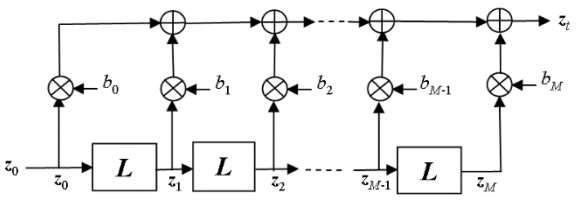


Fig.3 An implementation structure of Taylor series expansion (TSE) method.

Based on the above results, an implementation structure of TSE method is shown in Fig.3. Using $\boldsymbol{L} = \boldsymbol{D} - \boldsymbol{A}$ and $\boldsymbol{z}_{k+1} = \boldsymbol{L}\boldsymbol{z}_k$, the signal $\boldsymbol{z}_{k+1}$ can be calculated from $\boldsymbol{z}_k$ by

$$z_{k+1}(n) = d_n z_k(n) - \sum_{m \in \mathrm{N}_n} a_{n,m} z_k(m) \tag{19}$$

where notation N_n of neighbor denotes the set of vertices connected to the vertex v_n. When the signal z_1, z_2, ..., z_M are computed in a distributed manner by (19), the HKS signal z_t is easily obtained by the weighted sum in (18). Thus, the distributed computation of $\boldsymbol{z}_t = \boldsymbol{H}_d \boldsymbol{z}_0$ can be accomplished by the TSE structure in Fig.3.

IV. LAGUERRE SERIES EXPANSION METHOD

In this section, the Laguerre series expansion (LSE) method is studied. The k-th order Laguerre polynomials $p_k(x)$ are the solutions of the following differential equation:

$$x\frac{d^2 p_k(x)}{dx^2} + (1-x)\frac{dp_k(x)}{dx} + kp_k(x) = 0 \tag{20}$$

The closed-form solution of $p_k(x)$ is given by

$$p_k(x) = \sum_{r=0}^{k} (-1)^r \frac{k!}{(r!)^2 (k-r)!} x^r \tag{21}$$

Some typical solutions of $p_k(x)$ are given by $p_0(x) = 1$, $p_1(x) = 1 - x$, and $p_2(x) = \frac{1}{2}(2 - 4x + x^2)$. In the literature, it has been shown that $p_k(x)$ satisfies the following properties:
(i) The $p_k(x)$ can be obtained from the Rodriguez formula:

$$p_k(x) = \frac{e^x}{k!}\frac{d^k(x^k e^{-x})}{dx^k} \tag{22}$$

(ii) The $p_k(x)$ satisfies the following recursion relation:

$$p_{k+1}(x) = \frac{(2k+1-x)}{k+1} p_k(x) - \frac{k}{k+1} p_{k-1}(x) \tag{23}$$

with initial $p_0(x) = 1$ and $p_1(x) = 1 - x$.
(iii) The $p_k(x)$ satisfies the orthogonal relation below:

$$\int_0^\infty e^{-x} p_k(x) p_m(x) dx = \begin{cases} 1 & k = m \\ 0 & k \neq m \end{cases} \tag{24}$$

Based on the above orthogonal property, we have the fact:
Fact 2: Let $f(x)$ be a sufficiently smooth real function in the interval $[0,\infty)$, then it can be expanded in terms of the Laguerre polynomials $p_k(x)$ as

$$f(x) = \sum_{k=0}^{\infty} \alpha_k p_k(x) \tag{25}$$

If the α_k are sought to minimize the following error

$$J_1 = \int_0^\infty e^{-x} \left[f(x) - \sum_{k=0}^{\infty} \alpha_k p_k(x) \right]^2 dx \tag{26}$$

then the coefficients α_k are given by

$$\alpha_k = \int_0^\infty e^{-x} f(x) p_k(x) dx \tag{27}$$

The proof of this fact can be found in [10]. Now, let us choose the function $f(x)$ as the exponential function below:

$$f(x) = e^{-\beta x} \qquad \beta > 0 \tag{28}$$

then it can be shown that α_k are given by

$$\alpha_k = \frac{\beta^k}{(\beta+1)^{k+1}} \tag{29}$$

Thus, we have the following Laguerre series expansion:

$$f(x) = e^{-\beta x} = \sum_{k=0}^{\infty} \frac{\beta^k}{(\beta+1)^{k+1}} p_k(x) \tag{30}$$

After changing the variables $\beta \to t$ and $x \to \lambda$, the HKS spectral response $h_d(\lambda) = e^{-t\lambda}$ can be written as

$$h_d(\lambda) = e^{-t\lambda} = \sum_{k=0}^{\infty} \frac{t^k}{(t+1)^{k+1}} p_k(\lambda) \tag{31}$$

Based on this LSE result, the matrix exponential $\boldsymbol{H}_d = e^{-t\boldsymbol{L}}$ can be approximated by the polynomial graph filter:

$$\boldsymbol{H}_2 = \sum_{k=0}^{M} \frac{t^k}{(t+1)^{k+1}} p_k(\boldsymbol{L}) = \sum_{k=0}^{M} c_k p_k(\boldsymbol{L}) \tag{32}$$

The above coefficients c_k are given by

$$c_k = \frac{t^k}{(t+1)^{k+1}} \tag{33}$$

Substituting the eigen-decomposition $\boldsymbol{L} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^T$ into graph filter $\boldsymbol{H}_2$ in (32), it yields the result

$$\boldsymbol{H}_2 = \sum_{k=0}^{M} c_k p_k(\boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^T) = \boldsymbol{U}\boldsymbol{\Lambda}_2\boldsymbol{U}^T \tag{34}$$

where diagonal matrix $\boldsymbol{\Lambda}_2 = diag[h_2(\lambda_1), h_2(\lambda_2), \cdots, h_2(\lambda_N)]$ with filter spectral response

$$h_2(\lambda)=\sum_{k=0}^{M}c_k p_k(\lambda) \tag{35}$$

Based on error function in (26), it means that the c_k are obtained by minimizing the following spectral response error

$$\begin{aligned} J_2 &= \int_0^{\infty} e^{-\lambda}\left[h_d(\lambda)-\sum_{k=0}^{M}c_k p_k(\lambda)\right]^2 d\lambda \\ &= \int_0^{\infty} e^{-\lambda}\left[h_d(\lambda)-h_2(\lambda)\right]^2 d\lambda \end{aligned} \tag{36}$$

Therefore, the Laguerre series expansion method corresponds to a weighted-least-squares (WLS) graph filter design method. When $t=1.5$ and $M=15$ are chosen, Fig.4(a)-(c) depict the spectral responses $h_d(\lambda)$, $h_2(\lambda)$ and response error $E_2(\lambda)=|h_d(\lambda)-h_2(\lambda)|$. Clearly, the errors are small in the frequency band $\lambda\in[0,3]$. Next, the distributed computation of HKS using LSE is investigated. Let input signal $\boldsymbol{z}_0$ pass through the graph filter $\boldsymbol{H}_2$ in (32), its output signal $\boldsymbol{z}_t$ is given by

$$\boldsymbol{z}_t \approx \boldsymbol{H}_2\boldsymbol{z}_0=\left(\sum_{k=0}^{M}c_k p_k(\boldsymbol{L})\right)\boldsymbol{z}_0 \tag{37}$$

Using (23), the following recurrence relation can be used to get an efficient implementation structure:

$$p_{k+1}(\boldsymbol{L})=\frac{(2k+1)\boldsymbol{I}-\boldsymbol{L}}{k+1}p_k(\boldsymbol{L})-\frac{k}{k+1}p_{k-1}(\boldsymbol{L}) \tag{38}$$

where $\boldsymbol{I}$ is the identity matrix, initial value $p_0(\boldsymbol{L})=\boldsymbol{I}$ and $p_1(\boldsymbol{L})=\boldsymbol{I}-\boldsymbol{L}$. Multiplying both sides of (38) by the $\boldsymbol{z}_0$ and defining $\boldsymbol{y}_k=p_k(\boldsymbol{L})\boldsymbol{z}_0$, we have

$$\boldsymbol{y}_{k+1}=\frac{2k+1}{k+1}\boldsymbol{y}_k-\frac{1}{k+1}\boldsymbol{L}\boldsymbol{y}_k-\frac{k}{k+1}\boldsymbol{y}_{k-1} \tag{39}$$

with $\boldsymbol{y}_0=\boldsymbol{z}_0$ and $\boldsymbol{y}_1=\boldsymbol{z}_0-\boldsymbol{L}\boldsymbol{z}_0$. Based on equation (39), an implementation structure is shown in Fig.5. Clearly, the key step in this structure is the computation of the signal $\frac{1}{k+1}\boldsymbol{L}\boldsymbol{y}_k$. Using $\boldsymbol{L}=\boldsymbol{D}-\boldsymbol{A}$, signal $\frac{1}{k+1}\boldsymbol{L}\boldsymbol{y}_k$ can be computed by

$$\left(\tfrac{1}{k+1}\boldsymbol{L}\boldsymbol{y}_k\right)(n)=\frac{1}{k+1}\left(d_n\boldsymbol{y}_k(n)-\sum_{m\in \mathrm{N}_n}a_{n,m}\boldsymbol{y}_k(m)\right) \tag{40}$$

So, the signals $\boldsymbol{y}_2$, $\boldsymbol{y}_3$, ..., $\boldsymbol{y}_M$ are easily computed in a distributed manner by (39) and (40). The above notation N_n of neighbor denotes the set of vertices connected to the vertex v_n. Using (37) and $\boldsymbol{y}_k=p_k(\boldsymbol{L})\boldsymbol{z}_0$, the HKS signal $\boldsymbol{z}_t$ can be obtained by the following weighted sum

$$\boldsymbol{z}_t=\sum_{k=0}^{M}c_k\boldsymbol{y}_k \tag{41}$$

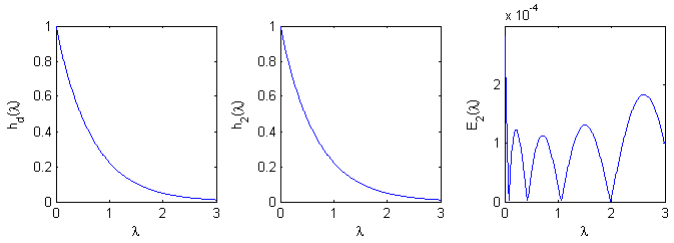

Fig.4 The spectral responses and error of LSE method. (a) Ideal response $h_d(\lambda)$. (b) The actual response $h_2(\lambda)$. (c) The error $E_2(\lambda)$.

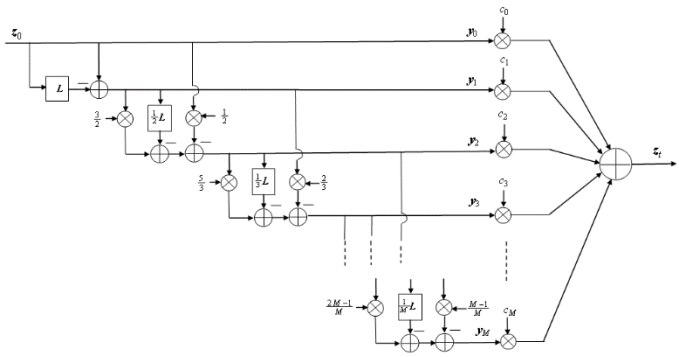

Fig.5 A distributed implementation structure of Laguerre series expansion (LSE) method.

Therefore, the distributed computation of $\boldsymbol{z}_t=\boldsymbol{H}_d\boldsymbol{z}_0$ can be accomplished by the LSE structure in Fig.5.

V. APPLICATION EXAMPLES

In this section, the denoising experiments of data collected from sensor network and social network are used to show the effectiveness of heat kernel smoothing method. To achieve this purpose, the initial signal $\boldsymbol{z}_0$ is chosen as the given noisy signal below:

$$\boldsymbol{z}_0=\boldsymbol{s}+\boldsymbol{\varepsilon} \tag{42}$$

where $\boldsymbol{s}=[s(1),s(2),\cdots,s(N)]^T$ is the clean data and $\boldsymbol{\varepsilon}=[\varepsilon(1),\varepsilon(2),\cdots,\varepsilon(N)]^T$ is the un-correlated white noise. Because the clean signal $\boldsymbol{s}$ is usually a low-frequency component and noise $\boldsymbol{\varepsilon}$ is a high-frequency component, the low-pass heat kernel smoothing signal $\boldsymbol{z}_t=e^{-t\boldsymbol{L}}\boldsymbol{z}_0=\boldsymbol{H}_d\boldsymbol{z}_0$ is the desirable denoised signal. The reason is explained below: From the spectral responses $h_d(\lambda)$ in Fig.2(a) and Fig.4(a), it can be seen that the smoothing filter $\boldsymbol{H}_d$ is a low-pass filter. The response $h_d(\lambda)$ at $\lambda=0$ is exactly equal to one and $h_d(\lambda)$ is a monotonically decreasing function with respect to

the frequency variable λ. The 3-dB cutoff frequency λ_c of $h_d(\lambda)$ needs to satisfy the following condition:

$$h_d(\lambda_c) = e^{-\lambda_c t} = \frac{1}{\sqrt{2}} \tag{43}$$

Solving the above equation, the value of λ_c is given by

$$\lambda_c = \frac{\ln\sqrt{2}}{t} \tag{44}$$

Thus, the variable t can be used to control the 3-dB bandwidth of low-pass smoothing filter $\boldsymbol{H}_d$. The larger t is, the smaller passband width filter has. Moreover, to make comparison, the denoised signal $\boldsymbol{s}_r$ of conventional matrix inversion method is given by

$$\boldsymbol{s}_r = (\boldsymbol{I} + \rho\boldsymbol{L})^{-1}\boldsymbol{z}_0 = \boldsymbol{H}_c\boldsymbol{z}_0 \tag{45}$$

where $\boldsymbol{H}_c = (\boldsymbol{I} + \rho\boldsymbol{L})^{-1}$, $\boldsymbol{I}$ is the identity matrix, and ρ is a prescribed number. The spectral response of the filter $\boldsymbol{H}_c$ is given by

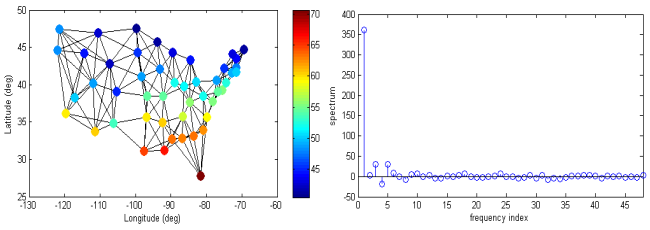
$$h_c(\lambda) = \frac{1}{1+\rho\lambda} \tag{46}$$

Obviously, $h_c(\lambda)$ is also a low-pass filter. To evaluate the performance of the denoised methods, the signal to noise ratio (SNR) of noisy and denoised signals are defined by

$$SNR_i = 10\log_{10}\left(\frac{\|\boldsymbol{s}\|_2^2}{\|\boldsymbol{z}_0 - \boldsymbol{s}\|_2^2}\right) \quad SNR_o = 10\log_{10}\left(\frac{\|\boldsymbol{s}\|_2^2}{\|\boldsymbol{s}_r - \boldsymbol{s}\|_2^2}\right) \tag{47}$$

where $\boldsymbol{s}_r$ is the denoised signal in the following four cases:

(a) In case 1, $\boldsymbol{s}_r$ is the denoised signal of the conventional matrix inversion (MI) method, i.e., $\boldsymbol{s}_r = \boldsymbol{H}_c\boldsymbol{z}_0$. Because matrix inverse needs to be computed, this method is only suitable for centralized computation.



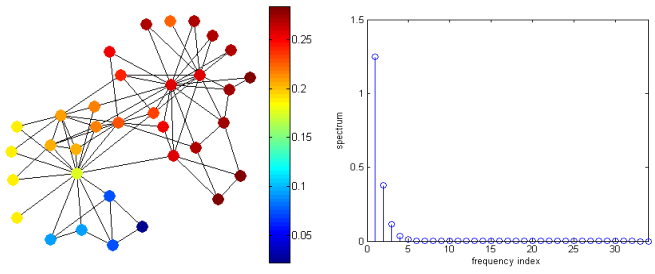
(b) In case 2, $\boldsymbol{s}_r$ is the denoised signal of the original heat kernel smoothing (HKS) method, i.e., $\boldsymbol{s}_r = \boldsymbol{H}_d\boldsymbol{z}_0$. Because eigen-decomposition of matrix needs to be computed, this method is only suitable for centralized computation.

(c) In case 3, $\boldsymbol{s}_r$ is the denoised signal of the Taylor series expansion (TSE) method, i.e., $\boldsymbol{s}_r = \boldsymbol{H}_1\boldsymbol{z}_0$. Because this method can be implemented by the structure in Fig.3, it is suitable for distributed computation.

(d) In case 4, $\boldsymbol{s}_r$ is the denoised signal of the Laguerre series expansion (LSE) method, i.e., $\boldsymbol{s}_r = \boldsymbol{H}_2\boldsymbol{z}_0$. Because this method can be implemented by the structure in Fig.5, it is suitable for distributed computation.

For these four cases, the larger SNR_o is, the better performance the denoising method has. In the following, the numerical examples of sensor network and social network are presented to study the performance.

Example 1: In this example, the temperature data of sensor network at USA is used to make experiment [16]. Fig.6(a) depicts the graphical representation of the sensor network. The number of vertices is $N = 48$. And, the edge is constructed by the nearest-neighbor rule. The unit of temperature data is given by Fahrenheit degree. Fig.6(b) shows the GFT spectrum of this temperature data. Clearly, it is a low-frequency signal. The noise $\boldsymbol{\varepsilon}$ is zero-mean white Gaussian noise. The SNR_i of noisy signal $\boldsymbol{z}_0$ is chosen as 17.29 dB. When the parameters are selected as $\rho = 0.7$, $M = 15$ and $t = 0.4$, Table I lists the SNR_o of the denoised signals $\boldsymbol{s}_r$ in four cases. It can be seen that the heat-kernel-smoothing related methods in cases 2, 3, 4 have better performance than conventional matrix inversion method in case 1. Moreover, the TSE and LSE methods in cases 3 and 4 almost provide the same SNR_o as the original HKS method in case 2.



(a) (b)

Fig.6 The denoising example of sensor network at USA. (a) Irregular temperature data. (b) The GFT spectrum of temperature data.

TABLE I: THE SNR_o OF THE DENOISED SIGNAL IN SENSOR NETWORK.

	case 1	case 2	case 3	case 4
SNR_o	22.88 dB	23.16 dB	23.15 dB	23.16dB

(a) (b)

Fig.7 The denoising example of the karate-club social network. (a) Irregular graph data. (b) The GFT spectrum of irregular data.

TABLE II: THE SNR_o OF THE DENOISED SIGNAL IN SOCIAL NETWORK.

	case 1	case 2	case 3	case 4
SNR_o	17.49 dB	18.05 dB	18.04 dB	18.05dB

Example 2: In this example, the data of karate-club social network is used to make experiment [17]. Fig.7(a) depicts the graphical representation of the karate-club social network. The number of vertices is $N = 34$. And, the edge is constructed by using the communication relation of individuals in the club. Fig.7(b) shows the GFT spectrum of this irregular data. Clearly, it is a low-frequency signal. The noise $\boldsymbol{\varepsilon}$ is zero-mean white Gaussian noise. The SNR_i of noisy signal $\boldsymbol{z}_0$ is chosen as 14.49 dB. When the parameters are selected as $\rho = 0.1$, $M = 15$ and $t = 0.1$, Table II lists the SNR_o of the denoised signals $\boldsymbol{s}_r$ in four cases. It is clear that the HKS related methods in cases 2, 3, 4 have better performance than the MI method in case 1. Moreover, the TSE and LSE methods in cases 3 and 4 almost yields the same SNR_o as the original HKS method in case 2.

VI. CONCLUSIONS

In this paper, the distributed computations of heat kernel smoothing using Taylor and Laguerre series expansion methods have been presented. The TSE method corresponds to a maximally-flat graph filter method, and LSE method corresponds to the weighted-least-squares graph filter method. The denoising experiments of data collected from sensor network and social network are also used to demonstrate the effectiveness of HKS methods in terms of the improvement of SNR. However, only Taylor and Laguerre series expansions are studied here. Thus, it is interesting to use other series expansions to implement the heat kernel smoothing method in a distributed manner in the future.

***Abstract* — This study presents a deep learning-based approach for recognizing Chinese characters written in the air. Chinese characters, which are composed of numerous strokes in a square shape, pose a challenge for recognizing real and virtual strokes when writing in the air. Existing Optical Character Recognition (OCR) models often result in inaccurate recognition due to this difficulty. Depth cameras can improve recognition accuracy, but they are more expensive than traditional optical cameras.**

To address these challenges, this study employs a deep learning model to track fingertips from a single optical camera. The approach incorporates an intuitive interface that distinguishes between real and virtual strokes while writing. Gesture recognition serves as commands to enable users to start and stop writing and to make corrections during input. This approach makes in-air handwriting behavior similar to writing on paper. To evaluate the effectiveness of the proposed approach, a comparative experiment was conducted to evaluate the model's performance for recognizing characters with and without virtual strokes. Eliminating virtual strokes enabled the OCR model to achieve over 90% recognition accuracy, which was 37% higher than the accuracy with virtual strokes. Moreover, the recognition accuracy of characters with virtual strokes fluctuated significantly in a stability test conducted one week later, while the input method without virtual strokes remained stable at over 90% recognition accuracy. These experimental results indicate that the proposed method can not only effectively remove virtual strokes in air writing but also make in-air handwriting easier for people.

I. INTRODUCTION

The development of contactless handwriting recognition input methods has gained significance in the post-COVID-19 era. Unlike traditional input methods, voice recognition and air handwriting can be input naturally and intuitively without physical contact with devices. In certain circumstances, air writing may be more favorable than voice recognition. However, recognizing air handwriting for Chinese characters arise a challenge due to the lack of clear differentiation between writing down (real strokes) and lifting up (virtual strokes) actions, resulting in the written characters have both types of strokes. In addition, In contrast to English, there are 4,808 frequently used traditional Chinese characters, making the problem be more complicated. The square shape of Chinese characters could make strokes become indistinguishable when there are many real strokes with virtual strokes, resulting in a significant difference in recognition success rates between air handwriting and writing on paper. Therefore, this study aims to alleviate the problem of connected strokes when air writing, allowing the results to more closely resemble those of regular writing results and reducing the difficulty and scale of data collection for air handwriting recognition models of traditional Chinese, which is a significant challenge in this field.

There are various approaches for in-air handwriting recognition. Chen et al. [1] proposed a fingertip detection method based on smart glasses that returned the coordinates of the detected fingertips as input. They utilized Google Input API's Chinese handwriting recognition model for recognition, achieving over 80% accuracy. Hayakawa et al. [2] proposed a method that employs the PS Move motion controller device for air handwriting. This method added a handheld device for precise detection of the writing position and lifting and laying down of the pen. It effectively eliminated virtual strokes during

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

the input stage and used the Japanese recognition model for recognition. However, its use of the PS Move motion controller device made it less convenient and portable as compared to other methods. Additionally, it could not circumvent the disadvantage of needing an additional handheld device in public places.

Another method to eliminate virtual strokes in air handwriting is to perform post-processing after writing. Wu [3] proposed an effective method for eliminating virtual strokes in English air handwriting. This method compared the input letters with all 26 English letters and converts connected letters into individual letters. By doing so, virtual strokes can be eliminated, and results similar to regular writing can be obtained. This method reduced the model's complexity and can use general handwriting data to build the model. However, users need to pre-enter the letters, and the processing time will increase proportionally as the word length increases, affecting the efficiency of each writing procedure. Additionally, this method cannot eliminate virtual strokes within a letter. It was mentioned in the literature that distinguishing between "i" and "l" can be challenging. Traditional Chinese characters usually have virtual strokes within them, making this method unsuitable for traditional Chinese character recognition.

Zou [4] proposed a method that utilized a Kinet and PrimeSense skeleton tracking kit to record the trajectories of writing movements. This approach required users to execute writing movements where the wrist was positioned higher than the shoulder, and the input data did not eliminate virtual strokes. Trajectory normalization, stroke segmentation, trajectory direction, and shape context were employed for recognition. However, this method necessitated pre-entering the writing trajectories of each character and was susceptible to stroke order, which could impact recognition accuracy. The character recognition model collected 300 handwriting characters from four testers to establish a recognition database of 2,400 trajectory data. 150 trajectory data (out of a total of 600) were collected for testing and compared with the data in the database. Although this method satisfied the requirements for contactless devices and did not necessitate additional equipment, the accuracy of the model was influenced by each user's stroke or writing habits. Furthermore, this method's recognition model could not use general writing characters for training. Each character's handwriting data had to be re-collected, increasing the difficulty of data collection for building the model. Chen et al. [5] proposed a method that used dual cameras. The recognition accuracy was impressive but the hardware requirement is relatively high.

After reviewing the above studies, this study presents three contributions:

1. An intuitive interface is designed that effectively eliminates virtual strokes in Chinese in-air handwriting characters, resulting in high recognition accuracy.
2. The proposed method only relies on an optical camera to reduce hardware requirements.
3. The recognition model can be built using regular handwritten data without the need to record writing order, thereby reducing modeling complexity.

II. Proposed Method

This study employs a Convolutional Neural Network (CNN)-based hand pose detection model proposed by Google [6], in conjunction with an optical camera, to detect hand poses and track fingertips frame by frame. In order to distinguish between real and virtual strokes, an intuitive method of marking a region of interest (ROI) on the image is proposed. The ROI moves with the movement of the hands, requiring the user to maintain a writing behavior in order to keep the fingertip inside the ROI. This approach enables handwriting results similar to writing on a plane. Finally, the fingertip trajectories inside the ROI are recorded to form the written character. The system architecture is illustrated in Figure 1.

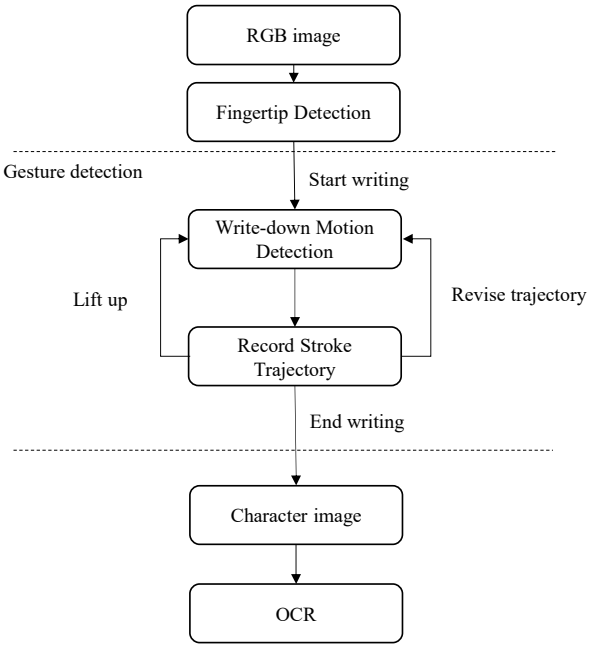

Fig. 1 System architecture

A. *Distinguishing real and virtual strokes*

To ensure that the results of aerial handwriting are similar to those of physical handwriting on a plane, an analysis of the actual way of writing with fingers was conducted, resulting in the following conclusions: When writing on a physical plane, touching the plane with the fingertips is considered to be the real pen, and lifting the fingertips off the plane is considered not writing (Fig. 2). Based on this concept, when writing in the air, an virtual plane is assumed. When the index finger touches the virtual plane, it is considered a real stroke, and when it leaves, it is considered a virtual stroke (Fig. 3). This allows for the differentiation between real and virtual strokes. When observed from the perspective of a camera, the distance between the plane coordinates of the fingertips and the plane coordinates of the proximal interchangeable joint of the index finger is shorter when touching the imaginary plane (real stroke) than when not touching it (virtual stroke). This rule is used as the core, and the ROI range is calculated for determining real and virtual strokes.

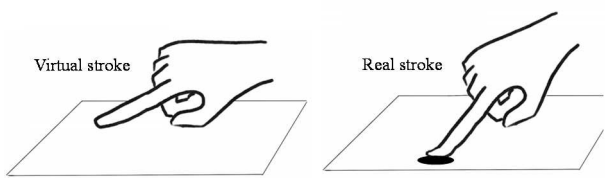

Fig. 2 Scenario of writing on a physical plane using fingertip.

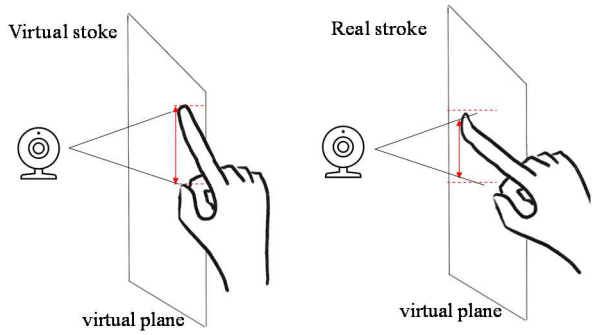

Fig. 3 Detecting write-down behavior when using a single non-depth camera

B. *Gesture recognition and OCR*

To accurately determine the timing of users' writing, a multi-layer perceptron [7-9] was designed as a model for gesture recognition. Three gestures were designed, representing the start of writing, the end of writing, and the correction function. This design allows users to communicate directly with the device without touching any other equipment, controlling the state of air handwriting in real-time, and achieving the desired input results.

After distinguishing between real and virtual strokes, the obtained trajectories are similar to flat writing. Then the trajectory image is converted into binary format and passed to any handwriting OCR model to obtain recognition results. Due to hardware and Mediapipe-hands calculation speed limitations, when writing speed is fast, recorded strokes appear as dotted intervals, which can affect the writing quality. Therefore, after each stroke is completed (lifting action), each point coordinate is calculated, and gaps are filled if they are too large.

III. Experimental Results

In this study, a comparative experimental analysis was conducted to evaluate the effectiveness of different methods for recognizing Chinese characters written in the air. The experiment utilized different handwriting input trajectories, namely, those with and without virtual strokes, and tested them with different handwriting recognition models, including Google Input API and Google Cloud Vision, for cross-comparison. Ten traditional Chinese words were designed with varying levels of difficulty to compare the recognition accuracy and input speed of each method. Since the deep learning models used in this study were all pre-trained models, we don't have to prepare additional dataset for training.

A. *Comparative results*

This study focuses on enhancing input methods by enabling users to avoid generating virtual strokes before recognition. The recognition results are compared using a series of comparative tests that involve different methods, as shown in Table 1. A fingertip detection method proposed by Chen et al. [1] was re-implemented in this study for comparison purposes. This method was chosen because it is highly similar to the approach used in this study, with both involving in-air fingertip tracking and subsequent processing by handwriting recognition models. The fundamental difference between the two methods is the presence or absence of virtual strokes, which allows us to effectively determine the impact of virtual strokes on the recognition model.

Three participants with varying levels of understanding of the presented system were arranged to conduct the test. The first participant was proficient in all four methods used in the experiment, having practiced specifically for many days. The second participant was informed of the four methods in

advance and had one day of practice. The third participant was tested directly after being explained the four methods during the initial experiment. During the test, all three participants used the four methods to input the samples designed in Table 2. In addition to the accuracy of the model, the stroke input time was calculated by dividing the input time of each question by the stroke count of that question. This was used as the evaluation indicator for the accuracy and input efficiency of this cross-comparison test. Results are shown in Table 3 to Table 5.

Table 1. Combinations of stroke type and OCR model.

Methods	Combinations
Method 1	Real stroke + virtual stroke + Google Input API
Method 2	Real stroke + virtual stroke + Google Cloud Vision
Method 3	Real stroke + Google Input API
Method 4	Real stroke + Google Cloud Vision

Table 2. Samples used in the experiment. Note that the input samples are Chinese characters in practice.

Input samples	Characteristics	# of strokes
我	Single character	7

	With virtual stroke		Without virtual stroke	
Accuracy	40%		96%	
time(s)	3.27		6.05	

B. Discussions

The results of this study demonstrated that Method 1 outperformed Method 4 with an average increase of 12.7% in accuracy across three participants. Furthermore, the Google Input API exhibited better recognition results than the Google Cloud Vision, with a minimum recognition accuracy of 59% when virtual strokes were included. Contrasively, eliminating virtual strokes significantly improved accuracy compared to including them, with an increase of 37%. This was particularly true for inexperienced subjects, who experienced an increase of 56% in accuracy. However, writing without virtual strokes was significantly slower than writing with virtual strokes, with an increase of approximately 2.6 seconds in input time per stroke. This was due to the subjects needing to lift their index fingers to avoid generating virtual strokes.

A follow-up experiment was conducted with the same subjects one week later. In the second experiment, accuracy fluctuated greatly when virtual strokes were included across the three participants, with Personnel 1 and Personnel 3 experiencing fluctuations of over 20% and high uncertainty in recognition. However, when eliminating virtual strokes, all participants achieved an accuracy rate of 90% or higher in the experiments, which was more stable. After training, Personnel

2 and Personnel 3 significantly reduced their input time, with an average decrease of 1 second and an average stroke time of 5.87 seconds, while maintaining an accuracy rate of 90% or higher. These results demonstrated that the proposed method can maintain recognition accuracy for those who are unfamiliar with in-air handwriting.

IV. CONCLUSIONS

This study presents an approach to resolve the challenge of recognizing Chinese characters written in the air. The proposed method utilizes an intuitive interface that effectively eliminates virtual strokes, allowing users to clearly distinguish between real and virtual strokes while writing. Handwriting trajectories almost exclusively include real strokes, resulting in high recognition accuracy even for inexperienced users of air handwriting input methods. The proposed method also allows users to correct stroke errors, reducing user stress and providing a more natural and intuitive input method. The virtual stroke-free approach is close to flat writing and is not affected by stroke order, reducing error rates and lowering the data collection threshold for building a recognition model for traditional Chinese air handwriting. Furthermore, the proposed method utilizes RGB images, reducing the hardware threshold for reproducing this technology. Overall, this study presents a significant contribution to the field of contactless handwriting recognition input methods, particularly in the post-COVID-19 era, where such methods have gained importance due to their natural and intuitive input capabilities without physical contact with devices.

***Abstract*— This paper represents the EffSegmentNet, which is a powerful real-time semantic segmentation model. It consists of two segments: (1) A novel MetaFormer-based encoder, termed the EffVisionFormer, is introduced. It captures multiscale image features efficiently. (2) A lightweight decoder which utilizes multiscale image features from the encoder is applied to conduct rapid yet accurate segmented result. The proposed EffSegmentNet achieves remarkable performance which takes the inference speed, accuracy, and model parameters into account. On the Cityscapes test set, we attain 71.9% mIoU with 195.1 frames per second (FPS) on a NVIDIA RTX 2080Ti card. Furthermore, the proposed EffSegmentNet utilizes only 4.4 million parameters, which demonstrates its advantage on real-time segmentation.**

I. INTRODUCTION

Semantic segmentation, a fundamental task in the field of computer vision, involves assigning pixel-level labels to images. Its applications span video surveillance, autonomous driving, medical image processing, etc., which demand the models to inference rapidly and accurately.

To meet these demands, researchers have proposed various real-time models based on Fully Convolutional Networks (FCNs), such as DFANet [4], BiSeNetV1 [5], and BiSeNetV2 [6]. While these methods satisfy the requirements for fast inference speed and up to par segmentation accuracy, they struggle to capture long-range image information due to their limited receptive fields.

Recently, transformer-based methods have demonstrated great prospects and have outperformed FCN-based methods in some cases. The encoders of transformer-based methods offer larger receptive fields, enabling the extraction of global contextual information. Due to their powerful ability to capture image information, their number of parameters have the potential to be compressed while fulfilling the demands for low-latency and satisfactory segmentation accuracy.

However, the Multi Head Self Attention (MHSA) mechanism at the core of transformers is computationally expensive, which is quadratic to the number of tokens. Models like Swin Transformer [11] and Twins [12] have addressed this challenge by introducing window-based self-attention, reducing computational complexity from quadratic to linear while maintaining performance. Although such designs are much more efficient theoretically, they are difficult to be deployed with TensorRT [1] or mobile devices.

In 2021, the introduction of spatial MLPs [13] as token mixers emerged as an alternative to attention mechanisms, achieving competitive results on image classification benchmarks. This development raised questions about the necessity of attention-based token mixers in image understanding. In 2022, a paper introduced the concept of the MetaFormer [14], a general structure derived from the Transformer, omitting the specification of the token mixer component but still achieving competitive performance.

This paper introduces EffSegmentNet, a powerful semantic segmentation model which considers FPS, number of parameters and accuracy. Our main contributions can be concluded as follows:

- EffVisionFormer, an innovative MetaFormer-based encoder, is introduced to capture robust multiscale information of images. It features a unique token mixer design that integrates local spatial MLP and global efficient attention mechanism, enabling the efficient extraction of rich contextual information.
- A thoughtfully-crafted lightweight decoder which aggregates hierarchical image information from the encoder to conduct

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

precise segmented prediction rapidly.

- Our method demonstrates its remarkable performance on the number of parameters, FPS, and segmentation accuracy. EffsegmentNet attains 71.9% mIoU on the Cityscapes test set, while maintaining a prompt inference speed of 195.1FPS on one NVIDIA GTX 2080Ti card. Moreover, the EffsegmentNet leverages only 4.4 million parameters, showcasing its superiority over other real-time alternatives.

II. Related Work

Semantic segmentation aims to categorize each pixel in an image into its corresponding class. The pioneering work of deep learning methods for semantic segmentation is FCN [2], which is a fully convolutional network that enables end-to-end pixel-to-pixel classification. Since then, extensive research [3, 4, 5, 6, 7, 16, 17] has been dedicated to improve FCN [2], which includes non-real-time and real-time methods. Real-time methods like ICNet [3], DFANet [4], BiSeNet [5], and BiseNetV2 [6] consider both the inference speed and the segmentation accuracy, making them suitable for applications requiring fast inference.

In 2020, the transformer architecture was introduced to vision tasks by Dosovitskiy et al [8]. Subsequently, numerous studies have emerged aiming to improve the transformer architecture specifically for vision tasks. DeiT [9] enhanced the training pipeline by distillation, thereby eliminating the requirement for extensive pretraining. PVT [10] introduced the pyramid structure into the transformer, creating the opportunity to leverage the Transformer model instead of the CNN model for dense vision prediction tasks like semantic segmentation. Building upon PVT's foundation [10], Swin Transformer [11] and Twins [12] adopted the pyramid structure and alleviated the computational complexity of the attention mechanism. ResMLP [13] challenged the necessity of the attention-based token mixer and introduced an alternative known as the spatial MLP token mixer. Drawing inspiration from the spatial MLP token mixer and other research works, the MetaFormer [14] concept emerged, asserting that token mixer design can be versatile and not limited to attention-based token mixers. In line with this concept, PoolFormer [14] was introduced, utilizing pooling as a simple token mixer and achieving competitive performance compared to other approaches that employ more intricate attention-based token mixers. Building upon the MetaFormer [14] concept and existing research, following works such as EfficientFormer [28] and EfficientFormerV2 [29] were proposed. These approaches leverage the pyramid structure and employ distinct token mixers at different stages of the network pipeline. Early stages utilize lightweight token mixers, such as pooling or depthwise convolution, for extracting low-level features (local information). This sophisticated design enables these models to excel in image classification tasks, boasting low latency and high parameter efficiency. These transformer-derived methods showcase their remarkable ability to extract image features, making them highly proficient in image classification tasks and well-suited as encoders for semantic segmentation.

III. Proposed Method

In this section, we introduce the EffSegmentNet, a powerful, and efficient real-time framework for semantic segmentation. Our encoder, EffVisionFormer, employs the pyramid structure and utilizes various token mixers at different stages of the network pipeline, aligning with the concepts of previous works. The core aspect of the encoder architecture lies in the meticulous design of token mixers in the late stages of the network pipeline, enabling efficient capture of global information. Our compact decoder architecture fuses spatial feature maps and contextual feature maps effectively to generate the semantic segmentation result. The overall architecture design is illustrated in Fig. 1.

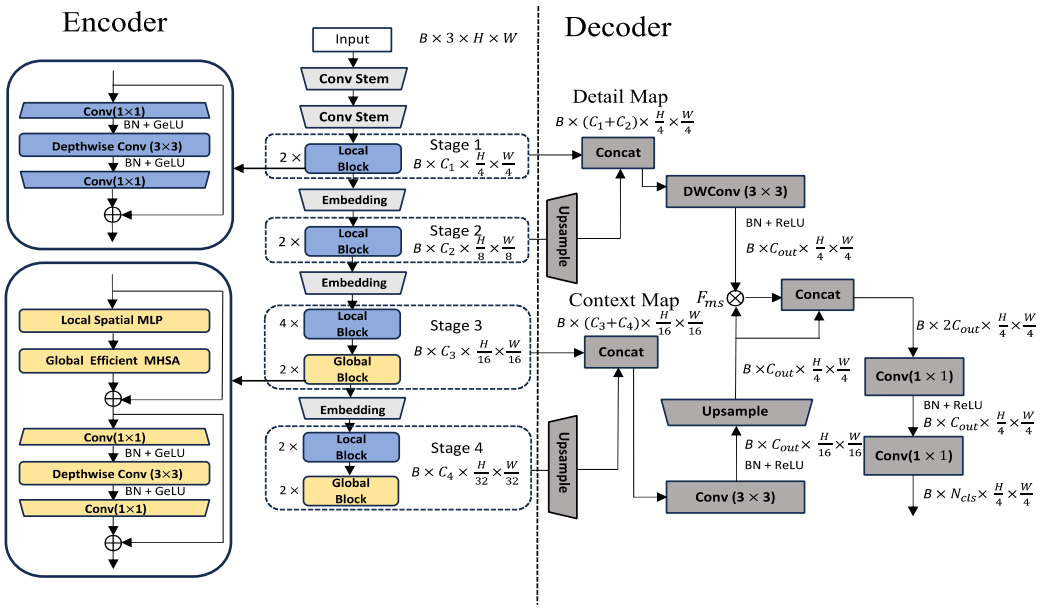
A. Encoder

As shown in Fig. 1(a), our sophisticated designed encoder, EffVisionFormer, includes convolutional stems, embedding layers, and two distinct block types: local blocks and global blocks. The convolutional stem efficiently downsamples the input using a 3×3 convolution with stride 2, followed by batch normalization (BN) and ReLU. After two convolutional stems, the resolution is reduced to 1/4 of the input resolution. The embedding layer is located between two adjacent stages. It reduces the resolution by half through a 3×3 convolution with a stride of 2 and BN.

The local block, as introduced in [29], is a variant of the MetaFormer block [14]. This variant [29] employs the depthwise convolution as a token mixer and positions it between two 1×1 convolutional layers to further enhance the ability of extracting local information. This configuration can be seen as integrating the local token mixer between two feedforward layers of the channel MLP in the MetaFormer block [14]. The essence of our design lies in the global block, which is placed in the last two stages of the encoder. The global block follows a similar architecture to the MetaFormer block [14], comprising two stages: the first stage features a meticulously-designed global token mixer, and the second stage employs the local block. In the global block, we employ

the local block as the improved version of the channel MLP, allowing the global block to extract a greater amount of information.

The token mixer of the global block contains two components. The first component is Local Spatial MLP. The original spatial MLP introduced in [13] utilizes a fully connected linear layer to exchange information across patches (tokens). Given a feature map F^{3D} of dimension $h \times w \times C$, where h represents height, w denotes the width, and C indicates the number of channels, the feature map F^{3D} needs to be flattened into F^{2D} with dimension $N \times C$ in order to feed it to the original spatial token mixer [13]. Here, N is defined as the number of input tokens (nodes) and is calculated as $N = h \times w$. The original spatial token mixer linearly projects N nodes to N nodes, resulting in the computational complexity of $O(N^2)$, which is computationally expensive. To solve this issue, our Local Spatial MLP design partitions the input tokens into R groups, with each group containing N/R input tokens. We assume that the total number of input tokens, N, are divisible by R. Within each group, a local fully-connected linear layer, which projects N/R nodes to N/R nodes, is applied to enable information exchange among N/R patches. The computational complexity of a local fully-connected linear layer for each group is $O(N^2/R^2)$, resulting in a total computational complexity of $O(N^2/R^2 \times R) = O(N^2/R)$ for R groups. This represents a reduction in computational complexity compared to the original spatial token mixer [13].



Moreover, when processing high-resolution inputs with the Local Spatial MLP design, we employ three local fully-connected linear layers, denoted as $f_{1,i}$, $f_{2,i}$, and $f_{3,i}$ for each group to further decrease the total computational complexity, where i denotes the i^{th} group. The first layer, $f_{1,i}$, linearly projects N/R nodes to N_c/R nodes, where $N_c = \alpha \times N$ with $0 < \alpha < \sqrt{2} - 1$ and $N_c \in \mathbb{N}$. The computational complexity of this layer is $O(NN_c/R^2)$. The second layer, $f_{2,i}$, linearly projects N_c/R nodes to N_c/R nodes. The computational complexity of this layer is $O(N_cN_c/R^2)$. The third layer, $f_{3,i}$, linearly projects N_c/R nodes to N/R nodes with the computational complexity of $O(NN_c/R^2)$. In a generic scenario, we assume that $N\%R = 0$ and $N_c\%R = 0$. The combined complexity of the three fully connected layers for each group is $O(N_c \times (N_c + 2N)/R^2)$, which leads to the total computational complexity of $O(N_c \times (N_c + 2N)/R) = O(\alpha N \times (\alpha N + 2N)/R) = O((\alpha^2 + 2\alpha)N^2/R)$. Based on the mathematical deduction, it becomes evident that the computational complexity can be further diminished when the condition $0 < \alpha^2 + 2\alpha < 1$ is satisfied. Solving the equation, we find that the requirement holds true when $0 < \alpha < \sqrt{2} - 1$.

Despite the computational efficiency provided by the Local Spatial MLP design, its information exchange is limited to tokens within the same groups. This limitation results in a smaller receptive field, affecting overall performance. To overcome this challenge, we introduce the Global Efficient MHSA as the second component of the token mixer of the global block. The Global Efficient MHSA enables the exchange of information between different groups, effectively resolving the issue. The attention process of the multi-head self-attention is formulated as:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_{head}}}\right)V, \quad (1)$$

where Q, K, V have dimensions of $n_{head} \times N \times d_{head}$. Here, n_{head} denotes the number of heads, N represents the number of tokens, and d_{head} is defined as the number of channels per head. The product of n_{head} and d_{head} is equal to C, which represents the total number of channels. The computational complexity of this process is $O(N^2)$, which indicates that it has a quadratic relationship with the number of tokens N. This quadratic complexity can be computationally expensive, especially for large values of N. In the Local Spatial MLP component, the N input tokens are divided into R groups, and the relationships among input tokens within each group are computed, generating N output tokens. These N output tokens are then utilized as Q in the Global Efficient MHSA module, with the dimensions of $n_{head} \times N \times d_{head}$. Additionally, the N/R output tokens from each group are averaged to obtain a group representative for each group. With the presence of R groups, R group representatives are produced, which fullfill the roles of K and V. As a result, the dimensions of K and V are reduced from $n_{head} \times N \times d_{head}$ to $n_{head} \times R \times d_{head}$. By employing this approach, the computational complexity of Global Efficient MHSA is $O(NR)$, which exhibits significant reduction in computational cost when $R \ll N$. In summary, the total computational complexity of the Local Spatial MLP and the Global Efficient MHSA is $O((\alpha^2+2\alpha)N^2/R + NR)$. To reduce the computational complexity, we choose $0 < \alpha < \sqrt{2} - 1$ and ensure that R is less than N. Selection of α and R directly influences the extent of computational complexity reduction.

Table 1 illustrates the architectural setting of the encoder designed for ImageNet-1K [31], which is a prominent image classification dataset. The input resolution of this structure is

(a) The architecture of the encoder (b) The architecture of the decoder

Fig. 1 The overall architecture of the EffSegmentNet. (a) The hierarchical encoder of the EffSegmentNet that extracts low-level and high-level image information. (b) The lightweight decoder of the EffSegmentNet that fuses multi-level features to conduct the semantic segmentation prediction.

224 × 224, and due to the relatively smaller image resolution, we employ a single fully connected linear layer for each group in the Local Spatial MLP Module.

On the other hand, Table 2 showcases the architectural configuration of the encoder tailored for Cityscapes [32], a prevalent dataset used for semantic segmentation tasks. The input resolution of this architecture is 512 × 1024, and owing to the higher image resolution, we utilize three fully connected linear layers for each group in the Local Spatial MLP module to further reduce the computational complexity. Although the two architectures share a similar design, the notable difference lies in the number of fully connected linear layers employed per group in the Local Spatial MLP Module. The hyper-parameters of our encoder are listed as follows:

- K: the kernel size utilized for Patch Embed;
- S: the stride value utilized for Patch Embed;
- C: the number of output channels at each stage;
- Q: the quantity of each type listed in Table;
- E: the expansion ratio of the local block;
- R: the number of groups in the Local Spatial MLP Module;
- F: the number of fully connected linear layers for each group in the Local Spatial MLP Module;
- α: the reduction ratio as illustrated above, its value falls within the open interval $(0, \sqrt{2}-1)$;
- N_c: $\alpha \times N$, where N is the number of tokens inputted into the Local Spatial MLP Module and $N_c \in \mathbb{N}$.

B. *Decoder*

The decoder plays a crucial role in aggregating the multiscale features generated by the encoder. Inspired by the Bilateral Guided Aggregation Layer in [6], we have developed a more streamlined decoder architecture. In order to capture detailed spatial information, we employ a combination of the output from stage 1 and stage 2 of the encoder. While the output from stage 1 remains unaltered, the output from stage 2 is subjected to a *2x* upsampling. These two outputs are then concatenated together to form the detail map. To further enhance the detail information, we apply depthwise convolution, batch normalization (BN) and ReLU operations to the detail map, allowing us to capture plentiful spatial details.

To capture abundant context information, our approach involves utilizing both the output from stage 3 and stage 4 of the encoder. While the output from stage 3 remains unchanged, the output from stage 4 undergoes a *2x* upsampling. These two outputs are then concatenated together to form the context map. To further strengthen the contextual information, we apply convolution, batch normalization (BN) and ReLU operations to the context map, enabling us to capture a rich array of semantic information. Next, we perform element-wise multiplication between the detail information and the contextual information to obtain the feature map $F_{multiscale}$ (F_{ms}), which contains a wealth of multiscale information. To further enrich the feature map F_{ms}, we concatenate it with the contextual information

Table 1. The configuration of the encoder designed for ImageNet-1K.

Stage	Output size	Type	Parameters		
Image	224 × 224				
Stem 1	112 × 112	Patch Embed	K = 3, S = 2, Q = 1, C = 16		
Stem 2	56 × 56	Patch Embed	K = 3, S = 2, Q = 1, C = 32		
1	56 × 56	Local Block	Q = 2, C = 32, E = [4,4]		
2	28 × 28	Patch Embed	K = 3, S = 2, Q = 1, C = 64		
		Local Block	Q = 2, C = 64, E = [4,4]		
3	14 × 14	Patch Embed	K = 3, S = 2, Q = 1, C = 128		
		Local Block	Q = 4, C = 128, E = [4,3,3,3]		
		Global Block	Q = 2, C = 128	Token Mixer	R = 4, F = 1
				Local Block	E = [4,4]
4	7 × 7	Patch Embed	K = 3, S = 2, Q = 1, C = 224		
		Local Block	Q = 2, C = 224, E = [4,3]		
		Global Block	Q = 2, C = 224	Token Mixer	R = 1, F = 1
				Local Block	E = [3,4]

and apply the 1 × 1 convolution, BN and ReLU operations.

Finally, we utilize a 1 × 1 convolutional layer to reduce the number of channels to match the number of classes N_{cls} in the dataset. In the case of the Cityscapes dataset, N_{cls} is set as 19. The overall architecture design of the decoder is illustrated in Fig. 1(b). Regarding the hyper-parameter configuration of the decoder, we set C_{out} to 320, and remarkably, the decoder consists of only 1.2 million parameters.

IV. Experimental Results

A. Datasets

We employ two datasets for evaluation: ImageNet-1K [31] and Cityscapes [32]. The ImageNet-1K [31] dataset is used to evaluate the effectiveness of our proposed encoder, EffVisionFormer. On the other hand, the Cityscapes [32] is utilized to assess the performance of our semantic segmentation framework, EffSegmentNet.

The ImageNet-1K [31] dataset is widely regarded as the most popular image classification dataset, which contains 1.28 million training images and 50000 validation images distributed across 10000 different classes.

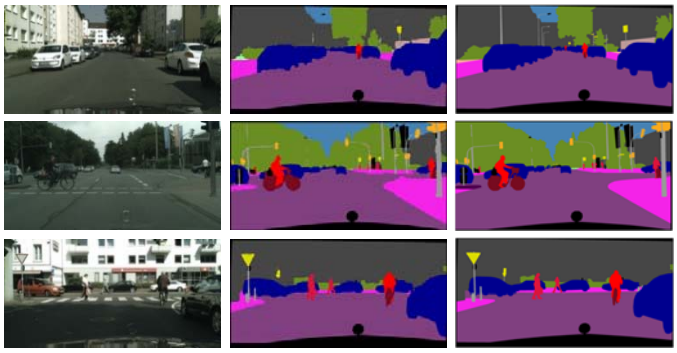
Cityscapes [32] is an urban segmentation dataset specifically designed for driving scenarios. It contains a total of 5000 images with fine annotations, out of which 2975 images are used for training, 500 images for validation and 1525 images for testing.

Table 2. The configuration of the encoder designed for Cityscapes.

Stage	Output size	Type	Parameters		
Image	512 × 1024				
Stem 1	256 × 512	Patch Embed	K = 3, S = 2, Q = 1, C = 16		
Stem 2	128 × 256	Patch Embed	K = 3, S = 2, Q = 1, C = 32		
1	128 × 256	Local Block	Q = 2, C = 32, E = [4,4]		
2	64 × 128	Patch Embed	K = 3, S = 2, Q = 1, C = 64		
		Local Block	Q = 2, C = 64, E = [4,4]		
3	32 × 64	Patch Embed	K = 3, S = 2, Q = 1, C = 128		
		Local Block	Q = 4, C = 128, E = [4,3,3,3]		
		Global Block	Q = 2, C = 128	Token Mixer	R = 4, F = 3, $\boldsymbol{\alpha}$ = 0.096, $\boldsymbol{N_c}$ = 196
				Local Block	E = [4,4]
4	16 × 32	Patch Embed	K = 3, S = 2, Q = 1, C = 224		
		Local Block	Q = 2, C = 224, E = [4,3]		
		Global Block	Q = 2, C = 224	Token Mixer	R = 1, F = 3, $\boldsymbol{\alpha}$ = 0.096, $\boldsymbol{N_c}$ = 49
				Local Block	E = [3,4]

B. Implementation Details

We train the model on a NVIDIA RTX 2080Ti card and a NVIDIA GTX 1080Ti card using CUDA 11.8, CUDNN 8.6.0. During inference, the model is run on a NVIDIA RTX 2080Ti card, utilizing CUDA 11.8, CUDNN 8.6.0, and TensorRT 8.5.3.1. A batch size of 1 is used to evaluate the computational capacity of our method.



Initially, we pretrain the encoder on the ImageNet-1K dataset with an input image resolution of 224 × 224. The pretraining process involves training the encoder for 300 epochs using an AdamW optimizer, a cosine annealing rate scheduler, and a linear warmup period of 5 epochs. A batch size of 1024, an initial learning rate of 0.001, and a weight decay of 0.025 are employed. Due to limited computational resources, the batch size on each card is set to 128. To simulate a batch size of 1024, we utilize gradient accumulation with accumulation steps of 4. During training, we incorporate various data augmentation and regularization strategies from [9], including Rand Augment, random erasing, Mixup, Cutmix, and label smoothing. However, due to limited computational resources, we do not employ the distillation approach of [9] to further enhance the accuracy of the model.

Table 3. Comparisons with other state-of-the-art real time semantic segmentation frameworks on Cityscapes. The table provides information on the input resolution and the GPU utilized for inference of each method.

Model	Encoder	Resolution	mIoU(%)		FPS	Params	GPU
			val	test

(a) Input (b) EffSegmentNet (c) Groundtruth

Fig. 2 Visualizations of multiple semantic segmentation results generated by the EffSegmentNet on the Cityscapes validation set. The figure consists of three columns: (a) shows the input images, (b) displays the predicted results obtained by the EffSegmentNet, and (c) represents the corresponding groundtruths of the input images.

Following the pretraining, we proceed to train the pretrained encoder in combination with the decoder on Cityscapes [32], using an input resolution of 512 × 1024. The EffSegmentNet is trained for 160000 iterations, employing an AdamW optimizer, a poly linear rate scheduler, and a linear warmup period of 1500 iterations. A batch size of 8, an initial learning rate of 0.00006, and a weight decay of 0.01 is used. During the training phase, we utilize multiple data augmentation methods to enhance the model's performance. In addition, we also adopt OHEM (Online Hard Example Mining) [33] and auxiliary losses to further boost the model's performance. It is notable that the model is trained on the training set and validation set

when evaluating on the test set.

C. Evaluation Metrics

To assess the performance of the backbone on the ImageNet-1K dataset [31], we employ top-1 accuracy, parameters and floating point operations (FLOPs) as the evaluation metrics. For evaluating the performance of the segmentation framework, we utilize mean intersection over union (mIoU), parameters, and frames per second (FPS).

D. Comparisons to State-of-the-Arts

In this section, we evaluate our backbone, EffVisionFormer, against existing methods on ImageNet-1K [31], and we compare the EffSegmentNet with other methods on Cityscapes [32].

In Table 3, we provide comparisons between the EffSegmentNet and other state-of-the-art real-time semantic segmentation frameworks on Cityscapes [32]. The images in the Cityscapes dataset [32] have a resolution of 1024 × 2048. During the inference phase, we first resize the image resolution to 512 × 1024 and input it into EffSEgmentNet. Then we upsample the prediction of EffSEgmentNet to restore it to the original resolution of 1024 × 2048. This entire process is accounted for in the measurement of inference time.

Upon analyzing the data provided in Table 3, it becomes apparent that our method strikes a commendable equilibrium between multiple evaluation metrics, including mIoU, FPS, and parameters. The EffSegmentNet attains a decent mIoU score of 71.9% on the Cityscapes test set, accompanied by a high FPS of 195.1, indicating its efficiency in processing images in real-time scenarios. Notably, these impressive results are achieved with a relatively small parameter count of 4.4 million, showcasing the effectiveness of our approach in efficiently utilizing computational resources. When compared to other methods with similar number of parameters, our method outperforms in terms of mIoU and FPS.

Examining Table 4 reveals that while our backbone does not attain the highest accuracy when compared to other lightweight backbones, it still delivers competitive performance with its relatively small parameters size.

To provide additional insights, Fig. 2 visualizes multiple semantic segmentation results, which show the model's ability in performing semantic segmentation tasks.

V. Conclusions

This paper introduces EffSegmentNet, a lightweight and powerful semantic segmentation model which comprises a hierarchical encoder, EffVisionFormer, and a compact decoder. The innovative design of the token mixer, combining Local Spatial MLP and Global Efficient MHSA, enables the encoder to capture global information efficiently. Moreover, the decoder is meticulously designed to effectively fuse the multiscale information obtained from the encoder. As a result, EffSegmentNet achieves an excellent equilibrium between mIoU, FPS, and parameters when compared to other state-of-the-art real time methods, making it a promising solution for various real-world semantic segmentation applications.

***Abstract*—The closed-form linear canonical Wigner distribution (CFLCWD), equipped with nine linear canonical transform (LCT) free parameters, is an effective time-frequency method suitable for extracting the principal features of linear frequency-modulated signals from an extreme strong stationary Gaussian noise background. However, the appropriate parameters for non-stationary non-Gaussian noise jamming nonlinear frequency-modulated signal processing are still unknown. To address this issue, we reveal the equivalence of the uncertainty product in CFLCWD domains and those in LCT domains, based on which we deduce the CFLCWD's uncertainty inequality, whose equality is achieved by a Gaussian signal. We further derive the universal optimal LCT free parameters with which the CFLCWD reaches the highest-resolution in time-frequency plane. In particular, the strong uncertainty inequality of the classical Wigner distribution is also revisited.**

I. Introduction

Wigner distribution (WD) is a mother distribution of the celebrated Cohen's class distribution [1], [2]. It acts a fundamental role in non-stationary signal time-frequency analysis [3], [4]. Many fundamental results of the WD are presently established, for example uncertainty principles [5]–[12] which are of importance in time-frequency analysis. Uncertainty inequalities of the WD given by [5], [11] are essentially the classical Heisenberg's results [2], [13]–[16]. The attainable lower bound derived is none other than Planck constant which imposes limits on the WD's resolution in time-frequency plane.

With the techniques of parametric time-frequency analysis, many attempts [17]–[28] have recently been made to introduce free parameters of the linear canonical transform (LCT) into the ordinary WD to break the traditional time-frequency resolution limit. The closed-form linear canonical Wigner distribution (CFLCWD) is a representative variation among them [29]. It equips three parameter matrices, i.e., nine LCT free parameters. Due to more degrees of freedom, the CFLCWD exhibits better detection performance on linear frequency-modulated signals corrupted with an extreme strong stationary Gaussian noise [30]–[33]. Namely, it is able to achieve higher resolution for this kind of noisy signals in time-frequency plane.

Despite the CFLCWD's advantage in time-frequency analysis, there remains a serious challenge in the use of it to non-stationary non-Gaussian noises jamming nonlinear frequency-modulated signals processing. Uncertainty principle of a time-frequency distribution yields a lower bound that depends only on the distribution itself [34]. For the CFLCWD, the corresponding lower bound relies merely on the embedded LCT free parameters. Generally speaking, a smaller lower bound yields a higher time-frequency resolution [28]. Uncertainty principle of the CFLCWD thus meets the intrinsic requirement of non-stationary non-Gaussian noise and nonlinear frequency-modulated signal time-frequency superresolution analysis.

In brief, to tackle a challenge in non-stationary non-Gaussian noise jamming nonlinear frequency-modulated signal processing, uncertainty principle of the CFLCWD is a critical foundational technology. The main purpose of the paper is therefore to formulate a universal strategy suitable for general noisy signals through the research of the strong uncertainty inequality of the CFLCWD. The academic contributions of the paper are concluded as follows:

- The paper establishes uncertainty principle of the CFLCWD and obtains an attainable lower bound that relies only on the LCT free parameters embedded in the CFLCWD.
- The paper proposes a universal optimal LCT free parameters selection strategy on non-stationary non-Gaussian noise jamming nonlinear frequency-modulated signal processing.

The rest of the paper is structured as follows. In Section II we collect many primary conceptions and notations on the CFLCWD. In Section III we define the uncertainty product in CFLCWD domains and expound the research question, method, purpose and significance. In Section IV we explore the CFLCWD's uncertainty principle. In Section V we discuss the optimal LCT free parameters of the CFLCWD. In Section VI we draw a conclusion.

II. Closed-form linear canonical Wigner distribution (CFLCWD)

This section mainly reviews the CFLCWD's definition.

Definition 1: The LCT of a signal $f(t) \in L^2(\mathbb{R})$ with the parameter matrix $\mathbf{A} = (a, b; c, d)$ is given by [35]–[39]

$$\widehat{f}_{\mathbf{A}}(u) = \begin{cases} \int_{\mathbb{R}} f(t)\mathcal{K}_{\mathbf{A}}(u,t)\mathrm{d}t, & b \neq 0 \\ \sqrt{d}\mathrm{e}^{\mathrm{j}\frac{cd}{2}u^2} f(du), & b = 0 \end{cases},$$

where

$$\mathcal{K}_{\mathbf{A}}(u,t) = \frac{1}{\sqrt{\mathrm{j}2\pi b}} \mathrm{e}^{\mathrm{j}\left(\frac{d}{2b}u^2 - \frac{1}{b}ut + \frac{a}{2b}t^2\right)}$$

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

denotes the kernel, and where a, b, c, d are real parameters satisfying $ad - bc = 1$.

The LCT is just a combination of scaling operations and square frequency modulation operations for $b = 0$. This specific case is of no interest to us. The paper thus focuses merely on the LCT with $b \neq 0$. Because of $c = \frac{ad-1}{b}$, three free parameters of the LCT are a, b, d.

Let $\widehat{f}_{\mathbf{A}}(v)$ be the LCT of $f(t) \in L^2(\mathbb{R})$ with $\mathbf{A}$, and $\mathcal{K}_{\mathbf{A}_1}(u, v)$ and $\mathcal{K}_{\mathbf{A}^{-1}}(t, v)$ be the kernels with $\mathbf{A}_1$ and $\mathbf{A}^{-1} = (d, -b; -c, a)$, respectively. The LCT is additive:

$$\widehat{f}_{\mathbf{A}_1\mathbf{A}}(u) = \int_{\mathbb{R}} \widehat{f}_{\mathbf{A}}(v)\mathcal{K}_{\mathbf{A}_1}(u, v)\mathrm{d}v$$

and is also invertible:

$$f(t) = \int_{\mathbb{R}} \widehat{f}_{\mathbf{A}}(v)\mathcal{K}_{\mathbf{A}^{-1}}(t, v)\mathrm{d}v.$$

The LCT with $\mathbf{A} = (0, 1; -1, 0)$ reduces to the ordinary Fourier transform (FT) $\widehat{f}(\omega)$.

Proposition 1: Let $\widehat{f}(\omega)$ be the FT of $f(t)$, and $\widehat{f}_{\mathbf{A}}(u)$ be the LCT of $f(t)$ with $\mathbf{A}$. Assuming $f(t) \in L^2(\mathbb{R})$. Then it has $\|f\|_2 = \left\|\widehat{f}\right\|_2 = \left\|\widehat{f}_{\mathbf{A}}\right\|_2$.

Definition 2: Let $\widehat{f}_{\mathbf{A}_k}(u)$ be the LCT of a signal $f(t) \in L^2(\mathbb{R})$ with $\mathbf{A}_k = (a_k, b_k; c_k, d_k)$, $k = 1, 2$, and $\mathcal{K}_{\mathbf{A}}(u, \tau)$ be the kernel with $\mathbf{A} = (a, b; c, d)$. The CFLCWD of the signal $f(t)$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$ is given by [24], [29]–[32]

$$\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u) = \int_{\mathbb{R}} \widehat{f}_{\mathbf{A}_1}\left(t + \frac{\tau}{2}\right)\overline{\widehat{f}_{\mathbf{A}_2}\left(t - \frac{\tau}{2}\right)}\mathcal{K}_{\mathbf{A}}(u, \tau)\mathrm{d}\tau.$$

Remark 1: The CFLCWD with $\mathbf{A}_1 = \mathbf{A}_2 = (1, 0; 0, 1)$ and $\mathbf{A} = (0, 1; -1, 0)$ reduces to the ordinary WD $\mathrm{W}_f(t, \omega)$.

III. Problem formulation

This section introduces some preparatory conceptions on the uncertainty product in CFLCWD domains. It also clarifies the motive and the meaning of the topic research.

A. Definitions of CFLCWD domains spreads and moments

Definition 3: Let $\widehat{f}_{\mathbf{A}}(u)$ be the LCT of $f(t)$ with $\mathbf{A}$. Assuming $f(t), u\widehat{f}_{\mathbf{A}}(u) \in L^2(\mathbb{R})$. Then the LCT domain spread and moment are defined as [40], [41]

$$\triangle\, u_{\mathbf{A}}^2 = \frac{\int_{\mathbb{R}} \left(u - u_{\mathbf{A}}^0\right)^2 \left|\widehat{f}_{\mathbf{A}}(u)\right|^2 \mathrm{d}u}{\|f\|_2^2}, u_{\mathbf{A}}^0 = \frac{\int_{\mathbb{R}} u \left|\widehat{f}_{\mathbf{A}}(u)\right|^2 \mathrm{d}u}{\|f\|_2^2}.$$

Remark 2: The LCT domain spread $\triangle\, u_{\mathbf{A}}^2$ and moment $u_{\mathbf{A}}^0$ reduce respectively to the time domain spread $\triangle\, t^2$ and moment t^0 for $\mathbf{A} = (1, 0; 0, 1)$, and to the FT domain spread $\triangle\, \omega^2$ and moment ω^0 for $\mathbf{A} = (0, 1; -1, 0)$.

Definition 4: Let $\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u)$ be the CFLCWD of $f(t)$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$. Assuming $f(t), t\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u), u\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u) \in L^2(\mathbb{R})$. Then the time-CFLCWD domain spread and moment are defined as

$$\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} = \frac{\iint_{\mathbb{R}^2} \left(t - t^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\right)^2 \left|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u)\right|^2 \mathrm{d}t\mathrm{d}u}{\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2},$$

$$t^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} = \frac{\iint_{\mathbb{R}^2} t \left|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u)\right|^2 \mathrm{d}t\mathrm{d}u}{\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2}.$$

The LCT-CFLCWD domain spread and moment are defined as

$$\triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} = \frac{\iint_{\mathbb{R}^2} \left(u - u^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\right)^2 \left|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u)\right|^2 \mathrm{d}t\mathrm{d}u}{\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2},$$

$$u^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} = \frac{\iint_{\mathbb{R}^2} u \left|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t, u)\right|^2 \mathrm{d}t\mathrm{d}u}{\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2}.$$

Remark 3: The time(LCT)-CFLCWD domain spread $\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}(\triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}})$ and moment $t^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}(u^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}})$ reduce respectively to the time(FT)-WD domain spread $\triangle\, t^2_{\mathrm{W}}(\triangle\, \omega^2_{\mathrm{W}})$ and moment $t^0_{\mathrm{W}}(\omega^0_{\mathrm{W}})$ for $\mathbf{A}_1 = \mathbf{A}_2 = (1, 0; 0, 1)$ and $\mathbf{A} = (0, 1; -1, 0)$.

B. The highest time-frequency resolution of the CFLCWD

Uncertainty principle of the CFLCWD is essentially an inequality that provides an attainable lower bound for the uncertainty product $\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} \triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}$ in CFLCWD domains. This lower bound is usually applied to characterize the CFLCWD's time-frequency resolution limit which is independent of both signal types and noisy types. Uncertainty principle of the CFLCWD is therefore the basic mathematical principle which can reveal the physical mechanism behind the highest-resolution in time-frequency plane triggered by the LCT free parameters.

The paper aims to first formulate an attainable lower bound for $\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} \triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}$, and then investigates the universal optimal parameters with which the CFLCWD reaches the highest-resolution in time-frequency plane by solving the lower bound minimization problem.

IV. Uncertainty principle of the CFLCWD

This section first explores Parseval equality in the CFLCWD domain and the reexpression of the CFLCWD in LCT domains. Then it translates the time(LCT)-CFLCWD domain spread into two LCT domain spreads, based on which it translates the uncertainty product in CFLCWD domains into four uncertainty products in LCT domains. Finally it uses the uncertainty inequality in two LCT domains to deduce the uncertainty inequality in CFLCWD domains.

A. Parseval's relation of the CFLCWD

Lemma 1: Let $\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)$ be the CFLCWD of $f(t)\in L^2(\mathbb{R})$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$. Then it has $\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2 = \|f\|_2^2$.

Proof: From Definition 2, there is

$$\begin{aligned}\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2 =& \iiint_{\mathbb{R}^3} \widehat{f}_{\mathbf{A}_1}\left(t+\frac{\tau}{2}\right)\overline{\widehat{f}_{\mathbf{A}_2}\left(t-\frac{\tau}{2}\right)}\\ &\times\overline{\widehat{f}_{\mathbf{A}_1}\left(t+\frac{\theta}{2}\right)}\widehat{f}_{\mathbf{A}_2}\left(t-\frac{\theta}{2}\right)\\ &\times\left(\int_{\mathbb{R}}\mathcal{K}_{\mathbf{A}}(u,\tau)\overline{\mathcal{K}_{\mathbf{A}}(u,\theta)}\mathrm{d}u\right)\mathrm{d}t\mathrm{d}\tau\mathrm{d}\theta.\end{aligned} \tag{1}$$

Thanks to

$$\int_{\mathbb{R}}\mathcal{K}_{\mathbf{A}}(u,\tau)\overline{\mathcal{K}_{\mathbf{A}}(u,\theta)}\mathrm{d}u = \mathrm{e}^{\mathrm{j}\frac{a}{2b}(\tau^2-\theta^2)}\delta(\tau-\theta)$$

and the sifting of Dirac delta operator δ, Eq. (1) becomes

$$\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2 = \iint_{\mathbb{R}^2}\left|\widehat{f}_{\mathbf{A}_1}\left(t+\frac{\tau}{2}\right)\right|^2\left|\widehat{f}_{\mathbf{A}_2}\left(t-\frac{\tau}{2}\right)\right|^2\mathrm{d}t\mathrm{d}\tau. \tag{2}$$

By taking the change of variables $t=\frac{u+v}{2}$ and $\tau=u-v$, there is

$$\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2 = \left\|\widehat{f}_{\mathbf{A}_1}\right\|_2^2\left\|\widehat{f}_{\mathbf{A}_2}\right\|_2^2. \tag{3}$$

Using Proposition 1 yields $\left\|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}\right\|_2^2 = \|f\|_2^4$. ■

Remark 4: From Remark 1, Lemma 1 reduces to Parseval's relation of the WD: $\|\mathrm{W}_f\|_2 = \|f\|_2^2$.

B. Reexpression of CFLCWD in LCT domains

Lemma 2: Let $\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)$ be the CFLCWD of $f(t)$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$, and $\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_1}(u)$ and $\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_2}(u)$ be the LCTs of $f(t)$ with $\breve{\mathbf{A}}\mathbf{A}_1$ and $\breve{\mathbf{A}}\mathbf{A}_2$, respectively, where $\breve{\mathbf{A}}=(a,b/2;2c,d)$ and $\breve{\mathbf{A}}=(a,-b/2;-2c,d)$. Assuming $f(t)\in L^2(\mathbb{R})$. Then, the CFLCWD can be reexpressed in LCT domains as

$$\begin{aligned}&\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\\ =&2\int_{\mathbb{R}}\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_1}(v)\overline{\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_2}(v-u)}\overline{\mathcal{K}_{\mathbf{A}}(2v-u,2t)}\mathrm{d}v.\end{aligned}$$

Proof: From Definition 2, taking the variable substitution $\tau=2(t-\theta)$ gives

$$\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u) = 2\int_{\mathbb{R}}\widehat{f}_{\mathbf{A}_1}(2t-\theta)\overline{\widehat{f}_{\mathbf{A}_2}(\theta)}\mathcal{K}_{\mathbf{A}}(u,2(t-\theta))\mathrm{d}\theta. \tag{4}$$

Thanks to the additivity and invertibility of the LCT, there is

$$\widehat{f}_{\mathbf{A}_1}(2t-\theta) = \int_{\mathbb{R}}\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_1}(v)\mathcal{K}_{\breve{\mathbf{A}}^{-1}}(2t-\theta,v)\mathrm{d}v,$$

where the parameter matrix $\breve{\mathbf{A}}^{-1}=(d,-b/2;-2c,a)$. By substituting into (4), and because of

$$\mathcal{K}_{\mathbf{A}}(u,2(t-\theta)) = \frac{1}{\sqrt{2}}\mathrm{e}^{-\mathrm{j}\left(\frac{d}{2b}u^2+\frac{2a}{b}t^2-\frac{2}{b}ut\right)}\mathrm{e}^{\mathrm{j}\frac{a}{b}\theta^2}\mathcal{K}_{\breve{\mathbf{A}}}(u,2t-\theta),$$

it follows that

$$\begin{aligned}&\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\\ =&\sqrt{2}\mathrm{e}^{-\mathrm{j}\left(\frac{d}{2b}u^2+\frac{2a}{b}t^2-\frac{2}{b}ut\right)}\int_{\mathbb{R}}\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_1}(v)\\ &\times\left(\int_{\mathbb{R}}\overline{\widehat{f}_{\mathbf{A}_2}(\theta)}\mathrm{e}^{\mathrm{j}\frac{a}{b}\theta^2}\mathcal{K}_{\breve{\mathbf{A}}}(u,2t-\theta)\mathcal{K}_{\breve{\mathbf{A}}^{-1}}(2t-\theta,v)\mathrm{d}\theta\right)\mathrm{d}v.\end{aligned} \tag{5}$$

Due to

$$\begin{aligned}&\mathrm{e}^{\mathrm{j}\frac{a}{b}\theta^2}\mathcal{K}_{\breve{\mathbf{A}}}(u,2t-\theta)\mathcal{K}_{\breve{\mathbf{A}}^{-1}}(2t-\theta,v)\\ =&\frac{1}{\sqrt{\mathrm{j}\pi b}}\frac{\overline{\sqrt{-\mathrm{j}\pi b}}}{\sqrt{-\mathrm{j}\pi b}}\mathrm{e}^{\mathrm{j}\frac{d}{b}u^2}\mathrm{e}^{-\mathrm{j}\frac{4}{b}ut}\\ &\times\mathrm{e}^{-\mathrm{j}\frac{d}{b}v^2}\mathrm{e}^{\mathrm{j}\frac{4}{b}vt}\mathrm{e}^{-\mathrm{j}\frac{d}{b}(v-u)^2}\overline{\mathcal{K}_{\breve{\mathbf{A}}}(v-u,\theta)}\end{aligned}$$

and the additivity of the LCT, Eq. (5) turns into

$$\begin{aligned}&\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\\ =&\frac{2}{\sqrt{\mathrm{j}2\pi b}}\frac{\overline{\sqrt{-\mathrm{j}\pi b}}}{\sqrt{-\mathrm{j}\pi b}}\mathrm{e}^{-\mathrm{j}\left(-\frac{d}{2b}u^2+\frac{2a}{b}t^2+\frac{2}{b}ut\right)}\\ &\times\int_{\mathbb{R}}\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_1}(v)\overline{\widehat{f}_{\breve{\mathbf{A}}\mathbf{A}_2}(v-u)}\mathrm{e}^{-\mathrm{j}\frac{d}{b}v^2}\mathrm{e}^{\mathrm{j}\frac{4}{b}vt}\mathrm{e}^{-\mathrm{j}\frac{d}{b}(v-u)^2}\mathrm{d}v.\end{aligned}$$

With a relation

$$\begin{aligned}&\mathrm{e}^{-\mathrm{j}\left(-\frac{d}{2b}u^2+\frac{2a}{b}t^2+\frac{2}{b}ut\right)}\mathrm{e}^{-\mathrm{j}\frac{d}{b}v^2}\mathrm{e}^{\mathrm{j}\frac{4}{b}vt}\mathrm{e}^{-\mathrm{j}\frac{d}{b}(v-u)^2}\\ =&\overline{\sqrt{\mathrm{j}2\pi b}}\,\overline{\mathcal{K}_{\mathbf{A}}(2v-u,2t)},\end{aligned}$$

we arrive the conclusion. ■

Remark 5: From Remark 1 and Lemma 2, the WD can be reexpressed in the FT domain as $\mathrm{W}_f(t,\omega) = \sqrt{\frac{2}{\pi}}\int_{\mathbb{R}}\widehat{f}(v)\overline{\widehat{f}(2\omega-v)}\mathrm{e}^{2\mathrm{j}(v-\omega)t}\mathrm{d}v$.

C. Time-CFLCWD domain spread

Lemma 3: Let $\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)$ be the CFLCWD of $f(t)$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$. Assuming $f(t), u\widehat{f}_{\mathbf{A}_k}(u), t\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\in L^2(\mathbb{R})$, $k=1,2$. Then the time-CFLCWD domain spread can be expressed by the LCT domain spreads:

$$\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} = \frac{\triangle\, u^2_{\mathbf{A}_1}+\triangle\, u^2_{\mathbf{A}_2}}{4}. \tag{6}$$

Proof: Similar to (1)–(3), there is

$$\begin{aligned}&\iint_{\mathbb{R}^2} t\left|\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\right|^2\mathrm{d}t\mathrm{d}u\\ =&\iint_{\mathbb{R}^2} t\left|\widehat{f}_{\mathbf{A}_1}\left(t+\frac{\tau}{2}\right)\right|^2\left|\widehat{f}_{\mathbf{A}_2}\left(t-\frac{\tau}{2}\right)\right|^2\mathrm{d}t\mathrm{d}\tau\\ =&\frac{\iint_{\mathbb{R}^2}(u+v)\left|\widehat{f}_{\mathbf{A}_1}(u)\right|^2\left|\widehat{f}_{\mathbf{A}_2}(v)\right|^2\mathrm{d}u\mathrm{d}v}{2}.\end{aligned}$$

Thanks to Lemma 1, it follows that

$$\begin{aligned}t^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} =&\frac{\iint_{\mathbb{R}^2}(u+v)\left|\widehat{f}_{\mathbf{A}_1}(u)\right|^2\left|\widehat{f}_{\mathbf{A}_2}(v)\right|^2\mathrm{d}u\mathrm{d}v}{2\|f\|_2^4}\\ =&\frac{u^0_{\mathbf{A}_1}+u^0_{\mathbf{A}_2}}{2}.\end{aligned} \tag{7}$$

Similarly, we have

$$\begin{aligned}&\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\\ =&\frac{\iint_{\mathbb{R}^2}\left(\frac{u+v}{2}-t^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\right)^2\left|\widehat{f}_{\mathbf{A}_1}(u)\right|^2\left|\widehat{f}_{\mathbf{A}_2}(v)\right|^2\mathrm{d}u\mathrm{d}v}{\|f\|_2^4},\end{aligned}$$

and then it turns into the conclusion (6) because of (7). ■

Remark 6: From Remarks 2 and 3, Eq. (6) reduces to $\triangle\, t^2_{\mathrm{W}}=\frac{\triangle t^2}{2}$.

D. LCT-CFLCWD domain spread

Lemma 4: Let $\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)$ be the CFLCWD of $f(t)$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$, and $\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(u)$ and $\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(u)$ be the LCTs of $f(t)$ with $\check{\mathbf{A}}\mathbf{A}_1$ and $\check{\mathbf{A}}\mathbf{A}_2$, respectively. Assuming $f(t),u\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(u),u\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(u),u\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\in L^2(\mathbb{R})$. Then the LCT-CFLCWD domain spread can be expressed by the LCT domain spreads:

$$\triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}=\triangle\, u^2_{\check{\mathbf{A}}\mathbf{A}_1}+\triangle\, u^2_{\check{\mathbf{A}}\mathbf{A}_2}. \tag{8}$$

Proof: From Lemmas 1 and 2, there is

$$\begin{aligned}&u^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\\ =&2\iiint_{\mathbb{R}^3}u\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(v)\overline{\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(v-u)\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(w)}\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(w-u)\\ &\times\left(\int_{\mathbb{R}}\mathcal{K}_{\mathbf{A}}(2w-u,t)\overline{\mathcal{K}_{\mathbf{A}}(2v-u,t)}\mathrm{d}t\right)\mathrm{d}u\mathrm{d}v\mathrm{d}w\Big/\|f\|_2^4.\end{aligned} \tag{9}$$

By using

$$\begin{aligned}&\int_{\mathbb{R}}\mathcal{K}_{\mathbf{A}}(2w-u,t)\overline{\mathcal{K}_{\mathbf{A}}(2v-u,t)}\mathrm{d}t\\ =&\mathrm{e}^{\mathrm{j}\frac{d}{2b}\left[(2w-u)^2-(2v-u)^2\right]}\delta(2w-2v)\end{aligned}$$

and the sifting of Dirac delta operator δ, Eq. (9) turns into

$$u^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}=\frac{\iint_{\mathbb{R}^2}u\left|\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(w)\right|^2\left|\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(w-u)\right|^2\mathrm{d}u\mathrm{d}w}{\|f\|_2^4}.$$

Taking the change of variable $u=-\mu+w$ yields

$$\begin{aligned}u^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}=&\frac{\iint_{\mathbb{R}^2}(w-\mu)\left|\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(w)\right|^2\left|\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(\mu)\right|^2\mathrm{d}w\mathrm{d}\mu}{\|f\|_2^4}\\ =&u^0_{\check{\mathbf{A}}\mathbf{A}_1}-u^0_{\check{\mathbf{A}}\mathbf{A}_2}.\end{aligned} \tag{10}$$

Similarly, we have

$$\begin{aligned}\triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}=&\iint_{\mathbb{R}^2}\left(w-\mu-u^0_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\right)^2\\ &\times\left|\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(w)\right|^2\left|\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(\mu)\right|^2\mathrm{d}w\mathrm{d}\mu\Big/\|f\|_2^4,\end{aligned}$$

and then it becomes the conclusion (8) because of (10). ■

Remark 7: From Remarks 2 and 3, Eq. (8) reduces to $\triangle\, \omega^2_{\mathrm{W}}=\frac{\triangle\omega^2}{2}$.

E. Uncertainty product of the time-CFLCWD domain and the LCT-CFLCWD domain spreads

Lemma 5: Let $\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)$ be the CFLCWD of $f(t)$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$, and $\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(u)$ and $\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(u)$ be the LCTs of $f(t)$ with $\check{\mathbf{A}}\mathbf{A}_1$ and $\check{\mathbf{A}}\mathbf{A}_2$, respectively. Assuming $f(t),u\widehat{f}_{\mathbf{A}_1}(u),u\widehat{f}_{\mathbf{A}_2}(u),u\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(u),u\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(u),t\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u),u\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\in L^2(\mathbb{R})$. Then the uncertainty product in CFLCWD domains can be expressed by uncertainty products in LCT domains:

$$\begin{aligned}&\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\\ =&\Big(\triangle\, u^2_{\mathbf{A}_1}\triangle\, u^2_{\check{\mathbf{A}}\mathbf{A}_1}+\triangle\, u^2_{\mathbf{A}_1}\triangle\, u^2_{\check{\mathbf{A}}\mathbf{A}_2}\\ &+\triangle\, u^2_{\mathbf{A}_2}\triangle\, u^2_{\check{\mathbf{A}}\mathbf{A}_1}+\triangle\, u^2_{\mathbf{A}_2}\triangle\, u^2_{\check{\mathbf{A}}\mathbf{A}_2}\Big)\Big/4.\end{aligned} \tag{11}$$

Proof: From Lemmas 3 and 4, multiplying (6) and (8) together yields the conclusion (11). ■

Remark 8: As stated in Remarks 6 and 7, Eq. (11) can reduce to $\triangle\, t^2_{\mathrm{W}}\triangle\, \omega^2_{\mathrm{W}}=\frac{\triangle t^2\triangle\omega^2}{4}$.

F. Uncertainty inequality of the CFLCWD

Theorem 1: Let $\widehat{f}(\omega)$ be the FT of a signal $f(t)$, $\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)$ be the CFLCWD of $f(t)$ with $\mathbf{A}_1$, $\mathbf{A}_2$ and $\mathbf{A}$, and $\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(u)$ and $\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(u)$ be the LCTs of $f(t)$ with $\check{\mathbf{A}}\mathbf{A}_1$ and $\check{\mathbf{A}}\mathbf{A}_2$, respectively. Assuming the conventional derivative $\frac{\mathrm{d}f}{\mathrm{d}t}$ exists at any point $t\in\mathbb{R}$, and $f(t),tf(t),\omega\widehat{f}(\omega),u\widehat{f}_{\mathbf{A}_1}(u),u\widehat{f}_{\mathbf{A}_2}(u),u\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_1}(u),u\widehat{f}_{\check{\mathbf{A}}\mathbf{A}_2}(u),t\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u),u\mathrm{W}_f^{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}(t,u)\in L^2(\mathbb{R})$. Then it has

$$\triangle\, t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\triangle\, u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}\geq\mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}, \tag{12}$$

where

$$\begin{aligned}\mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}=&\frac{b^2}{32}+\frac{1}{16}\left[a\left(a_1b_2-a_2b_1\right)-\frac{b}{2}\left(a_1d_2-b_1c_2\right)\right]^2\\ &+\frac{1}{16}\left[a\left(a_2b_1-a_1b_2\right)+\frac{b}{2}\left(a_2d_1-b_2c_1\right)\right]^2.\end{aligned}$$

Assuming $f(t)\neq 0$ almost everywhere, the equality holds iff $f(t)$ is a Gaussian signal $\mathrm{e}^{-\frac{1}{2\zeta}\left(t-t^0\right)^2+\sigma}\mathrm{e}^{\mathrm{j}\left(\omega^0t+\kappa\right)}$, where $\zeta>0$ and $\sigma,\kappa\in\mathbb{R}$.

Proof: $\check{\mathbf{A}}\mathbf{A}_1=\begin{pmatrix}aa_1+\frac{bc_1}{2} & ab_1+\frac{bd_1}{2}\\ 2ca_1+dc_1 & 2cb_1+dd_1\end{pmatrix}$ and $\check{\mathbf{A}}\mathbf{A}_2=\begin{pmatrix}aa_2-\frac{bc_2}{2} & ab_2-\frac{bd_2}{2}\\ -2ca_2+dc_2 & -2cb_2+dd_2\end{pmatrix}$. Thanks to Lemma 5 and the uncertainty inequality $\triangle\, u^2_{\mathbf{A}_1}\triangle\, u^2_{\mathbf{A}_2}\geq\frac{\left(a_1b_2-a_2b_1\right)^2}{4}$ in two LCT domains introduced by J. Zhao, R. Tao and their collaborators [40], [41], we arrive the conclusion (12). The equality of (12) is achieved iff the equality $\triangle\, u^2_{\mathbf{A}_1}\triangle\, u^2_{\mathbf{A}_2}=\frac{\left(a_1b_2-a_2b_1\right)^2}{4}$ is achieved, or equivalently, the equality of the classical Heisenberg's uncertainty inequality $\triangle\, t^2\triangle\, \omega^2\geq\frac{1}{4}$ [13], [14] is achieved. The equality $\triangle\, t^2\triangle\, \omega^2=\frac{1}{4}$ holds iff $f(t)$ is a Gaussian signal $\mathrm{e}^{-\frac{1}{2\zeta}\left(t-t^0\right)^2+\sigma}\mathrm{e}^{\mathrm{j}\left(\omega^0t+\kappa\right)}$. ■

Remark 9: As stated in Remark 8, the inequality (12) can reduce to the uncertainty inequality of the WD: $\triangle\, t^2_{\mathrm{W}}\triangle\, \omega^2_{\mathrm{W}}\geq\frac{1}{16}$.

V. TIME-FREQUENCY ANALYSIS OF THE CFLCWD

This section treats the lower bound minimization problem $\min_{a_kd_k-b_kc_k=1,k=1,2} \mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}$ as a conditional extremum problem and solves it to generate the universal optimal LCT free parameters with which the CFLCWD reaches the highest-resolution in time-frequency plane.

Theorem 2: The lower bound $\mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}$ is a function of a_k, b_k, c_k, d_k, $k = 1, 2$ and a, b. Its minimum is unattainable.

Proof: By using Lagrange multipliers method to solve the conditional extremum problem: Minimize $\mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}$; Subject to $a_kd_k - b_kc_k = 1$, $k = 1, 2$, the auxiliary function follows $\mathcal{L} = \mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}} + \sum_{k=1}^{2} \rho_k(a_kd_k - b_kc_k - 1)$.

For the case of $a_1b_2 - a_2b_1 = 0$, there are $a_1d_2 - b_1c_2 = \frac{b_1}{b_2}$ and $a_2d_1 - b_2c_1 = \frac{b_2}{b_1}$, based on which the equation $\frac{\partial\mathcal{L}}{\partial b} = 0$ becomes a contradictory equation $2 + \frac{b_1^2}{b_2^2} + \frac{b_2^2}{b_1^2} = 0$. As for the case of $a_1b_2 - a_2b_1 \neq 0$, combining $\frac{\partial\mathcal{L}}{\partial c_1} = 0$ and $\frac{\partial\mathcal{L}}{\partial d_1} = 0$ gives $a(a_2b_1 - a_1b_2) + \frac{b}{2}(a_2d_1 - b_2c_1) = 0$; combining $\frac{\partial\mathcal{L}}{\partial c_2} = 0$ and $\frac{\partial\mathcal{L}}{\partial d_2} = 0$ gives $a(a_1b_2 - a_2b_1) - \frac{b}{2}(a_1d_2 - b_1c_2) = 0$; then the equation $\frac{\partial\mathcal{L}}{\partial b} = 0$ becomes a contradictory equation $b = 0$. In a word, $\nabla\mathcal{L} = \overrightarrow{0}$ has no solution, where ∇ denotes gradient operator. ■

Remark 10: In general, there are no universal optimal LCT parameters with which the CFLCWD reaches the highest-resolution in time-frequency plane.

Theorem 3: Assuming b is a nonzero constant. Then the CFLCWD reaches the highest-resolution in time-frequency plane iff $\frac{a_1d_2-b_1c_2}{a_1b_2-a_2b_1} = \frac{a_2d_1-b_2c_1}{a_1b_2-a_2b_1} = \frac{2a}{b}$.

Proof: Since b is a nonzero constant, the lower bound $\mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}$ reaches its minimum $\frac{b^2}{32}$ iff $a(a_1b_2 - a_2b_1) - \frac{b}{2}(a_1d_2 - b_1c_2) = a(a_2b_1 - a_1b_2) + \frac{b}{2}(a_2d_1 - b_2c_1) = 0$. Note that $a_1b_2 - a_2b_1 \neq 0$, otherwise, there is a contradictory continued equality $\frac{b_1}{b_2} = \frac{b_2}{b_1} = 0$. ■

Remark 11: When b is a nonzero constant, there is a universal optimal LCT free parameters set

$$\left\{a_k, b_k, d_k, a, b, d, k = 1, 2 \middle| \frac{d_2}{b_2} + \frac{b_1}{b_2(a_1b_2 - a_2b_1)} = -\frac{d_1}{b_1} + \frac{b_2}{b_1(a_1b_2 - a_2b_1)} = \frac{2a}{b}, b \text{ is constant}, d \in \mathbb{R}\right\}$$

with which the CFLCWD reaches the highest-resolution in time-frequency plane.

VI. CONCLUSIONS

Uncertainty principle of the CFLCWD was formulated, based on which its time-frequency analysis theory was established. It turns out that the uncertainty product $\triangle\ t^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}} \triangle\ u^2_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A},\mathrm{W}}$ in CFLCWD domains equals to the sum of four uncertainty products $\triangle\ u^2_{\mathbf{A}_1} \triangle\ u^2_{\breve{\mathbf{A}}\mathbf{A}_1}, \triangle\ u^2_{\mathbf{A}_1} \triangle\ u^2_{\breve{\mathbf{A}}\mathbf{A}_2}, \triangle\ u^2_{\mathbf{A}_2} \triangle\ u^2_{\breve{\mathbf{A}}\mathbf{A}_1}, \triangle\ u^2_{\mathbf{A}_2} \triangle\ u^2_{\breve{\mathbf{A}}\mathbf{A}_2}$ in LCT domains. The lower bound on the uncertainty product in CFLCWD domains is shown as $\mathrm{B}_{\mathbf{A}_1,\mathbf{A}_2,\mathbf{A}}$, which is attainable by a Gaussian signal and depends only on the LCT free parameters $a_k, b_k, d_k, a, b, k = 1, 2$. The universal optimal LCT free parameters set of the CFLCWD is given by $\left\{a_k, b_k, d_k, a, b, d, k = 1, 2 \middle| \frac{d_2}{b_2} + \frac{b_1}{b_2(a_1b_2-a_2b_1)} = -\frac{d_1}{b_1} + \frac{b_2}{b_1(a_1b_2-a_2b_1)} = \frac{2a}{b}, b \text{ is constant}, d \in \mathbb{R}\right\}$, in which the highest time-frequency resolution is achieved.

***Abstract*—This paper investigates the application of autoencoder (AE) in supporting the training process of federated learning by reducing communication overhead and latency. We propose a scheduling algorithm to determine when and how to use autoencoder during training. Our simulation shows that federated learning with an autoencoder significantly reduces communication overhead without compromising testing accuracy. Moreover, the testing accuracy curve shows a more consistent increase over training rounds in federated learning with an autoencoder than in federated learning without an autoencoder. Additionally, the latency of federated learning with an autoencoder is lower than that of federated learning without an autoencoder.**

***Index Terms*—Federated learning, autoencoder, scheduling.**

I. Introduction

In recent years, federated learning has become a popular method of distributed learning. To protect the privacy of local devices and to reduce the communication resources, transmitting local model weights to a server is more feasible than transmitting data in a distributed learning setting [1]. Nonetheless, the complexity of transmitting model weights to the centralized server could still be very high, especially for applications demanding stringent performance measures (e.g. high accuracy or low mean-square error), consuming a significant amount of communication resources.

Several works have studied the problem of reducing required communication resources in wireless federated learning [1], [2], [3], [4]. In [1], the authors propose FedAvg, which leverages over-the-air computation to reduce the computation cost of aggregation. In [2], the authors optimize the number of iterations to reduce the computation consumption of both local devices and the server. Alternatively, compressing the required dimension of transmitting signals is a promising approach to reducing transmission overheads in wireless federated learning. While classical signal compression can directly address this issue, using lossless compression may not be the most effective way here since the updated information is only from the local model weights at each communication round and not all model weights are equally informative. In [3], [4], the authors replace the local model weights with the prompt to reduce the communication overhead between the local devices and the server. However, the server needs to have the pretrained global model before federated learning.

On the other hand, autoencoder (AE) offers a more efficient way of compression from the machine learning perspective, even though it is lossy, which features signal denoising capability. As an unsupervised learning model, autoencoder consists of an encoder and a decoder, where dimensionality reduction is realized at the encoder and the compressed data after the encoder is reconstructed at the decoder, e.g., [5], [6], [7] for image recovery applications, [8] for channel state information (CSI) recovery and [9] for beamforming vector design.

Despite the benefits of using an autoencoder for dimension reduction and denoising in various applications, little research effort is invested in applications for federated learning. Only one work can be found in the literature [10], which presents a novel approach for detecting and mitigating the impact of malicious model updates in federated learning using a conditional variational autoencoder. However, the paper does not discuss the specifics of when and how to train the autoencoder for this application. Thanks to the properties of dimensionality reduction and denoising, we are therefore motivated to employ AE in the wireless federated learning to reduce the transmission overheads and to alleviate the effect of heterogeneity in data and local devices by the denoising property. In particular, we develop protocols that allow the AE to update its encoder/decoder parameters during the federated learning training process and establish a local device scheduling algorithm to improve data reconstruction performance with low latency

The contributions of this research can be summarized as follows:

- To our best knowledge, this work presents the first study to use AE in federated learning for more efficient model parameters transmissions and for consistently improving learning performance by leveraging its denoising capability. Specifically, this lowers the number of model parameters needed for transmission compared to vanilla federated learning, thereby reducing communication overhead overall latency of the federated learning process.
- We introduce a scheduling for AE-enhanced FL (SAEL) algorithm to determine when to utilize the AE during the federated learning training process to validate the feasibility of this approach with reduced overall latency. This allows the central

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

server to make decisions on whether or not local devices should activate the autoencoder.
- We conduct extensive simulations that demonstrate the significant decrease in communication consumption with the use of an autoencoder, highlighting its potential for application in real-world federated learning scenarios.

The remainder of this paper is organized as follows. Section II introduces the structure of federated learning and autoencoder. Section III proposes the protocol and scheduling algorithm of federated learning with an autoencoder. Reduced communication overhead of the proposed protocol is analyzed in Section IV. In Section V, we present simulation results to verify the feasibility and effectiveness of our proposed method. Finally, Section VI provides concluding remarks and suggests future research directions.

II. System Model and Problem Formulation

Federated learning is a distributed learning architecture where a central server coordinates multiple local devices to train a shared machine learning model without sharing their raw data. Instead, the local devices train their own models using their own data and upload the trained model weights to the server. Then, the central server aggregates the model parameters from each local device to update the shared model [11]. More specifically, a *communication round* in a federated learning consists of three steps: global model broadcasting, local model updates, and global model aggregation. The communication round goes on until convergence.

In this paper, we combine federated learning with AE to improve the efficiency of the training process and the effectiveness of the training result. In particular, AE can reduce the dimensionality of model parameters being transmitted to the server in federated learning, which facilitates communication overhead reduction. Additionally, denoising capability in AE can be utilized to ensure consistency of model updates during federated learning training. By leveraging the strengths of both techniques, the resulting federated learning process can achieve better performance and be more applicable in real-world scenarios.

Autoencoder is a type of neural network that consists of an encoder and a decoder [12]. The encoder compresses the input data into a low-dimensional representation, while the decoder reconstructs the original input from the compressed representation.

A. Federated learning

The federated learning process starts by initializing the global model weights $\mathbf{w}$ on the server. In each communication round, a subset of local devices may be selected to participate in the training process. Each selected local device k updates its own model weights $\mathbf{w}_k$ by minimizing the local loss function $f_k\left(\mathbf{w}, \mathbf{x}_{k,m}, y_{k,m}\right)$ over its dataset D_k, where $\mathbf{x}_{k,m}$ is the mth data sample associated with label $y_{k,m}$. Then, the updated local model weights are transmitted to the server for aggregation, which computes the new global model weights as a weighted average of the received local model weights, where the weight for the kth edge device is the ratio of the number of data samples in its dataset to the total number of data samples from all devices. This process is repeated until convergence.

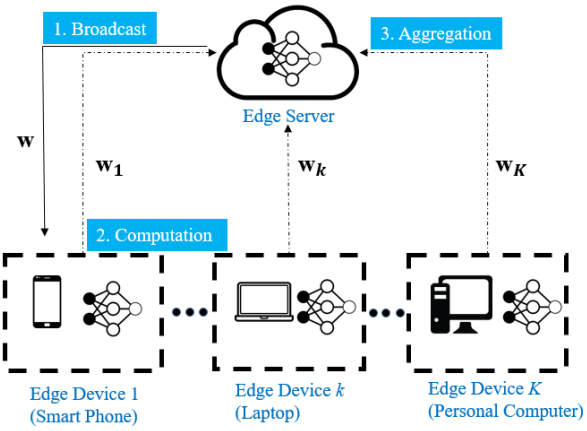

Fig. 1. An illustration for a federated learning network.

Examples of loss function

Model	Loss function
Linear regression	$\frac{1}{2}\left\|y_m - \mathbf{w}^T\mathbf{x}_m\right\|^2$
Cross-Entropy	$-\sum_{class} y_m \log(p(y_m \mid \mathbf{x}_m, \mathbf{w}))$

The global loss function in federated learning can be computed as a weighted sum of local loss functions from each edge device. Specifically, the global loss function can be expressed as

$$F(\mathbf{w}) = \frac{1}{|D|}\sum_{k=1}^{K}\sum_{m=1}^{|D_k|} f_k\left(\mathbf{w}, \mathbf{x}_{k,m}, y_{k,m}\right) \quad (1)$$

$$= \sum_{k=1}^{K}\frac{|D_k|}{\sum_{k'=1}^{K}|D_{k'}|}F_k(\mathbf{w}), \quad (2)$$

where $|D|$ is the total number of data samples in all local datasets and $F_k(\mathbf{w})$ is the overall local loss function of the kth edge node accounting for the entire local data.

The objective of federated learning is to minimize the global loss function by collaboratively training the model weights across all local devices. Mathematically, the learning problem can be expressed as

$$\min_{\{\mathbf{w}\}} \sum_{k=1}^{K}\frac{|D_k|}{\sum_{k'=1}^{K}|D_{k'}|}F_k(\mathbf{w}). \quad (3)$$

Figure 1 illustrates the process of training the global model weights by federated learning, which can be summarized as follows:

1) The central server broadcasts the current global model weights to all local devices.
2) Each local device computes its local model weights using its own local training dataset.
3) The local devices send their updated model weights to the central server, which aggregates the received model weights and produces an updated global model weights.

The above steps are repeated until convergence or that a predefined stopping criterion is met.

B. Autoencoder

An autoencoder is a type of neural network used for unsupervised learning, which is composed of two parts: an encoder and a decoder. The encoder takes the input data and maps it to a lower-dimensional representation, while the decoder takes the encoded representation and maps it back to the original input space. The objective of an autoencoder is to minimize the reconstruction error between the input and the output of the decoder. By doing so, an autoencoder can learn a compressed representation of the input data that captures its most important features.

III. Autoencoder-enhanced Federated Learning

In this section, we introduce the proposed AE-enhanced federated learning, in which an AE encoder is built in each local device to compress the parameters of the learning model before sending to the server. Particularly, instead of training the AE encoder on each local device, we relegate the training process to the centralized server. Therefore, a complete AE encoder and decoder have to be built in the server where the decoder is used to reconstruct the encoded model parameters sent from local devices and the AE encoder at the server is used for the purpose of training AE. The training process of AE at the server requires uncompressed model parameters sent from each device, and the trained AE model will be broadcast to all local devices from the server. In other words, an initial training process of the AE must take place before the AE on the local device can serve to compress the model parameters in federated learning.

The training process in the beginning for training AE and the global model parameters in federated learning is illustrated in Fig. 3. The server collects uncompressed model weights from local devices as in a typical federated learning process. The AE is not activated in this phase. Having trained with sufficient amount of data[1], the AE on the local device can be activated to compress the model parameters before sending to the server. Fig. 4 illustrates the training process of federated learning enhanced by an AE. Once each local device starts using the AE encoder during the training process of federated learning, the server can still continue to collect the model weights from local devices and employ these weights to update the AE.

A. Scheduling for AE-Enhanced FL (SAEF)

In the beginning phase, to update the autoencoder, original uncompressed local model weights are required to feed the AE at the server for training. To continuously improve the reconstruction performance of the AE, the server can utilized the reconstructed model parameters to futher update the AE, which however has limited

[1]This can be notified by the server when the loss value of the AE training starts to be lower than a predefined threshold

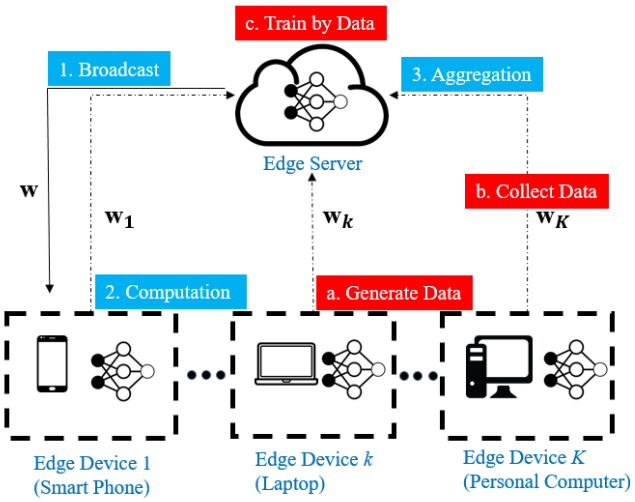

Fig. 2. An illustration of updating AE where the AE training takes place at the server. In AE-enhanced federated learning AE encoder compresses the local model parameters at local devices and AE decoder performs model reconstruction at the server.

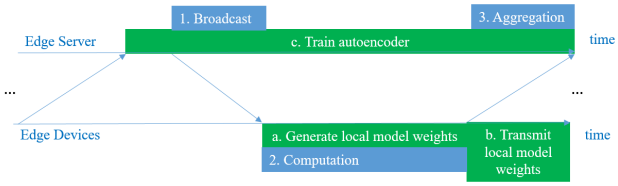

Fig. 3. Training process of the autoencoder. (Time slot.)

performance gain. Alternatively, a selected set of the local devices is scheduled to send uncompressed local model parameters to the server, while the remaining local devices are designated to transmit the compressed local model parameters using AE (after AE is activated) in federated learning.

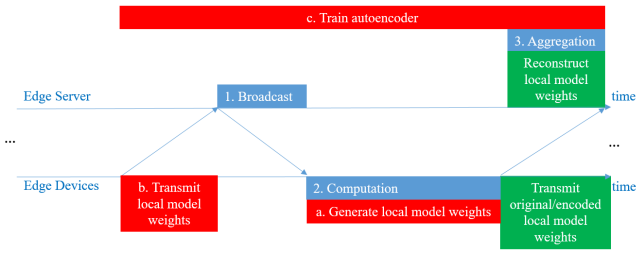

Fig. 4. Training process of federated learning.

The decision of whether a local device is selected to utilize AE for data compression in federated learning is made with consideration of latency in each communication round. Let the latency in the jth communication round be denoted by t^j_{round}. The scheduling mechanism of the AE-enhanced FL (SAEF) determines whether the kth local device should utilize the AE to compress the model parameters or send the uncompressed directly to the server such that t^j_{round} can be minimized. For the kth

local device, the latency can be evaluated by

$$t_{j,k}^{\text{cp}} + \frac{S_{j,k}}{r_{j,k}},$$

where, all in the jth communication round, $t_{j,k}^{\text{cp}}$ is the computation latency of the kth device, $S_{j,k}$ is the data size to be transmitted to server (either compressed or uncompressed) transmission data of the kth device, and $r_{j,k}$ is the transmission rate of the kth device

$$r_{j,k} = B \cdot \log_2 \left(1 + \frac{P_k |h_{j,k}|^2}{B N_0}\right), \tag{4}$$

with B the bandwidth, P_k the transmitted power, $h_{j,k}$ the corresponding channel between the kth local device and server, and N_0 is the noise power spectral density. The device scheduling result determines the data size $S_{j,k}$ and consequently has impact on the overall latency in each round.

B. SAEF Algorithm

In this paper, we propose the following SAEF algorithm to select local devices to transmit compressed local model parameters.

Algorithm 1 SAEF Algorithm

Input: $t_{j,k}^{\text{cp}}$, $r_{j,k}$, $S_{j,k}$,S^{AE} for $k = 1, 2, \ldots, K$
Output: $\hat{t}_{\text{round}}^{j}$, $S_{j,k}$
Find the maximum $t_{j,k'}^{\text{cp}}$ at k'-th local device
Let $t_{max} = t_{j,k'}^{\text{cp}}$
$\hat{t}_{\text{round}}^{j} = t_{max} + \frac{S^{AE}}{r_{j,k'}}$
parallel $k = 1, 2, \ldots, K$ **do**
    if $t_{j,k}^{\text{cp}} + \frac{S}{r_{j,k}} \geq \hat{t}_{\text{round}}^{j}$ **then**
        $S_{j,k} = S^{AE}$
    else
        $S_{j,k} = S_{j,k}$
end parallel

The SAEF algorithm is designed to address latency issues caused by stragglers, which are the primary contributors to overall latency. In particular, the local devices with the longer latency are (and should be) more likely to be selected to utilize AE encoder for data compression, where the data size of the encoded model parameters are denoted by S_{AE}. If the total time spend by a local device for data transmission is greater than $\hat{t}_{\text{round}}^{j}$, which is defined in the pseudo-code Algorithm 1 and calculated according to the longest computation latency among all local devices, the local device needs to utilize AE to reduce the communication latency. Specifically, we first identify the local device k' with the largest $t_{j,k'}^{\text{cp}}$ and compute $t_{max} \triangleq t_{j,k'}^{\text{cp}} + \frac{S^{AE}}{r_{j,k'}}$. We then can decide whether to apply autoencoder or not to other devices based on t_{max}.

IV. Performance Analysis

Because the autoencoder is trained by the server, the local devices only need to receive the autoencoder from the server. This does not raise any privacy concerns for the local devices. The autoencoder can help in reducing the uploaded communication cost. Therefore, we analyze the impact of using AE-enhanced federated learning on the communication overhead, specifically with respect to three AE-training strategies: 1) Separately training AE and global model (STAG) , 2) and 3) the SAEL scheduling. Let the number of hidden nodes in the AE be denoted by L, and the total number of local model weights is M.

A. Separately Training AE and Global Model (STAG)

A properly trained AE ensures that the reconstructed input of the autoencoder closely resembles the original input. One way of training the AE-enhanced FL is to train AE and global model separately (STAG), as illustrated in Fig. 5. The server collects the local model weights from federated learning and updates the model weights of the autoencoder until the AE is properly trained.

The STAG protocol can be summarized as follows:

1) The server broadcasts the global model parameters along with the AE encoder parameters to all local devices.
2) Each local device updates its local model weights using its local dataset.
3) The local devices use the encoder to compress their local model weights and transmit the encoded weights to the server.
4) The server receives the encoded local model weights from all devices.
5) After decoding the encoded local model weights, the server updates the global model by the reconstructed local model weights.

Steps 2 to 5 are repeated until all local datasets have been used in training. The training process of federated learning with the STAG protocol is illustrated in Fig. 6, where the AE parameters are not updated in this phase.

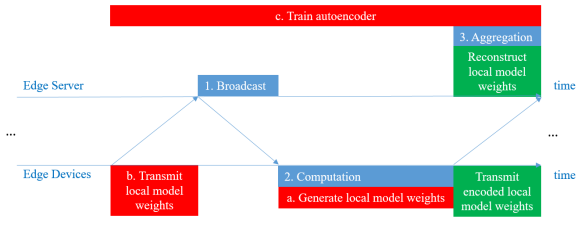

Fig. 5. Training process of the autoencoder. (Time slot of STAG.)

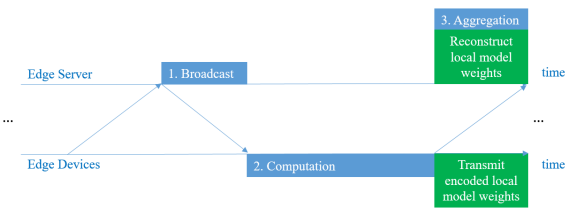

Fig. 6. Training process of federated learning with STAG autoencoder.

In federated learning without an autoencoder, the total communication overhead is $C_1 KM$, where C_1

is the number of communication rounds. On the other hand, using AE can reduce the upload communication overhead per round by a factor of $1 - \frac{L}{M}$, resulting in a total communication overhead of $C_1KL + C_2KM$, where C_2 is the number of communication rounds in federated learning with an AE. Therefore, the reduced total communication overhead can be calculated as $1 - \frac{(C_1KL+C_2KM)}{C_1KM}$.

B. Train AE and Global Model Simultaneously (TAGS)

The TAGS learning protocol is a special case of SAEF learning process. In TAGS all local devices activate AE encoders when AE is properly trained, whereas in SAEF only a subset of the local devices turn on the AE encoders. As such, the amount of information that needs to be uploaded in each communication round is reduced by a factor of $1 - \frac{L}{M}$. This reduction is due to the compression of local model parameters by the autoencoder before they are transmitted to the server.

C. SAEF Scheduling

In this case, the reduced upload communication overhead per round is $1 - \frac{LK_{on}}{MK}$, where K_{on} is lower than K. This means that the autoencoder not only compresses the local model weights but also reduces the number of non-zero elements, resulting in further reduction in the communication overhead.

V. Simulation Results

To evaluate the efficacy of our proposed method, we conduct simulations using deep neural network (DNN) on the MNIST and Fashion-MNIST dataset and evaluate testing accuracy. The simulation setup involves five local nodes in the network. For the dataset, each node collects a fraction of labeled training datasets $D_1, D_2, \ldots, D_5$, with $12,000$ training data at each device. We consider $t_{j,k}^{\text{cp}}$ to be uniformly distributed from 1s to 20 sec, while the available bandwidth B is 1 MHz. To simulate a realistic communication environment, we assume small scale Rayleigh fading $h_{j,k} \sim \mathcal{CN}(0,1)$ and set N_0 to be -107 dBm. The path-loss model we adopt is $PL[dB] = 128.1 + 37.6\log_{10}(d)$, where d in km is the edge-to-server distance. We assume a transmit power of 30 dBm for each local device.

The format of floating numbers in the storage can be either 32 or 64 bits. During transmission, we use 16 bits to transmit one element of model weights, so the size of transmission is the product of the number of weights and 16 bits.

The autoencoder model consists of a neural network with one hidden layer and 500 hidden nodes. The global model weights are represented by a neural network with one hidden layer and 100 hidden nodes, resulting in a total of $784\times100+1\times100+100\times10+1\times10 = 79,510$ elements in the global model weights. Two performance metrics are used to evaluate the proposed protocol: (1) separate training the autoencoder and the global model weights (STAG), and (2) train the autoencoder and the global model weights at the same time (TAGS).

In the simulation, we use $30,000$ data to construct $3,000$ model weights (training data) for the AE. Then, we use the remaining $30,000$ data to train the global model weights of STAG. To efficiently train the global model weights, training the AE and the global model weights at the same time offers a more practical option. However, the AE cannot be used in the beginning without initial training.

A. Performance Comparison

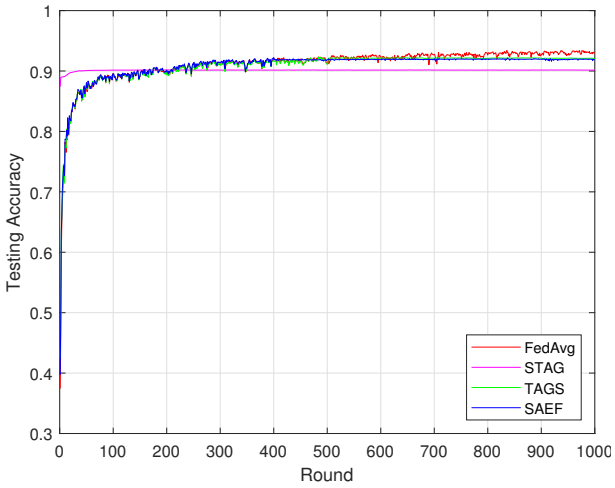

Fig. 7. Comparison of testing accuracy. (MNIST)

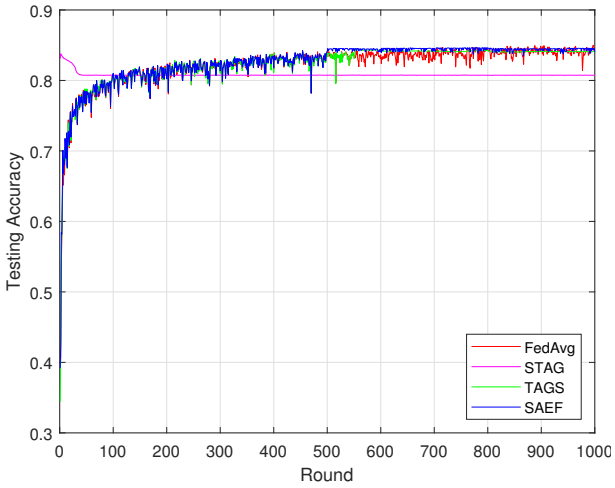

Fig. 8. Comparison of testing accuracy. (Fashion-MNIST)

Fig. 7 and Fig. 8 compare the proposed SAEL scheduling algorithm with FedAvg, STAG, and TAGS. The SAEL and TAGS update the AE every 50 communication rounds. It shows that STAG converges faster than the other methods because the AE in STAG has been trained with 3000 training data, allowing it to capture more information to update the global model weights. However, the AE in STAG is not updated during the training process of federated learning, resulting in worse testing accuracy when the model weights converge. In TAGS, local devices start to use the AE encoder in the 500th communication round. In SAEF, we use the testing accuracy to decide whether to use the AE or not, and we can observe that the server starts using the AE

TABLE I

LATENCY COMPARISON

$\hat{t}^j_{\text{round}}$	t^j_{round}	Latency without Autoencoder
73.09	2,440.67	386,912.57

at the 400th communication round. We can also observe from the figure that the AE-enhanced FL is more stable in the testing accuracy whereas the testing accuracy of FedAvg fluctuates more, which demonstrates the denoising property of the AE. Since all local devices use AE to transmit the local model weights, STAG has the best stability during the training process.

In TABLE I, we compare latency of different methods in one communication round. $\hat{t}^j_{\text{round}}$ represents the estimated time latency of the scheduling algorithm in the communication round, while t^j_{round} is the actual time latency computed by the server with the autoencoder. The latency without an autoencoder is the time latency of federated learning without an autoencoder. The unit of time in this table is seconds. It is evident that $\hat{t}^j_{\text{round}}$ and t^j_{round} are different, as the algorithm cannot predict the exact value of t^j_{round}. Our primary objective is to schedule the use of the autoencoder to reduce communication consumption, and the latency is a secondary target. The server only needs to wait for the last local device to finish transmission, and then it can get t^j_{round}. Overall, the proposed method achieves lower latency than other methods in one communication round.

In TABLE II, we present a comparison of the complexity between federated learning and federated learning with an autoencoder. The communication consumption column represents the number of elements transmitted between the server and local devices per communication round. In federated learning with an autoencoder, each local device needs to transmit the encoded local model weights, which is much smaller than the original local model weights. Thus, using an autoencoder reduces the communication consumption in federated learning. The reduced overhead column shows the difference in communication consumption between federated learning and federated learning with an autoencoder. The accuracy column displays the testing accuracy of federated learning and federated learning with an autoencoder after the training process. From the table, we can observe that federated learning with an autoencoder can significantly reduce the overhead and power consumption of local devices during the training process. Moreover, it achieves comparable testing accuracy to federated learning without an autoencoder.

TABLE II

COMPLEXITY COMPARISON (MNIST)

Method	Communication Consumption	Reduced Overhead	Accuracy
Federated Learning	79,510	0	92.97%
Federated Learning with Autoencoder	50	79,460(99.9%)	92.04%
	500	79,010(99.3%)	92.68%
	5,000	74,510(93.7%)	92.49%

VI. CONCLUSION

In conclusion, we proposed a novel approach for reducing communication consumption in federated learning using an autoencoder. We developed a scheduling algorithm to minimize the latency of the communication round. Our experimental results on the MNIST and Fashion-MNIST dataset demonstrate the effectiveness of our proposed method in terms of reducing communication consumption and improving the testing accuracy of the global model weights. In addition, we provided a complexity analysis of our approach compared to traditional federated learning. Our work contributes to the field of federated learning by providing a practical solution to reduce communication overhead and improve the efficiency of the training process. Future research can explore the use of autoencoders in other federated learning scenarios and investigate the potential advantages of our approach in real-world applications.

***Abstract*—This paper proposes a distributed multiple-input multiple-output signal detection algorithm based on DU (deep unfolding), which is known as the optimizing method of parameters involved in an iterative algorithm by using commonly used deep learning techniques such as backpropagation and stochastic gradient descent. In the distributed system, multiple distributed SPUs (sub processing units) having multiple antennas execute an iterative signal processing process to detect transmitted signals in cooperation with a CPU (central processing unit). In applications where SPUs are located distributedly, SPUs are placed under heterogeneous SNR (signal-to-noise ratio) environments depending on geographical location and distances from transmitters. We introduce weighting parameters corresponding to each SPU into the aggregation process of the proposed method to incorporate the heterogeneous SNR environments into the detection algorithm. In addtion, we apply DU to optimize the parameters and obtain improvement of the detection perfomance. Results of numerical experiments indicate that the proposed method with the parameters learned by DU improve detection performance by appropriately tuning the weighting parameters according to the heterogeneous SNR environments.**

I. Introduction

Towards the 6G (6th Generation mobile communication system) for the next-generation infrastructure for wireless communications, intensive research activities are currently underway [1]. In the 6G, it is expected to achieve faster and more reliable communication with lower latency, and to accommodate a tremendous number of mobile devices. Massive MIMO (Multiple-Input Multiple-Output) with hundreds of antennas is an essential system for dealing with increasing data traffic and achieving high spectral efficiency [2].

In massive MIMO systems, centralized signal detection methods such as ML (Maximum Likelihood), ZF (Zero-Forcing), and linear MMSE (Minimum Mean Squared Error) are commonly used [3]. However, these centralized signal processing methods require high data throughput and high computing power that highly likely exceeds existing hardware performance [4] in the 6G era due to the increased number of mobile devices. Specifically, the computational demands of a BS (base station) cannot be satisfied with the current BS architecture in the near future. The *load balancing* technologies to mitigate the concentration of computational load in a BS will be indispensable for achieving the goal of the 6G system.

Distributed MIMO signal detection methods have been proposed [2], [4]–[6], which can be regarded as a promising load balancing technique. The distributed methods cooperatively solve a signal detection problem with multiple computing units, consequently reducing computational loads in the BS. In [4]–[6], distributed MIMO detection algorithms composed of multiple SPUs (Sub Processing Units) and a single CPU (Centralized Processing Unit) were proposed. Zhao et al. [5] and Sanchez et al. [6] proposed a signal processing architecture where the SPUs sequentially execute processing tasks. Li et al. [4] proposed algorithms based on the CG (Conjugate Gradient) and ADMM (Alternating Direction Method of Multipliers) where SPUs executed in parallel under the orchestration of CPU. Although these methods [4]–[6] provide us useful insights for distributed MIMO methods, there are still several weak points. The distributed methods have a trade-off between the load balancing and performance in general. The performance of these methods can become close enough to that of the centralized method when the number of SPUs is small or under some system conditions. However, they cannot achieve exactly the same performance because each SPU can access only a limited channel state information due to the distributed nature.

Furthermore, in applications where SPUs can be regarded as being located distributedly [7]–[9], the SPUs with several receive antennas are placed under heterogeneous SNR (Signal to Noise Ratio) environments depending on the geographical location and the distances from the transmitters. A SPU located far from the transmitter receives relatively weak signals due to the path loss effect. Such a SPU might suffer from worse SNR and have possibly poor detection performance than other SPUs located closer to the transmitter. In other words, the heterogeneous SNR causes difference in detection performance of SPUs. The conventional methods [4]–[6] do not incorporate the heterogeneity into the detection algorithms. The appropriate exploitation of the difference in SNR among SPUs may yield an improvement of detection performance of the distributed MIMO detection methods.

In this paper, we propose a cooperative signal detection method for distributed MIMO systems, *LWSP (Learned Weighting Soft Projection)* method, which incorporates the difference in SNR among SPUs. The proposed LWSP method introduces trainable *weighting parameters* corresponding to each SPU, which are used in a message averaging process. These weighting parameters play a key role to *adjust* the message from SPUs under different SNR. The adjustment of the weighting parameters may lead to better detection performance and faster convergence of the detection processes that are the main feature of the proposed method. We apply DU (deep unfolding) technique to the proposed method to optimize the trainable weighting parameters. DU is an optimization technique for trainable parameters included in iterative algorithms [10], [11]. It has been widely used

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

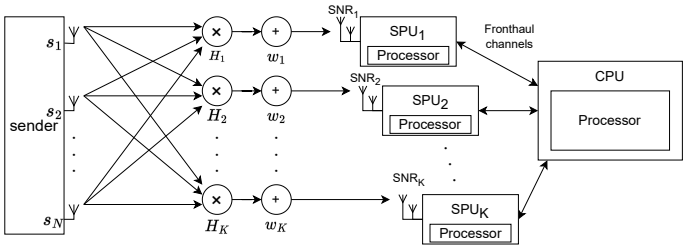

Fig. 1. Distributed MIMO system.

to improve signal detection performance in MIMO systems [12]–[15]. The proposed method is based on the gradient descent-based MIMO detection method with soft projection, which are reported to achieve high detection performance in a DU-based centralized detection method [16].

II. Preliminaries

A. Notation

We denote the zero and one vectors with boldface letters $\mathbf{0}$ and $\mathbf{1}$. The matrix $\boldsymbol{I}_n$ denotes the identity matrix of size $n \times n$. For a complex matrix $\boldsymbol{A} \in \mathbb{C}^{n\times n}$, $\boldsymbol{A}^T$ denotes a transpose and $\boldsymbol{A}^H$ denotes the Hermitian transpose of $\boldsymbol{A}$, respectively. We define $\mathcal{CN}(\mathbf{0}, \sum)$ as the circularly symmetric complex Gaussian distribution with mean vector $\mathbf{0}$ and covariance matrix $\sum$. For vector $\boldsymbol{w} = (w_1, \ldots, w_M)^{\mathrm{T}}$, $||\boldsymbol{w}||$ represents the ℓ_2 norm of $\boldsymbol{w}$.

B. Distributed MIMO System Model

In this paper, we consider a distributed MIMO system between a sender with N transmit antennas and a receiver composed of the CPU and the multiple SPUs [4]–[6], which is shown in Fig. 1. We assume that the CPU and the SPUs have computation capability required for the signal detection tasks. It is expected that an appropriate cooperating detection process of the CPU and the SPUs provides computational load balancing among them. A vector $\boldsymbol{s} = (s_1, s_2, \ldots, s_N)^T \in \mathbb{C}^N$ represents transmit signals from N antennas of the sender. The transmit signal $\boldsymbol{s}$ is received by K SPUs, each of which has m receive antennas.

We assume that each SPU is placed at geographically different locations [7]–[9]. This means that the receive power for each SPU might be different because of the different path loss effect. It is natural to assume that each SPU has distinct SNR, i.e., SPUs are under a heterogeneous SNR environment. In the subsequent formulation, we will use the following *equivalent heterogeneous SNR model*, which includes the SPU-dependent noise variances. This is because it allows a simpler discussion.

Throughout the paper, the kth SPU represents the SPU$_k$($k = 1, 2, \ldots, K$). As a received vector, SPU$_k$ receives

$$\boldsymbol{y}_k = \boldsymbol{H}_k \boldsymbol{s} + \boldsymbol{w}_k \in \mathbb{C}^m, \tag{1}$$

where $\boldsymbol{H}_k \in \mathbb{C}^{m\times N}$ is the channel matrix of SPU$_k$. A complex vector $\boldsymbol{w}_k \in \mathbb{C}^m$ is the noise vector that follows $\mathcal{CN}(\mathbf{0}, \sigma_k^2 \boldsymbol{I}_m)$.

Algorithm 1 CG-based Detection Method [4]

Input: $\boldsymbol{H}_k (k = 1, 2, \ldots, K), y_k, \rho$

$\boldsymbol{y}_k^{\mathrm{MRC}} = \boldsymbol{H}_k^H \boldsymbol{y}_k$
$\boldsymbol{y}^{\mathrm{MRC}} = \sum_{k=1}^{K} \boldsymbol{y}_k^{MRC}$
$\boldsymbol{r}^{(0)} = \boldsymbol{y}^{MRC}, \boldsymbol{p}^{(0)} = \boldsymbol{r}^{(0)}, \boldsymbol{x}^{(0)} = \mathbf{0}$
for $t = 1, \ldots, T$ **do**
  SPU$_k$($k = 1, 2, \ldots, K$):
  $\boldsymbol{w}_k^{(t)} = \boldsymbol{H}_k^H \boldsymbol{H}_k \boldsymbol{p}^{(t-1)}$
  CPU:
  $\boldsymbol{w}^{(t)} = \sum_{k=1}^{K} \boldsymbol{w}_k^{(t)}$
  SPU$_k$($k = 1, 2, \ldots, K$):
  $\boldsymbol{e}^{(t)} = \rho \boldsymbol{p}^{(t-1)} + \boldsymbol{w}^{(t)}$
  $\alpha = ||\boldsymbol{r}^{(t-1)}||^2 / ((\boldsymbol{p}^{(t-1)})^H \boldsymbol{e}^{(t)})$
  $\boldsymbol{x}^{(t)} = \boldsymbol{x}^{(t-1)} + \alpha \boldsymbol{p}^{(t-1)}$
  $\boldsymbol{r}^{(t)} = \boldsymbol{r}^{(t-1)} - \alpha \boldsymbol{e}^{(t-1)}$
  $\beta = ||\boldsymbol{r}^{(t)}||^2 / ||\boldsymbol{r}^{(t-1)}||^2$
  $\boldsymbol{p}^{(t)} = \boldsymbol{r}^{(t)} + \beta \boldsymbol{p}^{(t-1)}$
end for

Output: $\hat{\boldsymbol{x}} = \boldsymbol{x}^{(T)}$

SNR of SPU$_k$ is defined as $\mathrm{SNR}_k = 10 \log_{10}(N/\sigma_k^2)$. In addition, $\boldsymbol{w}_i$, $\boldsymbol{w}_j (i \neq j)$ are independent.

Since the SPUs cooperatively execute iterative processes to detect the transmitted signals, the total number of receiving antennas can be virtually considered as $M = mK$. It is assumed that the SPU$_k$ has only own received signal $\boldsymbol{y}_k$ and own channel state information $\boldsymbol{H}_k$. To detect the transmitted signal at each SPU, SPU needs to communicate with CPU, which can receive and aggregate the messages sent from all the SPUs. We assume that all the SPUs are connected to CPU with a fast fronthaul channel and that no transmission delays and error-free links between each SPU and the CPU.

C. CG-based Detection Method

We here briefly review the conventional CG-based MIMO detection method. The CG method is a numerical algorithm for solving linear equations [17]. Li et al. proposed the CG-based signal detection method for the distributed MIMO systems [4]. The CG-based detection method can achieve performance close to that of the centralized MMSE method by combining with error correcting codes.

The CG-based detection method is summarized in Algorithm 1. This algorithm includes a hyper parameter ρ to be determined. The method has two processes to calculate the estimated signal $\hat{\boldsymbol{x}}$. The first process is the preprocessing phase to calculate the temporary vector $\boldsymbol{y}^{\mathrm{MRC}}$. The second process is the iteration phase to calculate the estimated vector $\hat{\boldsymbol{x}}$. In the preprocessing phase, the method generates the temporary vectors $\boldsymbol{y}_k^{\mathrm{MRC}}$ and $\boldsymbol{y}^{\mathrm{MRC}}$ used for the iteration phase. Each SPU calculates the temporary vector $\boldsymbol{y}_k^{\mathrm{MRC}} = \boldsymbol{H}_k^H \boldsymbol{y}_k$ and CPU calculates $\boldsymbol{y}^{\mathrm{MRC}}$, where $\boldsymbol{y}^{\mathrm{MRC}}$ is the sum of the temporary vectors $\boldsymbol{y}_1^{\mathrm{MRC}}, \ldots, \boldsymbol{y}_K^{\mathrm{MRC}}$. In the iteration phase, the temporary vectors $\boldsymbol{e}^{(t)}, \boldsymbol{x}^{(t)}, \boldsymbol{r}^{(t)}, \boldsymbol{p}^{(t)}$ and state vector $\boldsymbol{x}^{(t)}$ are updated on the basis of the CG method at SPUs. The resulting estimated

signal $\hat{\boldsymbol{x}}$ can be obtained after T iterations.

In this paper, we will use the CG-based detection method for benchmark purpose.

D. Deep Unfolding

1) Overview of DU processes: DU is a method to improve performance of iterative algorithms by using deep learning techniques such as stochastic gradient descent (SGD) and back propagation. One can expand iterative processes of an algorithm to an unfolded feed-forward network similar to feed-forward neural network, where each layer of the network consists of the process of the algorithm. Next, some trainable parameters can be embedded in the unfolded network and the embedded parameters are optimized by using deep learning techniques.

2) Update of Trainable Parameters: In an iterative algorithm, several parameters included in the algorithm have a critical effect on performance of the algorithm. Let a set of parameters in an algorithm be the trainable parameters $\boldsymbol{\Theta}^{(t)}$, which depend on the time index $t = 1, \ldots, T$ corresponding to the iterative steps of the algorithm. The trainable parameters can be optimized by using deep learning techniques. The training data used for the training processes generally consist of mini-batches of input-output pairs and supervised learning is performed by using the training data. We denote a set of all trainable parameters as $\tilde{\boldsymbol{\Theta}} = \{\boldsymbol{\Theta}^{(1)}, \ldots, \boldsymbol{\Theta}^{(T)}\}$. A loss function $L(\tilde{\boldsymbol{\Theta}})$ and its gradient $\nabla L(\tilde{\boldsymbol{\Theta}})$ are required to be set to reduce error between outputs of the algorithm and the supervised signals. The cth update $(c = 1, \ldots, C)$ of the trainable parameters in the case of SGD is given by

$$\tilde{\boldsymbol{\Theta}}_c = \tilde{\boldsymbol{\Theta}}_{c-1} - \epsilon \nabla L(\tilde{\boldsymbol{\Theta}}_{c-1}), \tag{2}$$

where ϵ (> 0) is a learning rate.

3) Incremental Training: In DU, a training method, called incremental training, is known to provide excellent training results in many cases [18]. Generally, in deep learning, all trainable parameters are updated simultaneously. On the other hand, the incremental training trains parameters while increasing the number of layers one by one instead of the simultaneous update.

The detail of the incremental training processes is as follows. First, in the first layer, we optimize the trainable parameters $\boldsymbol{\Theta}^{(1)}$ by DU processes. Second, we add the second layer and optimize the trainable parameters $\boldsymbol{\Theta}^{(1)}$ and $\boldsymbol{\Theta}^{(2)}$. In this way, we optimize the trainable parameters up to Tth iteration while adding layers per the number of iterations and then obtain the trained parameters $\boldsymbol{\Theta}^{(1)}, \boldsymbol{\Theta}^{(2)}, \ldots, \boldsymbol{\Theta}^{(T)}$. The method allows us to concentrate on optimizing the trainable parameters of the added layers on each process. For this reason, we can mitigate the vanishing gradient problem [10].

III. Learned Weighting Soft Projection Method

In this section, we introduce the proposed detection method named *LWSP method*. Section III-A describes iterative processes of the proposed algorithm and Sect. III-B summarizes training procedure of the parameters included in the algorithm.

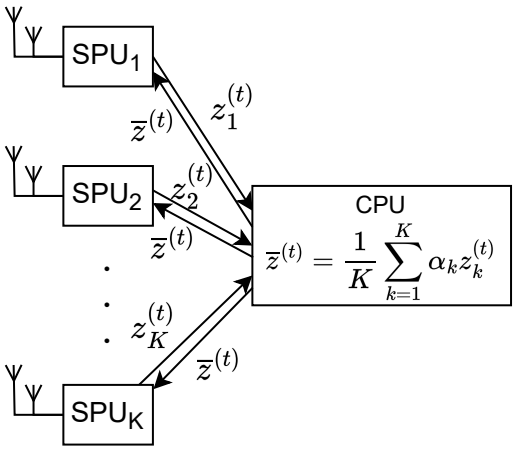

Fig. 2. Message exchange between CPU and SPUs

In addition, we summarize computational complexity of the proposed and conventional detection methods in Sect. III-C.

A. Learned Weighting Soft Projection (LWSP) Method

LWSP method is based on the gradient descent method with soft projection, which can be seen as a variant of *projected gradient descent*. The proposed procedure consists of parallel processing at SPUs and *weighted message aggregation* with the CPU. The proposed algorithm iterates the following three steps:

1) Gradient descent step in parallel at all SPUs,
2) Weighted message aggregation at CPU,
3) Soft projection step in parallel at all SPUs.

Figure 2 illustrates the message exchange between the SPUs and CPU of the proposed method. Each SPU$_k$ executes a gradient descent step and calculates a temporary estimated signal $\boldsymbol{z}_k^{(t)}$, which is sent to the CPU. The CPU then receives $\boldsymbol{z}_1^{(t)}, \ldots, \boldsymbol{z}_K^{(t)}$ from all the SPUs, and executes a weighted message aggregation, which is a process to evaluate the weighted average of the incoming messages. As a result, the CPU obtains the weighted average $\bar{\boldsymbol{z}}^{(t)}$ and send it back to all the SPUs. Each SPU$_k$ receives the weighted average $\bar{\boldsymbol{z}}^{(t)}$ and then executes a soft projection step. The above three steps are iterated T times, and the state vectors of SPUs at the end of the Tth iteration are the resulting estimated signal. A detailed description of each step is shown below.

Each SPU$_k$ has a state vector $\boldsymbol{x}_k^{(t)}$ at tth iteration. In the gradient descent step, each SPU executes a gradient descent step aiming at minimizing the global quadratic objective function:

$$L(\boldsymbol{x}) = \frac{1}{K}\sum_{k=1}^{K} ||\boldsymbol{y}_k - \boldsymbol{H}_k \boldsymbol{x}||^2. \tag{3}$$

The negative gradient of the objective function (3) is given by

$$-\nabla L(\boldsymbol{x}) = \frac{1}{K}\sum_{k=1}^{K} \boldsymbol{H}_k^H (\boldsymbol{y}_k - \boldsymbol{H}_k \boldsymbol{x}). \tag{4}$$

The global gradient, however, cannot directly be used because each SPU can access only its own received signal and channel matrix. Therefore, each SPU$_k$ obtains a temporary estimated signal $\boldsymbol{z}_k^{(t)}$ by using the vector $\boldsymbol{H}_k^H(\boldsymbol{y}_k - \boldsymbol{H}_k\boldsymbol{x}^{(t)})$ as a local gradient instead of the global gradient. The gradient descent step for SPU$_k$ becomes

$$\boldsymbol{z}_k^{(t)} = \boldsymbol{x}^{(t)} + \mu^{(t)}\boldsymbol{H}_k^H(\boldsymbol{y}_k - \boldsymbol{H}_k\boldsymbol{x}^{(t)}). \tag{5}$$

The parameter $\mu^{(t)}(>0)$ is a step-size parameter that affects convergence performance.

The gradient of (3) should be obtained from the sum of the $\{\boldsymbol{z}_k^{(t)}\}$. In the weighted aggregation step, the CPU receives the temporary estimated signals $\boldsymbol{z}_1^{(t)}, \ldots, \boldsymbol{z}_K^{(t)}$ from all the SPUs. The full gradient of $L(\boldsymbol{x})$, $\boldsymbol{z}^{(t)}$, is thus given by

$$\boldsymbol{z}^{(t)} = \frac{1}{K}\sum_{k=1}^{K}\boldsymbol{z}_k^{(t)}. \tag{6}$$

In the proposed algorithm, we will use the the following weighted average $\bar{\boldsymbol{z}}^{(t)}$ instead of $\boldsymbol{z}^{(t)}$:

$$\bar{\boldsymbol{z}}^{(t)} = \frac{1}{K}\sum_{k=1}^{K}\alpha_k\boldsymbol{z}_k^{(t)}. \tag{7}$$

The parameter α_k represents the weight assigned for SPU$_k$. The evaluation process of $\bar{\boldsymbol{z}}^{(t)}$ is called weighted aggregation.

The average $\bar{\boldsymbol{z}}^{(t)}$ can be seen as a *modified gradient*. The reason why we introduced the weighted average is the following. The weighting parameters $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \ldots, \alpha_K)^T \in \mathbb{R}_+^K$ allow us to weigh partial gradients according to its reliability. We may be able to increase the weight of SPU$_k$ if the SNR is enough high. It is expected that such an assignment leads to a better convergence behavior. These weighting parameters should be determined appropriately by incorporating the SNR differences among SPUs. The adjustment of the weighting parameters is of critical importance to achieve appropriate detection performance. The optimization of the weighting parameters is to be discussed later.

In the soft projection step, the state vector $\boldsymbol{x}_k^{(t)}$ is updated by the following soft projection step:

$$\boldsymbol{x}_k^{(t+1)} = \boldsymbol{x}_k^{(t)} - \eta(\boldsymbol{x}_k^{(t)} - \bar{\boldsymbol{z}}^{(t)}). \tag{8}$$

The parameter $\eta(>0)$ controls the strength of the soft projection. This step implies a smooth projection of $\boldsymbol{x}_k^{(t)}$ onto the weighted average $\bar{\boldsymbol{z}}^{(t)}$ instead of a hard projection $\boldsymbol{x}_k^{(t)} = \bar{\boldsymbol{z}}^{(t)}$. The soft projection was reported to yield performance improvement when combining DU [19].

The pseudo code of the proposed LWSP method is described in Algorithm 2.

The proposed algorithm includes free parameters $\mu^{(t)}, \boldsymbol{\alpha}, \eta$. The setting of these parameters causes significant influences to the detection performance of the proposed method. Finding an appropriate set of suitable parameters is not a straightfoward problem. We here employ DU to optimize these parameters. Namely, the values of these parameters are to be optimized by DU processes described in the next subsection.

Algorithm 2 LWSP method

Input: $\boldsymbol{H}_k(k=1,2,\ldots,K), \alpha_k, \boldsymbol{y}_k, \mu^{(t)}(t=1,2,\ldots,T)$, η, $\boldsymbol{x}_k^{(1)} = \boldsymbol{0}$ $(k=1,2,\ldots,K)$

1: **for** $t = 1, \ldots, T$ **do**
2: SPU$_k(k=1,2,\ldots,K)$:
$\boldsymbol{z}_k^{(t)} = \boldsymbol{x}_k^{(t)} + \mu^{(t)}\boldsymbol{H}_k^H(\boldsymbol{y}_k - \boldsymbol{H}_k\boldsymbol{x}_k^{(t)})$
3: CPU:
$\bar{\boldsymbol{z}}^{(t)} = \frac{1}{K}\sum_{k=1}^{K}\alpha_k\boldsymbol{z}_k^{(t)}$
4: SPU$_k(k=1,2,\ldots,K)$:
$\boldsymbol{x}_k^{(t+1)} = \boldsymbol{x}_k^{(t)} - \eta(\boldsymbol{x}_k^{(t)} - \bar{\boldsymbol{z}}^{(t)})$
5: **end for**

Output: $\hat{\boldsymbol{x}} = \boldsymbol{x}_k^{(T+1)}$

B. Parameter Learning by DU

The parameters $\mu^{(t)}$, η and $\boldsymbol{\alpha}$ affect the convergence performance of the proposed method. We thus need to determine these parameters properly. In order to optimize the parameters, we consider these parameters as trainable parameters $\tilde{\boldsymbol{\Theta}}$ and apply DU.

We here explain the procedure to optimize these parameters. In this study, we use training data generated from the probabilistic model of the distributed MIMO system defined in subsection II-B. A transmit signal $\boldsymbol{s}$ and noise vector $\boldsymbol{w}_k$ are randomly generated, and the received signal $\boldsymbol{y}_k$ is obtained by (1). The estimated signal $\hat{\boldsymbol{x}}_k^{(T+1)}$ is obtained by Algorithm 2. The transmit signal $\boldsymbol{s}$ is used as the supervised signal. The trainable parameters are updated to decrease the squared error loss function between the supervised signals $\boldsymbol{s}$ and estimated signals $\hat{\boldsymbol{x}}$. In addtion, we exploit incremental training described in subsection II-D3.

C. Computational Complexity

The required computational complexity for the proposed LWSP method, conventional CG-based detection method, and centralized (typical) MMSE detection method [3] is summarized in Table I. The LWSP and CG-based detection methods are distributed algorithms that consist of processing on multiple SPUs and CPU. The main computational factor for each SPU is the matrix-vector multiplication included in each iteration. CPU only calculates the sum so that it requires $O(N)$ in each iteration. On the other hand, the centralized MMSE method includes matrix inverse calculation that requires $O(N^3)$.

Table I reveals that the proposed LWSP method achieves load balancing into SPUs and CPU. The LWSP method is more computationally efficient than the centralized MMSE detection method.

TABLE II
PARAMETER SETTINGS OF EXPERIMENTS

IV. NUMERICAL EXPERIMENTS

In this section, we show results of numerical experiments to evaluate the detection performance of the proposed method by comparing with that of the conventional CG-based detection method [4] as the benchmark.

A. Experimental Settings

For the numerical experiments, the LWSP method was implemented using PyTorch 1.12 [20]. We assumed QPSK transmit signal points:

$$\left\{\frac{1+i}{\sqrt{2}}, \frac{-1+i}{\sqrt{2}}, \frac{1-i}{\sqrt{2}}, \frac{-1-i}{\sqrt{2}}\right\} \tag{9}$$

and the transmit symbol s_i was a randomly generated according to the probability:

$$\begin{aligned} P\left(s_i = \frac{1+i}{\sqrt{2}}\right) &= P\left(s_i = \frac{-1+i}{\sqrt{2}}\right) \\ &= P\left(s_i = \frac{1-i}{\sqrt{2}}\right) = P\left(s_i = \frac{-1-i}{\sqrt{2}}\right) = \frac{1}{4}. \end{aligned} \tag{10}$$

Each element of the channel matrix $\boldsymbol{H}_k$ was randomly generated according to $\mathcal{CN}(0,1)$. A channel matrix was generated before the training process and the same matrix was used during the numerical simulation. The trainable parameters were updated by Adam optimizer using mini-batches whose size was 1000 and a training process is executed with 10000 rounds. The initial values of $\mu^{(1)}, \ldots, \mu^{(T)}$ were set to 0.01 and that of η was 1.0, respectively. The initial vector of weighting parameters $\boldsymbol{\alpha}$ was set to $\mathbf{1}$. The parameter ρ of the CG-based detection method [4] was set to $\rho = 0$. The learning rate of Adam optimizer for $\mu^{(t)}$, η and α_k were 10^{-3}, 10^{-5} and 10^{-5}, respectively. The number of iterations of the LWSP method and conventional method was set to $T = 10$.

We prepared four experimental conditions presented in Table II. The experiment 1 is the case where the number of the SPUs is $K = 2$. We present the detection performance when SNR of SPU_2, SNR_2, varies relative to SNR_1 which is fixed to $\mathrm{SNR}_1 = 0$dB. In the experiments 2–4, we evaluate detection performances under various environments when the number of the SPUs is $K = 5$ or 10. The system parameters and SNR settings of each SPU are also summarized in Table II.

To confirm the effectiveness of index-dependent step-size parameters $\mu^{(t)}$, we also evaluated detection performance of the LWSP method that uses fixed, i.e., index-independent, step-size parameter μ.

B. Performance Evaluation

The results of the experiment 1 are shown in Figs. 3, 7, 11. Figure 3 presents SER (Symbol Error Rate) of the detection methods as functions of SNR_2. The LWSP method with the index-dependent step-size parameters $\mu^{(t)}$ yields the smallest SER when SNR_2 is larger than 10dB. This result implies that the LWSP method with index-dependent step-size performs better than the one with fixed step-size. The larger degree of freedom on the step-size parameters appears beneficial to improve the convergence speed of the LWSP method. The difference in SER between the LWSP method with index-dependent step-size parameters and the CG-based method is small when the SNR_2 is in the range from 0dB to 5dB. However, in the regime where SNR_2 is greater than 5dB, the LWSP method achieves significantly smaller SER than that of the conventional CG-based method. An appropriate setting for the weighting parameters in the LWSP method result in this huge difference.

Figure 7 shows the values of the trained index-dependent step-size parameters for $\mathrm{SNR}_2 = 20$dB. We can see that the value varies over a wide range depending on the iteration index. Figure 11 displays the trained parameter values of $\boldsymbol{\alpha}$ when SNR_2 is 20dB. The value of α_2 is much larger than that of α_1. It indicates that the message from SPU_2 with higher SNR is regarded as more important than that from SPU_1.

Figures 4–6, 8–10, and 12–14 show SER performance versus the number of iterations, the values of the trained index-dependent step-size parameters, and the values of the trained parameter $\boldsymbol{\alpha}$ in the experiments 2–4, respectively. From Figs. 4–6, the proposed LWSP method with index-dependent step-size parameters achieves the lowest SER in each iteration. We can find that the proposed method can provides superior detection performance to the conventional method in a variety of SNR setting. Figures 8–10 show the same tendency as the result in the experiment 1. These index-dependent step-size parameters yield the improvement in detection performance of the proposed method.

The trained weighting parameters $\boldsymbol{\alpha}$ shown in Figs. 12–14 can be interpreted as a reflection of the SNR setting. From these figures, we can see the correspondence between the value of trained weighting parameter α_k and SNR_k, i.e., a larger SNR_k leads to a larger α_k. This means that the weighting parameters in the proposed method can be appropriately learned by using DU according to the value of SNR_k.

In summary, the proposed LWSP method can achieve excellent signal detection performance under various heterogeneous SNR environments by introducing the weighting parameters

optimized by DU.

V. Concludeing Remarks

In this paper, we proposed the LWSP method for distributed MIMO signal detection. The proposed method is based on the gradient descent method with soft projection. The trainable weighting parameters are introduced to adapt heterogeneous SNR environments of SPUs. These weighting parameters are optimized by using deep unfolding and used for the weighting aggregation process at CPU. The numerical results show that the proposed method outperforms the conventional method if SPUs are in heterogeneous SNR environments. In addition, further performance improvement can be achieved by using index-dependent step-size parameter, which improves the convergence behavior of the proposed method.

The proposed method assumed the existance of CPU for weighting aggregation. A decentralized variant without CPU may be able to be developed based on the idea of the trainable weighting parameters. Such a direction remains as an interesting open problem.

Abstract — **In lobster farming, monitoring of lobsters is essential and must be performed. Aruna, one of the lobster trading startups in Indonesia, is still using manual monitoring by sending divers underwater to observe the progress of the lobsters. This way is considered less effective because it is done intermittently, only at certain times and in good weather conditions. In this study, we propose to investigate object detection for underwater surveillance cameras as a means of real-time monitoring and counting of lobsters. Underwater video data is fed into the proposed system based on a deep learning-based model. This system consists of three processes: image enhancement with WaterNet as noise reduction, object counting with the YOLOv6/7/8 model, and object tracking using StrongSORT. For details, we annotated the lobster data by head only and full body. Our test results show that YOLOv7, with head annotation, has stable mean Average Precision (mAP), making it suitable for the proposed system. Then, we implemented a combination of WaterNet, YOLOv7 and StrongSORT to the proposed system architecture for the Intelligent surveillance camera.**

I. INTRODUCTION

Monitoring livestock is one of the duties that must be performed daily in order to maintain livestock quality. Humans require nutritious sustenance to maintain their nutritional status. Consequently, monitoring of food constituents such as plants and animals is required. Occasionally, monitoring is problematic due to great distances, extreme weather, and the diverse nature of fresh/seawater organisms, such as lobsters. This can result in the loss of animal's cause preyed upon by other animals or environmental degradation.

A camera is required to monitor livestock. Drone Sheep Livestock [1] is one of the many tools developed to monitor livestock using a camera, and it is used to count the quantity of sheep. What if these animals are aquatic? This is one of the greatest challenges for humans, given that water has pressure, turbidity, etc. The objects are affected by the reflection of light near the surface of the water, and when they are in deep water, it is difficult to detect their margins or boundaries due to their dull colour and poor lighting [5]. Object detection requires clear images to capture the object distinctly and feed it into deep learning-based object detection systems such as YOLOv6

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

[7], YOLOv7 [13], and YOLOv8 [10]. Therefore, image enhancement is necessary in this circumstance.

Object detection one of many essential computer vision tasks that involves detecting instances of visual objects belonging to specific classes in digital images [15]. You Only Look Once, or YOLO, is a well-known and extensively utilized algorithm. YOLO is synonymous with its object detection function's characteristics [11]. In recent years, academics have published YOLOV6, YOLOV7, and YOLOV8 as successors to YOLO. The discussion in this research paper concentrates on combining Image Enhancement with these three YOLO variants. In the final phase, it will be necessary to demonstrate and justify the selection of appropriate unifying Image Enhancement or WaterNet [6], YOLOv7 [13] and StrongSORT [3] for smart surveillance system cameras on lobster detection, counting and tracking.

II. Related works

There have been numerous YOLO variations over the past few years that and be the state-of-the-art object detection model. In 2022, YOLOv6 was released [7]. This version is one of the still-popular YOLO versions in the field of object detection. YOLOv6 was designed as a rapid and precise single-stage system for object detection. It utilizes a singular convolution neural network to predict the type and position of image objects. The new architecture and optimization techniques employed render YOLOv6 more effective and accurate than its predecessor. Additionally, previous research compares the outcomes of YOLOv6 tests on prominent datasets with those of other object detection systems. The results indicate that YOLOv6 has excellent efficacy and industry application potential. Furthermore, YOLOv7 [13] is a variant of the YOLO model that has been enhanced. YOLOv7 employs the new architecture of real-time object detector, which is extended efficient layer aggregation networks (E-ELAN) based on ELAN and the corresponding model scaling technique and proposes the trainable bag-of-freebies method to improve object detection accuracy. YOLOv8 [10] is one of the most recent real-time object detection families in the YOLO family. The company Ultralytics has just published this version at the beginning of 2023. YOLOv8 has several enhancements and optimizations over the previous version, including an improved architecture, more efficient optimization techniques, and the use of a larger training data set. The efficacy of YOLOv8 in terms of speed and accuracy is dependent on the hardware specifications and image size employed during the detection process. However, YOLOv8 has excellent precision and relatively high speed, allowing it to be used in a variety of real-time object detection applications. Furthermore, kind of YOLO models have been utilized in the underwater applications task. For instance, the work in used YOLOv3 as the baseline for an underwater robot or remotely operated underwater vehicle (ROV) that proposed to monitor the kind of fish. Similarly, the work in [8] utilized the YOLOv3 baseline combined with data augmentation for underwater object detection. This research proves that the improved version of YOLO achieves good performance under various water conditions. On the other hand, the work in [1] employs the one version before the work in [8, 12] or YOLOv2 with the modified MobileNetV2 as the backbone and gets very high accuracy in kind of fish detection.

Marine engineering and aquatic technologies have paid significant attention to the enhancement of underwater images. In recent years, numerous algorithms for enhancing underwater images have been proposed [2]. However, these algorithms have been evaluated primarily using computer-generated datasets or a small number of actual images. As a result, it remains uncertain how well these algorithms would perform on images captured in natural underwater environments, and it is challenging to evaluate the progress in this field. To address this deficiency, the work in [6] present the first exhaustive perceptual investigation and analysis of underwater image enhancement using a large collection of actual images. In their study, they establish an Underwater Image Enhancement Benchmark (UIEB) consisting of 950 real-world underwater images and 890 reference images. The remaining sixty underwater images for which adequate reference images cannot be obtained are classified as problematic data. They conduct a comprehensive qualitative and quantitative analysis of the state-of-the-art algorithms for underwater image enhancement using this dataset. In addition, they propose the WaterNet network, which is trained on this benchmark and serves as an indication of the generalization capabilities of the proposed UIEB for training CNNs. The benchmark evaluations and WaterNet model results demonstrate the strengths and limitations of the current state-of-the-art algorithms, thereby providing valuable insights for future research in the field of underwater image enhancement.

In this work, we proposed to combine the current version of YOLO or YOLOv6,7,8, image enhancement and Simple Online and Realtime Tracking (SORT) to perform the application for lobster detection and counting in under the sea cage. Moreover, SORT is a pragmatic approach to tracking multiple objects with an emphasis on basic and efficient algorithms [14]. In addition, SORT methods include three

steps: detection with the Faster Region CNN detection framework [9], estimation model with the Kalman Filter [4], and classification with the Hungarian Algorithm [5]. DeepSort is a method for object tracking that integrates object detection and probabilistic data association (PDA)-based tracking techniques [14]. DeepSort utilizes object detection information to approximate the object's location in subsequent frames and updates this estimate whenever an object is detected. StrongSORT [3] is an algorithm for object tracking that is an enhancement over DeepSORT, or you could say that it is a Stronger DeepSORT. StrongSORT has three advantages over DeepSORT: IDF1, HOTA, and MOTA. StrongSORT has IDFI 82.3, MOTA 77.1, and HOTA 69.6, whereas DeepSORT has IDFI 77.3, MOTA 76.7, and HOTA 69.6. Performance-wise, StrongSORT is superior to DeepSORT.

III. PROPOSED SYSTEM

The method utilized in this investigation for lobster detection is the YOLOv6,7,8 [7, 10, 13] model. In this experiment, lobster images were trained with and without enhanced images using these detection models, and then the mAP of each was compared. The training results were then applied to the detection and counting of lobsters from the video input, which was then transmitted to the tracking algorithm, namely StrongSORT [14]. There are three stages in the monitoring procedure flow for lobsters, as illustrated in Fig 1.

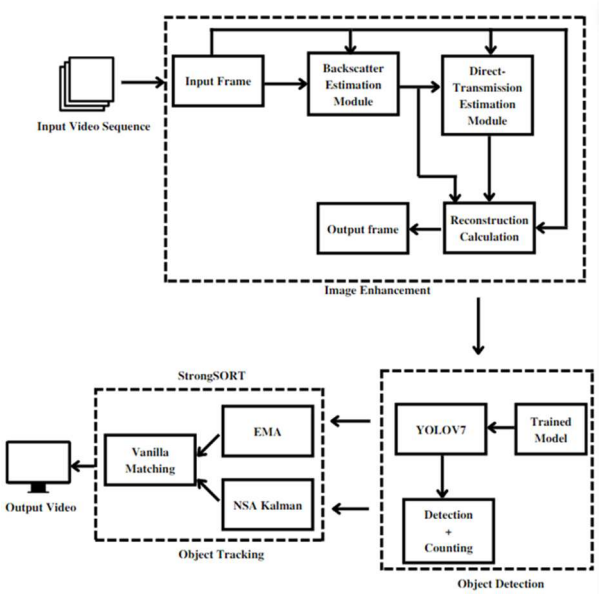

Fig. 1 The proposed intelligent camera for lobster monitoring system.

The first stage involves acquiring the frame from the underwater camera and involves enhancing the frame by using the WaterNet as the model for image enhancement. Next, the processing stage is the frame for the detection of lobster objects using YOLO, which has been trained, and the final stage is counting the number of lobsters detected on the frame. In addition, the third stage involves object tracking on detected objects using the StrongSORT algorithm and assigning an ID to each lobster object detected in the frame. The results of the final stage display the results as a video output for user monitoring.

IV. RESULTS AND DISCUSSIONS

Fig 2 shows the general architecture of the proposed monitoring system in the real environment of the cultivation site. The dataset used to create this lobster detector is a captured of a video in Aruna[1] lobster farm where the cage is about 15 meters under the sea. In total, there are 22 images of lobster captured, which are then processed and augmented to create 45 images, of which 40 are used for training, 2 for validation, and 3 for testing. We are separating the annotation into two scenarios. In the first scheme, we only annotate the main showing part of or the head of the lobsters, whereas, in the second scheme, we annotate the entire body. Additionally, to solve the limitation of the dataset, we conducted the experiment by fine-tuning the detection models by using a pre-trained weight that has been trained on another lobster dataset captured from public videos of a lobster farm[2]. This investigation focuses on comparing the mAP of each image enhancement. The device is divided into training and testing procedures, yet the calculation of the accuracy focuses on the testing part.

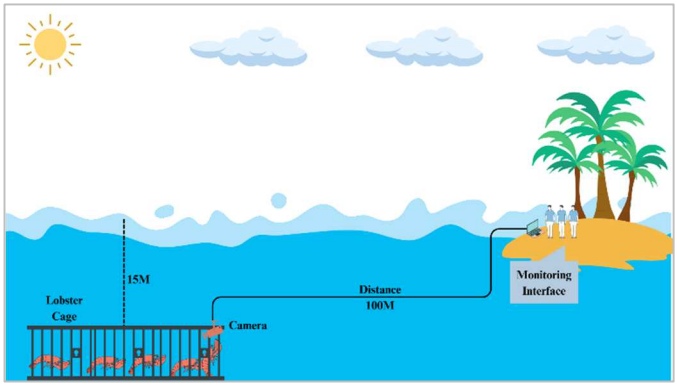

Fig. 2 The proposed of the architecture for lobster monitoring system.

[2] https://youtu.be/a5HpRgDwEgg

We utilized the Tesla T4 graphics processing unit (GPU) with 16GB of GPU memory and 12GB of RAM for the training procedure. The testing procedure for this endeavour employs the Windows 11 operating system and GPU NVIDIA GTX 1650 TI 4GB VRAM as well as the interface for using monitoring where the connection between the camera and this PC is about 100 Meters, as shown in Fig 2.

Table 1. The testing accuracy with head annotation of YOLOv6

Testing Scenario	mAP 0.5	mAP 0.5-0.95
YOLOv6	0.771	0.33
YOLOv6+Water Net	0.771	0.33
YOLOv6+Fine Tuning	0.836	0.405
YOLOv6+WaterNet+Fine Tuning	**0.836**	**0.405**

Table 2. The testing accuracy with head annotation of YOLOv7

Testing Scenario	mAP 0.5	mAP 0.5-0.95
YOLOv7	0.995	0.603
YOLOv7+Water Net	0.995	0.548
YOLOv7+Fine Tuning	0.996	0.51
YOLOv7+WaterNet+Fine Tuning	**0.996**	**0.515**

Table 3. The testing accuracy with head annotation of YOLOv8

Testing Scenario	mAP 0.5	mAP 0.5-0.95
YOLOv8	0.963	0.477
YOLOv8+Water Net	0.957	0.475
YOLOv8+Fine Tuning	0.935	0.499
YOLOv8+WaterNet+Fine Tuning	**0.995**	**0.5**

Table 4. The testing accuracy with full body annotation of YOLOv6

Testing Scenario	mAP 0.5	mAP 0.5-0.95
YOLOv6	0.618	0.21
YOLOv6+Water Net	0.618	0.21
YOLOv6+Fine Tuning	**0.845**	**0.358**
YOLOv6+WaterNet+Fine Tuning	**0.845**	**0.358**

Table 5. The testing accuracy with full body annotation of YOLOv7

Testing Scenario	mAP 0.5	mAP 0.5-0.95
YOLOv7	0.982	0.388
YOLOv7+Water Net	0.926	0.437
YOLOv7+Fine Tuning	0.996	0.483
YOLOv7+WaterNet+Fine Tuning	**0.996**	**0.514**

Table 6. The testing accuracy with full body annotation of YOLOv8

Testing Scenario	mAP 0.5	mAP 0.5-0.95
YOLOv8	0.995	0.614
YOLOv8+Water Net	**0.995**	**0.618**
YOLOv8+Fine Tuning	0.995	0.557
YOLOv8+WaterNet+Fine Tuning	0.995	0.551

Based on the experimental results in Table 1 to Table 6, several scenarios are: original YOLO models, added image enhancement or WaterNet, and added finetuning. It is evident that the combination of underwater image enhancement or WaterNet and YOLOv7 is useful for achieving the mean Average Precision or mAP 0.5 and also 0.5-0.95 with 99.6% and 51.5 %, respectively. It is only displayed for YOLOv7 head annotation, and mAP increases when underwater image enhancement is added. It is also particularly useful for YOLOv6 and YOLOv8. Moreover, Fig 3 shows the detected lobster from the surveillance system with the counted number.

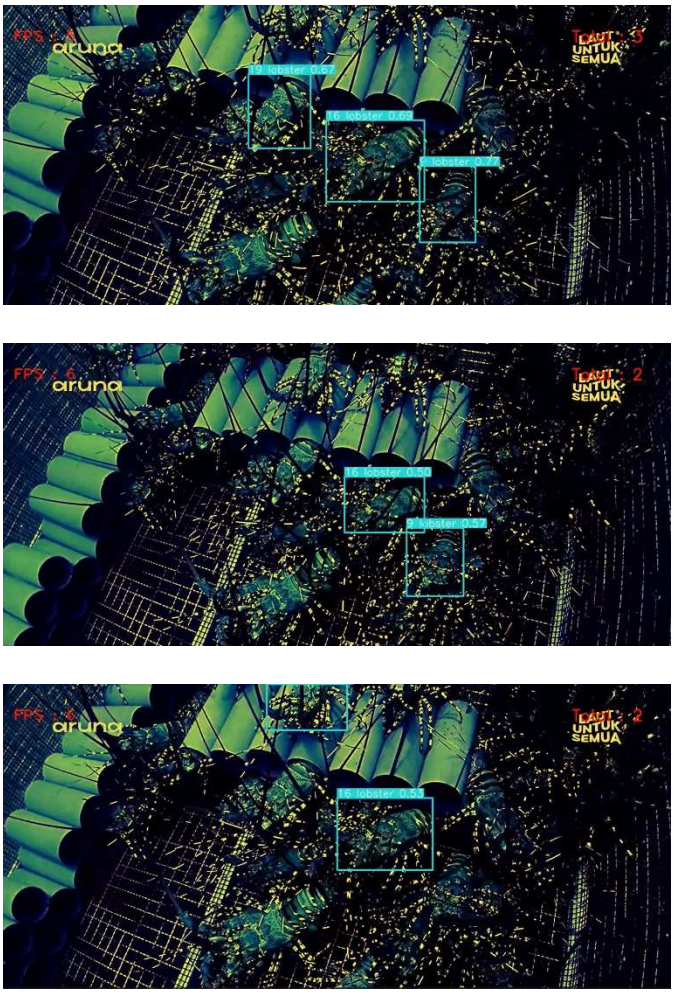

Fig. 3 The captured lobster from the monitoring system.

V. CONCLUSIONS

Our experiments have demonstrated that underwater image enhancement increases the mAP in some scenarios on YOLOv6, YOLOv7, and YOLOv8, with the most significant benefit in mAP 0.5-0.95 with YOLOv7 when the finetuning scenario is added. This result shows that the proposed work is suitable for the intelligent system of lobster surveillance camera.

***Abstract*—This paper presents a vision-based unmanned aerial vehicle (UAV) indoor obstacle avoidance using a deep reinforcement learning (DRL). The system consists of two parts a depth map compression and a UAV control. For the depth map compression part, the pre-trained Variational AutoEncoder model is used to improve obstacle avoidance and reduce the training time. The states include the UAV information, gray images and compressed features. A dueling double deep recurrent Q network model is used to control the UAV. The network is trained in the AirSim simulation. To validate the performance of the proposed algorithm some simulations are conducted. The results show that the proposed algorithm can avoid obstacles at a fast speed in a narrow space, and fly through a difficult L-shaped corner in an indoor simulation.**

Keywords—Unmanned Aerial Vehicle, Obstacle Avoidance, Deep Reinforcement Learning, AirSim, Variational AutoEncoder

I. INTRODUCTION

In recent years, the development of unmanned aerial vehicles (UAVs) has been advancing rapidly, and they are increasingly being used in various fields to complete tasks. For example, UAVs are used for a large-scale crop spraying, soil and crop analysis, or search and rescue mission, product delivery. In addition to the common outdoor applications, UAVs are also used indoors, such as indoor cleaning and disinfection, as well as patrolling factories, campuses, offices and managing warehouses.

Regardless of indoor or outdoor scenarios, during the execution of tasks, UAVs will face the situation that needs to avoid obstacles in front of them. The basis for a UAV to perform obstacle avoidance is to be able to know the distance between itself and the obstacle. Currently, there are various technologies that can be used to measure distance, including ultrasonic, infrared, laser and visual, each has its advantages and disadvantages. However, if we consider costs, power consumption, and weight, using only visual sensors for obstacle avoidance could be a better choice on different UAVs. The difference of indoor environment and outdoor environment is that the indoor environment is mostly an enclosed space that makes the control of UAVs more stringent. Also the indoor environment has more types of textures and colors than the outdoor environment, and there are also some objects without textures, such as white walls or glass that increases the difficulty of obstacle avoidance indoors. However, indoor flying is not affected by weather changes and has less interference than outdoor scenes.

Traditional obstacle avoidance methods, such as simultaneous localization and mapping that requires high computing power and accuracy of device, and it cannot detect the walls or glasses without texture. With the flourishing development of deep learning, more and more researches have applied it to the obstacle avoidance, path planning, safe landing, height control for UAV. This paper presents a UAV obstacle avoidance system based on deep reinforcement learning that can avoid the obstacle rapidly in both outdoor and indoor environments.

The contributions of this paper are mainly as follows:

- To add a VAE model to the DRL model to improve the training speed, collision rate, and UAV movement speed.
- To propose an algorithm to adjust the number of training times for different difficulty levels of initial points in DRL that can improve training effectiveness.
- To propose a quick and safe indoor DRL model and a reward algorithm to allow to pass through narrow indoor spaces or right-angled bend successfully.

The organization of this paper is as follows. Section 2 reviews the current obstacle avoidance using deep learning and the architecture of DRL. Section 3 presents the proposed method. In Section 4 the performance evaluation is conducted in the simulator. Conclusions are given in the last section.

II. RELATED WORK

A. Reinforcement Learning

Reinforcement learning is a part of machine learning, but it is different from supervised learning and unsupervised learning. The goal of reinforcement learning is to maximum the future reward. The element of reinforcement learning are shown in Figure 1. The agent selects the best action (A_t) based on the state (S_t) provided by the environment at each time step. The environment then provides a reward (R_{t+1}) and the next state (S_{t+1}) based on the action (A_t) selected by the agent. The design of the reward algorithm is important in reinforcement learning because it directly affects the agent's learning based on what reward should be given in different states.

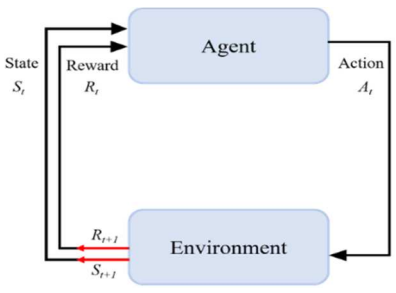

Figure 1. Reinforcement learning overview

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

Markov decision processes (MDPs) are the idealized mathematical form for reinforcement learning problems. All processes in MDPs are stochastic, and the next state (S_{t+1}) depends only on the current state (S_t). Reinforcement learning can be transformed into the format of MDPs (S,A,P,R, γ), where S is the set of state space, A is the set of actions, $P = P(s'|s,a), for\ all\ s \in S, a \in A$, indicates the probability of transitioning from s to s' after taking action a; $R = R(s,a,s')$ represents the reward obtained when transitioning from state s to state s' after performing action a; $\gamma \in [0,1]$ is the discount factor. The goal of reinforcement learning is to maximize future rewards, also known as the expected return. Therefore, a policy (π) is used to determine what action to take in a given state. As shown in equation (1), the probability of taking action a in state s is determined by the policy. This formula defines the behavior of a policy.

$$\pi(a|s) = \mathrm{P}(A = a|S = s) \tag{1}$$

An agent can have many policies, and to find the best one requires evaluating different policies using a value function. Equation (2) shows the expected return in the future G_t, where γ is a discount factor representing the degree of emphasis on the future rewards, with $0 \leq \gamma \leq 1$. To find the best policy, the state-value function and the action-value function are used for evaluation. Equation (3) represents the state-value function, which calculates the expected return from state s based on policy π. Equation (4) represents the action-value function, which calculates the expected return from taking action a in state s based on policy π.

$$G_t = R_{t+1} + \gamma R_{t+2} + \cdots = \sum_{k=0}^{\infty} \gamma^k R_{t+k+1} \tag{2}$$

$$V_\pi(s) = E[G_t|S_t = s] \tag{3}$$

$$Q_\pi(s,a) = E[G_t|S_t = s, A_t = a] \tag{4}$$

The Bellman equation is one of the key of many reinforcement learning algorithms and is used to simplify reinforcement learning or MDP problems. The Bellman equation divides the value function into two parts, immediate reward and future reward weighted by γ. Equations (5) and (6) represent the state-value function and action-value function using the Bellman equation. By using these two value functions, one can find the optimal policy that maximizes the expected return. The optimal policy is denoted as π^*, and the two optimal value functions are represented in equations (7) and (8). With these two optimal value functions, one can find the best policy.

$$V_\pi(s) = \sum_a \pi(a|s) \cdot \sum_{s'} p(s', r|s, a)[r(s, a, s') + \gamma V_\pi(s')] \tag{5}$$

$$Q_\pi(s,a) = \sum_{s'} p(s', r|s, a)[r(s, a, s') + \gamma \sum_{a'} \pi(a'|s') \cdot Q_\pi(s', a')] \tag{6}$$

$$V_{\pi^*}(s) = max_{a \in A} \sum p(s', r|s, a)[r + \gamma V_{\pi^*}(s')] \tag{7}$$

$$Q_{\pi^*}(s,a) = \sum_{s'} p(s', r|s, a)[r + \gamma max_{a'} Q_{\pi^*}(s', a')] \tag{8}$$

But in reality, the probability of state transitions is unknown, and the environment is not fully understood. Therefore, it is necessary to estimate the value function through experience by Monte Carlo (MC) and Temporal Difference (TD) that are called model-free methods, as they do not model the environment, but instead estimate V(s) by sampling enough rounds. With the MC method, updates are made only after a complete episode is run, while TD updates can be made after each state is completed through the concept of bootstrapping.

B. DQN

Mnih et al. [1] first proposed using Deep Q-Network (DQN) to play Atari games and beat human. By combining deep learning with reinforcement learning, the Q-table used in Q-learning, which is limited in recording states and actions, is replaced with a Q-network deep learning model to approximate the optimal policy, thus solve the limited capacity problem of the Q-table. Hasselt et al. [2] proposed Double DQN to reduce the problem of overestimation of Q values in DQN. Wang et al. [3] proposed Dueling DQN, which modified the architecture of DQN to improve the training performance and reduce the overestimation of Q values. Hausknecht et al. [4] replaced the fully connected layer in DQN with a Long Short-Term Memory (LSTM) model, called DRQN, which performed better than DQN in Atari games with partially observable Markov decision processes. Schaul et al. [5] proposed Prioritized Experience Replay by modifying Experience Replay, By using a prioritized sampling structure, the probability of important experiences being sampled is increased, making the model learning more efficient.

C. Actor-Critic

Actor-Critic is a model-free, off-policy RL algorithm, where the actor is based on policy gradient and the critic is based on Q-learning. The actor chooses an action and the critic judges the goodness of the action. Commonly used actor-critic based algorithms in UAV obstacle avoidance include Deep Deterministic Policy Gradient (DDPG), Twin Delayed DDPG (TD3) and Soft Actor-Critic (SAC).

Lillicrap et al. [6] combined DPG and DQN to propose DDPG, which addresses the inability of DQN to deal with continuous control problems by directly outputting deterministic actions. Fujimoto et al. [7] optimized DDPG and proposed TD3, which includes two additional models compared to DDPG. It uses two critic networks and selects the smaller one as the target Q-value for updating. Additionally, the critic network is updated more frequently than the actor network to ensure the stability of the critic network before training the actor network, reducing the potential for incorrect updates. Furthermore, TD3 adds random noise to the action to improve the stability of the model.

D. UAV obstacle avoidance using DRL

The literature related to deep reinforcement learning are mainly divided into indoor and outdoor scenes. In terms of model architecture, they can be divided into models based on Deep Q Network (DQN) and Actor-Critic. During training, models mostly use two types of data for training: depth maps and color images.

Singla et al. [8] proposed an indoor obstacle avoidance using cGAN+DRQN to train the cGAN model to convert color images to depth maps, then use real photos to do the fine-tuned. This model performs better than DQN and D3QN in obstacle avoidance and power consumption. Doshi et al. [9] trained a Double DQN model using different urban environments, including areas with stationary obstacles and areas with moving obstacles. The UAV is set to fly at a constant speed, and the model outputs five different yaw rates.

Roghair et al. [10] proposed improvements to exploration algorithms using D3RQN, where object detection was performed using RGB images to enhance obstacle range in depth maps. They proposed two exploration algorithms: Convergence Exploration and Guidance Exploration. Ou et al. [11] proposed DispNet to combine with D3RQN. DispNet is used to convert RGB images into depth maps that are then used as input for the D3RQN model. The effectiveness of DDQN, D3QN, DDRQN, and D3RQN were compared, and all models were tested in various scenarios. It achieves a success rate of over 90%. Thomas et al. [12] used the D3QN-SAM model, which showed good obstacle avoidance performance in different environments. The model takes a sequence of 5 consecutive depth maps as input. Kim et al. [13] used the FCRN model to convert color images into depth maps, which were then used as inputs for the D3QN model to perform indoor navigation.

III. PROPOSED METHOD

There are many research about obstacle avoidance based on DRL, but most of them only test in the simulate environment. To test the effectiveness of DRL in real-world scenarios, this system was tested on a 450-axis quadrotor UAV through actual experiments.

We extend the framework based on the previous research [14] and make some improvements. The system architecture is shown in Figure 2. The system uses Nvidia Jetson Nano as an onboard edge device instead of Raspberry Pi and transmits images and control commands through 4G/5G. Image information is obtained through the Intel RealSense D415 depth camera. The control package is ROS.

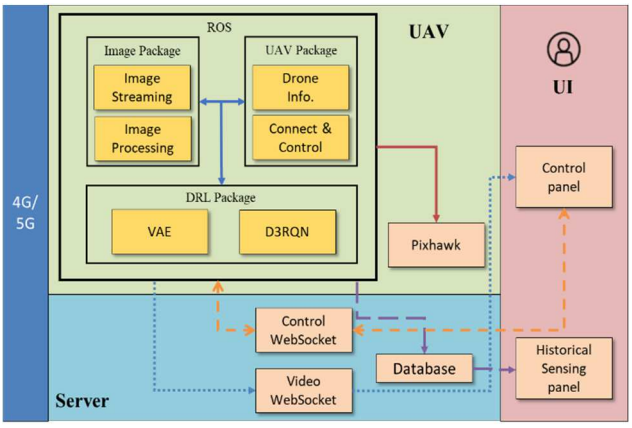

Figure 2. System architecture

Figure 3 shows the system model. The inputs include depth maps, RGB images, and UAV information. The image part is obtained through a depth camera, while the UAV information includes speed, yaw angular velocity, and so on. The RGB images are converted to grayscale, and both images are cropped to remove the regions without depth information. VAE is used to reduce the dimensionality of the depth map, and then the grayscale image, the reduced depth data, and UAV information, along with the past 7 data, are combined as the input to the deep reinforcement learning model. Finally, the output UAV action is obtained.

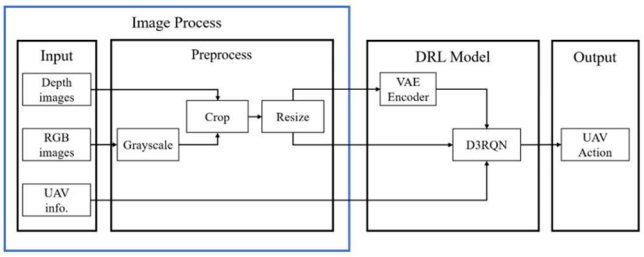

Figure 3. The proposed model

A. Image Processing

The acquired depth maps from the depth camera has some area with holes. In order to reduce the impact of holes on the actual flight test, it is necessary to preprocess the images to remove the holes before they can be used as inputs for the DRL model. Initially, a depth map and a color image with a size of 640x480 are obtained through the depth camera. The color image is aligned with the depth map during acquisition, because the camera positions are different, there are invalid depth areas around the depth map, as shown in the left image of Figure 4. To speed up the obstacle avoidance algorithm, the hole-filling algorithm is not used to repair the depth map, and only the areas around the image that have no depth information are removed.

To ensure the safety of personnel and equipment, a safety threshold is set at the end of the image preprocessing process to prevent collisions of the UAV. Before taking action based on the input image, we first determine whether the area of invalid depth pixels in the image exceeds 50% of the entire depth map. If it does, we judge that the UAV is too close to an obstacle in front, and command it to hover in place. In the deep depth map in the lower left of Figure 4, after cropping the surrounding area, the area of invalid depth pixels is 58%, indicating that the UAV is too close to the pillar on the right, and immediate hovering is necessary to avoid collision.

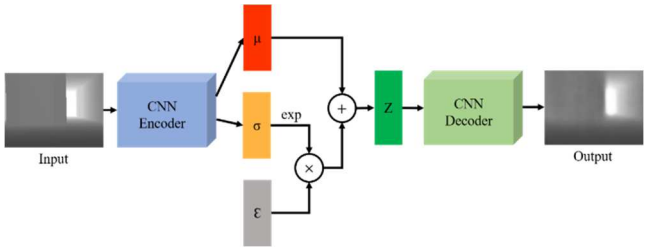

Figure 4. Depth images and Gray images

B. Variational AutoEncoder

VAE is a kind of Autoencoder and its architecture is shown in Figure 5. After passing through the encoder, the original encoded μ and the σ controlling the interference of noise are output. σ is exponentiated to ensure its value is positive, and multiplied by a normal distribution noise ε. The final encoded result is obtained by adding the original encoded result with the noise. Table 1 shows the parameters of each layer in the encoder and decoder, using Leaky ReLU as the activation function, stride is 2, and padding is 1. It was shown that adding VAE to DRL training can speed up the

training process [15]. Finally, the dimensionality-reduced

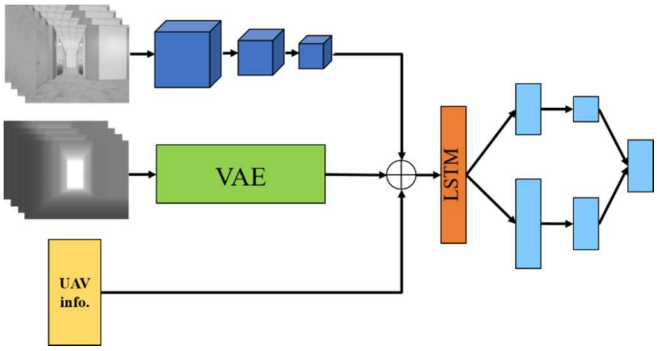
data Z is 64-dimensional, which reduces the data amount by 1200 times compared to the original 320x240 depth map. The decoder layer is not required in the subsequent D3RQN training and actual use.

Figure 5. The VAE architecture

Table 1 Parameters of each layer in the Encoder and Decoder

Layer	Encoder		Decoder	
	Channels	Kernel size	Channels	Kernel size
Input	1		512	
#1	16	[4, 4]	256	[5, 4]
#2	32	[4, 4]	128	[4, 2]
#3	64	[4, 4]	64	[4, 5]
#4	128	[4, 4]	32	[6, 8]
#5	256	[4, 4]	16	[8, 7]
#6	512	[4, 4]	1	[4, 6]

C. *Dueling Double Deep Recurrent Q Network*



The D3RQN model shown in Figure 6 combining Multi-step learning, Double Q-learning, Dueling network and RNN is used. Multi-step learning can improve the model's effectiveness and train better in tasks with the sparse reward. Double Q-learning and Dueling Network can effectively avoid overestimation of the Q value and accelerate the training speed and performance of the model. Adding RNN to assist in memory can achieve better results in partially-observable markov decision process.

The input of the model consists uav information, the gray images which is genrated by convolution network and depth maps from the VAE model. The data consists eight continous time steps that include the current time and the previous seven time steps. The model will output seven actions that are shown in Table 2. Note that V is velocity(m/s) and ω is rotation angle.

Table 2. UAV action

Choice	$[V, \omega]$
Action 1	[0.2, 0]
Action 2	[0.5, 0]
Action 3	[1.0, 0]
Action 4	$[V, 15^{\circ}]$
Action 5	$[V, -15^{\circ}]$
Action 6	$[V, 30^{\circ}]$
Action 7	$[V, -30^{\circ}]$

.

D. *Training Environment*

AirSim simulator is used as the training environment to provide highly realistic virtual scenes. Through the API of AirSim, UAVs can be controlled to perform different actions, and also can detect the collision of UAVs. The training environment is shown in Figure 7.

Figure 7. Two simulation environments

In the training scenario, there are 20 different starting points with varying difficulty levels. For example, when the starting point is one of the four corners of map, the UAV only needs to move forward without getting too close to the side walls throughout the entire episode. There are no obstacles and no need to turn, making it easier and faster to train. However, for other starting points, after moving forward for a distance, the UAV needs to dodge obstacles or turn at a right angle, resulting in a higher probability of collision and requiring more training and exploration. Therefore, during training, different training frequencies should be given according to the training situation of each starting point, while at least one training frequency is allocated for simpler starting points.

E. *Reward Function*

The reward function is divided into two parts, Reward_speed and Reward_depth, both of them are in the range of [0, 0.5]. During the training phase, three distance sensors located in the middle and on the left and right sides are added to detect obstacles in front. The distances obtained by the distance sensor are defined as Dis_{mid}, Dis_{left}, and Dis_{right} .The termination conditions for an episode are either exceeding max steps or collision of the UAV. The collision of the UAV is determined through the AirSim API or one of the distance sensors is less than 0.5 meter and set the reward to -2 when collision occurs.

The Reward_speed depends on the obstacles in front of UAV, if there is no obstacle in front of UAV, the UAV should go straight with higher speed, also the UAV should use

smaller displacement to avoid obstacles. The UAV's speed and yaw rate are defined as V and ω, respectively, and a threshold value δ is set as the UAV's safety distance. If all three distance sensors are greater than the threshold value δ, the UAV should use a faster speed and smaller angular velocity to avoid obstacles. Otherwise, a larger angular velocity should be used. The calculation of speed reward in the former case is given in equation (9) and the calculation of speed reward in the latter case is given in equation (10).

$$Reward_speed = V \times cos(\omega \times 2)/2 \quad (9)$$

$$Reward_speed = |\omega| \quad (10)$$

The reward_depth is calculated with the depth maps, the depth maps is divided to three parts :left, right and middle as shown in Figure 8. If the action of the UAV is to turn right, the depth map on the right side is used, the same goes for turning left and go straight. If the model focuses on the area that has an obstacle, the reward calculated from that area will be smaller, while a reward from an open area will be larger. This way, the model can learn from the depth map to know which direction it should face to obtain a higher reward. To calculate the reward, the depth map in each of the three parts is first normalized, averaged, and defined as D_{mid}, D_{left}, and D_{right}. Each of these is then divided by the average depth D_mean of the entire depth map and multiplied by 70 to obtain their respective rewards, defined as R_{mid}, R_{left} and R_{right} The calculation formulas are as follows:

$$D_{mid} = \text{mean}(D[90{:}150, 120{:}200]/255) \quad (11)$$

$$R_{mid} = (D_{mid}/D_{mean}) * 70 \quad (12)$$

IV. Experimental Result

This section describes the architecture of the simulation environment, as well as the design of the training and experimentation. The effectiveness of the depth reinforcement learning model in obstacle avoidance is verified in various simulation environments and compared with works in the existing papers. Finally the real test on 450 mm Quadcopter with Jetson Nano is conducted.

A. Variational AutoEncoder model

The hyperparameters of VAE model are shown in Table 3. The depth maps is acquired by random position and angle in the simulate environment . The input and output of VAE model is shown in Figure 9. The encoder layer can extract important features from depth map and the image can be restored through the decoder layer. One can see that the depth map can be roughly restored after going through the VAE, which proves that the VAE can effectively extract important features from the depth map as input for the D3RQN model.

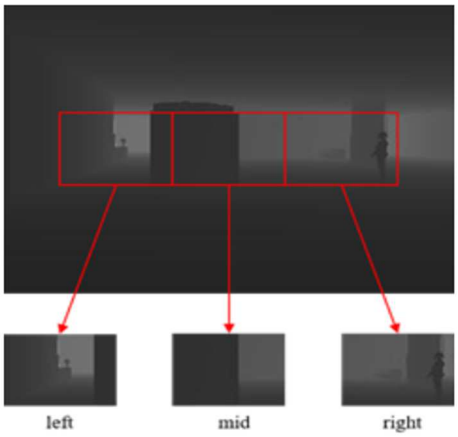


Figure 8. Divided depth image

Table 3. VAE hyperparameter

Hyperparameter	Value
No of images	20,000
Optimizer	Adam
Learning rate	0.001
Epochs	50
Batch size	64

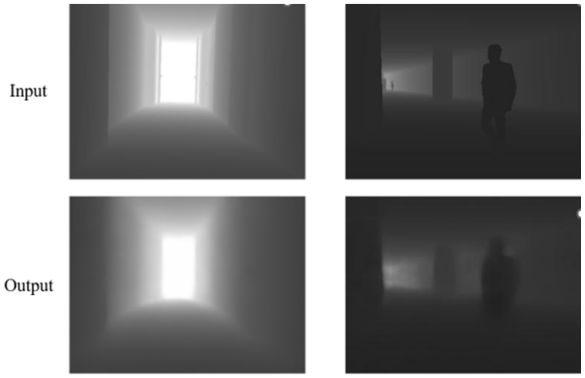

Figure 9. The input and output of VAE

B. Dueling Double Deep Recurrent Q Network

The pre-trained VAE model and the D3RQN model described in Section 3 are used to train in two simulation environments. The initial speed of UAV is set to 0.2m/s, and the height is set to 1 meter above the ground. The termination for each episode is when the UAV collides with an obstacle or the UAV exceeded 150 steps. The hyperparameters of D3RQN are shown in Table 4.

Table 4. D3RQN hyperparameter

Hyperparameter	Value
Max step	150
N-step	4
Optimizer	Adam
Learning rate	0.0001
Episode	4,000
Batch size	16
Target network update	5000
Initial epsilon	0.999
Final epsilon	0.001
Epsilon decaying	10,000
Replay memory size	4,000

C. *Training result*

First, we compared the method of adjusting the number of training times for each starting point and the method of fixing the training for 5 times for each starting point. The result is shown in Figure 10. We can see that the fixed number of training don`t show the significant improvement after training for 2,000 episodes. Giving different training times for different starting points can significantly improve the training effect of the model, allow the model to have more training and exploration opportunities for starting points with poorer performance.

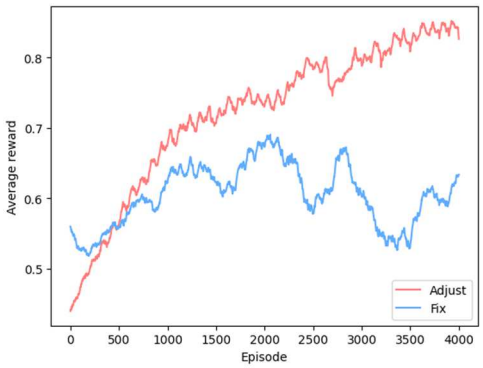

Figure 10. The result of the fixed and the adjust the number of training

Next, we tested whether using VAE can improve the training performance of the model. Using the same model architecture, we modify the VAE model to have the same convolutional layers as the grayscale image. Table 5 shows the results of testing 100 times. Using the VAE model can reduce the collision rate and make the model more likely to move at a faster speed.

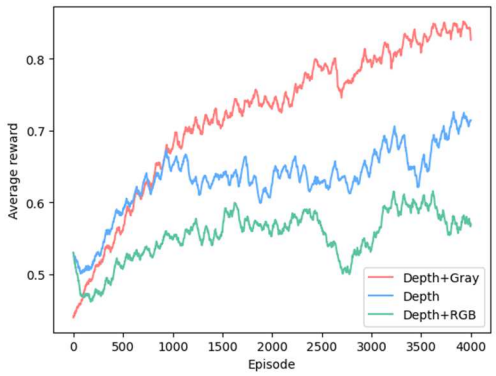
Table 5. Comparison with and without the VAE models

model	Collision rate	Avg total step	Minimum step	Avg velocity
w/ VAE	8%	145.62	43	0.97
w/o VAE	13%	143.61	77	0.43

Finally, the different combinations of images as input were compared : using only the depth map, the depth map with color image, and the depth map with grayscale image. Comparison results are given in Figure 11 and Table 6. Using only depth map and using depth map with grayscale image can improve the performance before 1000 episodes, but the grayscale provided additional information for better training of the model. Using the depth map with color image does not improve the performance of model. Table 6 shows that using the depth map with grayscale image as input had better results in terms of collision rate, average total steps, average velocity than the other two combinations.

Table 6. Comparison with different input

Input	Collision rate	Avg total steps	Minimum steps	Avg velocity
Grayscale + Depth	8%	145.62	43	0.97
Depth	11%	143.56	41	0.49
Depth + Color	23%	140.51	59	0.55



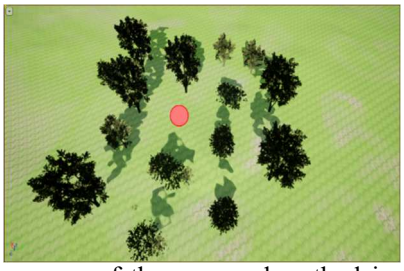


Figure 11. The average reward with different input

D. *Test the model and comparisons*

In order to verify that the model can successfully avoid obstacles in unseen environments without any prior training, three completely different test environments were built in the AirSim simulator. Each test map had 10 different starting points, and 10 episodes were tested at each starting point before moving on to the next one, for a total of 100 tests. The maps are shown in Figure 12.

Figure 12. Test environments

Performance of the proposed method is compared with some existing works. The training scene is similar to the one in [13], which is an indoor scene with different obstacles and turns. Therefore, the reward algorithm and hyperparameters in that paper were used, with only the action method modified to match the experiment here. A total of 10,000 episodes were trained. The training scene in [11] is an outdoor scene with only straight paths and no turns, and the reward algorithm used

in that paper may not be suitable for the scene here. Therefore, both the reward algorithm and the action method were modified to match our experiment. And a total of 4,000 episodes were trained. After training in their respective scenes, both methods were tested 100 times in both training and testing scenes, and compared in terms of collision rate, average total steps, minimum steps, and average velocity, as shown in Tables 7 and 8. The proposed method performs better than other two papers in terms of collision rate and velocity.

Table 7. Comparisons with different inputs on training

	Training environment			
Agent	Collision rate	Avg total steps	Minimum steps	Avg velocity
Random	92%	80.44	23	0.54
D3RQN [17]	26%	138.82	52	0.56
D3QN [21]	11%	142.24	56	0.67
The proposed algorithm	8%	145.62	43	0.97

Table 8. Comparisons with different inputs on test

	Test environment			
Agent	Collision rate	Avg total steps	Minimum steps	Avg velocity
Random	85%	86.57	25	0.54
D3RQN [17]	20%	134.77	33	0.51
D3QN [21]	17%	144.15	86	0.49
The proposed algorithm	14%	141.35	45	0.92

V. CONCULUSION

This paper implements an indoor obstacle avoidance system for UAVs based on deep reinforcement learning. A depth camera installed in front of the UAV provides grayscale images and depth maps, both of them are used as inputs for a deep reinforcement learning model that combines a variational autoencoder with a D3RQN algorithm. The proposed method was tested in simulated environments for training and testing, and compared to some existing works. The results show that the proposed algorithm can outperform Q3DN about 17% and 87% for collision rate and velocity.

***Abstract*—In recent years, malware infecting mobile devices has become serious issues. In this paper, we propose an approximate model representing the behavior of malware diffusion on wireless mobile devices with ordinary differential equations. The proposed model divides a target area into some fixed-size compartments. Then, for each compartment, it provides ordinary differential equations considering the movement of devices between the compartments. By doing so, we can reduce the number of ordinary differential equations to represent the malware diffusion on mobile devices, compared with conventional epidemic models. As a result, the computation time to obtain solutions showing infection dynamics can be reduced. Through numerical calculations, we show that our proposed epidemic model well approximates results obtained from a conventional epidemic model with low computation time.**

I. Introduction

In recent years, cyber attacks using malware has become serious issues [4]. Furthermore, malware infecting mobile devices has appeared [2]. For example, BlueBorne [5] exploits vulnerabilities of Bluethooth connections to attack mobile devices. In response to these issues, some epidemic model considering malware diffusion on mobile devices have been proposed.

In [3], the authors have introduced a stochastic epidemic model of malware on mobile devices using Bluetooth connections. They have discussed the behavior of malware spreading on mobile devices with the use of results obtained from simulation experiments. The authors in [6] have proposed a deterministic epidemic model that indicates the infection dynamics of malware spreading on mobile devices, with the use of ordinary differential equations. They have shown that the results of the numerical calculation of the epidemic model are very close to those obtained from simulation experiments. Although this model can obtain results in short time compared with simulation experiments, the computation time is still large. This is because this epidemic model requires a lot of ordinary differential equations to represent infection dynamics according to the scale of assumed environments.

To resolve this problem, in this paper, we propose an approximate model representing infection dynamics on mobile devices based on the deterministic epidemic model. The proposed model divides a target area into some fixed-size compartments. It then provides ordinary differential equations for each compartment, considering the movement of devices between the compartments. By doing so, the proposed model aims to reduce the number of ordinary differential equations to represent the malware diffusion on mobile devices. As a result, the computation time to obtain solutions showing infection dynamics can be reduced. We show that the results of our proposed epidemic model properly approximate those of a conventional epidemic model with low computation time through numerical calculations.

II. System model

In [6], the authors have proposed the deterministic epidemic model of malware diffusion on mobile devices, assuming the following system model. Note that our approximate model proposed in this paper also assumes the same system model.

Fig. 1 illustrates the system model assumed in this paper. In this model, there is a two-dimensional space represented by grid $\mathcal{G}$ of $M \times N$ cells as a target area where there exist a set $\mathcal{H}$ of mobile hosts. Each mobile host is located on one of the cells and can move to one of the adjacent cells. Let $\mathcal{C}_{(i,j)}$ denote the neighborhood cells of cell $(i,j) \in \mathcal{G}$ ($1 \leq i \leq M$, $1 \leq j \leq N$, $i, j \in \mathbb{N}$), which is given by

$$\mathcal{C}_{(i,j)} = \{(m,n) \mid |m-i| \leq 1, |n-j| \leq 1\}.$$

Furthermore, we denote the adjacent cells of cell $(i,j) \in \mathcal{G}$ as $\mathcal{A}_{(i,j)} = \mathcal{C}_{(i,j)} \setminus \{(i,j)\}$.

As shown in Fig. 1, the communication range of each host corresponds to the neighborhood cells $\mathcal{C}_{(i,j)}$. Specifically, each mobile host on cell (i,j) can communicate with other mobile hosts on the neighborhood cells $\mathcal{C}_{(i,j)}$. On the other hand, the adjacent cells $\mathcal{A}_{(i,j)}$ indicates the moving range of hosts at cell (i,j). In this model, we consider discrete timesteps t_d ($t_d = 0, 1, 2, \dots$). We denote the location (i.e., cell) of host $h \in \mathcal{H}$ at time t_d as $c_h(t_d) = (i,j)$. Each mobile host on each cell $(i,j) \in \mathcal{G}$ moves to one of adjacent cells $\mathcal{A}_{(i,j)}$ randomly selected at each time step. For instance, $c_h(t_d+1)$ is equal to $(i, j+1)$ if host h on cell (i,j) moves to the right cell at time t_d.

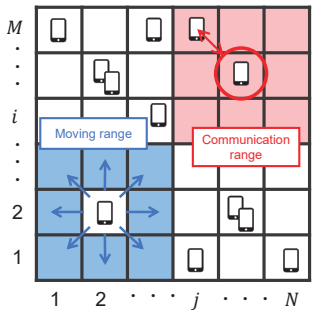

Fig. 1: System model.

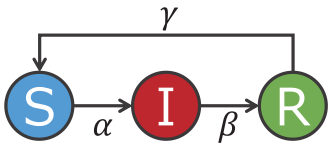

Fig. 2: SIRS model.

As a basic epidemic model that represents the state of each host, we assume an SIRS model shown in Fig. 2. Each host on the grid $\mathcal{G}$ has one of three states, i.e., Susceptible (S), Infected (I), and Recovered (R) states. The state S means that the host is not infected with malware but it has vulnerabilities that can get infected with malware. The state I means that the host is infected with malware. The state R means that the host is protected against malware. At each time step, the state transition of each host occurs based on the following events:

1) With the probability α_d, an infected host on each cell $(i,j) \in \mathcal{G}$ infects a susceptible host located on the neighborhood cells $\mathcal{C}_{(i,j)}$. In the next time step, the susceptible host transitions to an infected host.
2) With the probability β_d, an infected host removes the malware from itself. In the next time step, the infected host transitions to a recovered host.
3) With the probability γ_d, a recovered host is discovered a new vulnerability. In the next time step, the recovered host transitions to a susceptible host.

III. Epidemic Model of Malware Diffusion on Mobile Devices [6]

We here explain the epidemic model introduced in [6]. The epidemic model considers the continuous time environment instead of discrete timesteps discussed in the system model. In this case, discrete timestep t_d corresponds to continuous time t (≥ 0). Accordingly, the probabilities α_d, β_d, and γ_d correspond α, β, and γ, respectively, where α, β, and γ are parameters indicating the infection rate, the elimination rate, and the vulnerability discovery rate, respectively.

Let $S_{(i,j)}(t)$, $I_{(i,j)}(t)$, and $R_{(i,j)}(t)$ denote the number of susceptible hosts, infected hosts, and recovered hosts, respectively, on cell (i,j) at time t. The epidemic model based on the SIRS model represents the infection dynamics with the following differential equations, where $i = 1, 2, \ldots, M$ and $j = 1, 2, \ldots, N$:

$$\begin{aligned}\frac{d}{dt}S_{(i,j)}(t) =& -\alpha S_{(i,j)}(t)\left\{\sum_{(m,n)\in\mathcal{C}_{(i,j)}} I_{(m,n)}(t)\right\} \\ &+ \gamma R_{(i,j)}(t) - \mu S_{(i,j)}(t) \\ &+ \mu \sum_{(m,n)\in\mathcal{A}_{(i,j)}} \frac{1}{|\mathcal{A}_{(n,m)}|} S_{(m,n)}(t),\end{aligned} \tag{1}$$

$$\begin{aligned}\frac{d}{dt}I_{(i,j)}(t) =& \alpha S_{(i,j)}(t)\left\{\sum_{(m,n)\in\mathcal{C}_{(i,j)}} I_{(m,n)}(t)\right\} \\ &- \beta I_{(i,j)}(t) - \mu I_{(i,j)}(t) \\ &+ \mu \sum_{(m,n)\in\mathcal{A}_{(i,j)}} \frac{1}{|\mathcal{A}_{(m,n)}|} I_{(m,n)}(t),\end{aligned} \tag{2}$$

$$\begin{aligned}\frac{d}{dt}R_{(i,j)}(t) =& \beta I_{(i,j)}(t) - \gamma R_{(i,j)}(t) - \mu R_{(i,j)}(t) \\ &+ \mu \sum_{(m,n)\in\mathcal{A}_{(i,j)}} \frac{1}{|\mathcal{A}_{(m,n)}|} R_{(m,n)}(t),\end{aligned} \tag{3}$$

where μ denotes the moving rate of mobile hosts, which implies the migration speed of hosts to adjacent cells. The detailed discussion about the infection dynamics has been provided in [6].

This epidemic model formulates ordinary differential equations for each cell $(i,j) \in \mathcal{G}$ to represent infection dynamics on mobile devices. As a result, it requires $3 \times M \times N$ ordinary differential equations, and thus it spends a lot of time to calculate solution. Our approximate model proposed in this paper aims to reduce the computation time by decreasing the number of ordinary differential equations.

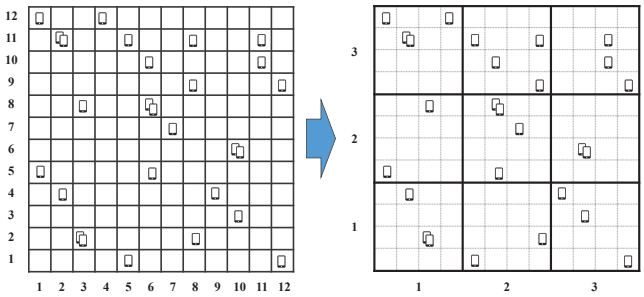

Fig. 3: Example of the proposed approximate model ($G = 12, d = 3$).

IV. Proposed Approximate Model

A. Assumption

In what follows, for simplicity, we consider scenarios where a target area consists of $G \times G$ cells, i.e., $M = N = G$. The proposed approximate model divides the target area into a set $\mathcal{D}$ of $d \times d$ compartments as shown in Fig. 3. In this case, each compartment consists of g^2 cells, where $g = \frac{G}{d}$. The proposed approximate model formulates ordinary differential

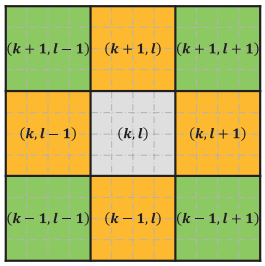

Fig. 4: $\mathcal{A}^{\text{side}}_{(k,l)}$ and $\mathcal{A}^{\text{diag}}_{(k,l)}$ of compartment (k,l).

equations for each compartment instead of each cell to reduce the number of equations.

Let $\mathcal{A}^{\text{side}}_{(k,l)}$ and $\mathcal{A}^{\text{diag}}_{(k,l)}$ denote sets of adjacent compartments of compartment $(k,l) \in \mathcal{D}$ $(1 \le k \le d, 1 \le l \le d, k, l \in \mathbb{N})$, which is defined as

$$\mathcal{A}^{\text{side}}_{(k,l)} = \{(k-1,l),(k,l-1),(k,l+1),(k+1,l)\},$$
$$\mathcal{A}^{\text{diag}}_{(k,l)} = \{(k-1,l-1),(k-1,l+1),(k+1,l-1),(k+1,l+1)\}.$$

Fig. 4 shows an example of $\mathcal{A}^{\text{side}}_{(k,l)}$ and $\mathcal{A}^{\text{diag}}_{(k,l)}$. In this figure, $\mathcal{A}^{\text{side}}_{(k,l)}$ is yellow-colored compartments and $\mathcal{A}^{\text{diag}}_{(k,l)}$ is green-colored compartments. Let K denote the number of mobile hosts in the target area. Let $S_{(k,l)}(t)$, $I_{(k,l)}(t)$, and $R_{(k,l)}(t)$ denote the number of susceptible hosts, infected hosts, and recovered hosts, respectively, on compartment (k,l) at time t. Note that $S(t) + I(t) + R(t) = K$ holds where $S(t) = \sum_{(k,l)\in\mathcal{D}} S_{(k,l)}(t)$, $I(t) = \sum_{(k,l)\in\mathcal{D}} I_{(k,l)}(t)$, and $R(t) = \sum_{(k,l)\in\mathcal{D}} R_{(k,l)}(t)$.

B. Formulation

Our proposed approximate model represents the infection dynamics for each compartment $(k,l) \in \mathcal{D}$ with the following differential equations, where $k, l = 1, 2, \ldots, d$:

$$\begin{aligned}\frac{d}{dt}S_{(k,l)}(t) =& -\frac{\alpha(3g-2)^2}{g^4}S_{(k,l)}(t)I_{(k,l)}(t)\\ &-\frac{\alpha}{g^4}S_{(k,l)}(t)\left\{\sum_{(m,n)\in\mathcal{A}^{\text{diag}}_{(k,l)}} I_{(m,n)}(t)\right.\\ &\left.+\sum_{(m,n)\in\mathcal{A}^{\text{side}}_{(k,l)}}(3g-2)I_{(m,n)}(t)\right\}\\ &+\gamma R_{(k,l)}(t)+\mu\left\{S^{\text{in}}_{(k,l)}(t)-S^{\text{out}}_{(k,l)}(t)\right\},\end{aligned} \tag{4}$$

$$\begin{aligned}\frac{d}{dt}I_{(k,l)}(t) =& \frac{\alpha(3g-2)^2}{g^4}S_{(k,l)}(t)I_{(k,l)}(t)\\ &+\frac{\alpha}{g^4}S_{(k,l)}(t)\left\{\sum_{(m,n)\in\mathcal{A}^{\text{diag}}_{(k,l)}} I_{(m,n)}(t)\right.\\ &\left.+\sum_{(m,n)\in\mathcal{A}^{\text{side}}_{(k,l)}}(3g-2)I_{(m,n)}(t)\right\}\\ &-\beta I_{(k,l)}(t)+\mu\left\{I^{\text{in}}_{(k,l)}(t)-I^{\text{out}}_{(k,l)}(t)\right\},\end{aligned} \tag{5}$$

$$\begin{aligned}\frac{d}{dt}R_{(k,l)}(t) =& \beta I_{(k,l)}(t)-\gamma R_{(k,l)}(t)\\ &+\mu\left\{R^{\text{in}}_{(k,l)}(t)-R^{\text{out}}_{(k,l)}(t)\right\}.\end{aligned} \tag{6}$$

$X^{\text{in}}_{(k,l)}(t)$ $(X \in \{S, I, R\})$ denotes the average number of hosts in state X that come into the compartment (k,l) from the adjacent compartments. On the other hand, $X^{\text{out}}_{(k,l)}(t)$ denotes the average number of hosts in state X that move from the compartment (k,l) to the adjacent compartments, which will be defined later.

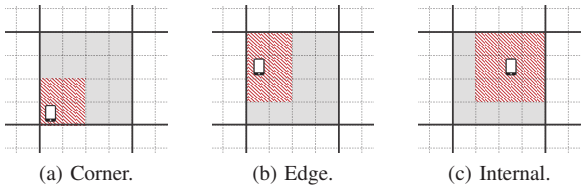
In (4), the first term indicates the average number of susceptible hosts that get infected with the malware in compartment (k,l). Susceptible hosts on a cell can get infected by contact with infected hosts in the neighborhood cells as discussed in the system model. We thus consider three cases of the contact shown in Fig. 5, namely, corner, edge, and internal cells. For susceptible hosts at a corner cell of the compartment, the number of neighborhood cells is 4. Thus, the average number of contacts between the susceptible hosts and infected hosts in the neighborhood cells is given by $\frac{S_{(k,l)}(t)}{g^2}\frac{4I_{(k,l)}(t)}{g^2}$, where $\frac{S_{(k,l)}(t)}{g^2}$ and $\frac{I_{(k,l)}(t)}{g^2}$ indicates the number of susceptible hosts and infected hosts, respectively, per cell on compartment (k,l). Also, for susceptible hosts at an edge cell and an internal cell, the average number of contacts between the susceptible hosts and infected hosts in the neighborhood cells is given by $\frac{S_{(k,l)}(t)}{g^2}\frac{6I_{(k,l)}(t)}{g^2}$ and $\frac{S_{(k,l)}(t)}{g^2}\frac{9I_{(k,l)}(t)}{g^2}$. Because the numbers of corner, edge, and internal cells are 4, $4(g-2)$, and $(g-2)^2$, respectively, the total number of contacts between the susceptible hosts and infected hosts in the neighborhood cells can be calculated as follows:

$$\begin{aligned}&\left\{\frac{S_{(k,l)}(t)}{g^2}\frac{4I_{(k,l)}(t)}{g^2}\times 4\right\}\\ &+\left\{\frac{S_{(k,l)}(t)}{g^2}\frac{6I_{(k,l)}(t)}{g^2}\times 4(g-2)\right\}\\ &+\left\{\frac{S_{(k,l)}(t)}{g^2}\frac{9I_{(k,l)}(t)}{g^2}\times (g-2)^2\right\}\\ &=\left\{\frac{9g^2-12g+4}{g^4}\right\}S_{(k,l)}(t)I_{(k,l)}(t)\\ &=\frac{(3g-2)^2}{g^4}S_{(k,l)}(t)I_{(k,l)}(t).\end{aligned} \tag{7}$$

The first term in (4) is given by the product of the infection rate α and (7).

The second term in (4) indicates the average number of susceptible hosts getting infected by contact with infected hosts located in adjacent compartments $\mathcal{A}^{\text{diag}}_{(k,l)} \cup \mathcal{A}^{\text{side}}_{(k,l)}$. This can be obtained from similar discussion to the first term. The third term means the average number of recovered hosts that transition to the susceptible state due to the discovery of a new vulnerability. The fourth term represents the average number of susceptible hosts that come into the compartment (k,l) or move to adjacent compartments.

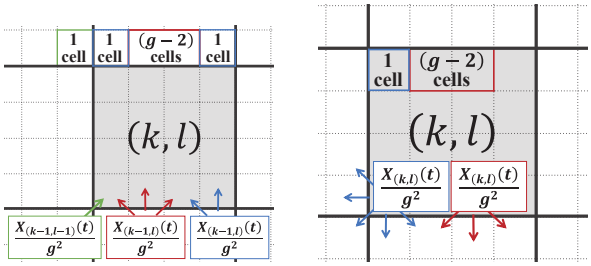
Similarly, in (5), the first term and second term indicate the average number of susceptible hosts getting infected by contact with infected hosts, i.e., the average increase in infected hosts.



The third term means the average number of infected hosts eliminating the malware and moves to the recovered state. The fourth term represents the average number of infected hosts that come into the compartment (k,l) or move to adjacent compartments. In (6), the first term and second term correspond to the third term of (5) and the third term of (4), respectively. The third term indicates the average number of recovered hosts that come into the compartment (k,l) or move to adjacent compartments.

We here discuss $X^{\mathrm{in}}_{(k,l)}(t)$ and $X^{\mathrm{out}}_{(k,l)}(t)$ $(X \in \{S,I,R\})$ in (4)-(6). We suppose that hosts randomly move to adjacent cells. Therefore, we consider the cases of migration between compartments shown in Fig. 6. We first consider the case where hosts in adjacent compartments come into compartment (k,l), which is shown in Fig. 6(a). For each compartment $(m,n) \in \mathcal{A}^{\mathrm{diag}}_{(k,l)}$, only hosts at a corner cell can come into compartment (k,l). Furthermore, the probability that hosts at the corner cell of compartment (m,n) moves to the adjacent cell of compartment (k,l) is $1/8$ because the hosts randomly select a cell to move from among 8 adjacent cells. Therefore, the average number of such hosts is $\frac{1}{8}\frac{X_{(m,n)}(t)}{g^2}$. On the other hand, for each compartment $(m,n) \in \mathcal{A}^{\mathrm{side}}_{(i,j)}$, hosts at corner or edge cells can come into compartment (k,l). The numbers of those cells are 2 and $g-2$, respectively. The probabilities are $2/8$ and $3/8$, respectively. Thus, the average number of hosts that come from the compartment is given by $\frac{2}{8}\frac{X_{(m,n)}(t)}{g^2} \times 2 + \frac{3}{8}\frac{X_{(m,n)}(t)}{8g^2} \times (g-2) = \frac{(3g-2)X_{(m,n)}(t)}{8g^2}$. Therefore, $X^{\mathrm{in}}_{(k,l)}(t)$ is given by

$$X^{\mathrm{in}}_{(k,l)}(t) = \frac{1}{8g^2}\left\{ \sum_{(m,n)\in\mathcal{A}^{\mathrm{diag}}_{(k,l)}} X_{(m,n)}(t) + \sum_{(m,n)\in\mathcal{A}^{\mathrm{side}}_{(k,l)}} (3g-2)X_{(m,n)}(t) \right\}. \tag{8}$$



We then consider the case where hosts in compartment (k,l) move to adjacent compartments. In this case, hosts at corner or edge cells can move to adjacent compartments as shown in Fig. 6(b). The numbers of those cells in the compartment is 4 and $4(g-2)$, respectively. The probabilities are $5/8$ and $3/8$, respectively. Thus, $X^{\mathrm{out}}_{(k,l)}(t)$ is given by

$$\begin{aligned} X^{\mathrm{out}}_{(k,l)}(t) &= \left\{\frac{5}{8}\frac{X_{(k,l)}(t)}{g^2} \times 4\right\} + \left\{\frac{3}{8}\frac{X_{(k,l)}(t)}{g^2} \times 4(g-2)\right\} \\ &= \left\{\frac{12g-4}{8g^2}\right\} X_{(k,l)}(t) \\ &= \frac{3g-1}{2g^2} X_{(k,l)}(t). \end{aligned} \tag{9}$$

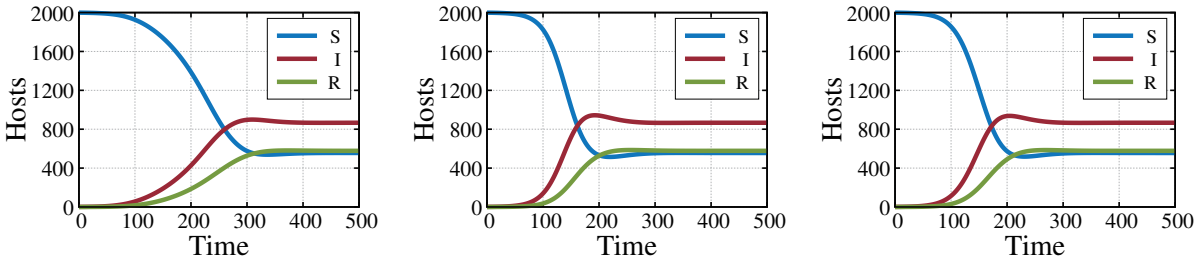
V. Numerical Calculations

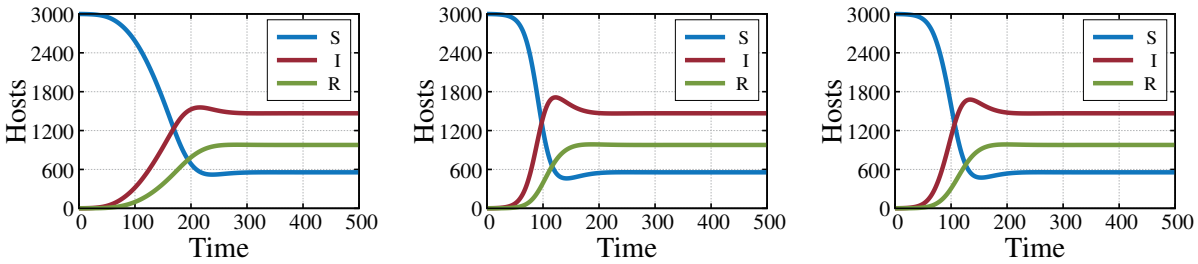
A. Model



In this paper, we conduct numerical calculations to discuss the effectiveness of our proposed approximate model. In the numerical calculations, we use DELL Precision 5820 with an Intel Xeon Sliver 5110 2.10 GHz CPU and 16 GB memory, running Ubuntu 20.04. In order to obtain solutions of our proposed approximate model, we calculate the ordinary differential equations (4)-(6) with the use of MATLAB [1]. We also calculate the ordinary differential equations (1)-(3) based on the epidemic model proposed in [6] for the sake of comparison (named ODE-all in the result figures).

We consider scenarios where a target area consists of 100×100 cells, i.e., $G = 100$, and the target area is divided into 10×10 and 20×20 compartments, i.e., $d = 10$ and 20. The number K of mobile hosts in the target area is set to $2,000$ and $3,000$. We assume that there exist one infected host and $K-1$ susceptible hosts at the initial state. Specifically, we set the initial value as $S(0) = K-1$, $I(0) = 1$, and $R(0) = 0$. We place each susceptible host on randomly selected cells in the area. We set the value of the system parameters as follows: $\alpha = 0.04$, $\beta = 0.02$, $\gamma = 0.03$, and $\mu = 1$.

B. Results



In Fig. 7, we show the change in the number of hosts in each state (i.e., $S(t)$, $I(t)$, and $R(t)$) against elapsed time t in the case of $K = 2,000$. Fig. 7(a) is the result of (1)-(3) based on the epidemic model proposed in [6]. Figs. 7(b) and (c) are the results obtained by calculating (4)-(6) in our proposed epidemic model, where $d = 10$ and 20, respectively.

From these figures, we observe that the number $S(t)$ of susceptible hosts decreases with time elapsed. Accordingly, the number $I(t)$ of infected hosts increases with time elapsed. The number $R(t)$ of recovered hosts also increases with time

(a) ODE-all. (b) $d = 10$. (c) $d = 20$.

Fig. 7: Number of hosts against time elapsed in the case of $K = 2,000$.

(a) ODE-all. (b) $d = 10$. (c) $d = 20$.

Fig. 8: Number of hosts against time elapsed in the case of $K = 3,000$.

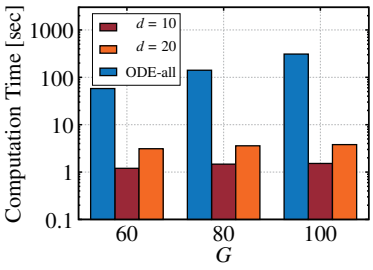


Fig. 9: Computation time.

elapsed. Finally, those values become stable at a certain level. We also observe that although the the proposed approximate model is more sensitive to the time elapsed, the proposed approximate model has similar characteristic to the ODE-all, regardless of the value of d. Specifically, they are stable at almost the same level.

In Fig. 8, we show the change in the number of hosts in each state against elapsed time t in the case of $K = 3,000$. As we can see from this figure, the result of our proposed model properly approximates that of ODE-all, similar to the result in the case of $K = 2,000$.

Finally, we measure the computation time of ODE-all and our proposed approximate model. Fig. 9 shows the computation time against the value of G, i.e., the size of the target area. As we can see from this figure, the computation time of our proposed approximate model is much smaller than that of ODE-all, regardless of the values of d and G. This is because the proposed approximate model reduces the number of ordinary differential equations to represent infection dynamics.

VI. Conclusion

In this paper, we proposed an approximate model representing the behavior of malware diffusion on wireless mobile devices, using ordinary differential equations. We showed that the results of our proposed epidemic model properly approximate those obtained from a conventional epidemic model with low computation time through numerical calculations. As future work, we will consider heterogeneous situations where mobile devices have different communication ranges and mobility characteristics (e.g., moving speed and patterns).

***Abstract*— Diverse and differential service types of 5G trigger the needs of novel technologies in radio resource allocation and management, and it is a challenging problem to enhance flexibility of radio resource allocation while improving radio spectrum efficiency. To tackle this problem, *numerology* and *time division duplex* (TDD) have been introduced accordingly. This paper presents analyses of asymmetric performance impacts of flexible 5G-TDD time slot configurations on the *downlink* (DL) and *uplink* (UL) data rates, using our lab system design and realization based on the hardware and software reference designs of the *OpenAirInterface* (OAI) 5G *stand-alone* (SA) system. For 5G *new radio* (5G-NR) at *frequency range 1* (FR1), aka sub-6 GHz, the adopted numerology scheme is $\mu = 1$, ensuring an enough *sub-carrier spacing* (SCS) of *30 kHz* for supporting higher mobility than 4G, in particular suitable for those bands above *3 GHz* in FR1. For this study, the adopted band is *n78* (3.3 - 3.8 GHz) due to its dominance among the 5G operators. In addition, six scenarios of TDD time slot configurations are studied for their impacts on the DL and UL data rates, in terms of TCP goodputs. Our measurement results show two effects: (1) asymmetric trend slopes of DL and UL data rates, and (2) symmetric performance degradation at the DL/UL extremes. Analyses of these two effects are proposed with respect to DL/UL traffic orientations, including DL-Heavy, UL-Heavy and Balanced applications, such as *internet of humans* (IoH), *internet of things* (IoT) and video conferencing respectively.**

I. INTRODUCTION

The *fifth generation* (5G) communication technology [1, 2] has revolutionized the telecommunication industry, providing faster data rates, lower latency, and enhanced connectivity. Such diverse and differential service types trigger the needs of novel technologies in radio resource allocation and management [3]. Considering the sky-high cost of radio spectrum licensing, how to improve radio spectrum efficiency while enhancing flexibility of radio resource allocation is a challenging problem. To tackle this problem, both *numerology* [4, 5] and *time division duplex* (TDD) [6] have been introduced. These two technologies work together to optimize radio resource utilization and meet the diverse requirements of differential services.

The 5G numerology defines the fundamental parameter sets which characterize the time-frequency structure of the 5G radio resources. It includes flexible parameter setting such as *sub carrier spacing* (SCS) in the frequency domain, and *symbol duration*, *slot duration* and *frame structure* in the time domain. Such flexible parameter setting in different numerology schemes allow for *adaptive granularity* and *low-latency timing* of data communications in the 5G system.

On the other hand, the 5G TDD allows for asymmetric and flexible *slot-level* or even *symbol-level* configurations of radio resource allocation between the *downlink* (DL) and *uplink* (UL), where more radio resource should be allocated if the traffic is DL-heavy, and vice versa if UL-heavy. Not only *flexible adjustment*, but also *real-time adaptation* to dynamic DL/UL traffic demands can be expected to be realized in the 5G system. Certainly, the realization is challenging since it involves a good understanding of the flexible and yet complicated TDD configurations, including both the DL/UL *transmission periodicity* and *slot configuration mapping patterns*. Moreover, *synchronization* between the *5G base station* (gNB) and *5G new-radio user equipment* (nrUE) is another technical challenge [7-9]. In addition, an advanced TDD concept called *sub-band full-duplex* (SBFD) is being studied by 3GPP R.18, aka 5G-Advanced [10-13].

In fact, the 5G numerology and the 5G TDD configurations are closely intertwined, working together to enable efficient resource allocation, meet the diverse traffic demands, and optimize the overall performance of the 5G system. The flexibility provided by the flexible TDD configurations within the framework of the various 5G numerology schemes allows for adaptive resource management and customization to meet differential and dynamic service requirements.

From the aspect of performance impact, this paper presents a better reasoning on the flexible and yet complex TDD configurations for the major 5G-numerology scheme ($\mu = 1$), particularly designed for the *5G new radio* (5G-NR) [14] around *frequency range 1* (FR1), aka sub-6 GHz. This paper also presents analyses of performance impacts of TDD time slot configurations (in terms of various DL/UL ratio scenarios) on the DL and UL data rates, from DL-heavy scenarios to UL-heavy ones. Analyses of DL and UL data rates and their sums can thus potentially lead to proposing a promising user-demand-oriented strategy between *internet of humans* (IoH) and *internet of things* (IoT) [15] traffic demands, where the IoH is more characteristic of DL-heavy traffic while the IoT is more featured by UL-heavy traffic.

The remainder of this paper is organized as follows. Section II presents our lab system design implemented with the OAI-5G reference designs in both the software and

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

hardware, and explains the working mechanisms of the adopted 5G TDD time slot configurations, together with the major numerology scheme of FR1 as aforementioned, aiming at carrying out the performance impacts of flexible TDD slot configurations on the DL and UL data rates. Section III presents the experimental results and the analyses of the aforementioned performance impacts. Section IV concludes and outlooks this paper.

II. System Design and Mechanisms

A. 5G-NR Based Lab System Design and Realization

OpenAirInterface (OAI) [16] provides the first open-source reference designs of 4G/LTE and 5G-NR, including both the UE end and the network end. The UE end could be implemented with a generic PC equipped with a *software defined radio* (SDR) unit or a commercial cellular phone. The network end consists of the base station (eNB for 4G or gNB for 5G) and the core network (EPC for 4G or 5GC for 5G). For phase I of 5G, the gNB can co-exist with the 4G network end, namely the eNB and the EPC, to form the *non-stand-alone* (NSA) scheme, aka EN-DC. As for phase II of 5G, the gNB can directly work with the 5GC in the *standalone* (SA) scheme, realized with the novel design concepts such as *software defined networking* (SDN) [17, 18] and *network functions virtualization* (NFV) [19, 20], where SDN improves the network management by separating its control- and user-planes in terms of south-bound interface whereas NFV automates and enriches service deployments of 5GC by decoupling software and hardware via the virtualization technology. The management plane of the 5GC is compliant to the 3GPP *service based architecture* (SBA) [21, 22] so as to be capable of deploying rich *micro services* in terms of *virtualized* or *containerized network functions*, aka VNFs or CNFs, which can interact with each other via a single common message bus or interface to greatly simplify the design of communication protocols among multiple component functions or novel future unknown add-on services, aka *service based interface* (SBI) [23].

Our 5G-NR lab design and realization follows the OAI 5G-NR reference design for the 5G SA scheme. Fig. 1 demonstrates the system architecture of our 5G-NR lab system, which consists of one OAI nrUE, one OAI gNB and one OAI 5GC. Each of these three entities is realized and hosted on an independent generic x86 *personal computer* (PC), and the details of hardware and operating system are summarized in Table 1. The adoption of i7-based CPUs follows the hardware recommendation of OAI. Considering the need of enough computing power for real-time signal processing between the nrUE and the gNB, the PCs with a CPU of 8 physical cores are provisioned, running with a real-time Linux kernel. On the other hand, a PC with a CPU of 4 physical cores, running with a generic non-real-time Linux kernel, can turn into 8 logic cores with the help of the Intel *virtualization technology for execution* (VTx), aka *hyper-threading* of CPU (i.e., each *physical* core can be hyper-threaded into 2 *logic* cores, with the benefit of improved computing power typically by around 140% increase). In other words, such a hardware virtualization technology can thus enable software virtualization for the micro-services based management-plane design (NFV-based) on top of the software-defined separation of *control* and *user* planes (SDN-based).

B. 5G-NR Channel Bandwidth and Resource Blocks

5G-NR is expected to support up to 100 MHz channel bandwidth for lower bands less than 6 GHz, aka sub-6 GHz or FR1 as aforementioned, and 400 MHz channel bandwidth for higher bands in the mm-Wave ranges. This paper focuses on how to calculate the number of *resource blocks* (RBs) in FR1. As given in Table II, 3GPP TS 38.101-1 [24] specifies the *maximum number of RBs* (N_{RBs}^{max}), available in different numerology configurations, such as $\mu = 0, 1, 2$, where the corresponding *sub carrier spacing* (SCS), *supported channel bandwidth* ($\Delta f_{s.ch}$) with a guard band (Δf_{gb}) on each side are also specified so as to deliver the corresponding *max number of RBs* (N_{RBs}^{max}). Note that the SCS is a function of μ, denoted as $SCS(\mu)$ and defined by Eq. (1), and the corresponding N_{RBs}^{max} can thus be carried out based on Eq. (2).

Table II: N_{RBs}^{max} **as a function of the numerology scheme** μ.

μ	$SCS(\mu)$	$\Delta f_{s.ch}$	Δf_{gb}	N_{RBs}^{max}
0	15 KHz	50 MHz	692.5 kHz	270
1	30 KHz	100 MHz	845.0 kHz	273
2	60 KHz	100 MHz	1370.0 kHz	135

$$SCS(\mu) = 2^{\mu} \cdot 15 \text{ kHz} \quad (1)$$

$$N_{RBs}^{max} = (\Delta f_{s.ch} - 2\Delta f_{gb}) / 12 \cdot SCS(\mu) \quad (2)$$

The main focus of this paper is to study the effect of TDD on the DL/UL throughput performances. In particular, only the major numerology scheme $\mu = 1$ for above 3 GHz of FR1 is considered, particularly designed for higher mobility than 4G-LTE. Technically speaking, however, one still has to take into consideration the factor of $\Delta f_{s.ch}$. In other words, $\Delta f_{s.ch}$ could potentially vary in reality in two cases: (1) the supported channel bandwidth of the actually licensed band owned by an operator could be less and different depending on the price paid, and (2) the supported channel bandwidth of the adopted RF unit. For this lab-based study, case (2) is the main concern since the adopted RF unit is USRP B210 and its $\Delta f_{s.ch}$ is limited to 40 MHz. Considering the $\mu = 1$ numerology scheme, Table II together with Eqs. (1) and (2) can thus work together to deliver the value of N_{RBs}^{max} to be 106.

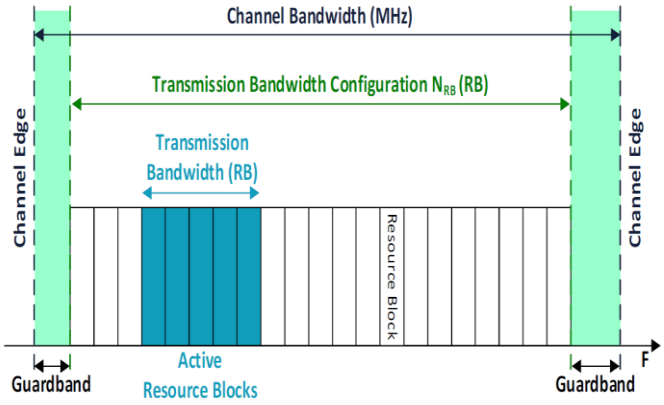

Fig. 2 5G-NR frame structure and time slot durations as a function of the numerology scheme (μ = 0, 1, 2, 3, 4) [2]

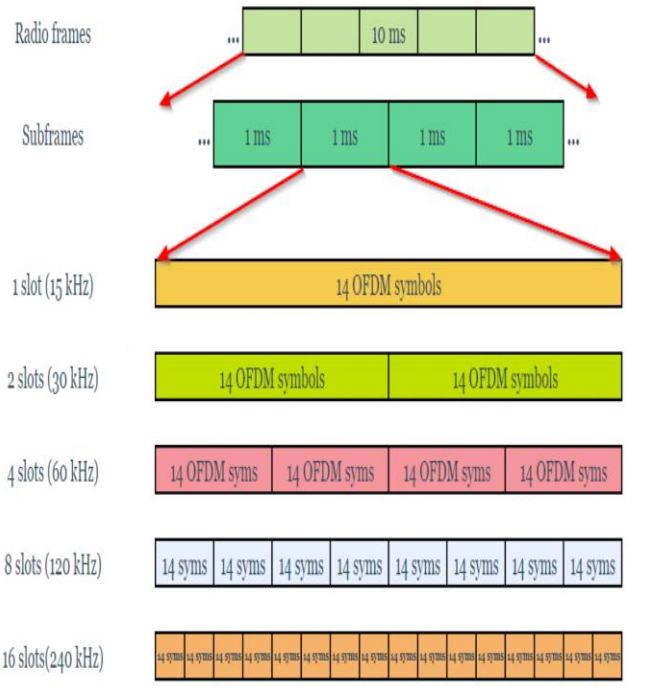

Fig. 3 5G-NR frame structure and time slot durations as a function of the numerology scheme (μ = 0, 1, 2, 3, 4) [5]

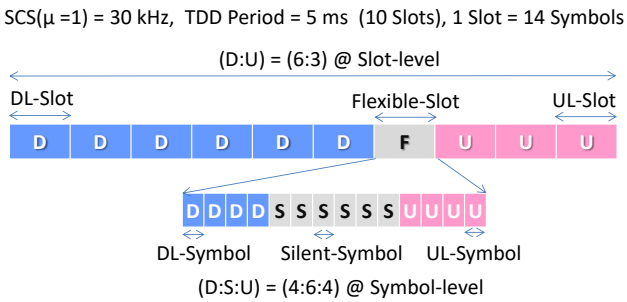

Fig. 4 A typical DL/UL time slot configuration of 5G-NR TDD for DL-Heavy applications, in the major numerology scheme (μ = 1) for RF1.

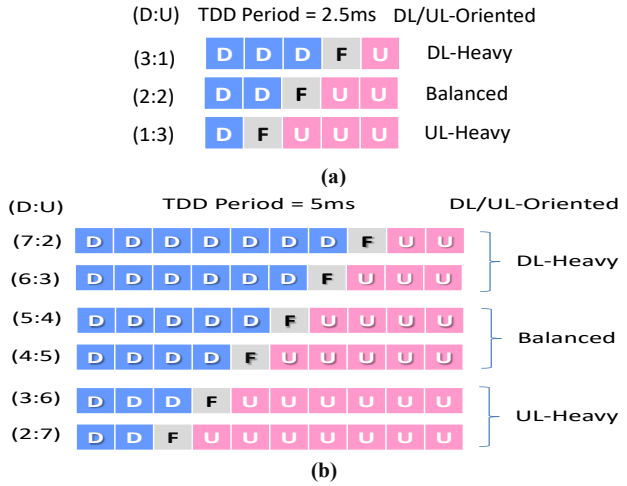

Fig. 5 5G-NR TDD slot configurations for different TDD periods and DL/UL orientations: (a) period = 2.5 ms, and (b) period = 5 ms.

C. Flexible Numerology Schemes for 5G-NR

As aforementioned in Section I, the 5G numerology defines the fundamental parameter sets which characterize the time-frequency structure of the 5G radio resources. Fig. 3 depicts the 5G-NR frame structure and the variation of time slot duration with the numerology scheme (μ = 0, 1, 2, 3, 4) [5], where it is clearly seen that the time slot duration decreases linearly as the numerology scheme index μ increases, meaning that the SCS(μ) also increases linearly, based on Eq. (1).

Compared to the concept of *fixed* SCS (15 kHz) for 4G-LTE, the concept of *flexible* SCS is new to 5G-NR. The most fundamental motivation behind this new concept is to support *higher mobility* for 5G-NR, where the Doppler frequency drift becomes larger with the higher speed demand of the UE, and also linearly with the higher frequency band adopted. To compensate the Doppler Effect, a wider SCS is thus needed. For frequency bands in between 3GHz and 6GHz, the μ = 1 scheme adopts a SCS of 30 kHz, namely 2 times the fixed SCS (i.e., 15 kHz) designed for those bands below 3 GHz, is already enough and thus becomes the major scheme for 5G FR1. As for mm-Waves, aka 5G FR2, those schemes with $\mu \geq 2$ will serve for the needs. Another benefit coming with a wider SCS is a shorter time duration for both time slots and symbols, which can thus generate a lower latency for time-

sensitive applications. However, the low-latency issues are out the scope of this paper. In this paper, the main focus is on the performance impact of TDD onto DL/UL data rates for the *n78* band (3.3 – 3.8 GHz), and the adopted numerology scheme is thus μ = 1, which will be the default scheme throughout the rest of this paper.

D. Flexible TDD DL/UL Slot Configurations for 5G-NR

Both 5G FDD and TDD have their advantages and are suitable for different scenarios. FDD provides good coverage, better signal propagation, and is suitable for a wide range of environments, including rural areas. On the other hand, TDD offers flexibility, efficient spectrum usage, and lower latency, making it ideal for dense urban environments with asymmetric traffic demands. Recall that, from Section 1, the 5G TDD allows for an asymmetric configuration of radio resource allocation between the DL and UL, where more radio resource should be allocated in the DL if the traffic is DL-heavy, and vice versa if UL-heavy.

Fig. 4 illustrates a typical DL/UL time slot configuration of 5G-NR TDD for DL-Heavy applications, in the major numerology scheme (μ = 1) for the *n78* band of FR1, where the ratio of DL-Slots to UL-Slots is denoted as (D:U), is (6:3). Note that one *flexible slot* (F-Slot) is needed for a special purpose: it contains 4 DL-Symbols and 4 UL-Symbols, separated by 6 Silent-Symbols as the *guard period* when switching from the DL to the UL. The physics for this guard period has been well explained in [25].

Fig. 5 demonstrates more 5G-NR TDD slot configuration scenarios for different TDD periods and DL/UL orientations, where (a) is for period = 2.5 ms, and (b) for period = 5 ms. In the scenario of (a), three (D:U) slot configurations are depicted and classified into three different DL/UL-orientations, namely (3:1) for DL-Heavy, (2:2) for Balanced, and (1:3) for UL-Heavy. The scenario of (b) presents more configurations, i.e., six (D:U) slot configurations classified into three different DL/UL-orientations: (7:2) and (6:3) for DL-heavy, (5:4) and (4:5) for Balanced, and eventually (3:6) and (2:7) for UL-Heavy.

In this study, periodicity (b) is adopted for its rich configurations so as to carry out performance impacts of 5G TDD slot configuration scenarios on the DL and UL data rates for different traffic-demand orientations.

III. Results and Analyses

A. Measurement Setup for TDD DL/UL Data Rates

Recall that Fig. 1 describes the system architecture of our 5G-NR lab design, and Table 1 summarizes the configuration of the associated hardware and software. In addition, Section 2.1 also details of such a lab design and its realization.

For this study, it is interesting to understand the aforementioned performance impacts on the achievable DL and UL data rates, together with their summed rates, due to the flexible time slot configurations of 5G TDD. As aforementioned and demonstrated by Fig. 5(b), the six slot configurations, classified into three DL/UL user-demanded traffic orientations, were adopted in the study.

In order to measure the achievable DL and UL data rates, the *iperf* toolset was utilized. The single software of *iperf* can play two roles, namely the traffic generator (client) or traffic receiver (server) when respectively followed with a command-line option of -c or -s. Both TCP and UDP traffic types are supported in iperf.

In this study, due to TCP's flow control, the TCP traffic type is more suitable and faster to explore the achievable DL and UL data rates than UDP. For the DL, the *iperf client* should be setup on the 5G network side, and the *iperf server* on the 5G UE side; and vice versa for the UL. In the telecom network, the achievable DL and UL data rates are the concepts based on *overlay networking* (a logical network over a physical network), realized by the GTP Tunnel. Hence, the 5G network side is referred to as the 5G-CN. Considering the fact that our 5G-CN is fully virtualized in terms of its component functions, it takes some tricks to locate and enter the container-based OAI-UPF (i.e., OAI-SPGWU), and eventually identify the GTP Tunnel End as the virtual network interface that either the *iperf server* or *client* has to bind. In addition, note that the measured data rates should be recognized as the TCP Goodputs, instead of the MAC Throughputs. In other words, the TCP Goodputs are the achievable maximum data rates at the layer of TCP, somewhat smaller than the MAC Throughputs.

B. Performance Impacts of TDD Slot Configurations

Fig. 6 summarizes the performance impacts of 5G TDD slot configuration scenarios on the DL and UL data rates (in terms of TCP Goodputs) for different traffic-demand orientations, as depicted in Fig. 5(b) and described at the end of the previous section. Fig. 6 delivers two distinguished effects as follows.

- Asymmetric trend slopes of DL and UL data rates

Generally speaking, one should expect that the DL data rate increases with the number of allocated DL-slots, and vice versa for the UL. In fact, the measured results show that such an expectation is somewhat naive: the expected increasing trends do exist, but their trend slopes are quite different. In other words, the much larger DL-trend slope supports that more DL-slots do help increasing the DL data rate substantially. However, such a substantial help is not seen in the UL due to the much smaller UL-trend slope. However, this asymmetry is not totally surprising and can be well explained by the huge difference of transmission power capabilities between the gNB (along the DL) and the UE (along the UL), even given the same channel condition. Obviously, the DL is much stronger, and thus much more sensitive and effective in its data rate enhancement given more DL-slots. On the other hand, although one more UL-slot does help the UL data rate effectively from D7U2 to D6U3, but not so much given any more. Eventually, this asymmetry effect also leads to asymmetric total data rates, i.e., the summed rates of both the links. Again, it seems that the small enhancement of the UL data rate is at the cost of the large degradation of the DL data rate. However, whether or not such a cost is worthwhile really depends on application scenarios.

- Symmetric performance degradation at DL/UL extremes

Another visible and interesting phenomenon happens, more or less symmetrically, at both the DL and UL extremes, namely D7U2 and D2U7. In other words, symmetric performance degradation is clearly seen at both the two extremes. However, it violates our basic intuitions. The question is why the performance on either link degrades when given more TDD slots. Presumably, it may come from TCP itself. If true, the most promising guess is due to the required ACK packets in the returned direction, for acknowledgements of the sent packets. In other words, if some ACK packets are late enough or simply lost, they will generate resent packets, and equivalently degrade the achievable data rate. Actually, it is quite possible for such an effect to occur at both the extremes, where the link direction of sent packets are allocated with too many slots so that too few slots are left for the ACKs, which will thus face much longer latencies or even congestions. Hence, for both the DL-Heavy and UL-Heavy applications over TCP, such a performance degradation effect should be skipped by avoiding going into both the extremes. However, it should not be the case for UDP where no ACK packets are required. For an application which is interaction based (such as video conferencing), Balanced configurations seem to be a good strategy no matter it is over TCP or UDP.

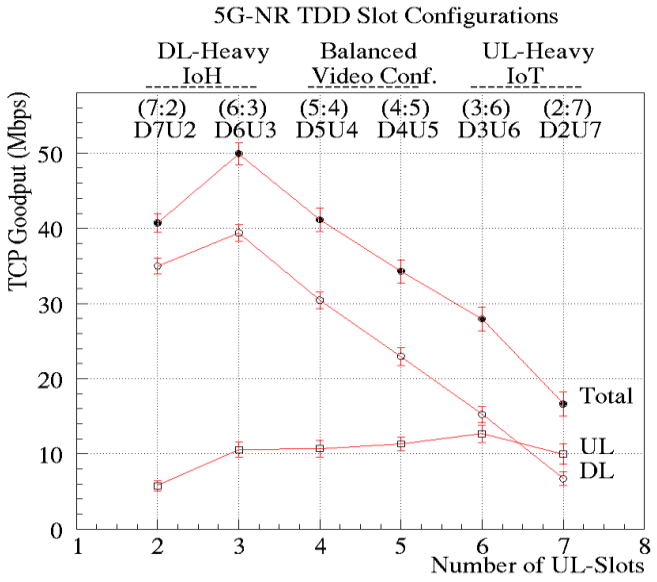

Fig. 6 Asymmetry effect of TDD DL/UL data rates under different 5G-NR TDD slot configurations (period = 5 ms).

IV. Conclusion and Outlook

In this paper, a 5G-NR based lab system design together with its realization has been demonstrated. The main focus has been placed on the performance impacts of 5G-TDD time slot configurations on the DL and UL data rates for the major band of 5G-NR, namely *n78* (3.3 – 3.8 GHz), suitable for the adoption of the $\mu = 1$ numerology (with a SCS of 30 kHz, 2 times larger than 4G-LTE) for higher mobility. The performance measurement results show two major effects: (1) asymmetric trend slopes of DL and UL data rates, and (2) symmetric performance degradation at the DL/UL extremes. Analyses of these two effects have also been proposed with respect to the DL/UL traffic orientations, including DL-Heavy, UL-Heavy and Balanced applications, such as *internet of humans* (IoH), *internet of things* (IoT) and video conferencing respectively.

As an outlook into the future, there are some works worth doing. First of all, the performance effects and their analyses carried out in this study are mostly based on the view point of TCP-Goodput based data rates. It is certainly interesting to extend the work to cover the view point of UDP, where one might still expect to see the asymmetry phenomenon similar to Effect (1) given the fact that the transmission power of the gNB is always stronger than that of the UE; but one might not see Effect (2) any longer, due to no returned ACK packets in the opposite link of sent packets.

Another useful view point can also be provided by a study on packet-based *latency* and *jitter* spectra, respectively important to *interactive* and *one-way* applications. However, the *ping*-based packet's *round-trip time* (RTT) information only provides two-way knowledge. Hence, a special time synchronization technique between the CN and the UE with a time resolution much more precise than the generic NTP protocol (only precise to the level of *ms*) is certainly wanted for resolving one-way knowledge down to the level of sub-μs, either along the DL or UL.

***Abstract* — In intelligent manufacturing, fault diagnosis of rotating machinery is indeed a critical and complex task. Most of the current research only classifies faults without considering the interpretability of classification. To fill this gap, inspired by the interpretable technology of computer vision, we propose 2DImages-CNN, a method combining 2D images and a convolutional neural network (CNN) for mechanical fault diagnosis and interpretation. First, we transform time series signals into distinct 2D images through two techniques: the Gramian angular field (GAF) and the Wavelet transform (WT). Then, we input 2D images into the ResNet34 model for fault recognition. We conducted experiments using transfer learning on the Case Western Reserve University (CWRU) bearing dataset. The results provide compelling evidence that, when compared to renowned methods, the 2DImages-CNN method achieves superior fault recognition accuracy. Finally, we use gradient-weighted class activation mapping (Grad-CAM) to interpret deep fault features. The results show that, for GAF images, the network shows a strong degree of activation in the area with large signal fluctuations. For WT images, the network shows a strong degree of activation in the area with large amplitude.**

***Keywords* —Convolutional Neural Network (CNN), Fault Diagnosis, Gramian Angular Field (GAF), Wavelet Transform (WT), Interpretation.**

I. INTRODUCTION

Bearings hold an indispensable role within the field of rotating machinery, serving as a critical component. They account for a substantial proportion of failures, estimated at 45% to 55%. Therefore, accurate and timely diagnosis of bearing issues is significant in improving the reliability of this machinery [1]-[2].

As intelligent technology continues to advance, various data-driven techniques, particularly those centered on deep learning, have gained extensive traction. This popularity is attributed to their robust data processing capabilities and remarkable learning prowess. CNNs automatically extract relevant features according to learning objectives and do not rely on expert experience. Therefore, CNNs have found broad utility in fault diagnosis. Zhang et al. [3] introduced a CNN model that utilizes time-frequency images generated through short-time Fourier transform (STFT) as input for fault diagnosis. In reference [4], the authors used the WPT method to generate spectral images of vibration signals and then used CNN for fault identification. Meanwhile, this paper employs simulated degradation algorithms to determine the optimal parameters. In reference [5], the authors developed a CNN-based model for bearing fault diagnosis that incorporates time-frequency image analysis. They investigated the model's performance with respect to three distinct time-frequency analysis techniques. Liang et al. [6] introduced the WT-MLCNN method. Initially, they applied the WT to transform vibration signals into 2D time-frequency images. Following this transformation, the subsequent step involved feeding these images into the MLCNN model, thereby enabling comprehensive fault diagnosis for gearboxes. Liang et al. [7] additionally presented the WT-GAN-CNN approach, where they applied the WT to convert the signals into time-frequency images. Following this, they employed GAN to generate additional training image samples, which were then used in conjunction with a CNN model for fault detection. The above researchers have combined 2D time-frequency images with CNNs for fault diagnosis. Time-frequency images describe the overall characteristics of signals. In reference [8], the authors used the GAF and MTF models to encode time series as images, thereby proving that the CNN could obtain excellent performance. Han et al. [9] introduced a fault diagnosis approach that incorporates the GAF, MTF, and capsule network. GAF and MTF images were input into the capsule network as two-channel images so that the network could obtain more complete fault characteristics. GAF images

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

describe the instantaneous characteristics of signals.

The above research indicates that inspired by computer vision, fault diagnosis methods using a combination of 2D images and CNNs are widely used. However, the above research only classifies faults without considering the interpretability of neural networks. In recent times, there has been a significant surge in interest surrounding the interpretability of deep learning methods. Researchers and practitioners alike have devoted substantial attention to unraveling the inner workings of deep learning models. The interpretable methods of neural networks include CAM [10], Grad-CAM [11], and Grad-CAM++ [12]. However, the disadvantage of CAM is that the original model structure needs to be modified and retrained. The Grad-CAM++ model is not clean enough visually, and a lot of background information is marked. Therefore, this paper uses the Grad-CAM method for visualization, which can establish the relationship between the key activation areas of the neural network and target categories, and solve the problem of black-box operation of the neural network.

This paper's contributions include:

(1) First, the GAF and WT methods encode time series signals into two types of 2D images. GAF and WT images describe the instantaneous and overall features of signals, respectively. This paper analyzes signals from different perspectives.

(2) Second, GAF and WT images are used as inputs to the Resnet34 model for fault detection. The experimental results demonstrate that the 2DImages-CNN method outperforms many existing methods.

(3) Finally, the black-box problem of fault diagnosis is explained through Grad-CAM visualization. The experimental results show that for GAF images, the network makes classification decisions in areas with large fluctuations in signal values; For WT images, the network makes classification decisions in areas with large amplitudes.

Section II of this paper presents the fundamental theories behind the GAF, WT, and 2DImages-CNN methods. Section III validates the effectiveness of 2DImages-CNN for fault diagnosis through experiments. Finally, Section IV offers the conclusion.

II. METHODS

A. Gramian Angular Field

The GAF [13] method can convert temporal signals into images with rich features, which contain the temporal correlation between any two data points. GAF coding steps are as follows:

(1) First, the time series $X = \{x_1, x_2, \ldots, x_n\}$ in Cartesian product coordinates are scaled to [0,1] by Equation (1).

$$\bar{x}_i = \frac{x_i - x_{min}}{x_{max} - x_{min}} \tag{1}$$

where x_i is the ith value in the original time series; $\bar{x}_i$ is the ith value in the reconstructed time series; and x_{min}, x_{max} are the minimum and maximum values of X, respectively.

(2) Then, the scaled value is encoded as the angular cosine $\emptyset$, and the time stamp is encoded as the radius r. We can represent the rescaled time series in the polar coordinate system. Equation (2) is as follows:

$$\begin{cases} \emptyset = \arccos(\bar{x}_i);\ 0 \le \bar{x}_i \le 1, \bar{x}_i \in \widetilde{X} \\ r = \frac{t_i}{N}; t_i \in N \end{cases} \tag{2}$$

where t_i is the time stamp, and N is the constant factor.

(3) Finally, we can leverage the angular perspective by assessing the trigonometric distinctions between each data point to discern time correlations within various time intervals. The GAF coding method can encode time series into feature images, which is defined as Equation (3).

$$G_{GAF} = \begin{bmatrix} \sin(\emptyset_1 - \emptyset_1) & \cdots & \sin(\emptyset_1 - \emptyset_n) \\ \sin(\emptyset_2 - \emptyset_1) & \cdots & \sin(\emptyset_2 - \emptyset_n) \\ \vdots & \ddots & \vdots \\ \sin(\emptyset_n - \emptyset_1) & \cdots & \sin(\emptyset_n - \emptyset_n) \end{bmatrix}$$

$$= \sqrt{I - \left(\widetilde{X}^2\right)^T} \cdot \widetilde{X} - \widetilde{X}^T \cdot \sqrt{I - \widetilde{X}^2} \tag{3}$$

where I is the unit row vector; $\tilde{X}^T$ is the transpose of X. GAF images of 10 different fault types of the CWRU dataset are shown in Fig. 1.

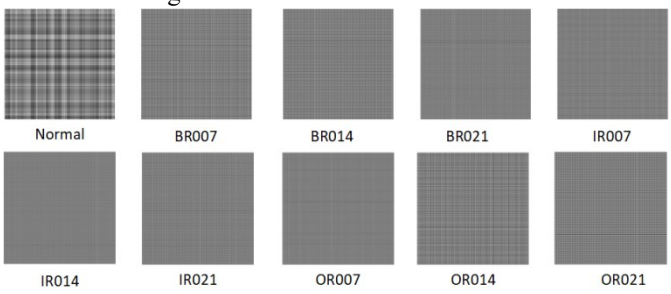

Fig. 1: GAF images of different fault types of the CWRU dataset.

B. Wavelet transform

WT is a modern approach to transform analysis. It builds upon the concept of STFT localization, addressing the limitation of fixed window size with respect to frequency. WT offers a "time-frequency" window that adapts to different frequencies and is defined by Equations (4) and (5).

$$W(a,\tau) = [x(t), \psi_{a,\tau}(t)] = \frac{1}{\sqrt{a}} \int x(t) \psi\left(\frac{t-\tau}{a}\right) dt \tag{4}$$

$$\psi_{a,\tau}(t) = \frac{1}{\sqrt{a}}\psi\left(\frac{t-\tau}{a}\right) \qquad a, \tau \in R, a > 0 \tag{5}$$

where, a is the scale factor; τ is the translation factor; $\psi_{a,\tau}(t)$ is the wavelet basis function. WT images of 10 different fault types of the CWRU dataset are shown in Fig. 2.

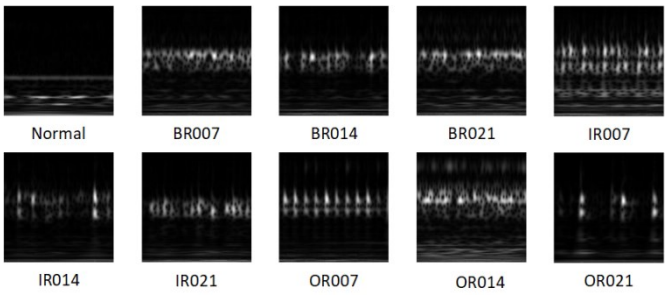

Fig. 2: WT images of different fault types of the CWRU dataset.

C. *Convolutional Neural Network*

This section provides a detailed introduction to the CNN framework used for fault diagnosis [14]. ResNet34 was chosen for the fault classification task in this paper for several reasons. First, ResNet34 contains residual structure [10], which can simplify network training and reduce network training parameters. Second, ResNet34 uses the batch normalization layer, which can avoid gradient disappearance and explosion. Finally, the CNNs are capable of extracting translation-invariant features, thereby improving robustness and mitigating the influence of noise. The specific algorithm for the CNN-based method is as follows:

Algorithm CNN-Based Fault Diagnosis Method

Input: GAF or WT images.

Step 1: Feature extraction.

The feature extractor can extract features from the original data and connect them to form a global representation.

Convolutional layer: $C^q = \sum_{p=1}^{P} W^{p,q} * X^p + b^q$

Batch normalization layer: $\widehat{c_i} = \frac{c_i - u}{\sqrt{\sigma^2 + \varepsilon}}$, $h_i = \gamma \widehat{c_i} + \beta$

ReLU activation layer: $R^r = ReLU(H^r) = max(H^r, 0)$

Max pooling layer: $M^r = \max_{T^r \in S} R^r$

Step 2: Fault classification.

Fault classifier identifies fault type according to the global representation.

Average pooling layer: $Z^r = \operatorname{avg}_{M^r \in S} M^r$

Full connected layer: $Z = [Z^1, Z^2, \ldots, Z^r, \ldots, Z^R]$, $G = \mathrm{ReLU}(W_g Z + b_g)$

Softmax function: $O_j = P(y = j|G;\theta) = \frac{exp(\theta^{(j)} G)}{\sum_{k=1}^{K} exp(\theta^{(k)} G)}$, $j = 1,2,\ldots,K$

Output: the target categories(Normal,BR007,.....,OR021.).

In the above algorithm, $q = 1,2,3,\ldots,Q$, Q represents the predefined number of filters; $p = 1,2,3,\ldots,P$, P is the number of convolution channels; $W^{p,q}$ and b^q represent the weight and bias of the filter, respectively; c is a minibatch of feature C, $c = c_1, c_2, c_3, \ldots, c_t$, σ^2 and u are the variance and mean of the minibatch, respectively; ε is the minimum value close to 0; H^r is result of the BN layer of channel r; S represents the range of the pooling function; W_g and b_g represent the weight and bias, respectively. O_j represents the estimated probability of category j; $\theta^{(j)}$ is the parameter of the softmax function; and K is the number of fault categories..

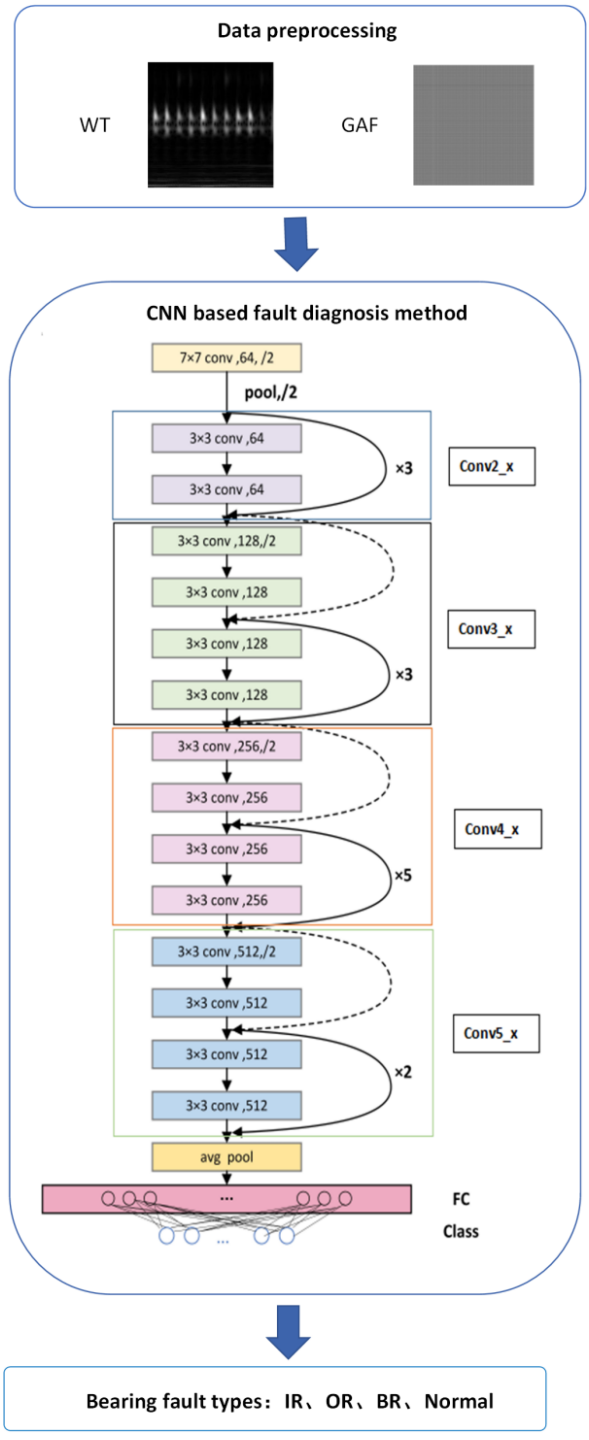

Fig. 3: 2DImages-CNN fault diagnosis method.

The 2DImages-CNN method is shown in Fig. 3. Firstly, the GAF and WT methods encode time series signals into two types of 2D images. Next, we input the 2D images into the ResNet34 model to perform feature extraction. The first layer convolution operation of the network uses 64 convolution kernels with a size of (7,7) and a moving step size of 2. After each convolution operation, the output sequentially undergoes batch normalization and activation layers. The remaining convolution layer operations are similar to those of the first layer. Each curved arrow represents a residual structure, and the number next to it represents the number of residuals stacked. We input the size of images as (224,224,1), after the operation of the first convolution layer the output feature map size becomes (112,112,64), and then through the Conv2_x, Conv3_x, Conv4_x, and Conv5_x layers, output feature map size changes in turn for (56,56,64) → (28,28,128) → (14,14,256) → (7,7,512). After a series of convolution operations, fault types are determined using successive layers including average pooling, fully connected layers, and the softmax function. Bearing failures can be categorized into four main types: inner race fault (IR), outer race fault (OR), bearing roller fault (BR), and normal (Normal).

D. Evaluation index of fault diagnosis

We further evaluated the classification results using evaluation indicators commonly used in machine learning. The commonly used evaluation indexes for multi-classification problems are Macro-precision (macro-P), Macro-recall (macro-R), and Accuracy. Evaluation indicators are defined as follows:

$$\mathrm{macro}-\mathrm{P}=\frac{1}{\mathrm{n}}\sum_{1}^{\mathrm{n}}\mathrm{P}_i\,,\ \text{where}\ \mathrm{P}_i=\frac{\mathrm{TP}_i}{\mathrm{TP}_i+\mathrm{FP}_i}\times 100\% \quad (6)$$

$$\mathrm{macro}-\mathrm{R}=\frac{1}{\mathrm{n}}\sum_{1}^{\mathrm{n}}\mathrm{R}_i,\ \text{where}\ \mathrm{R}_i=\frac{\mathrm{TP}_i}{\mathrm{TP}_i+\mathrm{FN}_i}\times 100\% \quad (7)$$

$$\mathrm{Accuracy}=\frac{\mathrm{Correct}}{\mathrm{Total}}\times 100\% \quad (8)$$

where the abbreviations TP_i, FP_i, TN_i, and FN_i represent the number of True Positives, False Positives, True Negatives, and False Negatives in the i-th category, respectively [15]. *Correct* denotes the count of samples correctly classified, while *Total* represents the overall number of samples.

E. The interpretability of fault diagnosis

For the black-box operation of the neural network, Grad-CAM is used to interpret the fault diagnosis results. Grad-CAM is a class-discriminative localization technique that assigns a score to each class based on gradient information from backpropagation and convolution activation values [11]. Grad-CAM provides a way to determine which specific parts of the image influence model decisions. Mathematically, the Grad-CAM calculation of the class discriminant positioning map is as follows:

$$\mathrm{L}^{\mathrm{c}}=\mathrm{f}\left(\sum_{\mathrm{k}}\mathrm{a}_{\mathrm{k}}^{\mathrm{c}}\mathrm{A}^{\mathrm{k}}\right) \quad (9)$$

where A^k is the k-th feature map of a CNN layer; a_k^c is the weight of A^k; and $f(\cdot)$ is a ReLU activation function.

III. Experimental Study

To evaluate the effectiveness of the 2DImages-CNN method we have proposed, we conducted a series of experiments utilizing the CWRU dataset. This dataset was chosen due to its well-established reputation for providing a robust and comprehensive basis for our evaluation process.

A. Experimental equipment and data description

Bearing failure stands out as a primary reason behind failures in rotating machinery. Therefore, the detection of bearing faults holds immense significance in preventing failures in rotating machinery. Precise bearing fault diagnosis contributes to enhancing equipment reliability and availability.

The CWRU dataset [16] includes the following:

(1) The fault points on the bearings are manually processed, and vibration acceleration signals from the faulty bearings are collected using an acceleration sensor.

(2) The vibration signals of the IR, OR, and BR with different fault diameters under different loads are collected by an accelerometer. The diameters are 0.007, 0.014, and 0.021 inches respectively. The loads are 0, 1, 2, and 3 HP respectively.

(3) We selected the bearing fault data of the drive end with a sampling frequency of 12 kHz and the normal data and used the DE-driving end acceleration data to experiment.

(4) The original dataset comprises samples with varying numbers of time course measurements. To augment the dataset and facilitate the training of a more precise model, we standardize the samples to ensure each one contains a consistent set of 1200 time course measurements.

The details of the CWRU dataset can be found in Table 1. In Table 1, Normal, IR, OR, and BR indicate the different states of the bearing. BR007 indicates a failure of a bearing roller with a diameter of 0.007 inches, IR007 indicates a failure of a bearing inner race with a diameter of 0.007 inches, while other categories follow a similar pattern.

Table 1: The details of the CWRU dataset.

Health states descriptions					Dataset
Types/Labels			Diameter (inch)	Load (HP)	Train/Test
Normal	Normal	Normal	-	0-3	1120/280
Failure	BR	BR007	0.007	0-3	320/80
		BR014	0.014	0-3	320/80
		BR021	0.021	0-3	320/80
	IR	IR007	0.007	0-3	320/80
		IR014	0.014	0-3	320/80
		IR021	0.021	0-3	320/80
	OR	OR007	0.007	0-3	960/240
		OR014	0.014	0-3	320/80
		OR021	0.021	0-3	960/240

B. Diagnosis results and comparative analysis

The 2D images generated by both GAF and WT techniques are randomly split into training and test sets, with an 8:2 ratio. The training set is used exclusively to train the ResNet34 model, while the test set is reserved for evaluating the model's performance.

For bearing fault diagnosis, three models are trained: the two-classifications model (Normal and Failure), the four-classifications model (Normal, IR, OR, BR), and the ten-classifications model (Normal, IR007, IR014, IR021, OR007, OR014, OR021, BR007, BR014, and BR021). According to different classification and prediction targets, the parameters are adjusted on the basis of the pretraining ResNet34 model. During training, we froze the parameters of Conv2_x, Conv3_x, and Conv4_x layers. The learning rate of the Adam optimization algorithm is set to 0.0001, the number of training iterations is set to 50, and the number of categories is set to 2/4/10. The experimental results of different classification models of bearing faults are shown in Table 2.

The findings presented in Table 2 demonstrate that employing both GAF and WT images in conjunction with the ResNet34 network model yields a high fault recognition rate. It's noteworthy that while the fault diagnosis rate of GAF images is slightly lower compared to WT images, this can be attributed to the more complex nature of fault information contained in GAF images. In contrast, WT images offer more intuitive fault information, resulting in superior network performance when classifying WT images. Our approach doesn't depend on prior knowledge; the measured data and their corresponding labels alone suffice for precise fault type classification.

Table 2: Experimental results of different classification models of bearing faults.

Types	Classification	macro-P	macro-R	Accuracy
GAF	Two-classifications	100%	100%	**100%**
	Four-classifications	98.78%	98.63%	**98.79%**
	Ten-classifications	94.13%	94.22%	**96.29%**
WT	Two-classifications	100%	100%	**100%**
	Four-classifications	100%	100%	**100%**
	Ten-classifications	100%	100%	**100%**

To more intuitively display the results and perform misclassification analysis, Fig. 4 shows the confusion matrix of GAF images in three models [17]. The vertical axis corresponds to the predicted label of the samples, while the horizontal axis represents the true label of the samples. As depicted in Fig. 4, in the case of GAF images and the bearing two-classifications fault diagnosis task, all samples are accurately categorized into their respective classes. In the four-classifications, a few samples of BR and OR categories were misclassified into adjacent categories. In the ten-classifications, most of the misclassification samples of the BR007 category are classified into the BR021 category. Because both BR007 and BR021 belong to the BR category, their fault characteristics have certain similarities, so there are certain challenges in network classification.

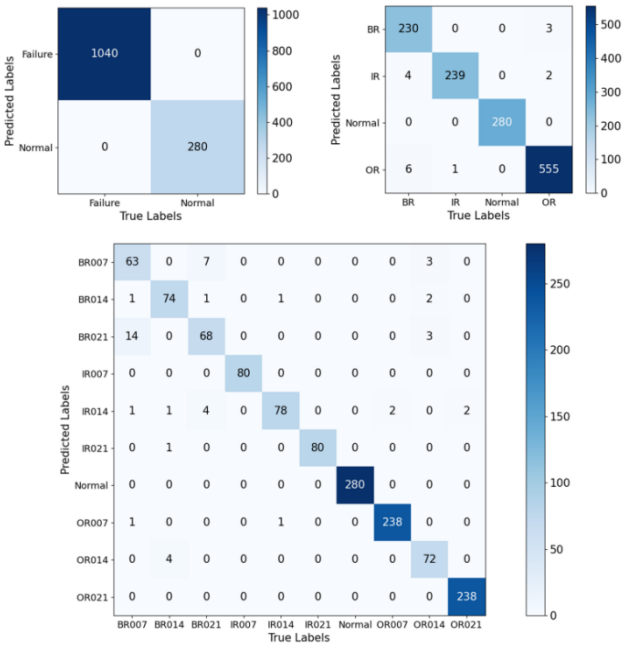

Fig. 4: Confusion matrix of GAF images in different classification tasks.

Fig. 5 shows the confusion matrix of WT images in three models. As can be seen from Fig. 5, WT images are correctly classified into corresponding categories in the tasks of bearing two-classifications, four-classifications and ten-classifications. Because the signal information expressed by WT image is more intuitive and simple. The experimental outcomes affirm the applicability of our approach within the domain of fault diagnosis.

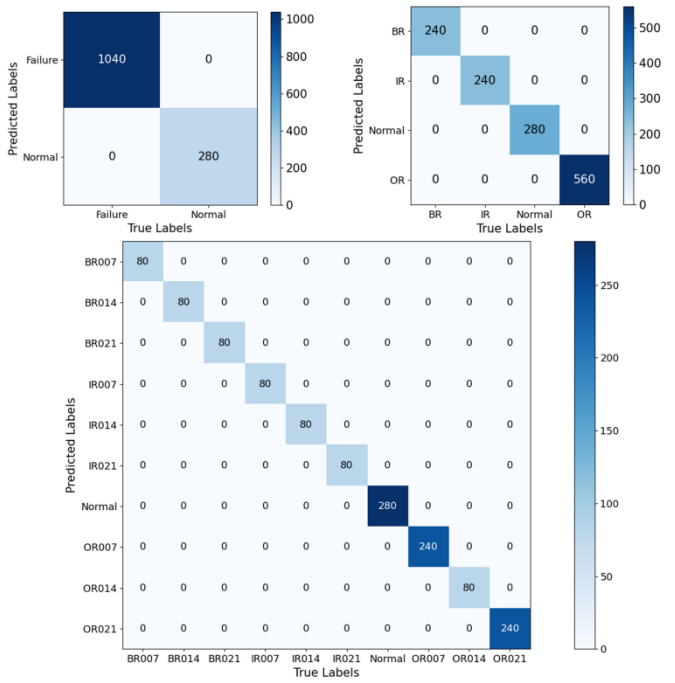

Fig. 5: Confusion matrix of WT images in different classification tasks.

To illustrate the performance of our proposed 2DImages-CNN framework, we compare it with other well-known approaches using the same dataset. The comparison results are shown in Table 3. The accuracy of the 2DImages-CNN model proposed by us is 100%, 98.79%, and 96.29% in two-classifications, four-classifications, and ten-classifications of GAF images, respectively. Our method achieves 100% accuracy on WT images, which is superior to many traditional methods. Additionally, compared with ANN, DBN, or SVM methods, which are applicable to only one or two kinds of classification tasks, the 2DImages-CNN method proposed in this paper can handle three kinds of diagnosis tasks in a unified framework and thus has wide applicability.

C. Grad-CAM explains deep fault features

To interpret the fault classification results, we use Grad-CAM to locate and highlight the key active areas at the final convolution layer of the Resnet34 model.

Select one sample from each of the four types of bearing failure GAF images for visualization and the visualization results are shown in Fig. 6. The first column of Fig. 6. shows the bearing original vibration signals, and it can be observed that the fluctuation of the normal signal is small, while the fluctuation of fault signals is significant. Therefore, bearing faults can be classified based on signal fluctuations. The red part of the image in the third column in Fig. 6 is the main part that affects the bearing fault classification. The experimental results show that the vibration signal of normal bearing is weak, and there is no obvious impact peak. The focus area of the network model is scattered on most segments of the input signal, which indicates that most signal sequences have basically the same contribution to the output; For bearings with outer race, inner race, and roller faults, the part with greater activation degree of the network is basically concentrated in the part with stronger vibration signal fluctuations, indicating that this part contains more fault feature information. The visualization results can prove that the area of concern of our proposed method in fault classification is correct, and solve the problem of black-box operation of neural network.

Table 3: Comparison of 2DImages-CNN method with other methods in bearing fault tasks.

Methods	Categories	Accuracy
2DImages-CNN(GAF)	**2**	**100%**
2DImages-CNN(WT)	**2**	**100%**
ANN [18]	2	92%
2DImages-CNN(GAF)	**4**	**98.79%**
2DImages-CNN(WT)	**4**	**100%**
LS-SVM [19]	4	89.50%
WT-CNN [6]	4	95.09%
RNN [20]	4	95.60%
2DImages-CNN(GAF)	**10**	**96.29%**
2DImages-CNN(WT)	**10**	**100%**
ConvRNN[21]	10	94.74%
DBN[22]	10	90%
WDCNN [23]	10	95.9%
CapsNet [9]	10	92.39%

Select one sample from each of the four types of bearing failure WT images for visualization and the visualization results are shown in Fig. 7. The second column of Fig. 7 shows that large amplitudes for different fault types are distributed over different frequency ranges. Therefore, networks can be classified based on areas with large

amplitudes. The third column in Fig. 7 shows that the experimental results show that our network pays attention to the right key area in fault classification, which solves the problem of black-box operation in fault diagnosis.

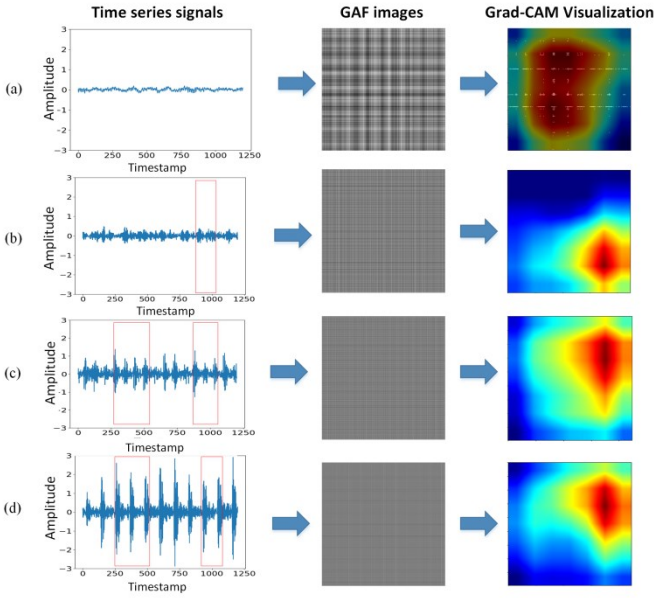

Fig. 6. Visualization results of GAF images: (a) Normal, (b) BR007, (c) IR007, (d) OR007.

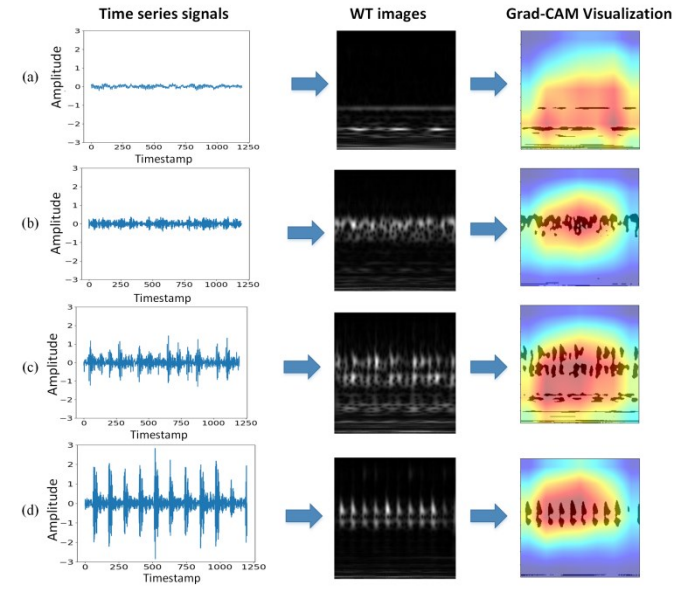

Fig. 7. Visualization results of WT images: (a) Normal, (b) BR007, (c) IR007, (d) OR007.

For commonly used deep learning networks, it is generally believed that they are a black-box and have weak interpretability. In response to this issue, many researchers are trying to explore its internal connections. However, the traditional method only classifies different fault types without considering the interpretability of fault classification. To fill this gap, we use Grad-CAM visualization. The experimental results show that for GAF images, the network makes classification decisions in areas with large fluctuations in signal values; For WT images, the network makes classification decisions in areas with large amplitudes.

IV. Conclusions

This paper introduced a bearing fault diagnosis approach utilizing 2DImages-CNN. Firstly, vibration signals are transformed into 2D images using the GAF and WT techniques. Then, the 2D images are input into the ResNet34 model for fault identification. The experimental results of the CWRU bearing dataset shows that the accuracy of our method is 100%, 98.79%, and 96.29% for two-classifications, four-classifications, and ten-classifications of GAF images, respectively. Our method achieves 100% accuracy in two-classifications, four-classifications, and ten-classifications of WT images. Our method demonstrates superior feature extraction capabilities and higher accuracy when compared to conventional approaches. This performance enhancement underscores the practical utility of our approach in fault diagnosis applications. Finally, Grad-CAM is used for visualization, and the visualization results show that when GAF images are visualized, the network classifies the bearing faults according to the correlation between areas with large signal fluctuations. When visualizing WT images, the network classifies bearing faults according to the areas with large amplitude.

In the future, we will attempt to apply the 2DImages-CNN model to the field of fault prediction. Secondly, we will conduct bearing failure experiments using our own dataset.

***Abstract* — For the defect detection of specular surfaces, the image of the light source and other images of surrounding objects tend to be recorded, increasing the complexity of recognition. The method of combined dark-and-bright field illumination has been shown to improve the image quality of the defects on specular surfaces. However, there is still an issue of background fringes. In this study, we design a compensating pattern for diminishing the background fringes. The experimental results show that the proposed method can effectively dilute these fringes and increase the detection efficiency by fewer capture images.** *

I. INTRODUCTION

Detecting defects on specular surfaces, such as metal, glass, or glossy surfaces, tends to shoot the image of the light source and other images of surrounding objects. As a result, more procedures of subsequent computer processing are required, and the complexity of defect recognition increases. Additionally, some defects are only apparent at certain angles of incidence. When they are under test, the adjustable range of the instruments is limited. To improve the defect detection for the samples with specular surfaces, Forte et al. reported a system of combined dark and bright field illumination. The illumination in that system is provided by a monitor, displaying dark and bright lines to perform the dark-and-bright-field illumination [1-2]. After each image of the sample is captured, the illumination pattern changes. Although that method successfully improves the image quality, the background fringe is still an issue. To further improve the image quality of defect detection for specular surfaces, we propose a formula based on Forte's system for designing a compensating pattern. With the proposed compensating pattern, the detected image of defects is optimized by reducing the background fringes, leading to a higher defect-detection efficiency.

II. THEORY

According to Forte's approach, the illumination is a sequent of patterns with shifting dark and bright lines, as shown in Fig. 1. By their algorism, the gray value at (i, j) of the output image is expressed as [1]:

$$I_{i,j}^{out} = \sum_{k=1}^{N} \left| I_{i,j}^{k} - \frac{1}{N} \sum_{l=1}^{N} I_{i,j}^{l} \right|, \quad (1)$$

where N is the number of images and is the ratio between the pixels of one period, T, to the number of shifted pixels per pattern change, P:

$$N = \mathrm{T/P}. \quad (2)$$

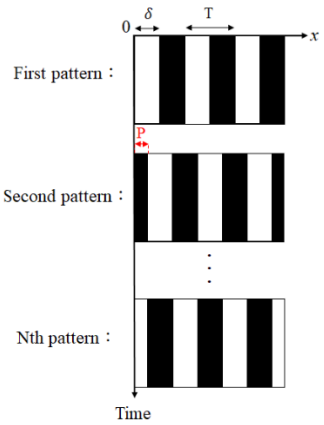

Fig. 1 Sequence of image patterns. δ, T, and P are the width of a bright line, the width of one period, and the number of shifted pixels between the adjacent patterns, respectively.

* The authors appreciate the financial support from the National Science and Technology Council, Taiwan, R.O.C (Grant Nos. 112-2221-E-008-053 and 112-2221-E-492-012).

The second term on the right side of Eq. (1) denotes the average gray values of these *N* images at *(i, j)*. The final output image I_{Final} is normalized by the formula:

$$I_{i,j}^{final} = I_{i,j}^{out} \times \frac{255}{I_{max}^{out}}. \quad (3)$$

The compensating image is for reducing the background dark fringes. These fringes are derived from the interface of each pattern shifting. Assume that in a row, the number of bright pixels per period, equivalent to the width of the bright line, is δ. Take a case with T = 3δ, P = 0.5δ as an example. The first background dark fringe occurs at the *x* coordinate of 0.5δ and 0.5δ+1, while the second one occurs at δ and δ+1. Thus, the compensating pattern is a set of bright lines in these regions. The modified algorism is

$$I_{i,j}^{out2} = \sum_{k=1}^{N} \left| I_{i,j}^{k} - \frac{1}{N} \sum_{l=1}^{N} I_{i,j}^{l} \right| + c \times I_{i,j}^{com} \ , \quad (4)$$

where $I_{i,j}^{com}$ is the gray value of the compensating pattern at *(i, j)*. *c* is a ratio factor. The final image is also normalized based on the following equation:

$$I_{i,j}^{final2} = I_{i,j}^{out2} \times \frac{255}{I_{max}^{out}}. \quad (5)$$

III. Results and Discussion

The experimental setup consists of an illumination source, a camera, and a sample, as shown in Fig. 2. The illumination source is an LCD monitor (ASUS) with 840 × 1050 active pixels. The camera is a CMOS camera (acA5472-17, Basler) with a lens (TUS-1220, TUSS). The illumination source and the camera are connected to a computer with codes for automatedly changing illumination patterns, triggering the camera, receiving the captured images, and processing images. The image processing codes include the algorithms above. The sample is a plate made of stainless steel, and the size of the specular surface is 12 cm × 11 cm. There are 14 hand-made defects, as shown in Fig. 3.

(a) (b)

Fig. 2 System setup (a) illumination pattern (b) sample, camera, and illumination source

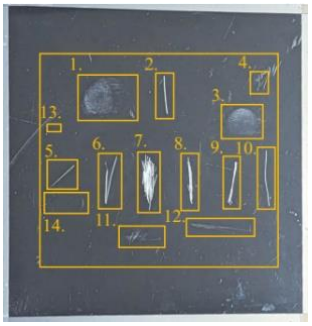

Fig. 3 Sample made of stainless steel with 14 hand-made defects

The compensating pattern can be predesigned by calculating the interface regions during pattern shifting and setting these regions with high gray values. The gray values of other regions are assigned as zero. However, the exact gray values for the interface regions are difficult to define by calculation. Thus, a pretest of the no-defect sample is done to examine the background fringes' gray values and to assign the proper gray values for the compensating pattern. An example of the compensating pattern is shown in Fig. 4.

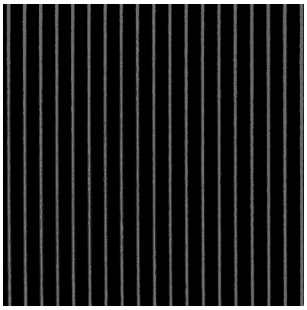

Fig. 4 Example of the compensating pattern

Firstly, the system is operated with three configurations whose numbers of shifted pixels P are δ, $\delta/2$, and $\delta/3$, respectively, to test the algorithm without compensating pattern. The width of the bright line of each configuration is kept the same: δ = 60 pixels. Then, the background fringes in the captured images are observable, as illustrated in Fig. 5. The results exhibit that with the decreasing number of shifted pixels, P, the background fringes become less apparent. However, according to Eq. (2), the required number of images, N, is increased when the period, T, is fixed.

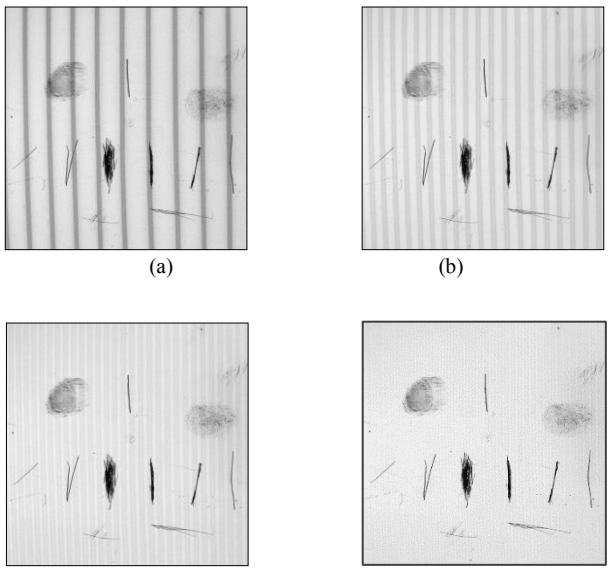

Fig. 5 Captured images without the compensating patterns in the configurations of P = (a) δ, (b) $\delta/2$, (c) $\delta/3$ and (d) $\delta/4$.

If the compensating patterns are applied, the background fringes of these three configurations become dilute, as shown in Fig. 6. Thus, the proposed method has effectively improved the image quality. The parameters of these configurations are listed in Table I. Because of the appended compensating pattern, the required number of images is N+1.

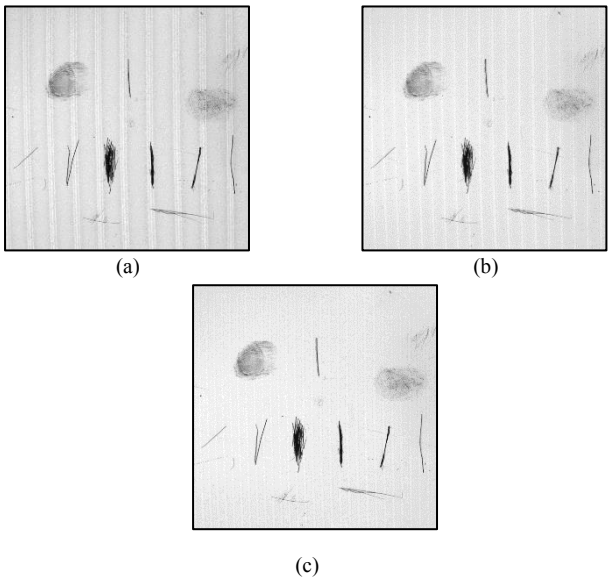

Fig. 6 Captured images with the compensating patterns in the configurations of P = (a) δ, (b) $\delta/2$, and (c) $\delta/3$

Table I Parameters of configurations

δ = 60 pixels				
T = 3δ				
Trial		1	2	3
P		δ	$\delta/2$	$\delta/3$
Required number of images	Without compensation	3	6	9
	With compensation	4	7	10
c (ratio factor)	With compensation	1.6	1	0.8

To enhance the contrast between the defects and the background, we processed the captured images by a modified binary technique [1,3]. Unlike the conventional Niblack's binarization using standard deviation and local mean to count the threshold [4-6], the modified binary technique consists of another ratio factor for adjusting the strength of the standard deviation. The processed image B_{Final} satisfies the the following equation [1]:

$$B_{Final,i,j} < A_{Temp,i,j} - Y \times S_{Temp,i,j}, \quad (6)$$

where Y is a ratio factor. $A_{Temp,\,i,j}$ and $S_{Temp,\,i,\,j}$ are the average gray value and the standard deviation of a region with the center coordinate of (i, j), respectively. The size of each region is (2M + 1) × (2N + 1). Meanwhile, $A_{Temp,\,i,j}$ and $S_{Temp,\,i,\,j}$ can be expressed as:

$$A_{i,j}^{Template} = \frac{1}{(2M+1)(2N+1)} \sum_{k=-N}^{N} \sum_{l=-M}^{M} \left[B_{i-k,j-l}\right] \quad (7)$$

and

$$S_{i,j}^{Template} = \left\{\sum_{k=-N}^{N} \sum_{l=-M}^{M} \left[(I_{i-k,j-l} - A_{i,j}^{Template})^2\right]\right\}^{1/2} \quad (8)$$

The defect images after binarization are illustrated in Fig. 7. These configurations are also all under δ = 60 pixels and T= 3δ. Figures 7(a) and 7(b) are based on the images without compensation, while Fig. 7(c) and 7(d) are from the compensated ones. The Y factor for these four configurations are 0.82, 0.6, 0.55, and 0.45, respectively. In addition to the configurations with P = δ, $\delta/2$, and $\delta/3$, as shown in Fig. 6, the configuration of P = $\delta/4$ without compensation was included in Fig. 7 for comparison. As shown in Fig. 5(d), the background black fringes of this configuration are unapparent. However, because the number of shifted pixels P is reduced to δ /4, the required number of images increases to N = 12, which adds to the processing time. The analyzed results show that the ratio of the dark pixels to the total pixels of the compensated output is

slightly higher than that without compensation, as shown in Fig. 8.

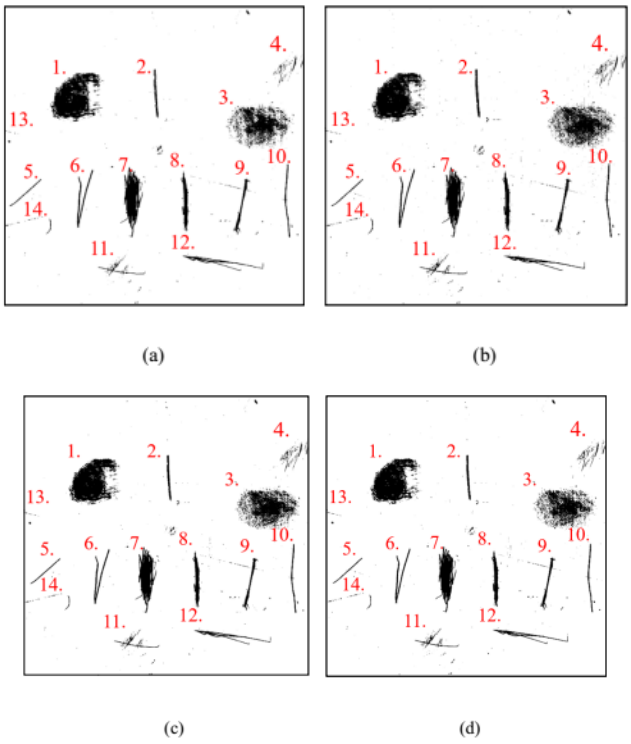

Fig. 7 Defect images after binarization in the configurations with δ = 60 pixels, T = 3δ, and P = (a) $\delta/3$ without compensation, (b) $\delta/4$ without compensation, (c) $\delta/2$ with compensation, and d) $\delta/3$ with compensation.

In other words, the defects in the compensated images are more obvious than those in the uncompensated images. It proves that the image quality of the compensated result is acceptable. Moreover, since the detection speed is one of the critical parameters of automatic optical inspection (AOI) techniques [7-8], fewer captured images can bring about faster detection. For the demonstrated configurations, the required number of images for the configurations in Fig. 7(a) to 7(d) are 9, 12, 7, and 10, respectively. Thus, the compensation configuration shown in Fig. 7(c) requires fewer capture images, implying the increment of the detection efficiency.

IV. Conclusions

This study is based on an image-processing method proposed by Forte et al. and aims to solve the background fringes of that image-processing method. According to the analyses of the captured background dark fringes, it is concluded that the junction of the bright and dark areas of the captured image induced these background dark fringes. Therefore, this study proposes a scheme that compensates for the illumination. From the experimental results, this scheme can effectively compensate for the dark fringes. The defects on the image after compensation do not have obvious fading or cracking. Finally, this paper uses the dark ratio as an indicator to compare the binarized images of several configurations. The final result shows that the configuration of P = $\delta/2$ with compensation has a better dark ratio, and its required number of images is fewer than other illustrated configurations, equivalent to the increment of the detection efficiency.

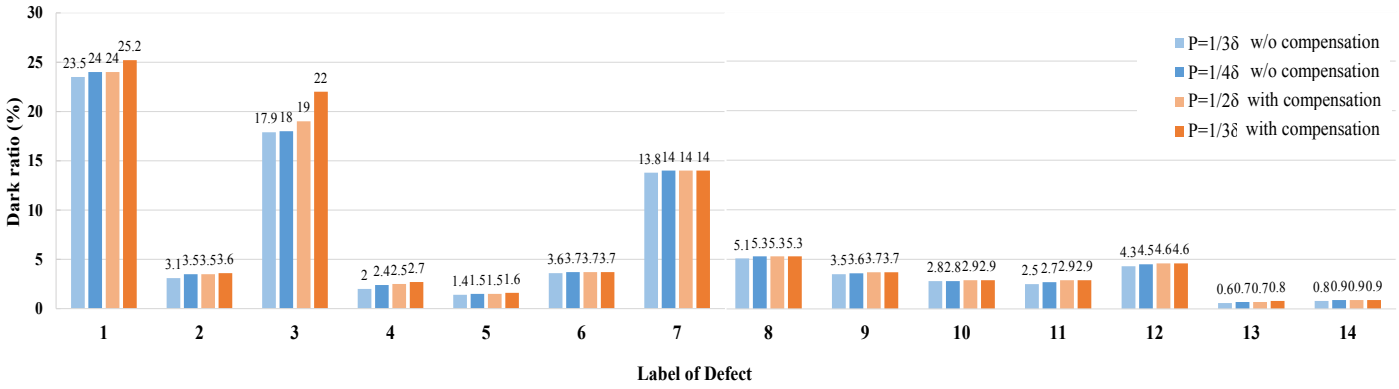

Fig. 8 Comparison of dark ratios of the configurations illustrated in Fig. 7.

***Abstract* — Accurate detection of faults in sensor data is essential for monitoring and controlling industrial processes, environmental conditions, and infrastructure to ensure reliability and enable informed decision-making. Resolving these faults ensures measurement quality and unlocks process optimization opportunities, resulting in improved performance, energy efficiency, and cost savings. We present a transformer-based fault detection model which adopts the anomaly-attention mechanism. Experiments have been performed on the benchmark faults injected Intel temperature sensor datasets using precision, recall, and F1-score metrics. The result outperforms the other classical and complex algorithms, proving our method's effectiveness.**

I. INTRODUCTION

Currently, there is a significant shift happening in the manufacturing industry. Integrating big data and machine learning, especially deep learning, is revolutionizing traditional manufacturing practices, ushering in the era of smart manufacturing known as Industry 4.0 (I4.0). This shift presents new opportunities for manufacturers. Within this context, the Industrial Internet of Things (IIoT) emerges and connects machines through various sensors, RFID tags, software, and electronics, allowing real-time data collection. The proliferation of intelligent sensors and the IoT serves as crucial facilitators for collecting and storing vast amounts of data in industrial settings [1, 2]. Sensor data is often used to detect abnormal conditions or events requiring immediate attention or action. It is crucial for accurately monitoring and controlling industrial processes, environmental conditions, and infrastructure. Detecting faults in sensor data ensures the reliability and quality of the measurements, which is vital for making informed decisions and maintaining process integrity. By identifying and resolving these faults, process optimization opportunities can be realized, leading to improved performance, reduced energy consumption, and cost savings [3, 4].

Sensor data can encompass various types of information, including numerical readings, categorical data, or even event-based data. Time series data refers to data collected and recorded over a sequence of time intervals or timestamps, where the order of the observations is essential. This is commonly seen in sensor data that captures measurements at regular intervals, such as temperature readings, humidity levels, or vibration intensity recorded at specific time points. Many works address the temporal variation of time series data, which is more meaningful and can reveal intrinsic properties of time series, such as continuity, regularity or trends, because one single point in time typically cannot give enough information for analysis [5].

A fault detection framework has been presented in [3] using a Support Vector Machine (SVM), which is optimized with a biologically-inspired technique, Grey Wolf Optimization (GWO). The results suggest that when the failure rate stays at a low level, an accurate diagnosis of sensor fault can be made. Recurrent Neural Network (RNN) is widely considered a powerful tool for analyzing and modeling time series data due to its ability to capture sequential patterns and dependencies. In [3] and [6], Long Short-Term Memory (LSTM), a variant of RNN, is utilized to make an end-to-end prediction fault diagnosis to prognosis. On the other hand, a stacked LSTM has fully exploited the long-term dependencies information and improved the fault diagnosis performance in [7]. Although using LSTM might be sufficient, architectures like Transformers, originally introduced for natural language processing tasks, have also gained attention in the time series domain, especially for tasks involving long sequences or capturing global dependencies. Several research studies [8-10] and practical applications have demonstrated the effectiveness of transformers in time series anomaly detection. Using transformers, one can capture long-range dependencies, exploit global context, and leverage self-attention mechanisms to

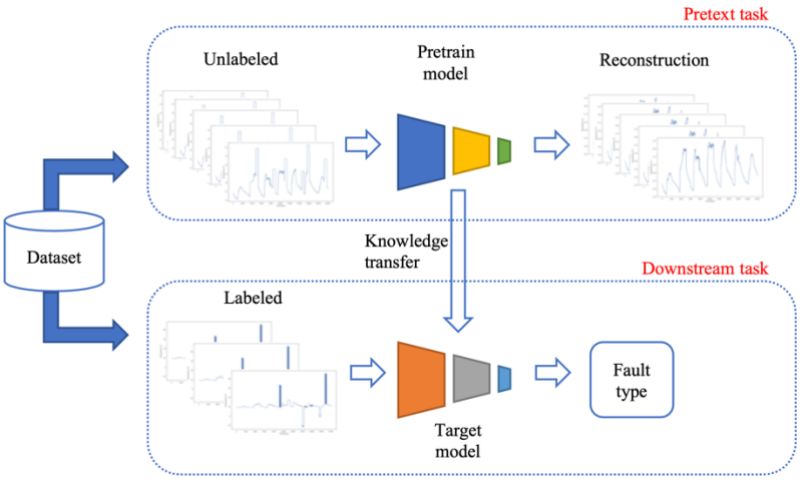

Fig 1. Proposed framework

detects anomalies in complex and high-dimensional time series data.

In order to obtain a progressive detection method to help the model distinguish sensor conditions, we adopt a Transformer-based network architecture from [11]. The literature utilizes the network to solve an unsupervised anomaly detection task. Inspired by a Self-Supervised Learning (SSL) approach, we first train the network model as a denoising network that attempts to remove the faults, which we consider as noise, from the one-dimensional input time series signal and reconstruct the output like the original clean input. In SSL, this first step is known as the pretext task. Next, given less quantity of labeled data, we finetuned the pretrained network model to detect faults based on their class. This step is known as the downstream task or target task in SSL. Furthermore, the experimental results are examined in a comparative manner to confirm the effectiveness of the method presented in this research paper for detecting temperature sensor faults.

II. METHOD

The proposed framework, shown in Fig. 1, is divided into two phases: the pretext task to direct the model toward acquiring intermediary representations of data and the downstream task to transfer the knowledge from the finetuned pretext model. We split our dataset for the pretext task and the downstream task. We use the interpolated time-series signal for each task to help the model observe the learnable pattern. We use the clean signal as the ground truth for the first task and the class label as the ground truth for the latter. Then, we apply the preprocessing techniques outlined in [11], including dividing the dataset into consecutive non-overlapping segments using a sliding window approach. The adopted network architecture introduces association discrepancy and incorporates an Anomaly-Attention mechanism that models the prior-association and series-association to the vanilla Transformer as the core element.

A. Anomaly-Attention Block

Instead of using point-wise representation, the original self-attention mechanism properties, using prior-association, which benefiting the unimodal property of Gaussian kernel, and Series-association, which is used to learn the associations from raw series, are found to be more informative. The adjacent-concentration prior and the learned real associations are also reflected in this approach and their differences are meant to be distinguishable between normal and abnormal cases [11]. Specifically, this association-based criterion attention block has demonstrated the ability to consistently yield smaller values for the normal component, which starkly contrasts the point-contextual and pattern-seasonal scenarios.

B. Focal Loss

Focal Loss [12] was proposed to address the problem of imbalanced data by introducing a new loss control function assigning higher weights to challenged or incorrectly classified cases. To reduce the loss contribution of highly classified examples and focus on more difficult examples is an important idea behind this loss function, shown in Eq. (1)

$$FL(p_t) = -\alpha_t(1-p_t)^{\gamma}\log p_t \qquad (1)$$

where $FL(p_t)$ represents the focal loss for a specific example with predicted probability p_t. α_t is a balancing factor to address class imbalance. It is often defined as the inverse of the class frequency or adjusted based on the dataset characteristics. γ is the focusing parameter that controls the rate of downweighing for well-classified examples and pt represents the predicted probability for the ground truth class. By incorporating Focal Loss into the training process, the model can focus more on the challenging examples, improving its ability to handle class imbalance and boost performance, particularly in scenarios where the number of abnormal examples is significantly lower than the number of normal examples. Since faults in sensor data are expected to happen infrequently, thus, we utilize focal loss for our target model's loss function.

III. Experiment and Analysis

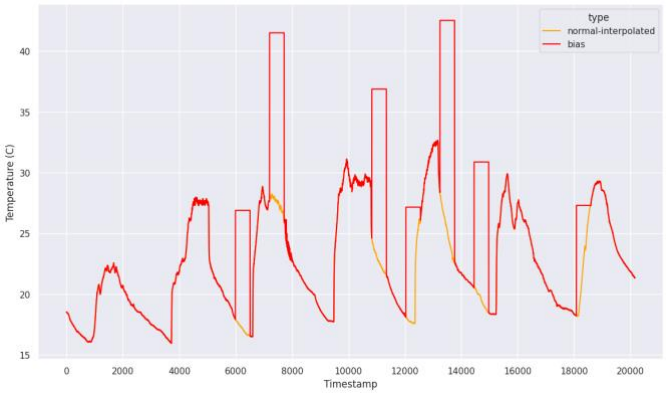
A. Dataset and Evaluation Metrics

Data-driven methods are highly prevalent and successful because they are based on data extracted from historical processes and large quantities of such data generated by modern production. However, for security reasons, this information is generally kept private. Thus, we conduct experiments using the public simulation data published by Intel Labs with injected faults from [13]. The injected fault types include bias, drift, malfunction, random, polynomial drift, and mixed, as shown in Fig. 2, along with the normal and interpolated original data. The original data is obtained from 10 sensors and a total data sample of 3,980,192. This fault detection task is evaluated using precision, recall, and the F1-score.

B. Implementation Details

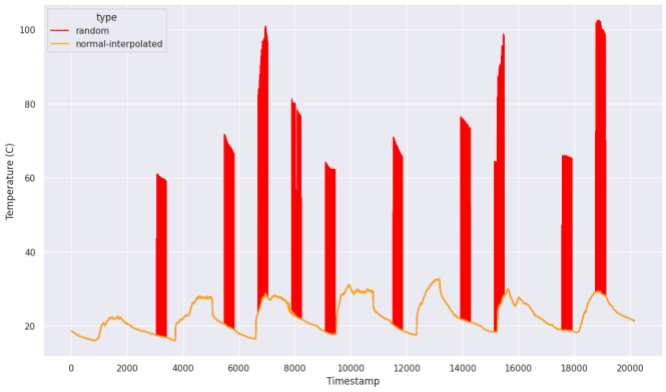
The temperature sensor data obtained are univariate, indicating that each time series example consists of only one channel. Consequently, we convert the time series into a multivariate format with a single channel by employing a straightforward reshaping technique using the Numpy library. The model has 3 layers and is trained for 10 epochs for each phase with batch size 64 and mean squared error (MSE) as the loss function for the pretext task. This approach will enable the data to fit the model with multivariate time series input. The experiments are implemented in PyTorch with a single NVIDIA GeForce GTX 1080Ti 11GB GPU.

C. Performance Comparison



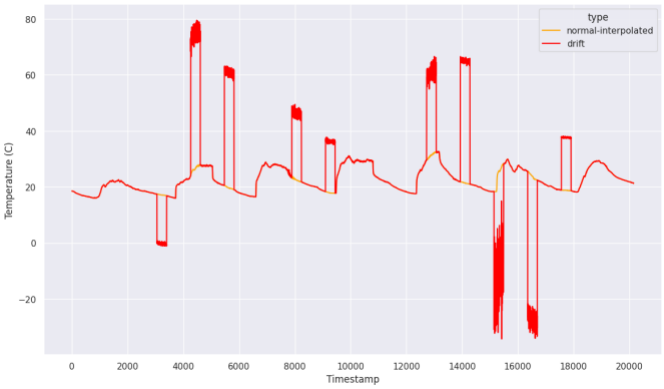
The fault detection task's performance evaluation relies on a critical metric, i.e., the probability of occurrence for the positive class containing faults. We require the commonly used performance metrics for the experiment: precision, recall, and F1-Score. Table I shows the performance comparison of our proposed method with other competing methods. FOCUSeR is based on fog computing that uses online learning and constant updating over time to avoid faults. The second method is a sensor fault diagnosis method based on α Grey Wolf Optimization Support Vector Machine (α-GWO-SVM). We compare our results with the reported results in the literature for the first two comparisons due to the code's unavailability. Lastly, the original Anomaly-Transformer is also tested on the dataset. In this experiment, we use the binary class (normal and fault) of the signal as the ground truth to the original model instead of the multi-class label. It can be seen that our method outperforms other methods on the benchmark dataset. Moreover, compared with the best performance of other methods, our method has a significant improvement on the F1-Score by 1.69% over the best results of other methods, which clearly shows that our method has good performance for the task.

TABLE I. PERFORMANCE COMPARISON OF DIFFERENT METHODS

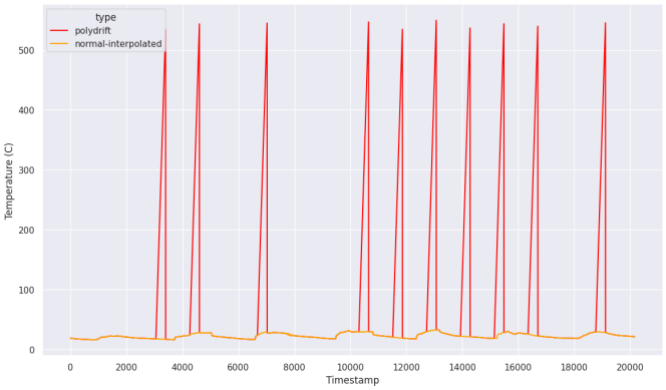


Method	Precision	Recall	F1-Score
FOCUSeR [14]	96.1%	97.7%	96.9%
α-GWO-SVM [3]	97.29%	-	-
Anomaly-Transformer [11]	90.43%	92.18%	91.29%
Ours	98.07%	99.11%	98.59%

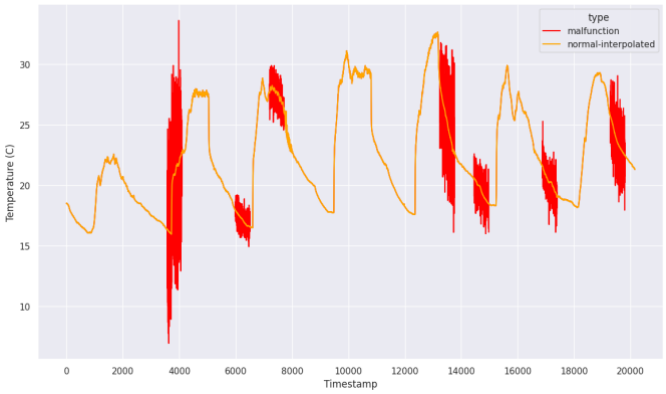
(-), not known, the authors did not evaluate the results of their methods using certain metrics nor make their codes available.



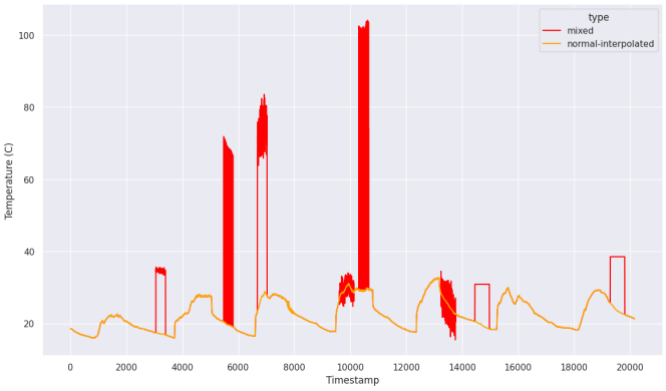
Our proposed method learns the pattern of the signals by reconstructing the clean signal from the fault-injected signal. This imposes the model to identify anomalous patterns that have never appeared in the clean signal. Moreover, the performance of the model indicates that the difference between normal and abnormal time points is effectively intensified by adapting the anomaly-attention block. Thus, our proposed method achieves the state-of-the-art result on an exhaustive set of empirical studies.



(a) Example of bias fault



(b) Example of random fault



(c) Example of drift fault

(d) Example of polynomial drift fault

(e) Example of malfunction fault

(f) Example of mixed fault

Fig. 2 Examples of injected fault

From a statistical standpoint, faults are infrequent occurrences, that happen less often than the normal class. The primary way to describe this behavior is by considering the anticipated occurrence rate of anomalies. Thus, the specific advantage of applying Focal loss for the experiment is observed. Table II demonstrates the effectiveness of using Focal loss as the target model's loss function. Focal loss can differentiate various signal conditions, enabling the model to adapt more effectively. This adaptation facilitates improved fault detection accuracy by enhancing the model's ability to accurately identify faults in diverse scenarios.

TABLE II. PERFORMANCE OF PROPOSED MODEL UNDER DIFFERENT LOSS FUNCTION

Method	Loss Function	F1-Score
Pretrain	MSE	96.58%
Target	MSE	
Pretrain	FL	94.87%
Target	FL	
Pretrain	MSE	98.59%
Target	FL	

IV. CONCLUSIONS

In this research paper, we propose an effective self-supervised approach for detecting multi-fault in temperature sensor data. Firstly, we enhance the discriminative power of the anomaly attention block. Next, we incorporate attribute information of sensor data into the model training through a customized loss, enabling the detector to differentiate better and adapt to diverse sensor conditions, resulting in improved accuracy in detecting faults. Lastly, experimental results validate the effectiveness of our proposed method, and our future work involves developing a more efficient model structure for temperature sensor data multi-fault detection.

***Abstract* — Deep learning (DL) methods are widely employed in the semiconductor manufacturing process to enhance pattern recognition and classification accuracy, specifically for addressing defect patterns. However, the classification performance of the current models is hindered by the imbalanced distribution of defect data within the test dataset. To tackle this issue, this study presents a feature extraction approach utilizing data transformation, and ensemble learning techniques aiming to enhance the model's classification performance. The primary objective of this study is to mitigate selection and imbalance problems in the dataset through random sampling and assigning distinct weights to individual classifiers. The results demonstrate that the proposed method achieves an impressive accuracy rate of 95.09%, thus substantiating its efficacy in improving the robustness of both the classification model and wafer classification.**

I. INTRODUCTION

Semiconductors, also known as integrated circuits (ICs), are essential to the economy and often display the crucial components of electronics. During these few years, the chip requirement of electronic devices become smaller, faster, and cheaper, which increases the degree of complexity [1]. To organize the manufacturing activities, the main production processes in the supply chain are ICs design in upstream, ICs manufacturing in mid-stream, and outsourced assembly and testing (OSAT) in downstream [2]. In wafer processing, wafers are composed of silicon extracted from sand. Then, it becomes the silicon rod called an ingot, which needs to be heated to get high-purity silicon [3]. An ingot gets cut into sliced wafers called a die.

After passing the Chip Probing (CP) test on manufactured wafers, engineers obtain some degree of Wafer Bin Map (WBM) on defective or non-defective chips and Systematic Defect or Random Defect [4]. While analyzing the result of pattern recognition, some particular figures could be the cause of machine abnormality. At the same time, Wafer Bin Map patterns' diversity and complexity are hard to recognize depending on domain knowledge from engineers, which wastes time and lacks systematic approaches. Most semiconductor companies are required to shorten cycle time and maximize the benefits. Therefore, how to use deep learning (DL) and data analysis methods to increase the yield rate, optimize the parameters adjustment, and respond to the defective pattern immediately and accurately is the core problem for the semiconductor industry.

DL is more mathematically complex in algorithms, which can be regarded as a subset of ML based on Artificial Neural Networks (ANNs) [5]. It is one of the approaches to learning good functions and is used in various NNs to solve complex problems. The main point of the DL process is that the feature extractions in the model are all self-learning by computer. The three most used neural networks in DL are Feedforward Neural Networks (FNNs) [6], Convolution Neural Networks (CNNs) [7], and Recurrent Neural Networks (RNNs) [8].

In the semiconductor industry, defects are a critical issue during the manufacturing process. Any defect can significantly impact the quality of the wafer, and it is essential to identify the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

subtle differences among them. Traditional methods often lack random sampling, which fails to ensure equal opportunities for every minority class in imbalanced problems and may lead to biased inferences. To address these challenges, we focus on ensemble learning methods that prevent training on noisy data and reduce model instability. Moreover, we propose a novel approach that combines the soft voting method with assigning different weights to individual classifiers, thereby increasing the likelihood of selecting minority classes to solve the imbalance problem. In this study, we incorporate the best-performing individuals into a weighted soft voting scheme, calculated using an optimization function. The primary objectives of this research are as follows: (1) employing random sampling in classification problems to minimize selection bias and sampling errors, and (2) combining the classification results of individual classifiers with different weights to enhance overall classification performance.

II. Related Work

A. K-nearest neighbors (KNN)

KNN uses the k-nearest neighbors to determine which group the new data point belongs to [9]. The algorithm adopts a majority vote and adds the data point into the specific group by calculating the distance between new data and the adjacent data. The benefits of KNN are its high accuracy and suitability for multiclass classification problems. The limitation of KNN was due to its requirement of huge processing data, which would weaken when met with small datasets.

In [10], a brief review of the KNN method and its modified versions, such as weighted adjusted KNN and SVM-KNN were described, and those variants removed the weakness of KNN. In [11], a new method called MSML-KNN by adding Matching Coordinate Rotation (MCR) and matching scratches based on KNN was proposed. It improved the KNN algorithms and provided valuable information about the scratches for semiconductor manufacturers. The research indicated that some KNN methods needed high computational costs, and noise might cause confusion.

B. Decision Trees Classification (DTs)

DTs classify the data using the greedy rule and generate the prediction result according to different conditional judgments of each layer [12]. The strengths of DTs are their robustness to noise and are good to handle large-scale data. In [13], a new DT-based wafer map failure pattern method with a radon transform feature was proposed, and [14] generated an Alternative Decision Tree (ADTree) classifier combined with cluster recognition. The combination of ADTree and cluster overcame the low signal-to-noise problem. In [15], the comparison between KNN, Naïve Bayes, and DTs classification techniques. The comparative parameter includes speed, accuracy, effectiveness, etc. The result indicated that the DTs have the highest accuracy and less error rate than KNN and Naïve Bayes.

C. Support Vector Machine (SVM)

SVM is used to find a decision boundary to maximize the margins between the two classes, and the support vector classification (SVC) is used for the classification problem [16]. The advantages of SVM are its high dimensionality and its suitability for small samples. In [17], it provided a comprehensive introduction to SVM and has proven that it was one of the best-supervised learning methods in the application. The weakness of SVM was selecting the parameters and the performance in unbalanced data sets. In [18], the SVM with multiple selected features combined with a CNN model gets a better result than only one model, which pointed out CNN model with SVM could yield improved consequences.

III. Proposed Method

A. Feature Extraction Method

Four feature extraction methods used in this research: density-based features, radon-based features, geometry-based features, and convolutional-based models. For example, we have selected labels 36, 255, 11, 151, 94, 39, 24, and 65, corresponding to eight wafer defect pattern types (Center, Donut, Edge-Local, Edge-Ring, Local, Random, Scratch, and Near-full) as shown in Fig. 1.

We evenly divided the wafer map into 20 parts and re-divided 13 regions using a density-based feature extraction technique [19]. It contains the top, right, left, bottom, and the same nine inner regions. Then, calculated the failure density of each region is. The radon-based features are related to the Radon transform, which can compute tomography for the medical field and gain a tomographic image from projections

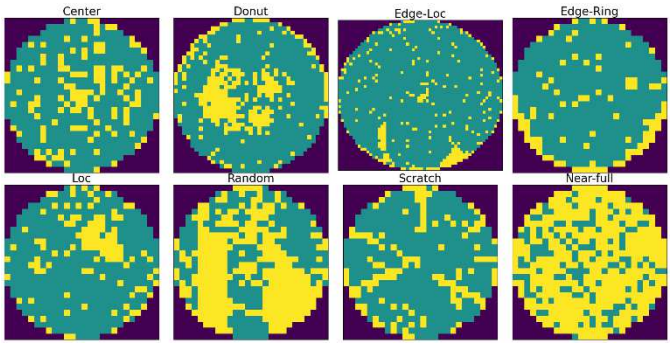

Fig. 1 An Example of Eight Wafer Defect Pattern Types.

[20]. Mathematically defined, the radon transform converts a two-dimensional planar function into a linear function in two-dimensional space. The concept of projection in the Radon transform transfers the 2D grayscale wafer map image at the specified angle by theta, and the Radon transform signal after projection is called a sinogram. Due to the multiple sizes of the wafer, we implement cubic interpolate to calculate the row mean and row standard deviation and each of them extracts 20 dimensions, which means the total is 40 dimensions.

The technique of geometry-based features is to evaluate the geometric characteristics of each wafer map [21]. Based on the salient region and the variety of wafer maps, the geometry-based features used to be obtained by computing local, statistical, and linear characteristics. The scale and rotation of these characteristics are invariant, and the region-labeling algorithm chooses the most salient region, which is the max region area of the wafer defect pattern. The six characteristics of geometry features choose by calculating area, perimeter, length of major axes, length of minor axes, solidity, and eccentricity. Solidity represents a measure of the concentration of an object, and it is the proportion of pixels in the object to its convex hull of defective areas. Eccentricity represents a measure of the elongation or stretching of an object and sets 0 as a round object and positive otherwise.

B. Classification of the Data

Fig. 2 shows the architecture of the proposed model framework. The individual classifier includes ML classifiers: KNN, SVM, CategoricalNB [22], DTs, and Multilayer Perceptron (MLP) in DNN. The ensemble classifier includes soft voting, hard voting, stacking, bagging, and AdaBoost.

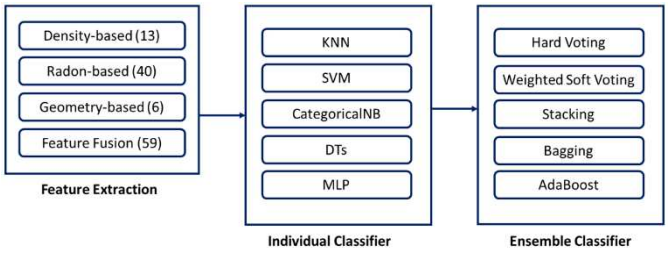

Fig. 2 The architecture of the proposed model framework.

KNN is an algorithm that determines which group the new data belongs to in the classification problem. Three steps of the algorithm process include deciding the value of *k*, finding the distance between each neighbor and itself, and joining the group which has the most neighbor. The algorithm compares the similarity between existing and new labels, then classifies them into the corresponding group. The classification accuracy of the KNN algorithm is high due to its robustness to noisy training data, and huge datasets, and is suitable for the multi-class problem.

MLP uses the concept of perceptron, a learning mechanism that imitates the neural network model in the human cerebral cortex, and the neurons transfer signals by layers. The structure with an input layer, one or multiple layers, and an output layer and uses back-propagation to learn from the previous errors. The hidden layer sizes are defined as the number of hidden neurons in the hidden layer. Less hidden layer sizes lead to underfitting and high bias, and more hidden layer sizes lead to overfitting and high variance. Three steps of the algorithm process, include creating the input layer and the hidden layer, recalculating after passing hidden layers, and creating the output layer.

C. Ensemble Classifiers

Hard voting is to use different models and aggregates the prediction results of these models for the major vote. The method needs to ensure that each model is independent and that the errors are irrelevant to achieve the best performance. Soft voting calculates the average probability of each model and ensures that all classifiers can estimate the probability of the category. Weighted soft voting is an approach to assign different weights on averaging, which depends on the importance of a model to the final prediction. Stacking shorts for stacked generalization, also called meta ensembling. Compared to bagging and boosting, stacking usually combines heterogeneous weak learners, which are different learning algorithms. The stacking method is a layered model integration framework containing a few layers, in which the meta-learner in level 1 learns the output features of the base learner in level 0 and improves the prediction effect. The meta-learner provides an interpretation of the prediction for the base learners. For regression tasks that predict a numeric value using linear regression as the meta-learner. Classification tasks that predict a class label using logistic regression as the meta-learner.

Bagging refers to Bootstrap Aggregating. The method is to use sampling with replacement and build the models for the subsets. Although the bias of each sub-model is low, the individual variance is high and prone to overfit. The bagging approach which is executed in parallel uses Bootstrap to produce training samples and feed them to a weak learner. The final classification result is produced by a majority vote and aggregates the weak learner output that can reduce the variance. Due to the similarity of the subset and using the same model, the based learners are independent and identically distributed. AdaBoost is aimed to strengthen the samples misclassified by the previous basic classifier and trains the next basic classifier

after the weighted sample. A weak classifier will add in each time, and end up with the best pair with a small error rate or the maximum number of sequential iteration. The repeat iterations reduce the bias of the model.

IV. The Experiment Results and Discussion

A. WM-811K Dataset

The public semiconductor dataset, WM-811K (LSWMD) from Kaggle [23], contains huge real-world wafer maps. With 811,457 wafer maps that provide information about the wafer map, die size, lot name, training or testing label, and failure pattern type. The dataset is divided into training and testing sets, and the defect types have been labeled by domain experts [24]. The dataset consists of 172,950 labeled wafers and 638,507 unlabeled wafers. There are only 25,519 wafer maps with failure patterns and 147,431 wafer maps with no failure pattern among the label wafers.

B. Classification with Individual Classifiers

Individual classifiers include KNN, SVC, CategoricalNB, DTs, and MLP. The parameter that chooses to fine-tune is the most influential one in the classifier, and the result will be different depending on the parameter. Feature fusion combined density-based feature, radon-based feature (mean), radon-based feature (std), and geom-based feature. In Table 1, the accuracy of the KNN model is 83%, where the parameter setting is based on the radon-based feature (mean) and the number of neighbors is 6. The accuracy of the SVC model is 82%, where the parameter settings are fusion features and gamma is 0.001. The accuracy of the CategoricalNB model is 62%, where the parameter setting is based on density features. The accuracy of the DTs model is 85%, where the parameter settings are fusion features and the max depth is 14. The accuracy of the MLP model is 86%, where the parameter settings are fusion features and the hidden layer size is 150.

Table 1 The Experiment Results with Individual Classifiers

Model	Feature	parameter	Accuracy	F1-Score
KNN	radon	n=6	0.83	0.82
SVC	fusion	gamma=0.001	0.82	0.80
CategoricalNB	density	default	0.62	0.62
DTs	fusion	max depth=14	0.85	0.85

C. Classification with Emsemble Learning

Ensemble classifiers include hard voting, soft voting, stacking, bagging, and AdaBoost. In Table 2, the accuracy of Hard Voting is 0.50%, where the parameter setting is based on feature fusion and SVC+DT+MLP model. The accuracy of Weighted Soft Voting is 0.95%, where the parameter setting is based on feature fusion and KNN+DT+MLP model. The accuracy of Stacking is 0.67%, where the parameter setting is based on the radon-based feature (mean) and KNN+DT+MLP model. The accuracy of Bagging is 0.83%, where the parameter setting is based on feature fusion and KNN model. The accuracy of AdaBoost is 0.62%, where the parameter setting is based on feature fusion and CategoricalNB model.

Table 2 The Experiment Results with Emsemble Learning

Mothod	Feature	Classifier	Accuracy	F1-Score
Hard Voting	fusion	SVC+DT+MLP	0.50	0.47
Weighted Soft Voting	**fusion**	**KNN+DT+MLP**	**0.95**	**0.95**
Stacking	radon	KNN+DT+MLP	0.67	0.62
Bagging	fusion	KNN	0.83	0.82
AdaBoost	fusion	CategoricalNB	0.62	0.60

V. Conclusions

As the advanced technique of finding the wafer map defect, it is crucial to discover how to use the DL method to improve the accuracy and increase the yield rate. The result may lead to bias due to the unequal selection and imbalance problem. We present the comparison of multiple classification models on wafer defect pattern classification. The research focuses on using voting, bagging, and Adaboost to solve the problem. Among them, the ensemble method using Weighted Soft Voting achieves the best performance, with an accuracy of 95%.

ABSTRACT

By providing enhanced knowledge retrieval capabilities, real-time decision support, and efficient information exchange, question answering (QA) systems play a crucial role in driving productivity, efficiency, and innovation in Industry 4.0. Today's most reliable knowledge-based QA systems require a large knowledge base, which tends to consume more reasoning time. In order to improve the inference speed and response accuracy of the system, this paper adds a Reranker between the Retriever and Reader of the traditional two-stage mechanism. This study uses pretrained Roberta to perform system retrieval and improve data processing and training methods. Experiments on Chinese Wikipedia show that the proposed system significantly reduces the system response time and improves the accuracy and scope of the response.

Index Terms— QA system, Pre-training model, Reranking

1. INTRODUCTION

Question answering (QA) systems fulfill the demands in Industry 4.0 with the following features: (1) Enabling rapid and accurate retrieval of relevant information from vast amounts of structured and unstructured data sources. (2) Providing real-time access to up-to-date information, enabling decision-makers to make timely and data-driven decisions. (3) Enabling effective communication and collaboration by providing a common platform for sharing knowledge, best practices, and troubleshooting information. Thus, QA systems is important to Industry 4.0.

QA system has been one of the most popular fields of natural language processing recently. Although the large-scale pre-training language model brings strong comprehension and answer extraction capabilities to the question answering system, its huge number of parameters result in long inference time. Inspired by RE^{3}QA [1], and IRRR [2], the proposed QA system has three stage architecture: Retriever, Reader, and Reranking. Different from previous works, this paper locates Reranking mechanism between Retriever and Reader. This approach would greatly reduce the number of paragraphs which need to be input into the QA model which greatly improves the response speed. It also reduces the possibility of the QA model being misled due to the large text content searched. Therefore, the proposed system can achieve better performance in experiments.

In addition, in practical applications, the input in various types such as spoken input cannot be included in the training data. It is easy to cause problems in the inference process and training gap. In order to provide model with better performance which can deal with diverse input, this paper introduces WebQA [3] dataset for training. The proposed system also adjusts and combines existing datasets in pre-processing, and adjusts the sample length during training, so as to further improve the adaptability of the system to different types of questions.

The contributions of this paper are as follows: First, the proposed system searches for answers more precisely and makes the answers more accurate. Second, the maximum system response time is significantly reduced, 30% less than the system using only TF-IDF without Reranker mechanism. Third, the proposed system response exact match (EM) score improves by 3~4% compared to traditional methods. Finally, the generalization ability of the model is improved.

2. PROPOSED METHOD

This paper proposes a Chinese question answering system with high accuracy and fast response. The architecture is shown in Fig. 1. The overall architecture can be divided into three parts: Retriever, Reranker and Reader.

2.1. Retriever

The goal of Retriever is to quickly find documents that are highly relevant to the question in a huge document database, so this study uses the TF-IDF algorithm to achieve this goal. Even though the Retriever using the TF-IDF algorithm has some shortcomings, it is still used in the Retriever tasks. The reason is that it is fast and the computational costs is not high after the statistic table of TF-IDF is constructed. The TF-IDF algorithm can easily find the document with the special keywords in the absence of Chinese corpus. To implement TF-IDF, a TF-IDF matrix must be created for all documents in the database, and a TF-IDF vector must be created for questions. This study first segmented all sentences, and then established bigrams that outperformed unary in experiments. Then this study uses MurmurHash3 to map these bigrams to

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

2^{24} hash fields, and finally this study uses TF-IDF for calculation. The reason why hash is used is that it is of great help in accelerating acceleration and saving memory.

2.2. Reader

After dividing the paragraphs, the reader needs to understand each paragraph and find the answer based on the question. This study uses the reading comprehension model of extractive question answering for Reader. The reason is that the document content in the database is reliable, and the model burden is smaller and the speed is fast enough even if it is slower than traditional model such as RNN. Under the same model specification, the answer can be given more quickly than the non-extractive question answering. In view of the powerful capabilities of large-scale pre-training language models, this paper adopts the pretrained Roberta [4] as the main model for Reader and the pre-training parameters is from Cui et al. [5]. The system architecture is shown in Fig. 1. A fully connected layer is added to the output of the encoder, and outputs the probability of the start index and the end index of the answer fragment. Each word in the input sequence will output these two probabilities. This study then uses (1) to multiply the output probability of the starting position and the ending position for all words, and take the index pair corresponding to the maximum value of the product as the start index and the end index.

$$P_{start}(i) * P_{end}(j), \text{ where } 0 \leq i, j \leq W \qquad (1)$$

where i, j are token indexes in the input sequence, $P_{start}(.)$ and $P_{end}(.)$ denote probability of the start position and the end position, respectively, and W is number of words in the input sequence. Since the proposed goal is to establish a Chinese question answering system, English vocabulary and letters or symbols of other languages in the Chinese training corpus are regarded as specific keywords. For such keywords, this study disassembles each non-Chinese word individually into the smallest unit, so as to force the model to understand that this type of text will be considered as keywords. The same way is used for Arabic numerals.

2.3. Reranker

In this paper, Retriever using the TF-IDF algorithm is very fast and has a certain degree of accuracy, but it lacks semantic information and cannot distinguish the meaning of the same word in different sentences. Therefore, we propose to add Reranker for re-scoring mechanism between Retriever and Reader in the system. This study can filter out the paragraphs where the answer is more likely to be located, according to the semantic meaning of the documents output by Retriever. This approach also greatly reduces the problem of slow reading caused by Reader using a large language model as the main body. Reranker in this paper use retrieval model with dual-encoder architecture. Both encoders use the pretrained Roberta model, which saves a lot of training time. Similar to the training methods of DPR and Siamese neural network, the independent encoders is to filter out paragraphs that are high relevant to the question. This approach achieves the transition from document-level filtering to paragraph-level filtering which greatly reduce the time of reading a large number of unrelated documents, and is also reduce the probability of Reader being misled. At the same time, the processing time for each question is controlled within a certain range. Reducing the number of paragraphs solves the problem of long and unfixed reading comprehension time due to large language models.

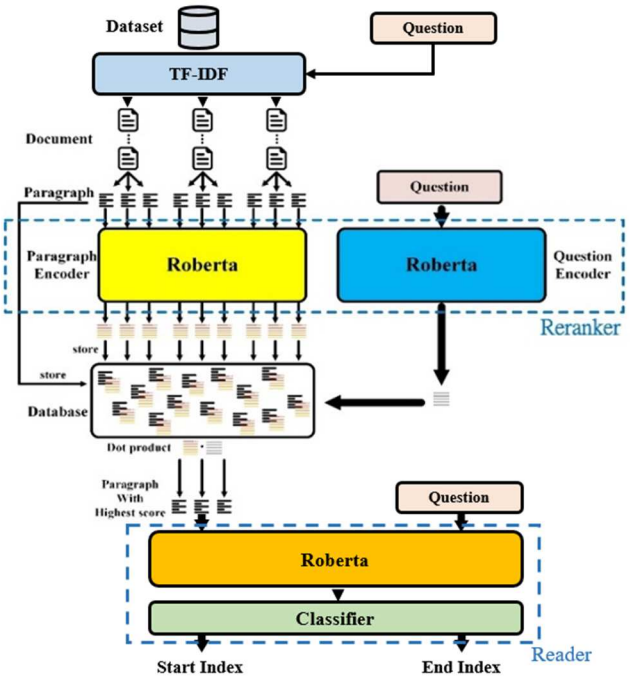

Fig. 1. Architecture of the proposed system.

2.4. Inverse cloze task training

Due to the dataset for training Reranker is the same as the dataset for training Reader, it was found that the data distribution learned by the two models is similar in the experiment. Although the system responds much faster after adding Reranker, the accuracy of answer is not improved. In order to further enhance the system capabilities, we need to expand the data distribution which is used to train Reranker and Reader, so as to help Reader more effectively. Wikipedia is used in the proposed system as an unlabeled document. Before training with the reading comprehension dataset, Reranker is pre-trained on the Inverse Cloze Task [6]. The Inverse Cloze Task is originally used to train Retriever and can increase the model's sensitivity and distinguishing ability on the correlation between sentences and paragraphs.

This study divides each document into paragraphs, and randomly selects sentences with 5 or more words from the paragraphs as the excavated sentence. Then, the excavated sentence and the corresponding excavated paragraph are formed as a pair. The question encoder and paragraph encoder of the dual encoders in Reranker is used to encode the excavated sentence and the excavated paragraph, respectively. During training, an excavated sentence will be trained together with its corresponding excavated paragraph and excavated paragraphs of other sentences. The model is

trained with Cross Entropy as the loss function to select the corresponding excavated paragraphs.

3. EXPERIMENT

This study uses AdamW with 2e-5 learning rate and 1e-4 weight decay. During training, the batch size is 4. This study trains for 500k steps, adopts a linear scheduler as the warm-up scheduler, and sets the number of warm-up steps to 25k.

3.1. Data

The document database used in the experiment is the Chinese Wikipedia database released in 2021. This study uses WikiExtractor [7] and extracts the title and content from it. Since the Chinese Wikipedia database is a mixture of traditional and simplified Chinese, this study uses the Opencc suite [8] to integrate all simplified and traditional Chinese characters, and then converts all punctuation marks to full-type fonts. Finally, we use the sqlite3 suite [9] to create the database and use the jieba suite [10] for tokenization. Regarding to the training dataset, in addition to using the DRCD dataset [11] and the CMRC dataset [12], this study has added WebQA [3] as the extended data. The reason is that all questions in WebQA are from real questions raised by real users. Thus, the questions are more consistent with the actual application situation. The paragraphs of the documents that reply to the question can be regarded as from the knowledge database on the Internet. That is, the answer only appears after the question. This feature is exactly the opposite of the two original datasets. In WebQA dataset, this study removes a small number of fill-in-the-blank questions and the tautology in the question and answer sentence is also removed, such as "question:", "answer:". In order to improve the generalization ability of the model, this study adopts the strategy of preserving punctuation marks and discarding samples without question marks when processing training data. After removing duplicate title paragraphs, the average paragraph length on Chinese Wikipedia is about 95 words. Therefore, the training strategy used in this study is to use question sentences and paragraphs with a total length of less than 256 words for 80% of the training steps. For the remaining 20% of training steps, train with question sentences and paragraphs with a total length of less than 512 words. Such an approach can improve the answering ability for documents of average length and consider the answering ability for long documents.

3.2. System accuracy improvement

This study first evaluated the improvement in system accuracy after adding Reranker. Exact match (EM) score was used as evaluation criteria. The results are shown in Table 1. After adding Reranker, the accuracy of the system increased by 3~4% on average. In addition to the capabilities of Reranker and Reader, the performance of question answering systems is also affected by Retriever tokenization. The score can be improved if the accuracy of the word segmentation and the defined stop words are more refined.

3.3. Effect of ICT training on Reranker

Then, this study validated the effect of the reverse cloze task (ICT) training. After Retriever selects the top five documents, this study uses Reranker for paragraph-level filtering and Top-K as the evaluation criterion. The results are shown in Table 2. This study verified that similarity filtering between question and answer passages is improved by Reranker after expanding learning data distribution for Reranker.

Table 1. EM-score results for Reranker evaluation.

	DRCD	CMRC
Retriever + Reader	33.2	26.7
Retriever + Reranker + Reader	**37.5**	**30.0**

Table 2. Top-K results for ICT training evaluation.

	Top-5	Top-20	Top-100
Reranker	40.6	75.2	86.0
Reranker+ICT	**43.4**	**77.9**	**87.8**

3.4. System response time improvement

In this experiment, this study evaluated the improvement of system response time after adding Reranker. When the system is implemented without Reranker, the paragraphs entering the Reader are all paragraphs in the top five documents found by Retriever. So, the number of paragraphs entering the Reader is uncontrollable. Sometimes there are thousands of paragraphs entering the Reader in the experiments, and the system takes more than 30 seconds to response. The advantage of adding Reranker is that the number of paragraphs received by Reader is controllable. This study seted different restrictions on the number of paragraphs for Reranker, and measure the system response time. The results are shown in Table 3. Note that in Table 3, 512 is the number of paragraphs received by Reader for most systems without Reranker. Subsection 3.3 shows that Reranker can output 87% of the paragraphs containing the correct answer under the conditions of Top-100. If the output of Reranker is limited to 128 paragraphs, we can ensure that the paragraphs received by the Reader have a high probability of containing the correct answer. Besides, this can also save more than 3 times the system response time. The paragraph restriction in Table 3 is the maximum number of paragraphs. If the number of paragraphs for the Reranker is less than the maximum number, the required system response time will be less than the value in Table 3.

Table 3. System response time for Reranker evaluation.

Reranker	**w/o**	**w/**	**w/**	**w/**	**w/**	**w/**
Paragraph restriction	512*	128	64	32	16	8
Response time (seconds)	15.4	4.60	3.02	2.26	2.01	1.83

3.5 Evaluation of dataset transfer performance

In order to test the performance of the system in different datasets and test the adaptability of the training results of the

Table 4. Results of datasets-transfer-analysis.

	DRCD			CMRC			WebQA				
	train	**dev**	**test**	**train**	**dev**	**test**	**train**	**dev A**	**test A**	**dev B**	**test B**
DRCD	97.0	78.6	**76.0**	34.7	54.0	20.4	61.6	69.8	70.0	68.7	70.3
CMRC	35.8	37.6	37.5	80.1	62.3	**51.2**	33.6	32.7	35.4	34.9	34.7
WebQA	37.6	38.1	36.3	15.5	27.8	8.1	96.6	78.2	**79.9**	78.8	**78.6**

system under different datasets, this study trained and tested the proposed system in DRCD, CMRC and WebQA datasets. The experiments used EM score as the evaluation criteria. Table 4 has shown the experimental results. the testing results on CMRC were generally unsatisfactory. We speculated there are mainly two reasons. First, CMRC dataset is originally constructed on simplified Chinese, but the proposed system was based on traditional Chinese, so we need to convert the simplified Chinese to traditional Chinese first, and then transformed into dictionary code, which increase the appearance possibility of the token [UNK]. Therefore, in order to prevent it from having too much influence on the performance, this study removed the paragraphs and questions with more than two [UNK]. The second reason is that the paragraphs of CMRC were usually longer than other datasets, after removing the paragraphs with more than 512 length, the size of the dataset was greatly decreased, which maked the training difficult. The performance on DRCD dataset was normal, but it was worth noting that when using DRCD dataset as the training set, the model performed well in WebQA dataset while it did not perform well in DRCD dataset when WebQA dataset was used as the training set. This study speculated that since the text lengths in WebQA datasets were usually short, it was difficult to learn the features of long text samples.

4. CONCLUSION

Question answering systems play a vital role in Industry 4.0. This study proposes a three-stage Chinese extractive question answering system. Reranking mechanism is added between Retriever and Reader. In addition to providing information judgment at the semantic level, the Reranking mechanism can effectively improve the system speed due to the use of less hardware resources. Besides, the proposed system also controls the processing time of each question to a fixed time. This study attempts to add datasets and process training data to improve the model's ability to generalize to spoken habits. Although its performance has improved in the experiment, there is no significant difference in numerical value. This research will continue with further research on the practical application scenario experience of open-domain question answering systems, including generalization, performance, and anthropomorphic responses.

***Abstract*—Deepfake speech, a misuse of speech technology, is of great concern since it seems natural and is difficult to detect. Although many methods using various speech features have been proposed, deepfake-speech detection accuracy must be improved, especially in real-world scenarios. Therefore, this paper presents a method for detecting deepfake speech on the basis of pathological features used by pathologists for assessing voice quality. The six-pathological features, including jitter, shimmer, harmonics-to-noise ratio, cepstral-harmonics-to-noise ratio, normalized noise energy, and glottal-to-noise excitation ratio, are fed to a multilayer perceptron neural network. We evaluated the proposed method using the Audio Deep Synthesis Detection Challenge dataset. The results indicate that the proposed model can be used for detecting deepfake speech. The proposed method's accuracy, precision, recall, and F1-score were over 98% on the development set, and it outperformed the baseline method on the adaptation set.**

I. Introduction

Deepfake speech is a misuse of speech technologies, such as voice conversion or text-to-speech techniques [1], [2], to synthesize fake speech. Since deepfake speech seems natural and is challenging to detect, it poses a significant threat to economies and societies. For example, criminals used deepfake speech to impersonate a CEO's voice and successfully swindled over USD $243,000$ [3]. Automatic speaker verification to authenticate personal voice is also vulnerable to such attack [4].

Several methods have been proposed to detect deepfake speech [5]–[9]. Many classifiers have been utilized, such as the Gaussian mixture model (GMM), deep neural networks (DNNs) [10], recurrent neural networks (RNNs) [11], convolution neural networks (CNN) [12], and residual neural network (ResNet) [13]. Also, many speech features, including spectrograms, linear-frequency cepstral coefficients (LFCCs) [14], mel-frequency cepstral coefficients [15], constant-Q transform [16], and constant-Q cepstral coefficients [17], have been used. For example, Yi [18] and Wang [19] independently proposed a method based on GMM that takes LFCCs as the input feature [20].

These features are represented in phase, power spectrum, and cepstral coefficients. However, to the best of our knowledge, there is a lack of attention on pathological features in deepfake-speech detection. Since pathological features are widely used to analyze voice disorders, we hypothesize that the voice quality of deepfake speech can be considered as a disordered voice. Hence, pathological features might be clues for deepfake-speech detection.

We, therefore, investigated six pathological features, including jitter, shimmer, harmonics-to-noise ratio (HNR), cepstral-harmonics-to-noise ratio (CHNR), normalized noise energy (NNE), and glottal-to-noise excitation ratio (GNE). These features are fed to a classifier for detecting deepfake speech.

The rest of this paper is organized as follows. Section 2 briefly describes the pathological features mentioned above. Section 3 presents the proposed method. Sections 4 and 5 present the evaluation of the proposed method, results, and discussion. Finally, Section 6 summarizes this work.

II. Pathological Features

Pathological features can be used to distinguish between normal and pathological voices [21] and diagnose diseases such as Parkinson's disease [22] neck and head cancers [23]. This study investigated whether the following pathological features can be used to recognize the deepfake-speech signal.

A. Jitter features

Jitter is the measure of the cycle-to-cycle variations of the fundamental frequency [24], [25]. As the characteristics of jitter can be identified by several methods, this work focuses on four types as follows.

1) Jitter (local): Jitter ($local$) is the average absolute difference between consecutive periods divided by the average period, that is:

$$\text{Jitter } (local) = \frac{\frac{1}{N-1}\sum_{i=1}^{N-1}|T_i - T_{i+1}|}{\frac{1}{N}\sum_{i=1}^{N} T_i} \times 100, \qquad (1)$$

where T_i represents the extracted f_0 period lengths, and N is the number of extracted f_0 periods [25].

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

2) Jitter (rap): Jitter (rap) is the average absolute difference between a period of its average and its two neighbors, divided by the average period. It is defined as:

$$\text{Jitter } (rap) = \frac{\frac{1}{N-1}\sum_{i=1}^{N-1}|T_i - (\frac{1}{3}\sum_{i=i-1}^{i+1} T_i)|}{\frac{1}{N}\sum_{i=1}^{N} T_i} \times 100. \quad (2)$$

3) Jitter ($ppq5$): Jitter ($ppq5$) is the average absolute difference between a period and its average and its five closest neighbors, divided by the average period. It is defined as:

$$\text{Jitter } (ppq5) = \frac{\frac{1}{N-1}\sum_{i=2}^{N-2}|T_i - (\frac{1}{5}\sum_{i=i-2}^{i+2} T_i)|}{\frac{1}{N}\sum_{i=1}^{N} T_i} \times 100. \quad (3)$$

4) Jitter ($ppq55$): Jitter ($ppq55$) is the average absolute difference between a period and its average and its 55 closest neighbors, divided by the average period. It is defined as:

$$\text{Jitter } (ppq55) = \frac{\frac{1}{N-1}\sum_{i=27}^{N-27}|T_i - (\frac{1}{55}\sum_{i=i-27}^{i+27} T_i)|}{\frac{1}{N}\sum_{i=1}^{N} T_i} \times 100. \quad (4)$$

B. Shimmer features

Shimmer is a variation of a signal in amplitude that results from irregular vocal fold vibrations. There are various ways to identify shimmer characteristics. We focused on two types of shimmer features.

1) Shim ($local$): Shim ($local$) refers to the average of absolute differences between the source-signal-amplitude-related in each index (A_i) and its next neighbor (A_{i+1}), divided by the average of the signal amplitudes. It is defined as:

$$\text{Shim } (local) = \frac{\frac{1}{N-1}\sum_{i=1}^{N-1}|A_i - A_{i+1}|}{\frac{1}{N}\sum_{i=1}^{N} A_i} \times 100, \quad (5)$$

where N is the number of fundamental frequency periods, and A_i denotes the signal amplitude at index i.

2) Shim (x-point amplitude perturbation quotients): Shim x-point amplitude perturbation quotients (APQx) is also defined similarly as Shim ($local$). However, it considers the absolute difference between the amplitude of each index and its $x-1$ closest neighbors. It is defined as:

$$\text{Shim } (\text{APQ}x) = \frac{\frac{1}{N-1}\sum_{i=1}^{N-1}|A_i - (\frac{1}{x}\sum_{n=i-m}^{i+m} A_n)|}{\frac{1}{N}\sum_{i=1}^{N} A_i} \times 100, \quad (6)$$

where $m = \frac{x-1}{2}$.

C. Harmonics-to-noise ratio (HNR)

The HNR is a measure of the proportion of the harmonic and noise components of speech. The noise (ι_{En}) is computed as the energy of the residual produced after subtracting the average waveform from each individual cycle. The harmonic energy (γ_{En}) is determined as the energy of an average waveform of a frame pitch built synchronously around ten consecutive glottal cycles. Hence, this feature requires an earlier f_0 estimation [26]. The HNR is defined as:

$$\text{HNR} = 20\log\frac{\gamma_{En}}{\iota_{En}}. \quad (7)$$

The HNR is calculated for each frame of analysis. The output HNR is the average of each frame.

D. Cepstral-harmonics-to-noise ratio (CHNR)

The CHNR is used to calculate HNR as the level difference between the total energy of the spectrum and noise energy, with the noise component being considered as the energy that cannot be related to the spectrum of the original signal [26]. The CHNR-calculation process is illustrated in Fig. 1.

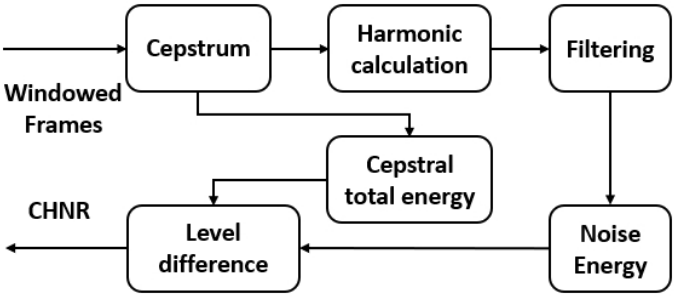

Fig. 1. CHNR calculation process [26].

E. Normalized noise energy (NNE)

NNE is another feature used to quantify the amount of additive noise, and it is defined as the ratio of the energy of the noise to the total energy of the signal for each frame of analysis [26]. The NNE-calculation process is illustrated in Fig. 2.

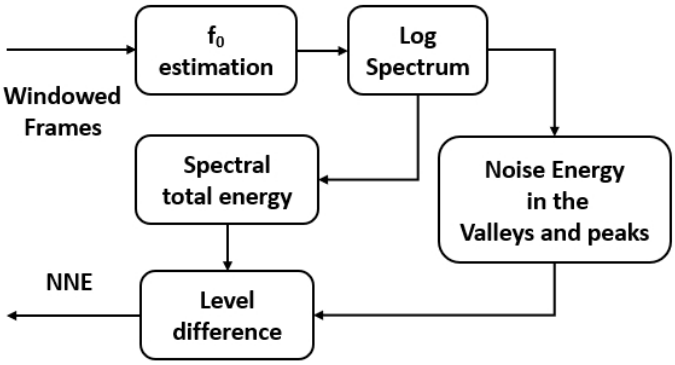

Fig. 2. NNE calculation process [26].

F. Glottal-to-noise excitation ratio (GNE)

The GNE is used to describe turbulent noise while disregarding modulation effects [27]. It is assumed that glottal pulses produce a simultaneous and synchronous excitation of multiple frequency channels, which is indicated by the correlation between Hilbert envelopes of multiple frequency bands [26]. The GNE-calculation process is illustrated in Fig. 3.

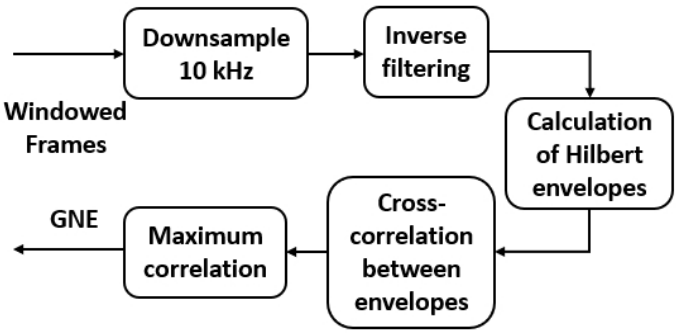

Fig. 3. GNE calculation process [26].

III. Proposed Method

The proposed method detects deepfake speech using a multilayer perceptron (MLP) neural network that takes a combination of the above pathological features as its input, as shown in Fig. 5.

A. Feature analyses

We first investigated those features that can be used to distinguish between genuine and fake speech signals. We conducted an experiment by using the dataset from the Audio Deep Synthesis Detection (ADD) 2022 Challenge [18].

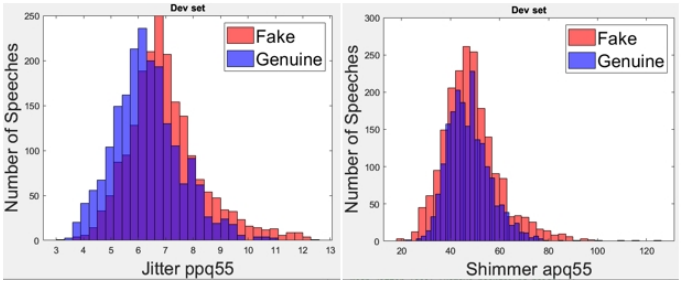

Fig. 4. Histograms of Jitter ($apq55$) and Shim (apq55) in the development set.

Figure 4 shows the histograms of the difference between genuine and fake speech signals for each pathological feature that is not useful in detecting fake speech signals. We randomly selected $2,000$ samples of both genuine and fake speech signals.

Figure 6 shows histograms of the difference between genuine and fake speech signals. for each pathological feature used for detecting fake speech in this paper.

For distinguishing genuine and fake speech, we found that Jitter ($local$), Jitter (rap), Jitter ($ppq5$), CHNR, NNE, and GNE help discriminate between genuine and fake speech signals.

Shim ($local$), Shim (APQ3), Shim (APQ5), Shim (APQ11), and HNR are less effective in discriminating between genuine and fake speech signals, as shown in Fig. 6.

On the other hand, it was found that Jitter ($ppq55$) and Shim (APQ55) are unsuitable for the discrimination because their genuine and fake speech histograms overlap, as shown in Fig. 4.

TABLE I
Number of utterances in ADD 2022 dataset [18]

Dataset	Number of utterances		
	Fake	Genuine	Total
training set	24,072	3,012	27,084
dev. set	26,017	2,307	28,324
adp. set	700	300	1,000

Therefore, we used Jitter ($local$), Jitter (rap), Jitter ($ppq5$), Shim ($local$), Shim (APQ3), Shim (APQ5), Shim (APQ11), HNR, CHNE, GNE, and NNE with an MLP neural network for detecting deepfake speech.

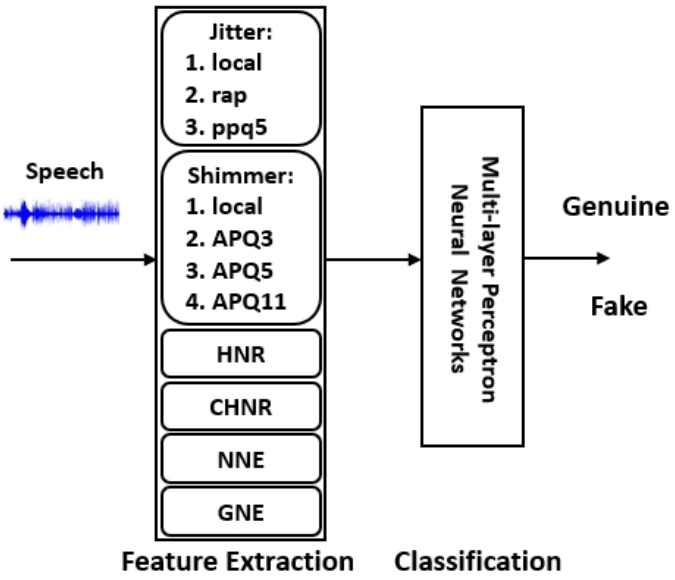

Fig. 5. Proposed method.

B. Experimental setup

The ADD 2022 dataset was used to evaluate the performance of the proposed method. The dataset is divided into three sets: training, development, and adaptation, as shown in Table I. From our observation, both training and development sets have a high signal-to-noise ratio (SNR), whereas the adaptation set has a low SNR with real-world background noise, such as background music and people chatting. In this research, our method was trained from the training set. We then evaluated the proposed method from the development and adaptation sets. For jitter and shimmer extraction, we used the perturbation analysis code implemented in MATLAB [28]. For HNR, CHNR, NNE, and GNE extraction, we used the AVCA-ByO MATLAB toolbox [26].

For classification, we applied the MLP neural network, 3 layers, 11 input features, 11 hidden-layer nodes, and one output layer. The number of training epochs was set to $1,000$. The model used an Adam optimizer, and a learning rate was set to 0.0001. The total number of parameters of our model were only 288.

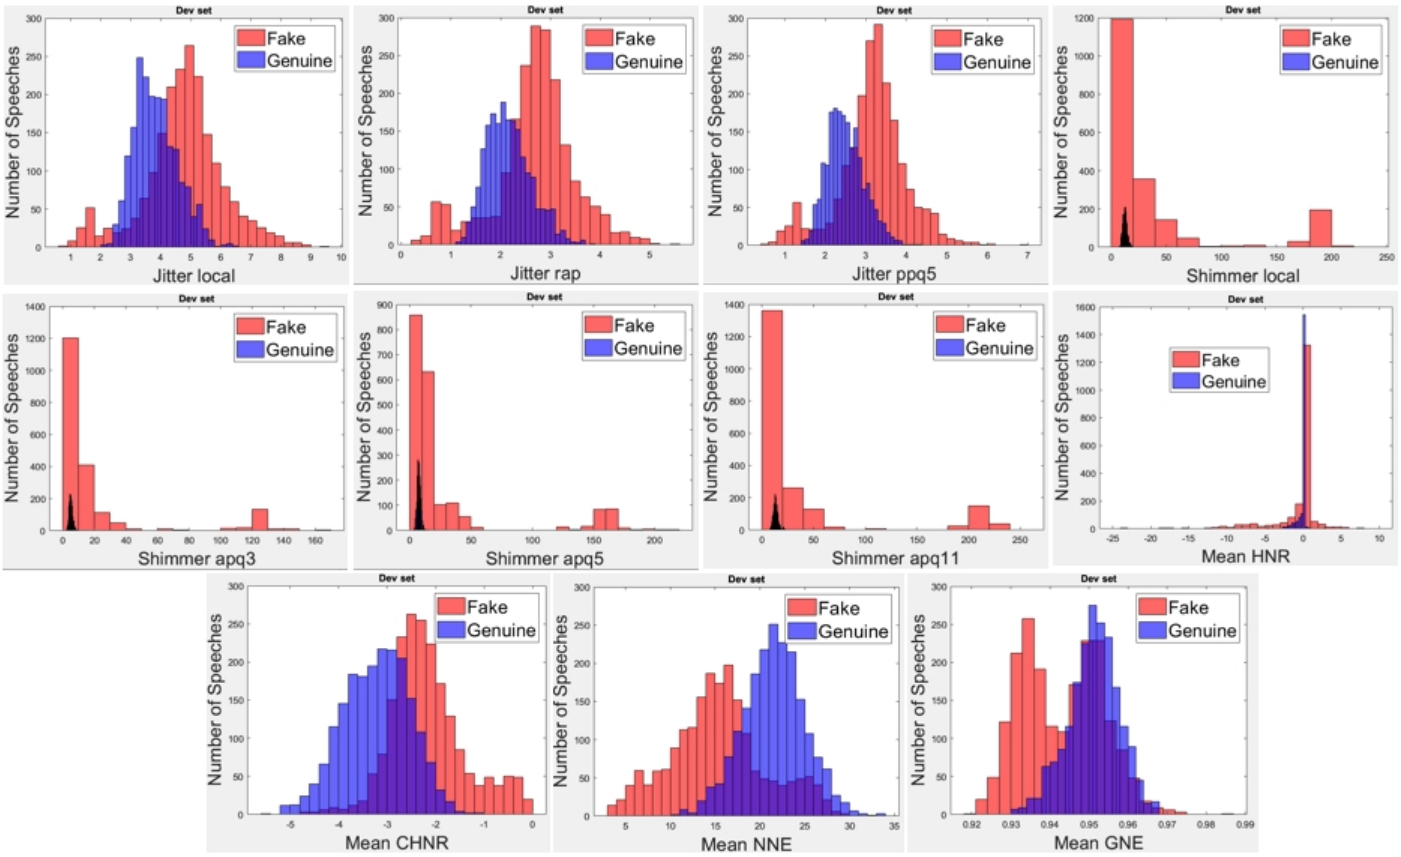

Fig. 6. Histograms of pathological features used in the development set.

IV. Results

We compared our method with two methods using the LFCC feature with two classifiers: GMM and CNN. The method using gammatone cepstral coefficients (GTCCs) with Resnet34 was also compared [29]. The results are shown in Table II. They indicate that even though the accuracy, precision, recall, and F1-score of the proposed method were slightly lower than those of LFCC with GMM, LFCC with CNN, and GTCC with ResNet34 in the development set, the accuracy, recall, and F1-score of our method were better than those of the three other methods in the adaptation sets. It means that the proposed method may be robust against speech signals with background noise, even though the proposed method has never been trained with speech signals with background noise before. The reason for this might be that the proposed method incorporates features such as GNE, HNR, and CHNR, which are related to the ratio between speech and noise, resulting in a particularly high recall rate of 97.14% and an F1-score of 85.16%

It can be seen from the table that using the pathological features alone is not good in terms of balanced accuracy. However, the proposed method can be improved further by incorporating these pathological features with others, e.g., features obtained from a CNN that takes LFCCs as its input, as shown in Fig. 7. The 11 pathological features and the flattened feature obtained from the CNN are combined and fed to an MLP neural network. The results indicate that the efficiency improved in both the development set and adaptation set, as shown by the fifth method of Table II. It can be concluded that the flattened feature from the CNN with LFCCs may marginally enhance the performance of the proposed method for the clean speech signal but considerably improve the balanced accuracy and precision for the noisy signal. However, such improvement costs a poorer recall.

V. Discussion

Although our method could successfully detect deepfake speech in the development set, the following problems and limitations should be discussed. First, the experimental results indicate that the proposed method could equally efficiently detect deepfake speech in the development set without background noise compared to the other methods regarding the accuracy, precision, recall, and F1 score. However, its balanced accuracy is poorer to some extent. The reason might be that the unbalanced dataset was used to train the proposed model. The investigation of the proposed method to be trained with a balanced dataset will be explored further. Second, the feature size of our proposed method is relatively small in comparison with the other methods. For example, for the same utterance, the size of the pathological features was only 11, whereas these

TABLE II
RESULTS OF PROPOSED METHODS COMPARED WITH EXISTING METHODS

Method	Dev. set evaluation (%)					Adp. set evaluation(%)				
	Accuracy	Precision	Recall	F1-score	Balanced accuracy	Accuracy	Precision	Recall	F1-score	Balanced accuracy
1. LFCC with GMM[18]	**99.99**	**99.99**	**100**	**99.99**	**99.97**	68.80	57.73	96.63	72.04	76.38
2. LFCC with CNN	99.92	99.98	99.94	99.96	99.84	73.00	95.74	64.29	78.81	78.81
3. GTCC with ResNet34	99.96	99.98	99.98	99.98	99.86	65.10	59.71	86.19	70.55	68.69
4. Pathological features with MLP (Proposed method)	98.09	98.47	99.47	98.97	91.02	76.30	75.81	**97.14**	**85.16**	62.40
5. Pathological features, LFCC and CNN features with MLP (Proposed method)	99.76	99.92	99.82	99.87	99.45	**79.90**	**96.46**	74.00	83.75	**83.83**

sizes for GTCC with ResNet34, LFCC with CNN, and LFCC with GMM were larger, which are 60×128, 60×128, and 57×100, respectively. Thus, the pathological features have discrimination potential for recognizing the deepfake speech. Suppose they are used well and smartly with other conventional features. In that case, they might reduce misclassification in decision-making in some cases with higher uncertainty. Third, the performances of our proposed method, LFCC with GMM, and GTCC with ResNet34, gradually degraded in noisy environments because all methods, trained from only the training set, were fragile under noisy conditions in the adaptation set. One possible way that we can try to solve this problem is to apply augmentation techniques so that the model can be trained with a noisy version of clean speech. Finally, in this study, we experimentally explore the usefulness of the pathological features by combining them with some conventional features, as shown in the fifth row of Table II. The overall performance is remarkably improved, especially in the balanced accuracy and precision. However, there is a trade-off between those improved aspects and recall. The reason for the recall decrease will be studied further. Also, the features used to combine with the pathological features in this study were chosen to prove the concept. They are not crafted in such a way that they go hand in hand with the pathological features. Thus, feature selection is left from this study and will be done in the future.

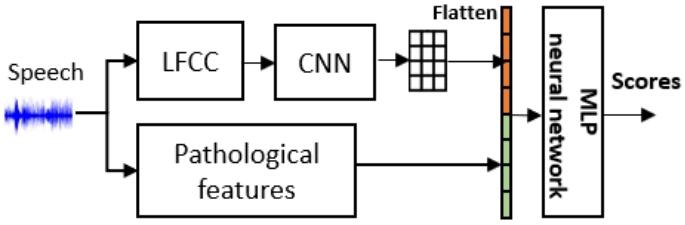

Fig. 7. Structure of proposed method using pathological features with LFCC and CNN feature, and MLP neural networks.

VI. CONCLUSION

This paper highlighted the study of pathological features to detect deepfake speech. We conducted experiments to investigate pathological features of genuine and fake speech. We then proposed a method that uses three jitter features, four shimmer features, HNR, CHNR, NNE, and GNE, for deepfake-speech detection. These pathological features, consisting of only 11 numbers, were classified using an MLP neural network to determine whether the speech was genuine or fake. The proposed method was evaluated on the basis of the ADD 2022 Challenge. The results indicate that the proposed method could effectively detect deepfake speech. Although the efficiency of the proposed method was still lower than the baseline in the development set, it was better than the baseline in the adaptation set. Thus, these pathological features can consistently account for synthetic voices and be used for deepfake-speech detection. In addition, we can improve the performance of the proposed method by combining these pathological features with some conventional ones (e.g., flattened features obtained from a CNN that takes LFCCs as its input) and then classifying the integrated features with an MLP neural network or other classifiers.

***Abstract* — Bipolar disorder is a prevalent mental illness characterized by a high relapse rate. In this study, we propose an early warning system that utilizes digital phenotyping to collect various data points from bipolar patients, including location information, self-assessment scales, daily mood reports, sleep patterns, and multimedia records, through a mobile application. These collected data are utilized to develop a predictive model for assessing the risk state of bipolar disorder. Compared to traditional recurrence prediction methods, this study incorporates medical records, medication data, and emergency records, as suggested by medical professionals, to define the five states of bipolar disorder, leading to enhanced accuracy. To account for data type correlation and temporal correlation, we employ a multitask self-supervised learning mechanism. The proposed method is trained on a Gated recurrent unit and demonstrates an improved prediction accuracy of 88.2% on the collected test data, as compared to the baseline accuracy of 85.1%. These findings highlight the significant importance of considering data type and temporal correlations in digital phenotyping for predicting the state of bipolar disorder.**

I. INTRODUCTION

Bipolar disorder (BD) is a chronic psychiatric condition characterized by episodes of depression, mania, or mixed states. It is estimated that BD affects approximately 435-544 million individuals worldwide, with a prevalence rate of 0.7% (0.6%-0.8%) [1]. Alarmingly, 25% - 50% of BD patients have attempted suicide, leading to significant social and economic consequences [2]. The World Health Organization recommends a psychiatrist-patient ratio of 1 doctor per 10,000 patients [3]. However, many regions struggle to meet this staffing requirement. While long-term monitoring can aid in managing BD [4], it also consumes substantial medical resources and personnel. Therefore, the objective of this study is to develop an early warning system to assist healthcare professionals in predicting the state of BD.

Numerous studies have explored early warning systems for bipolar disorder, with some focusing on monitoring patients' emotional or activity status [5, 6]. Digital phenotyping, involving the collection and analysis of various patient data, has become a common practice in this field [5, 7, 8]. Rating scales have been widely used for evaluating and diagnosing patients [9, 10]. Moreover, some studies have incorporated multimedia data, such as images and sounds, to detect potential BD symptoms [11, 12]. Building upon these methods, this study utilizes smartphones to collect digital phenotyping data from patients, including sleep patterns, Global Positioning System (GPS) information, emotional states, and weekly self-assessments, aiming for comprehensive monitoring.

However, most existing studies have not adequately assessed the temporal and data type correlations within long-term digital phenotyping data. To address this limitation, this study proposes the incorporation of multitask self-supervised learning [13], which allows the detection model to gain a more comprehensive understanding of the data by considering both temporal and data type correlations. Additionally, while many studies have focused on analyzing BD-related scale scores or determining whether a user has been diagnosed with BD [6, 14], this study takes a step further by observing patients' long-term medication and medical information to predict their future risk state. By integrating this information, the proposed model aims to provide doctors with a more intuitive basis [15].

This study makes two significant contributions. Firstly, it introduces a multitask self-supervised learning approach to enhance the prediction model's ability to capture the correlation between different data types and temporal sequences. The

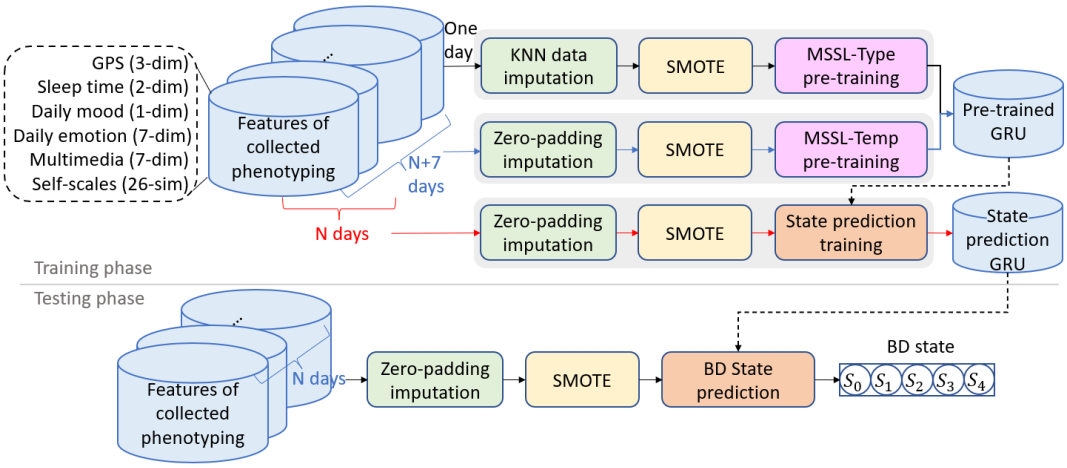

Fig.1 The system architecture proposed in this study.

model is first pre-trained using a pretext task and subsequently fine-tuned for bipolar disorder state prediction through downstream training. This method effectively leverages the benefits of self-supervised learning to improve the model's understanding of complex data patterns. Secondly, this study proposes the inclusion of medication and medical information of BD patients to differentiate their risk states. By considering these additional factors, the predictive model gains valuable insights that can aid in distinguishing different risk levels and informing clinical decisions.

II. Data Collection and Data Features

This study collaborated with the National Cheng Kung University Hospital to collect digital phenotyping data from patients diagnosed with bipolar disorder (BD). The project obtained approval from the Human Research Ethics Review Committee of the hospital (meeting number: A-ER-106-229). To be included in the study, patients had to meet the diagnostic criteria outlined in the DSM-5 Manual of Mental Disorders. The study involved a total of 166 participants, including 75 men and 91 women, with an average age of 34.3 years.

The data collection method employed in this study follows the approach used in a previous study [7][16]. A mobile application was used to gather data directly from the patients. The collected data can be categorized into two types: daily records and weekly records. The daily records encompassed information such as the patient's daily mood, emotions, location (GPS), multimedia records, and sleep duration. The weekly records included the Depression Anxiety Stress Scales (DASS-21) [17] and the Altman Self-Rating Mania Scale (ASRM) [18]. These records provided valuable insights into the patients' mental state and served as crucial data for analysis and prediction in this study.

In this study, 3-dimensional features were extracted from the latitude and longitude of the patients' GPS. The location features are the Local Variance, the Transition Time, and the Total Distance [19]. We calculate the variability of longitude and latitude separately, add them and take the logarithm to get the Local Variance. The Transition Time is the proportion of points with speed in all recorded GPS points in one day. The Total Distance is the sum of the distances between all recorded GPS points in one day. The self-scales are DASS-21 and ASRM. There are 21 questions in DASS-21, and each question is 0-3 points for depression, anxiety, and stress-related questions. The ASRM has 5 questions, and it is a mania scale of 0-4 points per question. By taking out the scores of each question of the two scales, the 26-dimensional self-scale features can be obtained. The 1-dimensional feature of patients' daily mood is the scores of emotional valences (-3 to 3) recorded by patients every day. The 7 daily recorded emotions are anger, boredom, disgust, nervousness, happiness, sadness, and surprise. And the corresponding scores are (0-3) for each emotion, which we use as the 7-dimensional emotional feature. The patient's sleep time is the wake-up and bedtime, and we convert it into numbers in minutes as a 2-dimensional sleep time feature. In the multimedia records, we extract the emotion profile of the utterance as features. Users can choose to record text, speech, or audio-visual records every day. We use emotion recognition models to classify multimedia data into 7 emotion classes, including anger, sadness, neutral, happiness, fear, surprise, and disgust. The feature of the audio-visual data is the averaged emotional profile of the obtained speech emotion and facial expression. The speech emotion recognition

model is wav2vec-2.0, the text emotion recognition model is BERT, and the facial expression recognition model is ResNet18.

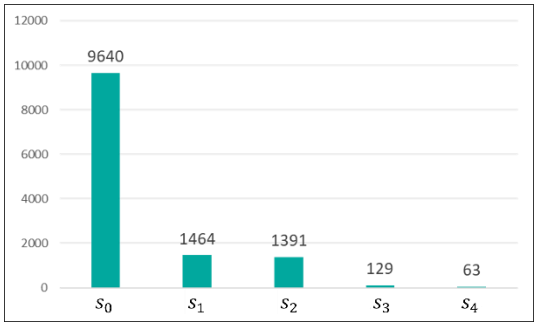

Fig. 2 The amount of data in each state

The goal of this study was to use data from the past N days to predict the BD states of patients in the coming week. The state is defined by extracting the inpatient emergency records and hospitalized records from the medical records. It can be divided into five states. s_0 is in a stable state, in which the patient's consultation interval and medication dose in the next week will be predicted as unchanged. s_1 is a state of relief, which is defined as a predicted increase in the interval between visits in the next week or a decrease in the dosage of medication, indicating that the condition of patients is relieved. s_2 is an aggravated state, and the patient's visit interval for the next week decreases or the dosage of medication increases, indicating that the patient may have a worsening condition. s_3 is in a serious state, and the patient has emergency records in the next week. This state means that the patient needs to be notified to return to the clinic immediately, and there may be a risk of recurrence. s_4 is the most serious state. The patient has a hospitalization record in the next week, and the patient should be returned to the clinic immediately. If multiple states occur at the same time, the data will be marked with the most severe state. The final data distribution is shown in Fig. 2. In the data statistics, as the patients must meet the aforementioned DSM-5 criteria to participate in data collection, and their status is relatively stable, the number of s_4 is relatively low.

III. Proposed Methods

The proposed system is divided into two main phases, as depicted in Fig. 1. The input to the system consists of the extracted data features, as described in Section 2 of the paper.

In the training phase, several steps are performed. Firstly, data imputation and data balancing are conducted for the consecutive data features spanning 1 day, N+7 days, and N days. This is followed by multitask self-supervised learning based on type correlation, multitask self-supervised learning based on temporal correlation, and BD state prediction training, respectively. Here, N represents the value of 21 in this study.

In the testing phase, the data features for the consecutive N days are utilized for state prediction after undergoing data imputation. Given the limited amount of data and the necessity to capture temporal correlation, the Gated recurrent unit (GRU) model [20] is employed as the prediction model. This model is chosen due to its ability to comprehend temporal dependencies effectively. Overall, this system framework combines data imputation, multitask self-supervised learning, and state prediction using a GRU model.

A. Multitask Self-Supervised Learning based on Type Correlation (MSSL-Type)

Missing data issues in the collected dataset are addressed using K-nearest neighbors (KNN) imputation. This method fills in missing values by estimating them based on nearby data points, approximating the true raw features. To handle class imbalance, Synthetic Minority Over-sampling Technique (SMOTE) [21] is employed. SMOTE generates synthetic data points for the minority class, effectively balancing the dataset and preventing overfitting. The multitask self-supervised learning approach (MSSL-Type) enables the model to understand the relationships between different data types. By training the model with this method, it can infer the target data type using information from other types of data. Fig. 3 illustrates how the trained model leverages different data types to improve overall understanding of the dataset.

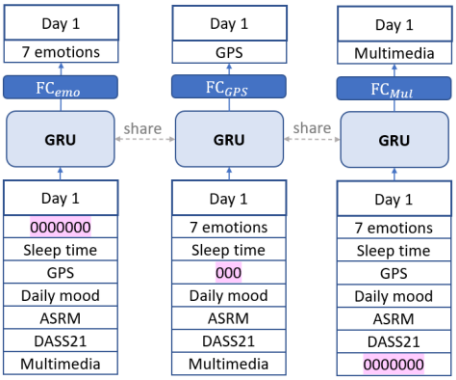

Fig. 3 MSSL-Type training process.

For the training process, the data features of a single day are utilized. Each type of feature is masked (replaced with zero) individually, and the remaining unmasked data is used to predict the masked data. This is done for various tasks, as outlined in Tab. 1. These tasks involve classification, using the cross-entropy loss function, and are trained on GRU and fully connected layers (FC). The tasks include predicting 7 daily

emotions, the midpoint of sleep time, and clustering the 3-dimensional GPS features into K groups (K=3 in this study). The classes for these tasks are defined based on the distribution of data in each class. Since the training data consists of only one-day data, the model is trained for a single time step, and all training shares the same GRU model parameters. In summary, the training process involves masking and predicting various data features for classification tasks, including daily emotions, sleep time midpoint, and GPS clustering, utilizing a single time step with shared GRU model parameters.

Tab. 1: The self-supervised training tasks.

Type	Classification Task
Daily 7 emotions	7 classes (emotions)
Daily mood	7 classes (-3~+3)
Sleep time duration	3 classes (≤ 320mins ≤ 450 mins <)
Sleep time median	3 classes (≤ 2 a.m. ≤ 4 a.m. <)
DASS-21	5 classes (≤ 9 ≤ 13 ≤ 20 ≤ 27 <)
ASRM	2 classes (≤ 5 <)
Multimedia emotion	7 classes (emotions)
GPS	3 classes (K-means clusters)

B. *Multitask Self-Supervised Learning with Temporal Correlation (MSSL-Temp)*

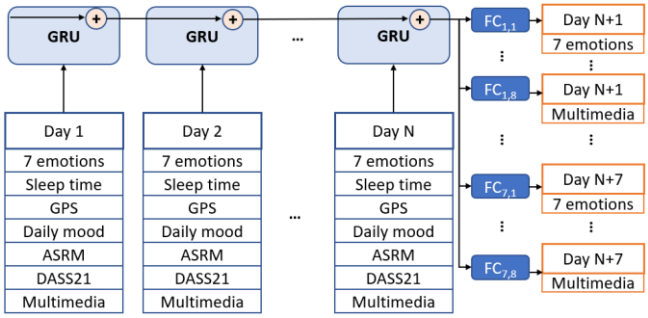

Fig. 4 MSSL-Temp training process.

This study employs multitask self-supervised learning with temporal correlation (MSSL-Temp) to predict future data based on past data, as depicted in Fig. 4. The aim is to predict the types of data for each of the next seven days using data from the previous N days. Zero-padding is utilized as an imputation method to simulate missing data, capturing the influence of missing data as a feature that affects the results. For instance, patients often neglect to record data during unstable periods, indicating potential fluctuations in their BD state. To address class imbalance, SMOTE is employed for data balancing. The training data consists of digital phenotyping data for N days encompassing seven types of features, with the target being the eight classification results mentioned in Tab. 1. The N days of data features are arranged sequentially based on the days and recursively input into the GRU model. The GRU model performs eight classification tasks for each day from the N+1st day to the N+7th day. Each training iteration involves 56 tasks (8 tasks * 7 days) and shares the same model parameters. In summary, the study uses MSSL-Temp to predict future data based on past data, considering missing data through zero-padding. SMOTE is applied for data balancing, and the GRU model performs eight classification tasks for each day from N+1 to N+7, with shared model parameters across the tasks.

C. *Bipolar state prediction training*

In this supervised training, digital phenotyping from the past N days is used to predict the next weekly BD state. This training uses zero-padding as the data imputation method to simulate the real situation. The SMOTE method is used to balance the data. The GRU pre-trained by MSSL-Type and MSSL-Temp is used as the initial model, and it is trained by the state prediction task together with a fully connected layer. This training is the final downstream task, and we feed the data recursively into the GRU model.

IV. Experimental Results

A. *Emotion Recognition of Multimedia Records*

The multimedia emotion recognition models are the emotion recognition models of text, speech, and image, respectively. The recognition results of each modality are shown in Tab. 2. We used the pre-trained Chinese BERT-base model as the text emotion recognition model. The Ren-CECps corpus [22] was used for fine-tuning, and the accuracy on the Ren-CECps testing set was 59.2%. We fine-tuned the pre-trained wav2vec-2.0 using the RAVDESS corpus [23]. After fine-tuning, the model had a recognition accuracy of 93.8% on the RAVDESS testing set. Resnet18 was used as the facial expression recognition model, and we used the RAF-DB database [24] for training. The recognition accuracy of the model on the RAF-DB testing set achieved 89.0%. It can be seen that these models have acceptable emotion recognition ability.

Tab. 2 Performance of emotion recognition models.

Modalities	Models	Datasets	Accuracy
Text	BERT	Ren-CECps	59.2%
Speech	Wav2vec-2.0	RAVDESS	93.8%
Facial	ResNet18	RAF-DB	89.0%

B. *Performance on the data used for evaluation*

The data collected in this study are long-term data, and the duration in days of the data collection period would affect the model performance. According to the recommendations of the cooperating doctors, the duration of the transition of BD patients in principle is no more than one month, and the short one is one week [25]. The data collected in this study consists of weekly self-scales, so the data unit is weekly data. Different numbers of weeks were used as the input lengths for this experiment, including 7 days, 14 days, 21 days, and 28 days. We trained the data on a GRU, and the 5-fold cross-validation results are shown in Fig. 5. It showed that too short an input length may contain insufficient information, and too long input may contain too much noise. Subsequent experiments will be performed with 21 days as the input length.

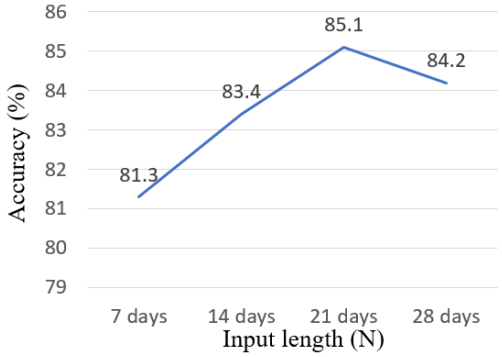

Fig. 5 Performance of different input lengths on GRU.

We also compared the effect of the amount of data balanced by SMOTE on GRU model performance. In Fig. 6, the optimal amount of data is 3500. That is, balancing each state of the training set to 3500 data can get the best performance on the testing set. We used this SMOTE setting for subsequent experiments.

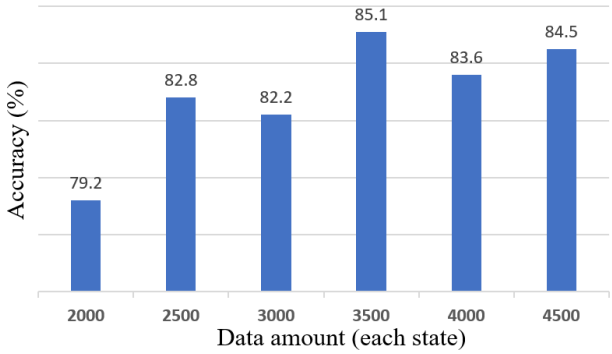

Fig. 6 Performance of different amount of balanced data.

C. *Performance of Different Detection Models*

This experiment compared other commonly used models in the research of BD, including logistic regression, random forest, SVM, and GRU. Tab. 3 shows the 5-fold cross-validation results of each method in the five BD state prediction tasks. Evaluation metrics included unweighted accuracy, macro-precision, macro-recall, and macro-F1 score. GRU had the best performance among various evaluation metrics, with an accuracy of 85.1%. GRU can better predict the long-term tracking of BD data by considering the time series relationship. Subsequent experiments would be based on GRU.

Tab. 3 Performance of different detection models.

	Recall	**Precision**	**F1**	**Accuracy**
Logistic	27.3	22.6	21.0	39.9%
Random Forest	52.3	50.5	50.8	77.9%
SVM	35.7	34.4	34.6	66.6%
GRU	**86.8**	**65.5**	**73.5**	**85.1%**

Tab. 4 Ablation studies.

	Recall					**Precision**					**F1 score**					**Acc.**
State / **Methods**	s_0	s_1	s_2	s_3	s_4	s_0	s_1	s_2	s_3	s_4	s_0	s_1	s_2	s_3	s_4	
GRU	85.0	86.4	84.0	86.8	92.0	96.7	65.5	60.1	48.9	56.3	90.5	74.5	70.0	62.5	69.8	85.1

GRU with both MSSL	**88.4**	86.4	**87.8**	88.3	**96.8**	**97.0**	**69.1**	**67.5**	67.4	**67.7**	**92.5**	**76.8**	**76.3**	76.5	**79.7**	**88.2**

D. Ablation studies

This study compares the effect of adding different self-supervised learning methods on the model effect, including the original GRU, autoregressive self-supervised learning, our proposed MSSL-Type, and MSSL-Temp. Among them, the training objective of autoregressive self-supervised learning is to restore data values and train the model with MSE loss. This study is a prediction task, so the autoregressive objective is set to predict the data value of the next 7 days. The 5-fold cross-validation results are shown in Tab. 4. The methods proposed in this study all outperformed the traditional autoregressive self-supervised learning methods. MSSL-Temp may be more similar to downstream tasks, and the prediction task is also more detailed, which can bring the most improvement. Finally, the two self-supervised learning methods proposed in this study achieved the best accuracy.

V. Conclusions

his study makes two main contributions: predicting the BD risk state and considering the impact of correlations between temporal and data type in digital phenotyping. By using self-supervised learning for pre-training, the model's understanding of the data is enhanced. Temporal correlations are also crucial due to the long-term nature of digital phenotyping. The combination of both self-supervised learning methods improves BD state prediction accuracy from 85.1% to 88.2%. Specifically, MSSL-Type improves accuracy by 1.2%, and MSSL-Temp improves accuracy by 2.1%.

The digital phenotyping data used in this study was collected directly by the BD patients themselves, which introduces subjectivity to the information. However, considering that people with BD interact with others in their daily lives, the connections between individuals may also impact their condition. In future research, collecting relatively objective data from the observations and interactions of the patient's family and friends will be explored to enhance the prediction of BD states and improve overall prediction performance.

Abstract— **Electrolarynx (EL) is a communicative aid for the patient after laryngectomy to generate communicable speech. Since EL speech exhibits low speech intelligibility and produces loud noise, understanding the content of the speech remains challenging for listeners, even if the patient is proficient in using the EL device. Accordingly, it is important to develop the tools that offer additional communication methods. Automatic speech recognition (ASR) of EL speech emerges as a method worth considering in this regard. However, the problem of under-resourced data dramatically degrades the recognition performance of EL speech. Data augmentation is one of the viable solutions for addressing the issue of under-resourced speech data. However, even with an increased health training corpus, the improvement in EL speech recognition may not be satisfactory. Because the characteristics of the EL speech still differ significantly from those of health speech. This paper proposes a data selection method using the phoneme affinity matrix to prioritize the selection of health speech that closely resembles EL speech for data augmentation. The affinity between two phonemes is defined as the similarity of the Phone Posteriorgrams(PPGs) of the two phonemes, considering the phoneme models. The experimental results demonstrate that the approach utilizing data selection based on the phoneme affinity matrix yields superior results compared to both the baseline and the method employing random sampling to select the augmented health speech corpus.**

INTRODUCTION

For patients undergoing laryngectomy, some may only be able to produce disordered speech due to surgery or lesions on their vocal organs. This can result in communication barriers between the patient and others [1, 2]. Since laryngectomy involves the removal of the vocal cords, patients typically rely on the use of the Electrolarynx (EL) [3], a communication device that serves as a substitute for the vocal cords. However, the EL speech has low speech intelligibility [4], even the listener is familiar with the EL device. The listener typically struggles to fully comprehend the content of EL speech. There are two primary reasons for the poor quality of EL speech: (1) The EL produces a mechanical tone that sounds unnatural and lacks variation in pitch. (2) The proficiency of the patient in using the EL device. Furthermore, the proper use of the EL device requires full hand control from the patient. Although EL devices with manual tone control [5] have been introduced, they are still challenging to popularize.

In previous research, the majority of speech processing applications related to EL focused on voice conversion (VC). VC aims to transform EL speech into normal speech in order to enhance the communication abilities of patients [6-11]. Although VC has approached maturity in converting normal speech, learning the mapping relationship between EL speech and normal speech remains challenging due to the variability of EL speech. On the other hand, automatic speech recognition (ASR) is a choice worth investigating.

Despite the fact that EL-ASR can produce reasonable transcriptions after post-processing, it still faces the challenge of under-resource. Since collecting the EL speech corpus is more challenging compared to gathering the health speech, addressing the problem of under-resource primarily relies on novel training methods or data augmentation techniques [12-17]. In the case of ASR applied to health speech, novel training methods such as meta-learning [18-21] aim to construct the target ASR task by training on related tasks. For data augmentation, classical methods include perturbation of speed and volume [22] or SpecAugment [23]. To address the EL-ASR challenge, a related method [24] involves prolonging voiceless phonemes that exhibit high discrimination in EL speech.

Even if we augment the amount of EL speech data by incorporating more health speech, the augmented speech corpus remains inadequate for training the EL-ASR model. This is because the characteristics of EL speech differ not only in terms of volume or rhythm, but more importantly, in the acoustic characteristics specific to each patient based on their proficiency in using the EL device. It is crucial to propose a data selection method that can effectively select speech data beneficial for EL-ASR. Additionally, due to the scarcity of previous research on EL, it is challenging to determine the characteristics of EL speech for the purpose of data selection.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Given the limited prior knowledge available, utilizing the existing ASR model for data selection is a viable approach. In this paper, we propose a data selection method that utilizes the phoneme affinity matrix to identify speakers whose speech data closely resemble EL speech. In a similar method based on dysarthria, another speech disorder, researchers have used an ASR model trained on dysarthric speech to select similar speakers based on speech tempo [25] or convert the phoneme distribution into a Gaussian distribution to select similar utterances [26]. Due to the variable severity of dysarthria, the pronunciation of each patient may differ. Therefore, in [26], the entire phoneme distribution was used for data selection. Although EL speech may have lower intelligibility compared to dysarthric speech, the symptoms are roughly similar for each patient (i.e., complete removal of vocal cords). Selecting data based on individual phonemes is a valuable approach. This paper proposes a data selection method that utilizes the phoneme affinity matrix to prioritize the selection of health speech that is similar to EL speech for data augmentation.

PROPOSED METHOD

A. Data description

The EL speech is primarily generated by patients with speech disorders using the EL device, which produces excitation signals to replace the vibrations of the human vocal folds. The spectrograms of the EL speech are shown in Fig. 1. In Fig. 1, there are three speech samples recorded: one from a healthy individual and two from EL patients. From the three spectrograms, it is evident that the components with frequencies above 2500Hz are noise, resulting from the mechanical sound radiation noise produced by the EL device. For the healthy speaker using an EL device, there is a distinct speech pattern present below 2500Hz, since the healthy speaker possesses intact vocal organs and is proficient in operating the EL device. Patient speaker 1, who is acquainted with the EL device, produces a less clear speech pattern compared to the one produced by the healthy speaker. Patient speaker 2, who is unfamiliar with the EL device, produces a more muffled speech pattern with significant noise in the lower frequency. This can be attributed to their lack of familiarity with the EL device and their current condition shortly after surgery.

The EL speech corpus is collected by the Department of Otolaryngology at National Cheng Kung University Hospital. The speakers consist of 6 EL patients and 4 healthy speakers. Each patient has undergone laryngectomy surgery. The language of the transcription of the EL speech corpus is Mandarin. The EL speech corpus consists of 4280 utterances with a total duration of approximately 4 hours. Each utterance in the EL speech corpus consists of 10 Mandarin characters. The details of the EL speech corpus are shown in Table 1.

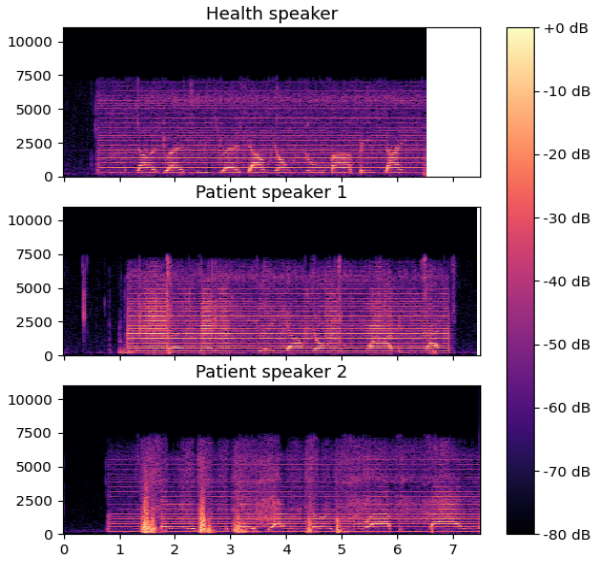

Fig. 1 The spectrograms of the EL speech (For details about the speech samples, please visit https://nd8081026.github.io/).

Table 2 The specification of the EL speech corpus.

	No. of utt.	No. of spk.	Total dur.	Dur. per utt.
Patient	1070	6	2.5 hrs.	2.89 sec.
Healthy	3210	4	1.5 hrs.	7.42 sec.
Total	4280	10	4 hrs.	

B. Data selection based on phoneme affinity matrix

Since the data augmented by a random selection mechanism for training the EL-ASR without knowing the characteristics of the EL cannot achieve the expected performance, a feasible data selection method is expected to assist in selecting useful data through the existing EL-ASR. The proposed method is shown in Fig. 2. The idea is to select speakers with similar articulation by utilizing Phonetic PosteriorGrams (PPGs) derived from a speaker-independent automatic speech recognition system. It is assumed that these PPGs can represent the articulation of speech sounds in a speaker-normalized space and correspond to spoken content independently. Firstly, the trained EL-ASR is applied to generate a phoneme affinity matrix for each EL or healthy speaker. If the phoneme affinity matrix of a specific healthy speaker's speech is similar to that of the EL speaker, the speech data of the healthy speaker is preferentially selected and added to the training corpus. The large health speech corpus is decoded by the trained EL-ASR model to generate the phoneme affinity matrix for each healthy speaker. The entire EL corpus is divided into two parts. The first part is used to train the EL-ASR model depicted in Fig 2. The second part is used for generating the phoneme affinity matrix. However, because the EL corpus is extremely scarce to accurately build a phoneme affinity matrix based on each

speaker, the phoneme affinity matrix of the EL speech is constructed for all EL speakers.

Before obtaining the phoneme affinity matrix, the PPGs and alignment information of the speech need to be obtained. The PPGs are extracted by the acoustic model of the trained EL-ASR. They represent the probability of phoneme frames in the speech. The alignment information is obtained from the Gaussian mixture models-hidden Markov models (GMM-HMM) of the trained EL-ASR model, which establishes the correspondence between the GMM and the frames within each phoneme.

The phoneme affinity matrix represents the reference phoneme as rows and the predicted phoneme as columns. Given a set of N phonemes $\{p_1, p_2, \ldots, p_N\}$, it can construct a similarity graph by computing similarities of each phoneme p_i with respect to all phoneme models, M_j $(1 \leqq j \leqq N)$. Let $M \in R^{N \times N}$ be the affinity matrix of the graph. The affinity of two phonemes p_i and p_j is defined as the PPGs of the phoneme p_i aligned to phoneme models, M_j. The speech of each healthy speaker will be traversed frame by frame to generate the affinity matrix for each speaker. Next, these phoneme affinity matrices need to be averaged by the total frame of each reference phoneme of the alignment information due to the imbalanced phoneme duration of each phoneme.

After averaging all the phoneme affinity matrices, the differences between the phoneme affinity matrix of each healthy speaker and that of all the EL speakers are estimated. The speech of the top-K healthy speakers with the smallest matrix differences is selected as the supplementary data to be added to the training database for data augmentation. The estimation of the difference matrices between each phoneme affinity matrix of the healthy (normal) speakers and global phoneme affinity matrix of the EL speakers is shown in Fig 3.

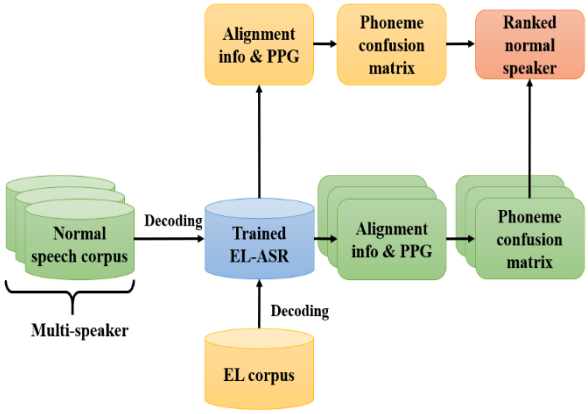

Fig. 2 The data selection mechanism based on phoneme affinity matrix.

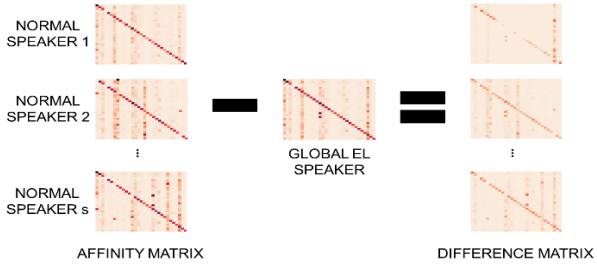

Fig. 3 Estimation of the difference matrices between each phoneme affinity matrices of the normal (healthy) speaker and the global phoneme affinity matrix of the EL speakers.

Experimental Results

A. Experimental Settings

This paper utilized the Kaldi speech recognition toolkit [27] as the foundational framework, which encompasses feature extraction, utterance alignment using the GMM-HMM acoustic model (AM), factorized time delay neural network (TDNN-F) AM [28], and a linguistic decoder. Since the EL speech corpus is very scarce, in order to find the best ASR parameter setting, this paper divided the EL speech corpus into a training set, a validation set and a test set. The validation set and test set each consisted of 100 randomly selected utterances, while the remaining utterances in the EL corpus were used for training. The AM utilized in this study consisted of 8 layers of TDNN-F, and a 5-gram language model [29] trained on a dataset of 1,643,267 utterances. The details of the parameters of the AM of the EL-ASR are listed in Table 2. For the subsequent experiments, to mitigate the issue of speaker dependency, this paper recalibrated the distribution of the EL corpus. For fairness, the leave-one-speaker-out verification method was employed to conduct the subsequent experiments. In each round of experiments, the corpus of one speaker was used as the test set, while the remaining speakers were used as the training set. After traversing all speakers, the final test result can be obtained by averaging all the traversed results.

Table 2 Specification of the AM of the EL-ASR.

Category	Hyperparameters	Values
Feature extraction	Dimension of MFCC	40
	Dimension of i-vector	100
GMM-HMM	Gaussian mixture components	1000
	Number of training iterations	40
TDNN-HMM	Dimension of all hidden layer	512
	Number of layers	8
	Number of epochs	4
	Learning Rate	10^{-3} to 10^{-4}

Table 3 Specification of the augmented speech corpus.

Corpus name	KING-ASR-044
Language	Mandarin
Number of the utterance	1,641,659
Duration (hours)	2,181.70
Number of the speaker	2,352 Male and 2,874 Female
Sampling rate	16000Hz

Next, for data selection, the data pool used for selection is the KING-ASR-044 [30]. The content of the augmented speech corpus is shown in Table 3. Due to the abundant data and speakers in KING-ASR-044, it is expected that our proposed data selection method can be used to select highly similar healthy speakers.

B. Evaluation of the EL-ASR

The first experiment investigated whether the EL-ASR relies on tone for phonemes. Due to the removal of the larynx after laryngectomy surgery, the patients are unable to adjust the pitch themselves, resulting in a very flat quality of the generated speech. There are five tones in Mandarin, and the Mandarin phoneme set comprises a total of 31 phonemes. If a phoneme contains a tone, the tonal phoneme set consists of 155 phonemes. For this issue, this paper applied the parameter settings obtained from Table 2 and conducted evaluations using only the EL speech corpus. The results are shown in Table 4.

Table 4 Comparison of the EL-ASR with/without tone.

Phoneme with/without tone	Test corpus	CER (%)
Phoneme with tone	Healthy	44.35
	Patient	84.28
Phoneme without tone	Healthy	41.88
	Patient	77.56

From the results shown in Table 4, it can be observed that both healthy and patient speakers achieved a lower character error rate (CER) for phonemes without tone. For the healthy speakers, the phonemes without tone yielded a CER improvement of approximately 2.47% compared to the phonemes with tone. For the patient speakers, the phonemes without tone showed an improvement of approximately 6.72% in CER compared to the phonemes with tone. From the analysis of the experimental results, the patients exhibited the most significant improvement in their results. It is speculated that the speech characteristics of the patients exhibit a wide range of diversity. Some patients have low speech intelligibility, some patients struggle to pronounce specific phonemes smoothly, and some patients are not familiar with the use of the EL device. Due to these diverse reasons, the patients have extremely low recognition ability, and incorporating tones into the phoneme set makes it even more challenging for the EL-ASR to generalize the features of each phoneme. The experimental results of healthy speakers using the EL device showed a slight improvement in the recognition ability of the EL-ASR, whether tones were included or not in the phoneme set. Due to the involuntary adjustment of speech tone or the absence of vocal cords, the EL speech, even when imitating the patient's usage, exhibits slight differences. Therefore, subsequent experiments were conducted using phoneme sets without tones.

For the evaluation, considering that the original EL corpus is very limited, if a large number of selected corpus are added, it may offset the recognition objects of the EL-ASR. Accordingly, only a small amount of data from selected speakers were added to the training set. In the experiment, data from the top 50, top 100, top 200, and top 400 healthy speakers were selected and added to the training set. Additionally, to demonstrate the effectiveness of the phoneme affinity matrix in selecting similar speakers, randomly selected samples from the healthy speakers were added to the experiment for comparison. The experimental results are shown in Table 5.

Table 5 The CER (%) of the EL-ASR with data augmentation.

Train corpus	Healthy speaker	Patient speaker
baseline	41.88	77.56
+top 50 speakers	36.72	69.45
+random 50 speakers	37.43	73.35
+top 100 speakers	33.56	65.30
+random 100 speakers	34.89	68.26
+top 200 speakers	**31.49**	**62.93**
+random 200 speakers	32.04	67.36
+top 400 speakers	31.58	63.44
+random 400 speakers	32.08	67.42

The experimental results demonstrated the effectiveness of the data selection method using the phoneme affinity matrix. The recognition results of the data selection method using the phoneme affinity matrix outperformed those of the random selection method.

Regarding the recognition results of the patient speakers, compared with the baseline results, the methods using the data

from the top-50, top-100, top-200, and top-400 speakers showed improvements of 8.11%, 12.26%, 14.63%, and 14.12% respectively. When compared with the previous set, the recognition results increased by 8.11%, 4.15%, 2.37%, and -0.51% respectively. For the recognition results of the healthy speakers, the corresponding improvements compared to the baseline were 5.16%, 8.32%, 10.39% and 10.3%, respectively. Compared to the previous set of quantifications were 5.16%, 3.16%, 2.07% and -0.09%, respectively. The improvement in the experimental results of the patient speakers was significantly greater than that of the healthy speakers. And the largest improvement was achieved when the top-50 speakers were added, as the phoneme characteristics of the top 50 healthy speakers closely resembled those of the EL speakers. When the top-200 speakers were added, both healthy and EL speakers reached their peak CER. However, after adding the top-400 speakers, the CER of both healthy and EL speakers decreased. Therefore, it can be concluded that the phoneme characteristics of speech pronounced by the top-200 speakers were similar to those of the EL speakers.

For the experimental results of healthy speakers, the difference between the results obtained from the two selection mechanisms was not greater than that observed for the EL patients. Because the EL speech of healthy speakers is closer to health speech in terms of speech intelligibility, tonal characteristics, etc., compared to the EL speech of the patients.

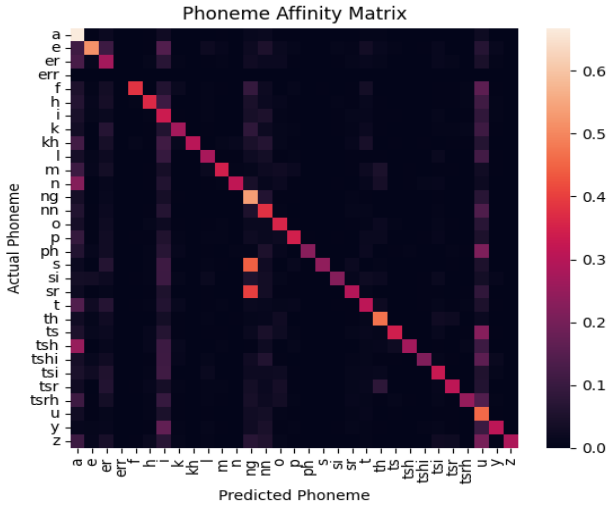

Fig 4. The phoneme affinity matrix of the EL patient.

Fig. 4 shows an example of the patient's phoneme affinity matrix. It can be observed that the diagonal PPGs of the phoneme affinity matrix exhibit high similarity. Apart from that, the PPGs of vowels such as /a/, /i/, and /u/, which are influenced by the vocal cords, are relatively more scattered compared to other phonemes.

Based on previous experiments, it is known that EL speech poses significant challenges in the ASR task. However, our proposed data selection method has shown considerable improvement in EL speech recognition performance. To demonstrate the data selection method proposed in this paper can select similar acoustic characteristics, we further utilize a VC model to transform healthy speech into EL speech. The converted speech is generated using STAR-GAN [31], an unsupervised many-to-many voice conversion model. By reducing the difference between healthy speech and EL speech, the data selection method aims to obtain EL converted speech, thus enhancing the ASR's recognition ability. The corresponding results are presented in Table 6.

Table 6 The CER (%) of the EL-ASR with data selection by the health speech and the converted speech.

Train corpus	Health speaker	Patient speaker
Baseline	41.88	77.56
+top 200 speakers	31.49	62.93
+STAR-GAN (top 200 speakers)	**30.19**	**62.46**

Based on the previous best experimental settings, the top-200 condition is used for data selection. From Table 6, it can be observed that selecting the converted speech yields the best CER for both healthy and patient speakers. And it proves that the data selection method proposed in this paper can indeed select the speech similar to the target speech.

Conclusion

The goal of this paper is to enhance the accuracy and stability of EL-ASR. In this paper, considering that the EL corpus is a low-resourced corpus, the method of data augmentation is used to improve the recognition ability of EL-ASR. Furthermore, due to the scarcity of resources similar to EL speech, randomly selecting data may not contribute to improving the recognition ability of EL-ASR. Therefore, this paper proposed a data selection method based on the phoneme affinity matrix. From a large Mandarin corpus, speakers with a highly similar phoneme recognition distribution to EL speech are added to the EL training set to augment the available data. The experimental results demonstrated that when incorporating the speech of the top-200 most similar healthy speakers, both patients and healthy speakers exhibited a significant improvement in recognition ability compared to the baseline. After, in order to reduce the difference between the characteristic of the health and patient, VC model was applied to generate the converted speech, and selected from the data selection method, more robust recognition ability of the ASR was obtained.

However, the expansion of the corpus through this data selection method will eventually reach its limit. The research on improving EL-ASR encompasses not only data augmentation but also exploring methods to extract speech

features that are beneficial to EL-ASR, which is another direction worthy of investigation.

***Abstract* — Self-supervised learning is increasingly valued in medical imaging, with the hope of solving the problem of scarce high-quality labeled medical image datasets. This study proposes a self-supervised learning training framework for single-view and multi-view images, which combines multi-task and semi-supervised loss applied to medical image classification and detection problems. It can save more than 50% of labeled training data and significantly reduce the demand for medical images and labeled data. Meanwhile, the proposed method achieves high performance in the classifications.**

I. INTRODUCTION

In recent years, the field of artificial intelligence and deep learning has flourished. In addition to natural image processing, the analysis of medical images has also attracted widespread research interest. Based on the significant achievements of deep learning models in many medical imaging tasks, including, X-ray images, computational topology (CT), magnetic resonance imaging (MRI), ultrasound, pathological sections, and various medical data [1], the technology assisted doctors in disease detection and diagnosis [2], and had been gradually deployed in various countries to obtain medical device licenses and commercialization. However, in the development process of artificial intelligence models for medical imaging, it often requires a considerable cost to collect images and annotate lesions or diseases. Unlike general natural images, which can be annotated through relatively simple observation, medical images must be annotated by experienced radiologists or doctors in related fields. What is more difficult is that these professional doctors are already very busy with their tasks in hospitals and clinics. It is not easy to obtain a large amount of medical image annotation data. How to reduce the impact of insufficient medical image annotation data is a very important issue. Self-supervised learning has received considerable attention in academia in recent years. It can be analogous to the effectiveness of training supervised learning with a large number of images, such as the well-known benchmark ImageNet in the field of natural images. The pre-training model obtained by self-supervised learning can be used to improve the effectiveness of supervised learning with relatively few images using transfer learning technology [2][3].

Compared to natural images, there has been relatively less research on the application of self-supervised learning in medical imaging in recent years. However, in order to solve the problem of scarce high-quality labeled medical image datasets, more and more research is using self-supervised learning technology to seek effective solutions [4]. For example, Ghesu et al. proposed using more than 100 million medical images of various modalities [3], including X-ray images, CT, MRI images, and ultrasound images, to train pre-training models using self-supervised learning and further transfer learning to the required application images to improve overall model performance. In [4], Shurrab and Duwairi mentioned that the use of pre-training models trained on natural image ImageNet in many past medical image studies has always been a controversial issue. Therefore, 40 recent research papers on self-supervised learning in the field of medical image analysis are organized to reveal recent innovations in this field and serve as possible reference directions for future research. In many cases, medical images collected usually contain more unlabeled images than labeled images. Therefore, how to use unlabeled data more effectively to improve the training efficiency of labeled images is very important. In [5] and [6], the authors proposed more effective self-supervised learning strategies applied to 2D ultrasound images, CT images, MR images, skin lesion images, and chest X-ray images. In [7], Taleb et al. presented a method specifically for self-supervised learning of 3D medical image processing. Furthermore, Chen et al. used self-supervised learning techniques to deal with the problem of difficulty in obtaining medical image annotation data [8].

In addition to common 2D single images (such as X-rays,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

pathological sections, and ultrasound), 3D images (such as CT, and MRI), multi-view image processing (such as mammography, and multi-view skeletal images) is also a common research topic in medical imaging. How to use deep learning to process multi-view images is based on the concept of taking different perspectives with a camera in natural images to deal with the problems caused by dead angle occlusion in individual perspectives. For example, in [9] and [10], the researchers utilized multi-view convolutional neural network (CNN) architecture to deal with surveillance detection or object recognition problems. More detailed introductions to the principles of related multi-view techniques can be obtained from [11]. In [12], Yan et al. summarized past research on multi-view image processing and summarizes the CNN architecture into two mechanisms: one-view-one-net and multi-view-one-net for analysis. Through these two mechanisms, some research has also been used to process multi-view medical images. In [13] and [14], the authors extracted different perspective cross-sectional images of computer tomography and input them into a CNN model for analysis using the concept of multi-view to perform preliminary screening for COVID-19 pneumonia and identification of benign and malignant lung nodules. Even a single medical image can be pre-processed in multiple ways and analyzed using a multi-view CNN architecture [15]. It can even be combined with a multi-task CNN architecture to process multi-view mammography images and predict radiological evaluations related to cancer [16].

In this study, we propose a method that combines multi-task learning, semi-supervised loss, and self-supervised learning to deal with the problem of difficulty in obtaining medical image annotation data. The main contributions are: (1) analyzing how much self-supervised learning can reduce the amount of medical image annotation data, and (2) evaluating the impact of reducing the insufficient amount of annotation data for single images and multi-view images respectively.

The structure of this paper is as follows: Section II briefly introduces self-supervised learning techniques and the concept of Spatial Transformer Networks used in multi-view image analysis; Section III describes our proposed self-supervised learning methods for single images and multi-view images respectively; Section IV presents the results of reducing the impact of insufficient data using our proposed self-supervised learning methods on single image and multi-view image datasets respectively. Finally, Section V summarizes this study.

II. Related Works

A. *Self-supervised Learning*

Self-supervised learning is a robust training method in the field of deep learning in recent years. It can train models without manual annotation to solve the problem of difficulty in obtaining high-quality labeled medical image datasets. It can usually be classified into three approaches: predictive, generative, and contrastive. The main concept is to first use a large number of unlabeled image datasets to generate pseudo labels for training and produce a pre-training model. Then use a small amount of labeled data that has been obtained to perform transfer learning with this pre-training model and fine-tune the entire CNN model. This allows a small amount of labeled data to achieve robust performance in model training [4] [17], as shown in Fig. 1.

This study mainly adopts the generative approach, such as the Models Genesis method [18]. The main concept is to randomly pre-process the input image through transformations such as non-linear, local-shuffling, out-painting, and in-painting. After feature extraction by the CNN encoder, it is connected to the decoder to generate the final image, so that the generated image is restored to the original image. Therefore, a large number of unlabeled datasets can be used to learn the CNN model and produce a pre-training model. This pre-training model can further provide a small amount of labeled data for transfer learning and fine-tune the final model.

B. *Spatial Transformer Networks*

Spatial Transformer Networks (STN) is a learnable module that can be connected to CNN. It is used to solve the problem that CNN cannot handle spatial invariance, including translation, scale, rotation and more generic warping [19]. This method is mainly divided into two parts: Localisation Network and Sampling grid generator, as shown in Fig. 2. The Localisation Network can generate the angle θ required to estimate the parameters of the transformation $\mathcal{T}_\theta$ from the input feature map, where $\mathcal{T}_\theta$ can be a 2D affine transformation A_θ.

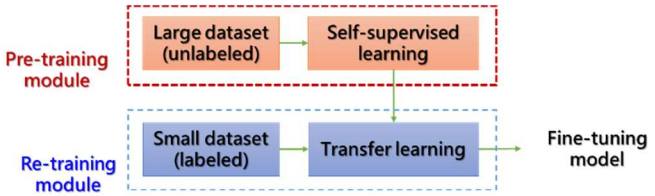

Fig. 1. Self-supervised learning main workflow

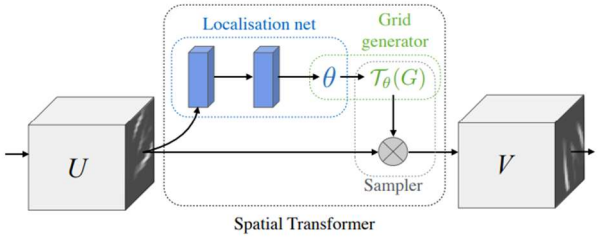

Fig. 2. Architecture of a spatial transformer module [18]

The sampling grid generator uses this estimated 2D affine transformation A_θ to resample the input feature map into the result after affine transformation, allowing the input image to be automatically corrected and making the CNN model recognition more accurate [19].

III. The Proposed Method

This study analyzes self-supervised learning and transfer learning for single images and multi-view images in medical imaging in order to reduce the amount of annotation data required for medical images. The following introduces the self-supervised learning methods for single images and multi-view images respectively.

A. Self-Supervised Learning in Single-view Image

The most commonly taken X-ray and ultrasound images in medical imaging are usually used to check the health of various parts of the body, such as bones, lungs, and abdomen. They are often used as preliminary examination tools and a large part of them are single image shooting and processing. If these single images are used for the purpose of auxiliary screening or diagnosis, and AI model development and training are carried out, in the case of insufficient image or annotation data, we propose a method that combines self-supervised learning and a multi-task architecture that can simultaneously perform image classification and detection.

As shown in Fig. 3, a classifier and a decoder are connected to a backbone architecture at the same time. The classifier performs image classification, while the decoder is connected to the backbone in a U-Net-like architecture and is trained to generate suspicious lesion locations. Since this is an encoder-decoder architecture, the generative approach in Self-Supervised Learning (SSL) can be used at the same time, such as the Models Genesis method proposed in [18], which uses a large number of unlabeled images to train and generate pre-trained models. The input images are subjected to various random preprocessing transformations, and the results generated by the decoder are expected to be restored to the original image.

Artificial labeling usually includes identification labeling of image anomalies, labeling of lesions or organ areas, and not necessarily all kinds of labeling data exist in every case. Therefore, in the design of the loss function, a semi-supervised loss must be used. When each type of labeling data is used as ground truth, individual loss L_i is multiplied by a weight w_i so that when the label exists, w_i is 1, otherwise w_i is 0 when it does not exist. We can use a large number of unlabeled images to train a pre-trained model with SSL, and then use this with artificial labeling data to perform transfer learning and fine-tuning to produce the final model with the goal of improving the overall performance of the model.

B. Self-supervised Learning in Multi-view Images

In addition to taking a single image, many diseases often require examination through images from different perspectives to reduce the problem of missed interpretation due to partial obstruction by body tissues or bones. Multiple perspective images taken include chest X-rays, limb skeletal lesions, mammography, etc. Therefore, if image analysis is performed, the CNN model must be able to input multiple perspective images simultaneously and cannot directly use the architecture shown in Fig. 3 for analysis.

Therefore, we adjusted the CNN architecture for multi-view image analysis, as shown in Fig. 4. The CNN architecture can input multiple view images at the same time. Each image is input into the same backbone structure and then connected to a classifier and a decoder at the same time as Fig. 3. The images from the second view and above are connected to the Spatial Transformer Network (STN) after the decoder and provide more classification information to the classifier.

During SSL training, the approach is similar to that of single-view image, using a generative approach. Images from each perspective undergo various random preprocessing transformations. The results generated by the decoder are expected to be restored to the original image or restored to the first perspective image after STN processing to generate a pre-trained model. Then, transfer learning is performed with manually labeled data, and like single-view image, training is done using a semi-supervised loss. The decoder outputs the lesion area for each perspective separately, allowing the model to simultaneously produce case classification results and suspicious lesion locations.

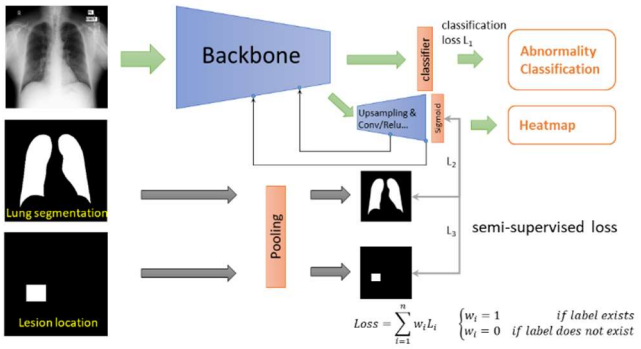

Fig. 3. CNN architecture with self-supervised learning in single-view image

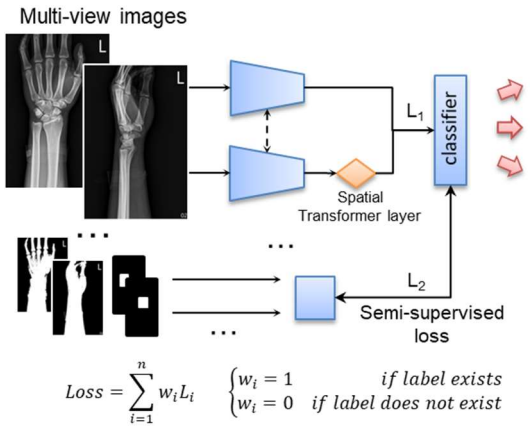

Fig. 4. CNN architecture with self-supervised learning in multi-view images

C. Datasets

In this study, the single-view image experiment mainly performs tuberculosis classification. The datasets used for tuberculosis are taken from Montgomery [21], Shenzhen [21], Kaggle [22], TB Portal [23], TBX11K [24], and TBXpredict [25]. After cleaning, it contains 4,988 tuberculosis positive images and 11,633 tuberculosis negative images (including non-tuberculosis abnormal and normal). This dataset is divided into a test dataset, which includes 530 tuberculosis positive images and 1,152 tuberculosis negative images. The chest X-ray datasets used for self-supervised learning include NIH Chest X-ray [26] with 112,120 images and CheXpert Dataset with 224,316 images [27].

The images used in the multi-view images experiment include 158,626 cases of mammography images and 12,071 cases of two-view wrist fracture datasets obtained through the hospital Institutional Review Board (IRB). In the experiment, the wrist fracture datasets were divided into a test dataset, which includes 347 wrist fracture positive images (radius fracture) and 451 negative images.

IV. The Experiment Results

This experiment analyzes single-view images for tuberculosis classification in chest X-rays. For multi-view images, it uses wrist fracture classification in two-view X-ray images for experimental analysis.

A. Tuberculosis Classification

As listed in Table I, the baseline, named Model A, uses ImageNet as a pre-trained model to train a tuberculosis classification model with the tuberculosis classification dataset we collected and organized. Model B uses two large chest X-ray datasets, NIH Chest X-ray and CheXpert Dataset, with over 330,000 images to train a pre-trained model for single-view images using the SSL method introduced in Section III. Transfer learning is performed with different proportions of training data and compared with the performance of Model A, including evaluating the Area under the Curve of ROC (AUC), sensitivity (SEN), and specificity (SPE) for tuberculosis classification. The suspicious tuberculosis heatmap images are shown in Fig.5. From the experimental results, it can be found that when we use only 50% of the training data for transfer learning on the SSL pre-trained model, its performance is still better than Model A. The training data can be saved by more than 50%, greatly reducing the demand for medical images and annotation data.

B. Wrist Fracture Classification

As listed in Table II, Model A still uses ImageNet as a pre-trained model and trains on a single-view image architecture. The performance evaluation is based on the ensemble results of individual performances from multiple perspectives. Model B uses mammography images and wrist fracture images obtained through the hospital IRB, with two views as one case, to train a pre-trained model for multi-view images using the SSL method introduced in Section III. Transfer learning is performed with different proportions of training data and compared with the performance of Model A. The suspicious wrist fracture heatmap images are shown in Fig.6. From the experimental results, it can be found that when we use only 40-50% of the training data for transfer learning on the SSL pre-trained model, its performance is still better than Model A. Similar to the results of single-view images experiments, the training data can be saved by more than 50%, greatly reducing the demand for medical images and annotation data.

V. Conclusions

In this study, we propose a CNN architecture that combines SSL with semi-supervised loss and multi-task in medical

Table I. Performance comparison of tuberculosis classification data with different proportions

Model	Proportion	Data	AUC	SEN	SPE
Model A (baseline)	100%	13,316	0.945	75.8%	94.7%
Model B (SSL)	100%	13,316	0.968	84.9%	97.3%
	80%	10,825	0.957	83.3%	93.3%
	50%	**6,737**	**0.949**	**80.3%**	**95.5%**
	30%	4,042	0.907	74.2%	91.5%
	20%	2,692	0.803	65.2%	79.3%
	10%	1,344	0.823	69.7%	79.8%

Table II. Performance comparison of wrist fracture classification data with different proportions

Model	Proportion	Data	AUC	SEN	SPE
Model A (baseline)	100%	11,226	0.925	82.1%	92.9%
Model B (SSL)	100%	11,226	0.943	87.6%	92.6%
	80%	8,988	0.940	84.6%	93.1%
	50%	5,619	0.934	82.5%	92.6%
	40%	**4,494**	**0.934**	**82.4%**	**92.7%**
	30%	3,370	0.927	79.0%	92.7%
	20%	2,248	0.922	79.6%	92.6%
	10%	1,124	0.906	69.6%	92.6%

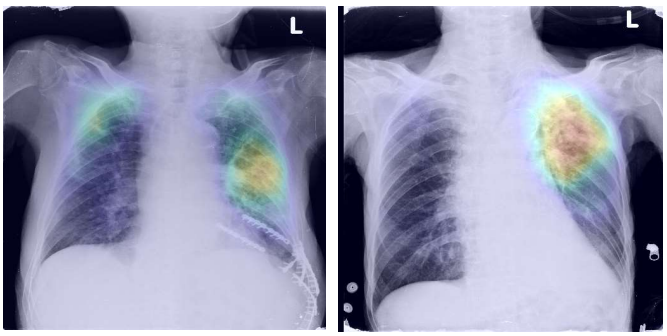

Fig.5. The heatmaps show that some suspected tuberculosis lesions are present on the left lung in both chest X-ray images. The higher the heat in the heatmaps, the higher the level of suspicion.

imaging and is applied to single-view images and multi-view images. A large number of unlabeled medical images are used to train the SSL pre-training model, and the final model is fine-tuned using transfer learning. It is evaluated on single-view images for tuberculosis classification and multi-view images for wrist fracture classification. Both can save more than 50% of labeled training data and can be used to solve the problem of scarce high-quality labeled medical image datasets. Furthermore, the sensitivities were, respectively, 82.4% and 80.3% for wrist fracture classification and tuberculosis classification.

Fig. 6. The heatmap shows wrist fracture X-ray images. The left image shows the radius fracture in a frontal view X-ray image, while the right image shows the radius fracture in a lateral view X-ray image.

***Abstract*—Fingerprints play a vital role in person authentication and verification. To achieve accurate recognition, fingerprint images should contain 25 to 80 minutiae points, which define the unique characteristics of a fingerprint. However, due to various factors such as changes in the environment, the fingerprint structure can become corrupted, resulting in low-quality fingerprints. This corruption leads to a limited number of extractable minutiae points, making it challenging to establish the uniqueness of an individual. In this paper, we propose STUA-Net, a novel approach that incorporates Swin Transformer into the encoding and decoding layers to effectively map corrupted regions. Additionally, we introduce Soft Collective Attention to suppress the activation of relevant features. Our proposed method serves as a foundation for future research to improve recognition accuracy, particularly in scenarios involving low-quality fingerprints. It addresses an important problem in the field and contributes to the advancement of fingerprint recognition technology**

***Index Terms*—Fingerprint Reconstruction, Corrupted Region, Swin Transformer, Soft Collective Attention**

I. Introduction

Automated Fingerprint Identification Systems (AFIS) have been widely used in embedded and mobile applications [1], [2]. Due to changes in both inner and outer environments, the fingerprint structure is often corrupted, resulting in low-quality fingerprints. Wetness, oiliness, and dirtiness affect the internal environment, thereby destroying the fingerprint structure. When a person has oily fingers, the contrast between ridges and valleys diminishes, making the pattern less visible [3], [4]. Consequently, we cannot find enough minutiae points that can be used to uniquely identify the person. The occurrence of corruption in the fingerprint structure is also highly dependent on an individual's occupation. People who are required to frequently disinfect their hands at work, such as doctors, chemical workers, and lab workers, experience corruption and damage to their fingerprints. Therefore, the reconstruction or recovery of low-quality fingerprint images is a significant issue that needs to be addressed before recognition and matching can be performed [5].

Recently, learning-based methods have emerged as an alternative solution and have been successfully deployed in fingerprint reconstruction [6], [7], [8]. Machine and deep learning approaches, such as convolutional networks, generative adversarial networks, and autoencoder networks, have been employed to learn the probability structure of the damaged areas in fingerprints. These approaches can efficiently and automatically estimate numerous parameters and attributes.

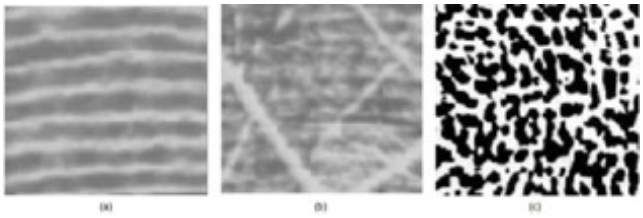

Fig. 1. Fingerprint areas of (a) Well-defined area, (b) Re- coverable corrupted region, and (c) Unrecoverable corrupted region.

Unlike face, iris, and voice data, fingerprint structures are highly detailed and susceptible to damage, requiring high-quality data collection. Consequently, directly applying ordinary deep learning models to reconstruct fingerprints with strict constraints is challenging.

The Transformer architecture, known for its attention mechanism, has gained popularity in language processing. However, adapting the Transformer to vision tasks faces challenges due to the differences between the two domains. These differences include significant variations in the size of visual entities and the higher pixel resolution in images compared to words in text. To address these challenges, the hierarchical Swin (Shifted Window) Transformer has been proposed. This approach limits self-attention computations to non-overlapping local windows while allowing cross-window connections, resulting in improved efficiency [9], [10].

They presented a novel approach based on the Swin Transformer, which showcased superior performance compared to CNN-based methods, leading to state-of-the-art results. Inspired by their work, we integrate the Swin Transformer [9] and Soft Collective Attention within the U-Net [11] Attention framework, called STUA-Net. The contributions of our work can be summarized as follows:

1) Due to the highly detailed and susceptible nature of fingerprint images, integrating the strengths of the Swin Transformer into the Encoding and Decoding layers allows for effective learning of long-range dependencies and contextual information related to rigid fingerprint features.
2) We introduce Soft Collective Attention (SCA) based on soft-attention, which actively suppresses activation at both coarse and fine levels when connecting the encoder and decoder stages.
3) We combine per-pixel loss and perceptual measurement

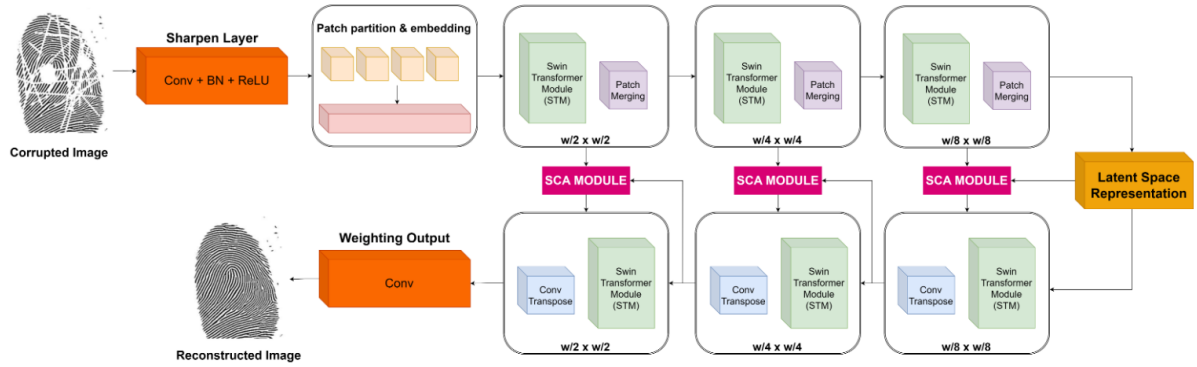

Fig. 2. The network architecture of our proposed method.

as a loss function to select a perceptually correlated metric.

However, our proposed method has limitations for selecting which corrupted image can be reconstructed, as seen in Fig 1.

II. Proposed Method

A. Datasets

Our study was conducted by generating a dataset using the Synthetic Fingerprint Generator (SFinGe) software, followed by preprocessing stages. Subsequently, the training data was prepared for training, validation, and testing purposes. Initially, the training dataset was separated from the testing dataset. Image quality assessment metrics were then calculated, using a split of 90% for training, 10% for validation, and 81 images from the FVC2004 dataset [12] for testing.

Generation of Corrupted Region aims to simulate the noise and corruption that occur in real fingerprints. This is achieved by applying a random configuration that includes line scratches and ellipses. Specifically, for the ellipses representing wrinkly scars, a set of random parameters, denoted as $\{x_0, y_0, E_w, E_l\}$, is generated. Here, (x_0, y_0) represents the center of the ellipse, which can be any point within the fingerprint area, while E_w and E_l correspond to the width and length of the ellipse, respectively. Using these parameters, a closed elliptical mask is created as follows:

$$E(x,y) = \begin{cases} x = x_0 + \frac{E_w}{2}\cos\theta \\ y = y_0 + \frac{E_l}{2}\cos\theta \end{cases} \quad (1)$$

B. Proposed Architecture

Convolutional Autoencoder. Motivated by the architecture employed in previous works [6], [7], [8], we employ a convolutional autoencoder to incorporate a corrupted region. The proposed architecture follows a deep network structure with four routes and includes encoder and decoder stages. The STUA-Net model (see in 2 is composed of three main modules: 1) Sharpen Layer, 2) Swin Transformer Layer, and 3) Soft Collective Attention (SCA). This architecture has been designed to address the challenges of reconstructing corrupted fingerprint images, offering a novel approach for improved performance.

Sharpen Layer. Given the corrupted image $I_c \in \mathbb{R}^{H\times W\times 3}$, where $H \times W$ represents the image resolution, we apply a harmonic extraction [Conv+BN+ReLU] to obtain sharp information. The convolutional filter size is set to $[3\times3]$, which determines the size of the connecting regions. Batch Normalization [13] and ReLU [14] activation are employed to enhance gradient performance and reduce the dependency of gradients on size. The output, denoted as $L_{sharpen} \in \mathbf{R}^{H\times W\times 3}$, is defined as follows:

$$L_{sharpen} = ReLU(BN(Conv(I_c))) \quad (2)$$

Swin Transformer Layer. The typical U-Net system learned spatial information on both the encoder and decoder stages using a convolutional (Conv) layer. In this work, we upgraded each Conv layer with a Swin Transformer Module (STM) [9]. Swin Transformer is constructed by replacing the multi-head self-attention (MSA) module in a Transformer block by a Window-based MSA (W-MSA) and Shifted Window-based MSA (SW-MSA). The consecutive equation 3 and 4 are used for W-MSA and SW-MSA, respectively. The $\hat{z}^l$ and z^l denote the output features of the SW-MSA module and the MLP module in l^th.

$$\hat{z}^l = W - \text{MSA}(\text{LN}(\hat{z}^{l-1})) + z^{l-1} \quad (3)$$

$$z^l = \text{MLP}(\text{LN}(\hat{z}^l)) + \hat{z}^l \quad (4)$$

$$\hat{z}^{l+1} = SW - \text{MSA}(\text{LN}(\hat{z}^{l-1})) + \hat{z}^l \quad (5)$$

$$z^{l+1} = MLP(LN(\hat{z}^l)) + \hat{z}^l + 1 \quad (6)$$

Encoder Stage. The output from the sharpen layer is initially divided into non-overlapping patches of size $W/s\times W/s$, where $s(=2)$ represents the patch size. Each patch is treated as a "token" and passed through a linear embedding layer, projecting it to a dimension of C. These patch tokens are then fed into the four-stage Swin Transformer, which consists of a series of W-MSA and SW-MSA blocks at different levels. As the network's depth increases, the number of tokens decreases to provide a hierarchical representation. Thus, the output resolutions are $W/s\times W/s$, $W/2s\times W/2s$, and $W/4s\times W/4s$.

STUA-Net w SCA	**18.419**	**0.914**	**0.0190**

Decoder Stage. In each stage of the decoder, the input features are upsampled by 2 and then concatenated with the corresponding skip connection feature maps from the encoder in the same stage. The output is fed into Swin Transformer block. We modified the skip connection by adding Soft Collective Attention (SCA). It can build the dense interac- tion between encoder and decoder to achieve decoding performance. The attention will highlight the important feature and ignore the irrelevant feature. After this stage, it will produce the reconstructed image $I_r \in \mathbb{R}$

Soft Collective Attention: In the decoder stage, when performing upsampling, the recreated spatial information may lack precision. To address this issue, we incorporate skip connections that capture spatial context from both the down and up sampling paths. To further enhance this process, we introduce Soft Collective Attention (SCA) to selectively activate relevant regions and reduce the transmission of redundant features. SCA effectively suppresses noise at both coarse and fine levels in the connections between the encoder and decoder stages. SCA takes two input vectors: $x \in \mathbb{R}^C$, which is copied from the down sampling path, and $g \in \mathbb{R}^C$, obtained from the up sampling path, where C represents the dimension of the feature maps.

On both vectors, the Conv + Dropout $[1 \times 1]$ layers, denoted as ${W_T}^x$ and ${W_T}^g$, are utilized to weight the information in their respective feature maps. The feature maps are cross-weighted to produce feature dependencies q', and a Leaky ReLU activation function $(\sigma(x) = \max(0.1x, x))$ is applied to prevent computational growth. Finally, the output is passed through Conv + Dropout $[1 \times 1]$ $({W_n}^T)$ and Sigmoid activation function $(\sigma_2(x) = \frac{1}{1+e^{-x}})$ to obtain the final output, expressed as:

$$q' = \sigma({W_T}^x * g + {W_T}^g * x) \tag{7}$$

$$q = \sigma_2({W_n}^T * q') \tag{8}$$

Loss Function ($\mathcal{L}$). Per-pixel loss functions like MSE and MAE have become a major concern because these functions only analyze loss per pixel [6]. To address this problem, we combine per-pixel loss with Structural Similarity Index Measurement (SSIM). Then, we determine the optimal combination of loss functions for our experiment setting. The equation of the loss function with weight δ is shown as follows:

$$\mathcal{L} = \delta * \mathcal{L}_{SSIM}(\delta) + (1 - \delta) * \mathcal{L}_{MSE}(\delta) \tag{9}$$

III. EXPERIMENTS AND DISCUSSION

A. Ablation Study

We conducted experiments to evaluate the impact of different components in our proposed method. Specifically, we focused on the SCA attention module and different up-sampling techniques to determine the most suitable architecture for our problem. The experimental scenarios are summarized in Table I.In Config-3, we placed emphasis on the skip connection with SCA as the recommended method. The inclusion of SCA resulted in significant improvements, with an increase in PSNR by 18.261, SSIM by 0.936, and a reduction in MSE by 0.0214. The SCA module effectively highlighted relevant features during training, allowing the model to focus more on key regions, leading to improved performance.Furthermore, in Config-4, we updated the up-sampling technique to Conv2DTranspose, which incorporates a kernel for optimizing the up-sampling process during training. This modification yielded the best evaluation metrics among the different configurations, with a PSNR of 18.419, SSIM of 0.941, and MSE of 0.0190.

These findings demonstrate the importance of the SCA attention module and the choice of up-sampling technique in achieving superior performance for our fingerprint reconstruction problem.

B. Comparisons with State-of-the-art

We conducted a comprehensive comparison of our proposed technique with state-of-the-art methods [7], [8]. In order to ensure a fair evaluation, we adopted their published methods and applied them to our specific scenario and dataset. The results of the comparisons are presented in Table II.

Compared to the previous methods, our STUA-Net demonstrates proficiency in understanding long-range relationships and capturing the contextual information of rigid fingerprint features. It effectively addresses the coarse- and fine-level connections between the encoder and decoder stages. The quantitative experimental results clearly indicate the superiority of our STUA-Net, as we achieved a significant improvement

in the overall evaluation metrics compared to the corrupted image. Specifically, we observed a 37.2% increase in PSNR, a 43.2% increase in SSIM, and a 3.7% decrease in MSE.

To further evaluate the subjective impression of our reconstruction, we provide visualizations of each arrangement in Fig. 3. To facilitate a more precise comparison, we magnified the region within the red box in Fig. 4 by a factor of four for better visualization. Additionally, we trimmed the size of the image to reveal the correct pixel values. Our approach effectively reconstructs fingerprint patterns while eliminating irrelevant patterns, resulting in improved image quality.

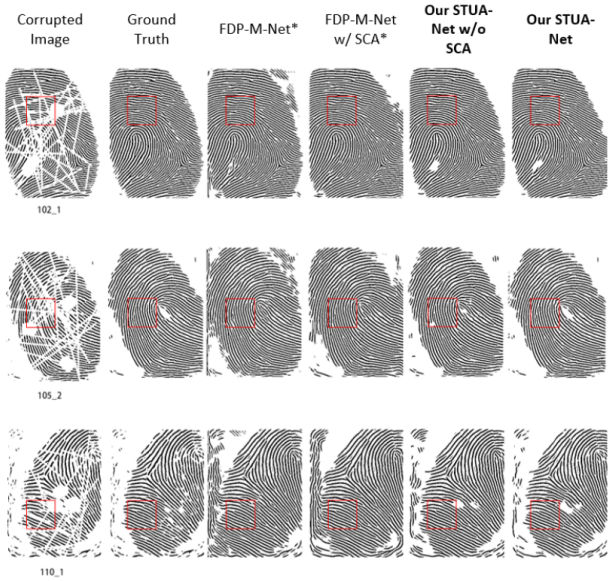

Fig. 3. The reconstruction result of corrupted image..

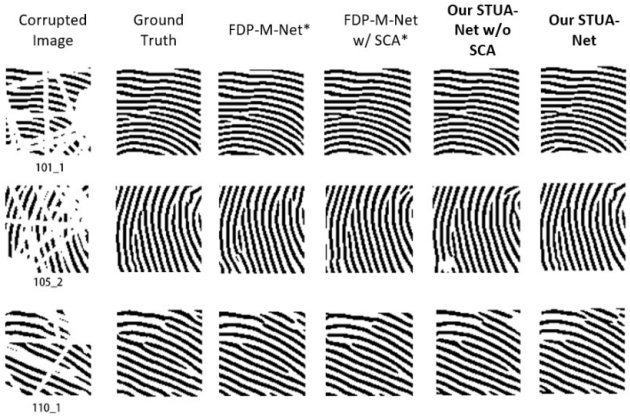

Fig. 4. The reconstruction result of corrupted image at 4 scale.

These comparisons with state-of-the-art methods, along with the subjective visualizations, collectively demonstrate the superiority and effectiveness of our STUA-Net in fingerprint image reconstruction.

IV. Conclusion and Future Work

Fingerprint reconstruction aims to restore the missing regions in fingerprint images. In our approach, we leverage the combination of Swin Transformer and Soft Collective Attention within the U-Net architecture, which we refer to as STUA-Net. Our proposed method yields satisfactory results in both objective and subjective evaluations. The introduced techniques significantly enhance the assessment metrics when comparing the reconstructed images to the corrupted ones.

When it comes to deep learning, depth plays a crucial role. However, deeper networks often come with increased sequential competition and higher latency. To address this issue, we consider the application of a low-cost and efficient fingerprint system. In this regard, A. Goyal et al. [15] proposed the PareNet block as a potential solution. In our future work, we intend to explore and integrate the PareNet block into our fingerprint reconstruction model to further enhance its performance.

Coarse-Age Loss: A New Training Method Using Coarse-Age Labeled Data for Speaker Age Estimation

* NTT Corporation

***Abstract*—We propose *Coarse-age loss* for a new training method that uses coarse-age labeled speech samples for numerical speaker age estimation. The estimation performance of existing approaches can be degraded by a mismatch in the acoustic characteristics between the training and test phases. The age estimation model must be fine-tuned to suit the test condition. It is easier to collect coarse-age labeled samples, such as ten-year step size, than exact-age labeled speech samples due to privacy concerns. However, special care is needed in using coarse-age labeled samples because they cannot be used as is for training numerical age estimation models. A conventional method converts the coarse-age labels into their median value as tentatively-correct labels (e.g., twenties is converted to 24.5 years old). However, errors between the correct and the tentatively-correct labels negatively influence the model training phase. A key idea of our method proposed here is that the coarse-age labels indicate continuous correct- and incorrect-age ranges. Coarse-age loss trains the model so that it does not misestimate the incorrect range by minimizing a sum of posteriors corresponding to the incorrect range without using exact-age labels. In experiments, the proposed method reduces the mean absolute errors by up to 30.1 % and 10.8 % compared to the baseline and the conventional method, respectively. Also, the results indicated that somewhat broad coarse-age labels, such as the ten-year step, are suitable for the proposed method.**

***Index Terms*—Speaker age estimation, coarse-age label, exact-age label, x-vectors**

I. Introduction

The performance of speaker age estimation is increasing by use of deep neural networks (DNNs) [1]–[11], and application is expected in various service fields[12]–[14]. Speake age estimation can be categorized into two types; categorical and numerical estimations. The categorical estimation uses a classifier that estimates some age groups, such as Child, Young, Adult, and Senior [12]. On the other hand, the numerical estimation uses a regressor or classifier that estimates age values. Modern DNN-based speaker age estimation techniques tackled numerical age estimation [1]–[11].

Most DNNs-based models can achieve impressive high performance, however, the performance can seriously degrade due to the differences in acoustic characteristics between training and test phases. For example, some conventional studies reported that the mismatches in speaking styles and noise conditions caused a serious performance degradation [8], [9], [15], [16]. In spite of this matter, most current studies focus on constructing a general age-estimation model using publicity available speech corpora annotated with exact-age labels, such as TIMIT [17], Fisher English [18], NIST Speaker Recognition Evaluation (SRE) 08/10 [19], [20], and AgeVoxCeleb [7], [21]. Therefore, it is essential to fine-tune or adapt the general model to the target domain using the data collected in the target condition for practical usage.

In actual use, there exists a possibility wherein only speech samples labeled with coarse-age categories, such as five-year step [22], ten-year step size [23], [24], or categorical age labels [12], are available for the model training due to privacy concerns. However, we cannot directly utilize these coarse-age labeled samples as training data in a numerical estimation model. Therefore, careful considerations are required if we intend to utilize the coarse-age labeled samples for training the numerical age-estimation model.

A simple solution is to convert the coarse-age labels into tentatively-correct age labels. For example, Kwasny et al. use median values of ten-year step labels as tentatively-correct age labels (e.g., twenties is converted into 24.5 years old) [3], [25] [1]. However, the error between the correct and the tentatively-correct age labels can degrade performance. Another solution is to make the model train the order relation of the coarse-age labels by using the ranking learning method [26]. However, this approach also handles the samples with different exact-age labels as the same age if they have the same coarse-age label. Therefore, a new training method is necessary that can well handle the difference between the tentatively- and correct age label.

We propose a new loss function, *Coarse-age loss*, to train a DNN-based speaker age-estimation model using coarse-age labeled speech samples without setting tentatively exact-age labels. In the model training phase, Coarse-age loss minimizes the sum of posterior probabilities corresponding to the incorrect-age range obtained by coarse-age labels. This method cannot train the model to estimate the exact-age label. However, using the tentatively exact-age label for the model training phase is unnecessary. Therefore, we expect that our proposed loss will reduce the degradation of the estimation

[1] We confirmed with the authors of [3] that they use the median value as the tentatively-correct age even though it is not specified in their papers

performance.

II. Related works

A. Related works about weakly-supervised learning

Our Coarse-age loss is related to a complementary label used in weakly-supervised learning.

In weakly-supervised learning, complementary labels that indicate incorrect classes have been explored [27]–[29]. In typical supervised learning, a DNN classifier is trained to estimate the correct class. Conversely, in weakly-supervised learning with complementary labels, the objective is to train the classifier to avoid misestimating the incorrect classes.

Motivated by this concept of weakly-supervised learning, we propose the Coarse-age loss in our approach. The coarse-age labels serve to indicate the correct-age range as well as the incorrect-age range. Since human age spans a finite range and age values are continuous, the coarse-age labels can effectively represent all the incorrect-age ranges. For instance, a coarse-age label indicating the twenties age range signifies that the correct range is from 20 to 29 years old, while any other age below 19 or above 30 is considered an incorrect range. Thus, the coarse-age label can be viewed as a form of a complementary label.

However, it is important to note that while general classification tasks that use complementary labels often involve discrete relationships among classes, age labels exhibit continuous relationships among themselves. Therefore, we design the Coarse-age loss by specifically considering this characteristic of age labels.

B. Related works about EM-algorithm based method

Kashima et al. proposed an expectation-maximization (EM) algorithm based method using coarsely labeled samples [2] for general regression tasks [30]. In their method, a regressor is optimized so that the predicted output falls within the range of the coarse label based on the EM algorithm. This method is similar to our approach; both their and our approaches aim to have the estimated value/probabilities are fallen within the range of the coase label.

Their experimental results showed the tendency that the estimation performance of their conventional method, which converts the coarse label to the predicted value, and their proposed method were dependent on the datasets. Also, they focused on only adding the coarsely labeled samples to the exact labeled samples.

In this paper, we apply such method to spekaer age estimation for the first time and propose a new loss function for DNN-based models. Alos, we conduct speaker age experiments using both exact- and coarse-age labeled dataset for cross-corpus domain adaptation, in addition to the data addition experiment. Furthermore, we reveal optimal combination of various kinds of ranges of the coarse-age label and our conventional/proposed loss functions.

III. Speaker Age Estimation

A. Model training using exact-age labeled speech samples

We define a DNN-based speaker age estimation model as a classification model that estimates posterior probabilities for each age value of 0 to 100 years old. DNN-based speaker age estimation models can be categorized into two types; regression [1]–[4] and classification [5]–[11] We use the classification approach because classification models tend to yield better estimation performance than regression models [5].

The classification model is formulated as the estimation of the speaker's actual age y_i from input an acoustic feature sequence X_i. It is defined as,

$$\hat{y}_i = \sum_{k=0}^{100} P(k|X_i, \Omega)k, \tag{1}$$

where $\hat{y}_i$ is the estimated speaker age that is computed as the expected value of speaker age using the posterior probabilities [6], [10], [16], [31], [32], $P(k|X_i, \Omega)$ is the posterior probabilities for each age value $k \in [0, 100]$, and Ω is a set of model parameters. The sum of posterior probabilities is normalized to 1.0 using a softmax function. The set of model parameters Ω is optimized by a stochastic gradient descent algorithm. Recently, some works have trained the model considering the label distribution. For example, they define the actual target as the normal distribution $\mathcal{N}(y_i, \sigma^2)$, where σ is the hyper-parameter [6], [10], [16]. In this paper, we use soft-target cross entropy (SCE) loss [6], defined as,

$$\mathcal{L}_{\mathrm{SCE}} = \frac{1}{I}\sum_{i=1}^{I}\left(-\sum_{k=0}^{100}\mathcal{N}(k|y_i, \sigma^2)\log P(k|X_i, \Omega)\right), \tag{2}$$

where I is the number of exact-age labeled samples in a mini-batch.

B. Model training using coarse-age labeled speech samples

We define a new loss function, *Coarse-age loss* $\mathcal{L}_{\mathrm{CAL}}$, that trains the model as preventing estimation for the incorrect-age classes. In the training phase, the posterior probabilities $P(k|X_j^{\mathrm{c}}, \Omega)$ are estimated from the coarse-age labeled training sample X_j^{c}. Since its exact-age label y_j is unknown, the loss function for the exact-age labeled samples, such as the

SCE loss, cannot be used. Our Coarse-age loss minimizes the posterior probabilities corresponding to the incorrect-age range.

Referring to binary cross-entropy loss, Coarse-age loss is defined as,

$$\mathcal{L}_{\mathrm{CAL}} = \frac{1}{J}\sum_{j=1}^{J} -\log\left(\sum_{k=\min(Y_j)}^{\max(Y_j)} P(k|X_j^{\mathrm{c}},\Omega)\right), \quad (3)$$

where J is the number of coarse-age labeled samples in the mini-batch, X_j^{c} is coarse-age labeled acoustic feature sequence, and Y_j is the set of age values corresponding to the correct-age range indicated by the coarse-age label of X_j^{c}. Coarse-age loss maximizes the sum of posterior probabilities corresponding to the correct-age range. It means minimizing the sum of posterior probabilities corresponding to the incorrect-age ranges since the sum of the posteriors of all age values is become 1.0 by the softmax function. Coarse-age loss realizes the model training without defining tentatively-exact age labels.

Figure 1 shows an example of a case where the coarse age label is defined as twenties (i.e., $Y_j \in [20, 29]$). The posterior probabilities outside a red square correspond to the incorrect-age range. Coarse-age loss is calculated from the posterior probabilities in the red square and minimizes the sum of the posterior probabilities outside the red square.

There are two types of training methods; one is *single-step* model training that uses mixed exact- and coarse-age labeled training samples at the same time. The SCE loss is computed from the exact-age labeled samples, and Coarse-age loss is computed from the coarse-age labeled samples. We use the weighted sum of the SCE and Coarse-age loss; it is defined as,

$$\lambda_{\mathrm{CAL}}\mathcal{L}_{\mathrm{SCE}} + (1-\lambda_{\mathrm{CAL}})\mathcal{L}_{\mathrm{CAL}}, \quad (4)$$

where λ_{CAL} is the weighted value.

The other type is *double-step* model training; first, a model is pre-trained using the exact-age labeled samples, then the model is fine-tuned using the coarse-age labeled samples. In practical use, only the coarse-age labeled speech samples can be collected reliably due to privacy concerns. Training the model by mixing exact- and coarse-age labeled speech samples for each application environment is too expensive. In terms of the cost, it is reasonable to fine-tune the pre-trained model to each application environment using only the coarse-age labeled samples. Then, the SCE and Coarse-age loss are used separately.

IV. Speaker Age Estimation Experiment

A. Experimental setup

1) Dataset: We used SRE08/10 [19], [20], Fisher [18] and AgeVoxCeleb (AVC, [7] as adjusted using [21]). SRE08/10 and Fisher contain channel-separated telephone conversation speech samples generated by two speakers quantized at 16 bits with sampling frequency of 8 kHz. AVC contains human speech extracted from interview videos and was converted into single-channel, 16 bit stream with 16 kHz sampling rate and downsampled to 8 kHz. Table I shows details of each dataset, and Figures 2, 3, and 4 show histograms of the number of speakers per age in each dataset. We divided SRE08 and AVC's training set into training and validation sets; SRE08 was separated using the same method as [5], and AVC were divided randomly at a ratio of 8:2 to avoid duplication of the speakers. The training datasets were augmented by adding noise [33] and convolving room reverberations [34] following the technique of [5].

TABLE I
Details of each dataset

Corpus	Speaking styles	Data subset: train	validation	test
Fisher	telephone conversation	√		
SRE08	generated by	√	√	
SRE10	two speakers			√
AVC (train)	human speech	√	√	
AVC (test)	from interview videos			√

To evaluate the proposed method, we quantized the exact-age labels of each dataset to yield three kinds of coarse-age labels: five-year steps, ten-year steps, and categorical consisting of *Young* (12–24 years old), *Adult* (25–54 years old) and *Senior* (55–90 years old) following [12].

2) System configurations: We employed a time delay neural networks (TDNN)-based model (a.k.a. x-vector architecture [35]); details are shown in Table II. Referring to [5], 23-dimensional MFCCs were extracted with energy-based voice activity detection and normalized by cepstral mean normalization with three-second windows. We used the MFCCs clipped into the chunk size of 3000 frames (30 sec.) randomly in each training phase and full chunk size in each test phase. For model training, we used RAdam optimizer [36] by setting its initial learning rate, β_1, and β_2 to 1e$-$4, 0.9 and 0.999, respectively. The mini-batch size was 32, and the minimum learning rate was 1e$-$6. The learning rate was fell, and training was deemed completed following the method in [5]. The weighted value λ_{CAL} in Equation (4) was set to 0.6.

We employed two kinds of loss functions for the exact-age labeled samples; one is the SCE loss defined in Equation (2). The other is a label distribution learning (LDL) loss consisting of the soft-target, L1, and variance loss functions [10], because [10] indicated that the LDL loss can yield better performance than the soft-target loss. Both the SCE and the LDL loss used the soft target $\mathcal{N}(k|y_i,\sigma^2)$ as the actual target, and their σ values were set to 3.6 and 1.5, respectively. The weight values of LDL loss λ_1, λ_2, and λ_3 in Equation (6) of [10] were set to 1.0, 1.0, and 0.01, respectively.

As the conventional methods, we used the median value of the coarse-age label as the tentatively-correct age [3], and the ranking training method [26]. As the hyper-parameters of the ranking method, λ in Equation (8) of [26] was set to 0.01 with α in Equation (3) of [26] was 2.5, 5.0, and 10.0 for the coarse-age label size of five-years, ten-years and categorical, respectively. All hyper-parameters were decided based on the performance of the validation set.

Output	$\{0\}$	101	Softmax

"BN" denotes Batch Normalization [37]

We used mean absolute error (MAE) and Pearson's correlation coefficient ρ to evaluate estimation performance.

B. In-domain data-addition experiments

We assumed that the exact- and coarse-age labeled datasets were collected in the same domain and made a simulation using exact-age labeled SRE08/10 and coarse-age labeled Fisher. SRE08/10 and Fisher are same-domain datasets since both datasets consist of the telephone conversation (to see Table I). Speech samples of both datasets are used as training samples at the same time. The loss was defined as the weighted sum of the SEC and Coarse-age loss, as defined in Equation (4).

Table III shows the lower bounds of MAE and the upper bounds of ρ values for SRE10 and AVC obtained by the model that was trained using exact-age labeled SRE08 and Fisher. Table IV shows the estimation performance for SRE10 obtained by the model that was trained using exact-age labeled SRE08 and coarse-age labeled Fisher.

1) Results and discussions: The proposed method achieved high performance by using the SCE loss for the exact-age labeled samples, while the coarse-age labels of ten-year and categorical is used. When using the coarse-age labels of ten-year step, the MAE yielded by the proposed method was significantly reduced, by 19.3 % and 3.8 % (6.53/5.48→5.27), relative to the results of upper-bound of the baseline (Table III) and the conventional method using median loss (Table IV), respectively. However, the conventional median loss yielded higher performance than the proposed method when using the coarse-age labels of five-year step size. There is a possibility of a small negative effect on model training because the error between correct and tentatively-correct age was small due to the narrow coarse-age label of five-year step. Our proposed method is effective for coarse-age labels with wider coarse-age windows, such as the ten-year step size or more.

The MAEs were not reduced by the conventional ranking method. However, ρ values were higher than the other two methods; for example, in Table III, ρ was 0.73 when the MAE was 7.96. On the other hand, ρ values were 0.82 and 0.81 for MAEs of 7.12 and 7.54, respectively, see Table IV. It is considered that this method yielded model training that utilized the order relationship shown by the coarse-age labels. Hereafter, we use only median loss [3] as the conventional method in assessing the proposed method.

The proposed method yielded worse results by using the LDL loss for exact-age labeled samples. The LDL loss trains the model by minimizing the variance of the posterior distribution (i.e., rigorous model training). However, our Coarse-age loss trains the model to avoid misestimating the speaker age using coarse-age labeled speech samples (i.e., ambiguous model training). Therefore, our proposed method is incompatible with rigorous training methods, such as LDL loss.

2) Summary of Experiments in Section IV-B: In the in-domain additional-corpus condition, our proposed method for coarse-age labeled samples yielded better estimation performance. There is a tendency that suitable windows of the coarse-age labels are different in the proposed method and the conventional method that uses the median value of the coarse-age labels. The narrow coarse-age label, such as five-year, is suitable for the conventional method. On the other hand, the wider coarse-age labels, such as ten-year or more, are suitable

(MAE/ρ)

for the proposed method. In particular, the proposed method yielded comparable performance to the lower bound (5.27 vs. 5.22 in MAE) when using the coarse-age labels of ten-year step. However, rigorous training methods such as LDL loss, and the ranking training method [26] are not suitable for the proposed method.

C. Experiments on Coarse-age loss and distribution of actual target

We verify the relationship between the label distribution of the actual target and Coarse-age loss, to be clear why the performance was degraded when the LDL and Coarse-age loss were combined. In the previous section, using the LDL loss degraded the estimation performance compared to using the SCE loss. We used exact-age labeled SRE08, and exact- and coarse-age labeled Fisher as training samples. The window of the coarse-age label was set to ten-years. We used only the SCE loss for the exact-age labeled samples. Table V shows the MAEs for SRE10 with σ value of SCE loss ranging from 0.0 to 5.0.

The MAEs obtained by the model that trained using exact-age labeled SRE08 and coarse-age labeled Fisher were degraded compared to the baseline (2nd row of Table V) as the σ value decreased. The LDL loss optimizes the model by minimizing the variance of the posterior distribution using a small σ value and the variance loss to yield rigorous speaker age estimations. On the other hand, Coarse-age loss optimizes the model so as not to misestimate speaker age, that is, it is a form of ambiguity model training. The performance was degraded because rigorous training methods, such as SCE loss with small σ values, and LDL loss and ambiguous training methods, such as Coarse-age loss, are incompatible.

Hereafter, we use SCE loss to train the model with exact-age labeled speech samples.

D. Domain adaptation learning experiments

1) Experimental configurations: We assume a practical situation where only a coarse-age labeled speech dataset is available for the training phase and verify the effectiveness of Coarse-age loss. We use SRE08/10 and AVC as mutually out-of-domain datasets since these datasets consist of different speaking styles. Experiments have shown that the estimation performance falls in the cross-corpus condition using SRE08/10 and AVC [9], [15], [16]. We evaluate the proposed method using two training methods; the single- and the double-step model training, as described in Section III-B.

Experimental results are shown in Table VI and VII. The baseline performance is the upper bound obtained the model that was trained using only exact-age labeled samples, shown in Table III. Table VI shows the performance for AVC obtained by the model that was trained using exact-age labeled SRE08 and coarse-age labeled AVC. Table VII shows the performance for SRE10 obtained by the model that was trained using exact-age labeled AVC and coarse-age labeled SRE08.

2) Results and Discussions of single-step model training: The MAEs for the out-of-domain dataset of the exact-age labeled samples were reduced by using our proposed method. Comparing the upper bound, the proposed method reduced MAEs by up to 31.1 % in AVC when the model was trained using exact-age labeled SRE08 and coarse-age labeled AVC (11.29→8.77/7.78/9.51, to see Table III and 2nd row of Table VI), and by up to 21.23 % in SRE10 when the model was trained using exact-age labeled AVC and coarse-age labeled SRE08 (7.96→6.98/6.27/7.74, to see Table III and 2nd row of Table VII). Also, the conventional method reduced the MAEs by up to 13.1 % in AVC (11.29→8.59/8.76/9.81, to see Table III and 1st row of Table VI), and by up to 21.2 % in SRE10 (7.96→6.28/6.40/7.89, to see Table III and 1st row of Table VII), in same training condition above, respectively.

Similar to the experiment in Section IV-B and Table IV, there is the tendency that the conventional method outperformed the proposed method when using the coarse-age labels with five-year step size. The MAEs for AVC obtained by the conventional and proposed method using exact-age labeled SRE08 and coarse-age labeled AVC were comparable (8.59 vs. 8.77, to see 1st and 2nd rows of Table VI) The proposed method could not reduce the MAE for SRE10 relative to the conventional method using exact-age labeled AVC and coarse-age labeled SRE08 (6.28→6.98, to see 1st and 2nd rows of Table VII).

Similarly, there is the tendency that the proposed method outperformed the conventional method when using coarse-age labels of ten-year step and categorical. The conventional and proposed methods achieved comparable MAEs for AVC using exact-age labeled SRE08 and coarse-age labeled AVC of the ten-year step (8.76 vs. 8.78, to see Table VI). The proposed method yielded reduced MAE for AVC compared to the conventional method using exact-age labeled SRE08 and coarse-age labeled AVC of categorical (9.81→9.51, reduced by 3.1 %). The proposed method reduced the MAEs for SRE10

	ours	8.97/.63	**8.94/.64**	**9.47/.58**

TABLE VII
MAEs AND ρ VALUES FOR SRE10; EXACT-AGE LABELED AVC AND COARSE-AGE LABELED SRE08 WERE USED AS TRAINING SET

Training step	Loss for coarse-age label	Window of coare-age label		
		5-year step	10-year step	categorical
single	median [3]	**6.28/.83**	6.40/.81	7.89/.76
	ours	6.98/.76	**6.27/.83**	**7.74/.78**
double	median [3]	**7.50**/.72	8.16/.72	13.36/.58
	ours	8.07/**.75**	**7.34/.76**	**11.64/.59**

compared to the conventional method using exact-age labeled AVC and coarse-age labeled SRE08 with the ten-year step size (6.40→6.27, reduced by 2.0 %) and categorical (7.89→7.74, reduced by 1.9 %, to see Table VII).

3) Results and Discussions of the double-step model training: This experiment yielded the same trend as single-step model training. In particular, the proposed method attained the greatest reduction in MAE when using the coarse-age labels of the ten-year step size. The MAEs were significantly better, 20.8 % in AVC and 7.8 % in SRE10 than the results of baseline (11.29/7.96→8.94/7.34, to see Table III and 4th row of Tables VI and VII), and 4.5 % in AVC and 10.0 % in SRE10 than the results of the conventional method in the target domain (9.36/8.16→8.94/7.34, to see 3rd and 4th row of Tables VI and VII).

However, the performance obtained by the proposed method with double-step training was degraded compared to single-step training. This runs counter to the expectation that double-step model training should be superior as it used only the target-domain dataset in fine-tuning the model. This is explained by the catastrophic forgetting caused by using only coarse-age labeled speech samples with Coarse-age loss. The model became unable to estimate the age rigorously.

4) Summary of Experiments in Section IV-D: In the out-of-domain cross-corpus condition, both the proposed and conventional methods indicated that they could adapt the model to the condition of coarse-age labeled dataset. Similar to the in-domain additional-corpus experiment in Section IV-B, suitable windows of the coarse-age labels for the conventional and proposed method are different; the narrow window is suitable for the conventional method and the wider windows are suitable for the proposed method.

We conducted two training methods considering model training cost; one was the single-step that uses both exact- and coarse-age labeled datasets at the same time. The other was the double-step that fine-tuned the model using only the coarse-age labeled dataset. The model has been pre-trained using only the exact-age labeled samples. Both training methods indicated reducing the MAEs for the domain of the coarse-age labeled dataset. However, the estimation performance obtained by the single-step were better than the double-step because of catastrophic forgetting.

V. CONCLUSIONS AND FUTURE WORKS

We proposed a new model training method with *Coarse-age loss* for numerical speaker age estimation using coarse-age labeled speech samples. Most current works using deep neural networks train a general age-estimation model using publicly available exact-age-labeled speech samples. In practical environments, collecting coarse-age labeled samples is easier than the exact-age labeled speech samples due to speakers' privacy concerns. However, using coarse-age labeled samples makes special care in training the model necessary since existing numerical speaker age estimation techniques require exact-age labels.

We focused on coarse-age labels as they indicate the correct- and incorrect-age ranges. Coarse-age loss minimizes the sum of posterior probabilities corresponding to the incorrect-age ranges. Therefore, unlike conventional methods, Coarse-age loss does not require exact-age labels. We mainly conducted two experiments; one used both exact- and coarse-age labeled speech samples in the same speaking style. Our proposed method reduced the mean absolute errors (MAEs) by 19.3 % and 3.8 % compared to the baseline and the conventional method, respectively. The other used the exact- and coarse-age labeled speech samples in different speaking styles. This simulated the situation in which acoustic characteristics are an out-od-domain condition between the training and actual use environments. In this experiment, the proposed method reduced the MAEs by up to 30.1 % and 10.8 % compared to the baseline and the conventional method, respectively. Also, the results indicated that the proposed method is more effective for somewhat broad age windows such as ten-year, or more step size. In future work, we verify by this mixing various types of coarse-age labeled samples.

ACKNOWLEDGMENT

***Abstract*—Handling multiple languages under noisy reverberant conditions has become increasingly important for speech emotion recognition (SER). Previous studies found that modulation spectral features (MSFs) are robust to noisy reverberant conditions for SER. However, they mainly focused on specific languages; the universality of MSFs among languages is still unclear. To address this issue, we compared MSFs, hand-crafted features, Wav2Vec2.0-based features, MSFs+hand-crafted features for SER on four languages under 12 noisy reverberant conditions. Intra-lingual results showed that MSFs+hand-crafted features performed best on most conditions of all languages. Inter-lingual results showed that MSFs performed best on most conditions of test languages except training on a tonal language and testing on others. The results demonstrate that MSFs are robust to multilingual SER under noisy reverberant conditions and suggest that MSFs are potentially language-independent features for nontonal languages.**

I. Introduction

Speech-emotion recognition (SER) has become an increasingly important technique in a wide range of fields, including psychology for detecting emotional disorders. In real-world applications, noise and reverberation can have a significant impact on the quality and clarity of speech signals [1]–[5].

To address the challenge of the lack of robustness against noise and reverberation in SER, researchers have proposed methods based on speech signal processing to improve SER. Modern physiological [6] and psychological [7] models suggest that the human auditory system contains an auditory filterbank that decomposes speech signals into channel signals, such as the temporal amplitude envelope (TAE) and temporal fine structure. Several studies have proved that the TAE and its modulation cues play an important role in speech recognition [8]–[10]. Based on these findings, a previous study proposed modulation spectral features (MSFs) that were extracted based on the modulation analysis processing of the TAE and showed that MSFs are important cues for human emotion recognition [11]. Furthermore, MSFs were shown to be more robust on SER under noisy and reverberant conditions compared to widely used feature sets IS09 and eGeMAPS [12], [13].

So far, studies on MSFs were mainly focused on specific languages, such as Japanese [12], [13] and German [14]. However, handling multiple languages is also important for SER [15], [16]. Whether or not MSFs retain their robustness in multilingual SER and remain unaffected by noise and reverberation is still unclear. On the other hand, inspired by human perception, researchers have recently proposed to use spectral features with the three-layer model for multilingual emotion recognition tasks [17]–[19]. This suggests that spectral features inspired by human perception, such as MSFs, may reflect the essential characteristic of emotions under noisy reverberant conditions among languages.

Accordingly, this study investigated the potential universality of MSFs in intra-lingual and inter-lingual SER under noisy and reverberant conditions. To do so, we used support vector machine (SVM) to compare the SER performance of MSFs, hand-crafted feature sets, MSFs + hand-crafted feature sets, and Wav2Vec2.0-based features on different languages under noisy reverberant conditions. Specially, we investigated intra-lingual and inter-lingual SER performances on recognizing four common emotions (happy, neutral, sad, and angry) in four languages (Japanese, German, English and Chinese) under 12 noisy reverberant conditions. To the best of our knowledge, we are the first to investigate the robustness of MSFs in multilingual and cross-lingual SER under noisy reverberant conditions. The findings of this study will not only advance the understanding of the importance of MSFs in the speech perception mechanism, but also contribute to the development of robust SER systems, such as speech-based human-machine interaction under noisy reverberant conditions.

II. Modulation spectral features

We utilized the same MSFs that were shown to be robust to noise and reverberation in previous studies [11]–[13]. To extract modulation spectral cues such as MSFs of modulation spectrogram, it is necessary to calculate the modulation spectrogram using the modulation filterbank first. Figure 1 shows the auditory-based process used in this study to calculate the MSFs of modulation spectrograms.

Emotional speech signals s were divided into several frequency bands by using an auditory-based band-pass filterbank,

$$s_k(n) = s(n) * h_k(n), \tag{1}$$

where * denotes the convolution operator, $h_k(n)$ is the impulse response of the k^{th} channel, and n is the sample number in

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

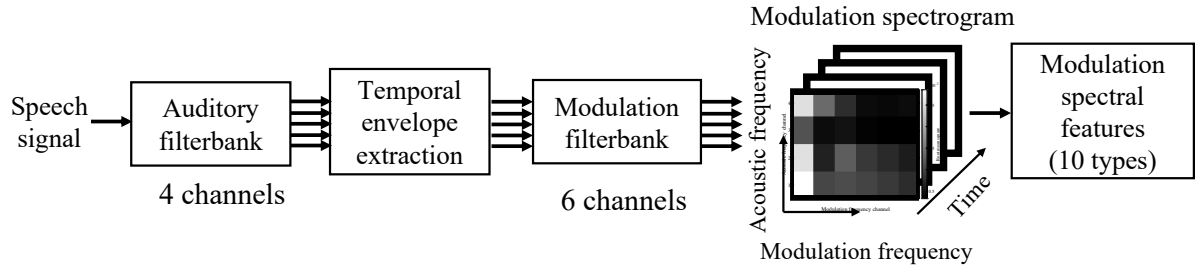

Fig. 1. Process of extracting MSFs [13].

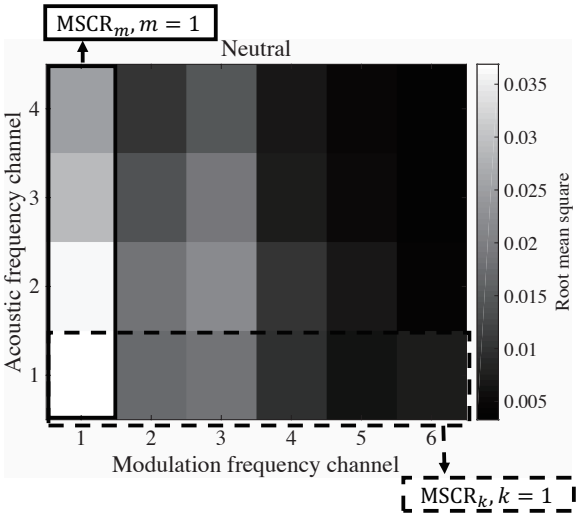

Fig. 2. Calculation example of MSCR$_m$ and MSCR$_k$ [11].

the time domain. The 6^{th}-order Butterworth infinite impulse response (IIR) band-pass filterbank was used as the auditory filterbank. The bandwidth of each filter was the bandwidth of the human auditory filter, and the order of the filters was determined in accordance with the equivalent rectangular bandwidth (ERB_N) and ERB_N-number scale, where the unit of ERB_N-number is Cam. The boundary frequencies of the band-pass filters (BPFs) were defined as ERB_N-number from 3 to 35 Cam with an 8 ERB_N bandwidth, and the number of channels was 4.

The temporal envelope of the output signal from each BPF $s_k(n)$ was extracted using the Hilbert transformation, and a 2^{nd}-order Butterworth IIR low-pass filter (LPF) (cut-off frequency is 64 Hz) as follows,

$$e_k(n) = \text{LPF}\left[|s_k(n) + j\mathcal{H}[s_k(n)]|\right], \tag{2}$$

where $\mathcal{H}$ denotes the Hilbert transform.

The next step involved decomposing the temporal envelope into several modulation-frequency bands by using a modulation filterbank,

$$E_{k,m}(n) = g_m(n) * (e_k(n) - \overline{e_k(n)}), \tag{3}$$

where m is the channel number of the modulation filter, $g_m(n)$ is the impulse response of the modulation filterbank, and $\overline{e_k(n)}$ is the time-averaged amplitude of $e_k(n)$. The modulation filterbank consisted of six filters (one LPF and five BPFs). The boundary frequencies of the filters were spaced on an octave frequency band from 2 to 64 Hz.

The root-mean-square of $E_{k,m}(n)$ is calculated as the modulation spectrogram,

$$\bar{E}_{k,m}(n) = \sqrt{\frac{1}{N}\sum_{n=1}^{N} E_{k,m}^2(n)}, \tag{4}$$

where the N is the length of the speech signal $s(n)$.

Then, we calculated the high-order statistics of the three-dimensional modulation spectrograms (time, acoustic frequency, modulation frequency) in the acoustic frequency direction and modulation frequency direction as MSFs. The ten types of MSFs are the modulation spectral features in the acoustic frequency domain (the subscript is m) and in the modulation frequency domain(the subscript is k): the modulation spectral centroid (MSCR$_{m/k}$), modulation spectral spread (MSSP$_{m/k}$), modulation spectral skewness (MSSK$_{m/k}$) and modulation spectral kurtosis (MSKT$_{m/k}$), which are defined as follows.

$$\text{MSCR}_\text{m} = \frac{\sum_{k=1}^{K} k\bar{E}_{k,m}}{\sum_{k=1}^{K} \bar{E}_{k,m}} \tag{5}$$

$$\text{MSSP}_\text{m} = \frac{\sum_{k=1}^{K} [k - MSCR_m]^2 \bar{E}_{k,m}}{\sum_{k=1}^{K} \bar{E}_{k,m}} \tag{6}$$

$$\text{MSSK}_\text{m} = \frac{\sum_{k=1}^{K} [k - MSCR_m]^3 \bar{E}_{k,m}}{\sum_{k=1}^{K} \bar{E}_{k,m}} \tag{7}$$

$$\text{MSKT}_\text{m} = \frac{\sum_{k=1}^{K} [k - MSCR_m]^4 \bar{E}_{k,m}}{\sum_{k=1}^{K} \bar{E}_{k,m}} \tag{8}$$

$$\text{MSCR}_\text{k} = \frac{\sum_{m=1}^{M} m\bar{E}_{k,m}}{\sum_{m=1}^{M} \bar{E}_{k,m}} \tag{9}$$

$$\text{MSSP}_\text{k} = \frac{\sum_{m=1}^{M} [m - MSCR_k]^2 \bar{E}_{k,m}}{\sum_{m=1}^{M} \bar{E}_{k,m}} \tag{10}$$

$$\mathrm{MSSK_k} = \frac{\sum_{m=1}^{M}[m - MSCR_k]^3 \bar{E}_{k,m}}{\sum_{m=1}^{M} \bar{E}_{k,m}} \quad (11)$$

$$\mathrm{MSKT_k} = \frac{\sum_{m=1}^{M}[m - MSCR_k]^4 \bar{E}_{k,m}}{\sum_{m=1}^{M} \bar{E}_{k,m}} \quad (12)$$

The final two MSFs, the modulation spectral tilts ($\mathrm{MSTL}_{m/k}$) are the linear regression coefficients obtained by fitting the first-degree polynomial to the modulation spectrograms. Figure 2 shows an example of calculating MSCR_m and MSCR_k.

III. Noisy reverberant conditions

In this study, we used the same method as in previous studies [11]–[13] to add noise and reverberation to speech to simulate noisy, reverberant, and noisy reverberant conditions.

For noisy conditions, we added white Gaussian noise and the adjusted noise to the speech at SNR levels of 20, 10, and -5 dB. The noise conditions were three in total. For reverberant conditions, we used the convolution method and a statistical room impulse response (Schroeder model). We convoluted the original speech with two types of room-impulse responses, with reverberation times (T_{R}) of 1.0 and 2.0 s, respectively. The reverberation conditions were two in total. For noisy reverberant conditions, we used the combination of the above three noise conditions and two reverberation conditions. The noisy reverberant conditions were six in total. With the clean condition (original speech), we conducted experiments under 12 conditions in total.

IV. Experiments

A. Datasets

We used datasets of Japanese, German, Chinese, and English in this study. We chose happy, neutral, sad, and angry emotions in these datasets, because these emotions are common emotion categories that guarantee the emotion categories in each dataset are the same for experiments. Table 1 shows the statistics of utterances of emotions in each dataset.

Fujitsu dataset: The Fujitsu Japanese Emotional Speech Database is a Japanese dataset that was used for emotion recognition [11]–[13]. **Berlin EmoDB dataset**: This is a German dataset, which has also been widely used in previous research [18]–[20]. For convenience, we will refer to Berlin EmoDB as Berlin for short. **IEMOCAP dataset**: IEMOCAP is an interactive emotional dyadic motion capture database in English [21], [22]. For emotion categories, we combine the emotions excited and happy together as the emotion happy, as was done in previous studies [23], [24]. **CASIA dataset**: The CASIA emotional speech dataset [18], [19], [22] is a Mandarin emotional speech dataset. This dataset does not contain the emotion of happy, but it has joy, a closely related emotion. Accordingly, we use joy as the emotion happy for this dataset.

TABLE I
Statistics of utterances of emotions in each dataset

Dataset	Happy	Neutral	Sad	Angry	Total
Fujitsu	20	20	20	20	80
Berlin	71	79	62	127	339
IEMOCAP	1636	1708	1084	1130	5531
CASIA	1600	400	1599	1597	5196

B. Baseline feature sets

Hand-crafted feature sets: InterSpeech2009 (IS09) [25] and eGeMAPS [26] are two widely used hand-crafted feature sets in the emotion recognition area. We used two feature sets separately in our experiments.

Wav2Vec2.0-based feature: Wav2Vec2.0 [27] is a self-supervised learning pre-trained model for representing speech. We used Wav2Vec2.0-large-xlsr models that were fine-tuned on each language to make fair comparisons. These models were obtained from jonatasgrosman/Wav2Vec2.0-large-xlsr-53-[Japanese, German, English, Chinese] from HuggingFace. To make a fair comparison with MSFs, we did not fine-tune Wav2Vec2.0 models on SER tasks but froze those models to use them as feature extractors only. For feature extractions, as Wav2Vec2.0's output is a sequence of vectors corresponding to frames sequence, we refered to previous studies [28], [29] to obtain fixed-length features for each speech. Specifically, we computed the mean of the last layer, the sum of the last layer, the mean of all layers, and the sum of all layers as four different features. Each feature is a 1024-dimension vector.

C. MSFs

In this study, we investigated the performance of each of the ten types of MSFs and the four combinations of MSFs. Combination features include the combination of all types of MSFs, the combination of acoustic-frequency domain MSFs, the combination of modulation-frequency domain MSFs, and the modulation spectral tilts (MSKT_k and MSTL_k). The last two features have been demonstrated to be robust to all daily noise and reverberation conditions in a previous study [13]. We concatenated corresponding MSFs together to obtain the combination of features.

Moreover, since MSFs are hand-crafted features, we also used MSFs + hand-crafted feature sets to investigate whether or not MSFs are complementary to conventional feature sets. Specifically, we concatenated all types of MSFs with IS09 and all types of MSFs with eGeMAPS as two kinds of MSFs + hand-crafted features.

D. Intra-lingual and inter-lingual experiment setting

We used SVM as a classifier to conduct experiment recognition experiments, which has also been widely used in many studies related to SER (as examples, see [30] and [31]). The input was the feature vector of MSFs, MSFs + hand crafted, hand crafted, and Wav2Vec2.0-based features. The output was the emotion from the four emotion classes.

For the intra-lingual experiment, we performed five-fold experiments to comprehensively evaluate the performance. Specifically, we split the data of each emotion into a five-fold average for each dataset. Then, we performed five experiments by using four of the folds as the training set and the remaining

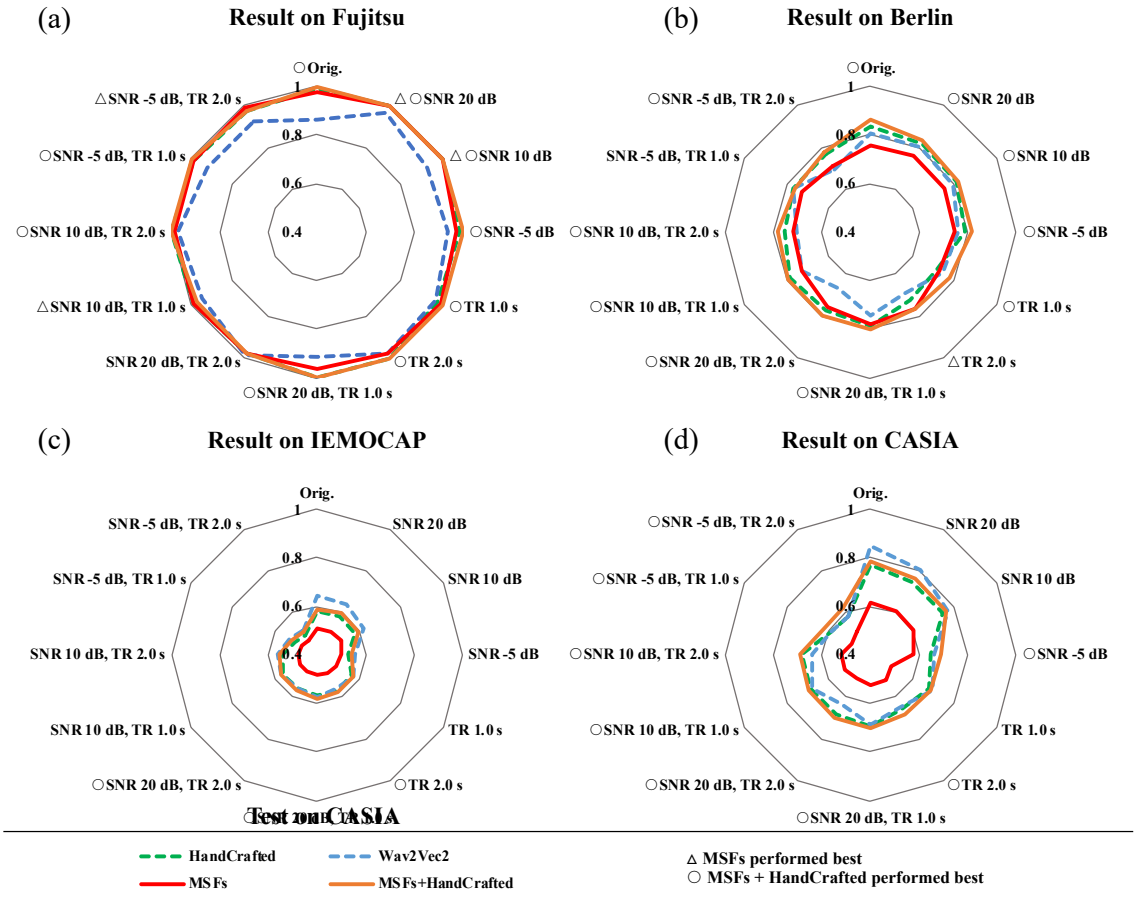

Fig. 3. Result of intra-lingual SER on four datasets: (a) result of train on Fujitsu and test on Fujitsu, (b) result of train on Berlin and test on Berlin, (c) result of train on IEMOCAP and test on IEMOCAP, and (d) result of train on CASIA and test on CASIA.

one as the test set. Moreover, we splited 80% of the training set for training and the remaining 20% for validation. After using each fold as the test set, we used the average performance of the five experiments for evaluation.

For the inter-lingual experiment, we trained the model on one dataset and tested it on the other three datasets separately. Specifically, we used 80% of each emotion's data from the training dataset as the training set and the remaining 20% of each emotion's data for validation. All data from test datasets were used for the test. We conducted experiments by training the model on each dataset and testing it on other datasets to evaluate the performance.

We used weighted accuracy that considers the imbalance of each emotion as the evaluation metric.

V. Results and Discussion

Figure 3 and 4 show radar charts of intra-lingual and inter-lingual results. Different axes represent the original speech and 12 noise reverberant conditions; values on axes represent the weighted accuracy. To show comparisons between four feature sets clearly, and due to space limitations, we only show the best result in categories of hand-crafted feature sets, Wav2Vec2.0-based features, MSFs, and MSFs + hand-crafted feature sets. For convenience, we hereafter refer to these categories as hand-crafted, Wav2Vec2.0-based, MSFs, and MSFs + hand-crafted. In Figure 3 and 4, different colored lines represent different feature categories: the green dashed line, blue dashed line, red line, and orange line indicate the highest weighted accuracy from hand-crafted, Wav2ec2-based, MSFs, and MSFs + hand-crafted, respectively. Conditions with △ indicate conditions where MSFs performed the best. Conditions with ◯ indicate conditions where MSFs + hand-crafted performed the best.

As seen in Fig. 3, MSFs + hand-crafted performed best on 9 of 12 conditions on Fujitsu, 10 of 12 conditions on Berlin, and 8 of 12 conditions on CASIA, with average improvements from the best baseline of 0.69%, 2.03%, and 1.85% on Fujitsu, Berlin, and CASIA, respectively. The reason MSFs + hand-crafted improved relatively less is because the best baselines and MSFs + hand-crafted have 100% weighted accuracy on many conditions in the Fujitsu dataset. On the other hand, MSFs + hand-crafted performed best on 3 of 12 conditions on IEMOCAP, while Wav2Vec2.0-based performed best on more conditions in IEMOCAP. The reason could be that Wav2Vec2.0 was originally pre-trained in English, and it captures characteristics of emotions in English well. However,

Fig. 4. Result of inter-lingual SER that train the model on a single language and test on other languages: (a) result of train on Fujitsu and test on other datasets, (b) result of train on BERLIN and test on other datasets, (c) result of train on IEMOCAP and test on other datasets, and (d) result of train on CASIA and test on other datasets.

although Wav2Vec2.0 models were fine-tuned on languages other than English, MSFs + hand-crafted performed better than Wav2Vec2.0-based on most conditions of other languages. Meanwhile, Wav2Vec2.0 is a large model that needs more computational resources, while MSFs + hand-crafted can be effectively obtained. These results demonstrated that MSFs are complementary with conventional hand-crafted features and are effective features that are robust in noisy reverberant conditions in different languages.

As seen in Fig. 4, MSFs performed best on most of the conditions when training on Fujitsu and testing on other datasets, training on Berlin and testing on Fujitsu and CASIA, and training on IEMOCAP and testing on other datasets, training on CASIA and testing on Fujitsu. MSFs + hand-crafted performed best on most conditions when training on Berlin and testing on IEMOCAP. These results demonstrated that MSFs are robust in emotion recognition in noisy reverberant conditions across languages. On the other hand, MSFs or MSFs

+ hand-crafted performed best on relatively fewer conditions when training on CASIA and testing on Berlin and IEMOCAP. Since Chinese was the only tonal language in our experiments, the emotion perception in Chinese may be influenced by tone and other reasons. These results suggested that MSFs potentially describe common characteristics of emotions under noisy reverberant conditions among non-tonal languages.

For the MSFs combination that performed best in the results, among all 48 conditions (12 conditions $\times$ 4 datasets) in multilingual SER, features containing MSFs performed best on 33 conditions, and among them, 30 combinations are MSFs + hand-crafted features. On the other hand, among all 144 conditions (12 conditions $\times$ 4 datasets $\times$ 3 cross-lingual) in cross-lingual SER, features containing MSFs performed best on 120 conditions, and among them, 29 of the best performing features are $\mathrm{MSSK_m}$. Therefore, $\mathrm{MSSK_m}$ is considered the universal feature in cross-lingual SER.

VI. Conclusion

This study investigated the robustness of MSFs in multilingual and cross-lingual SER under noisy reverberant conditions. We utilized SVM to compare the SER performance for recognizing four common emotions. These comparisons were conducted on intra-lingual and inter-lingual SER in four languages under 12 noisy reverberant conditions. The results demonstrate that MSFs are complementary with conventional hand-crafted features and they are robust under noisy reverberant conditions in different languages. The results also suggest that MSFs potentially describe common characteristics of emotions in noisy reverberant conditions among non-tonal languages.

For future work, it would be interesting to investigate the applicability of MSFs in recognizing emotions in other tonal languages to further examine the language-dependency of these features. Additionally, it would be worthwhile to explore the use of deep learning techniques to further enhance the performance of SER systems utilizing MSFs.

***Abstract*—Data augmentation is essential for constructing reliable automatic speaker verification (ASV) systems. It is well known that data augmentation increases the number of utterances by adding noise and is effective in most methods. However, the number of speakers in the training data also plays an important role in enhancing ASV system performance. The robustness of speaker embedding networks, which are used in ASV systems, relies on the number of speakers present in the training data. To address this, we propose a method called pseudo-speaker augmentation, which utilizes a technique called vocal tract length (VTL) warping. By changing a parameter, the VTL warping technique alters speaker characteristics, allowing us to easily increase the number of speakers. Since the speaker embedding network aims to classify speakers, having a larger number of speakers enhances its robustness. In our experiments, the pseudo-speaker augmentation method improved the performance of the speaker embedding-based ASV system, achieving an equal error rate of 4.058% on the JTubeSpeech database.**

I. Introduction

With the spread of spoken dialogue systems, automatic speaker verification (ASV), a biometric authentication technology using voice, has been actively researched in recent years. As many deep learning-based approaches advance, various deep neural network (DNN)-based ASV methods, such as x-vector [1] and ECAPA-TDNN [2], have been proposed and achieved remarkable performances. In these methods, a fixed-length feature vector called speaker embedding, extracted from the embedding layer of the DNN, is used to represent the personal characteristics of a speaker. In order to construct a reliable model in such a deep learning-based ASV system, a large amount of annotated data is required for model training. The most famous solution for insufficient annotated data is data augmentation by adding noise. Additionally, self-supervised learning (SSL) is also paid attention for ASV systems [3].

Data augmentation is an essential technique for constructing reliable speaker embedding networks. It is well known that data augmentation increases the number of utterances by adding noise and is effective in most methods [4], [5]. This technique also improves the generalization ability and robustness of the model by augmenting not only the amount of data but also the diversity of the data. In ASV tasks, data augmentation techniques to increase the number of utterances are generally used, such as the addition of noise or echoes [1], specaugment [5]. On the other hand, in a speaker embedding-based ASV system, it is known that the classification performance of the speaker embedding networks depends on the number of speakers in training data. Therefore, in constructing an ASV system, not only the number of utterances in the training data but also the number of speakers is considered an essential factor for improving the performance [6]. However, it is hard to collect large amounts of annotated data, including speaker labels. In [6], an augmentation method using speed perturbation [7] is proposed to increase the number of speakers at a small cost. It is reported that generating new speakers increases the range of speaker representation in the embedding space and improves the performance of ASV systems.

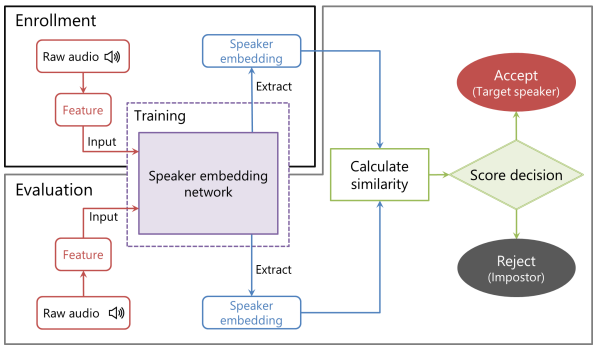

Fig. 1. Framework of speaker embedding-based ASV

Vocal tract length normalization (VTLN) [8] is used to counteract the effects of differences in vocal tract length. This technique can be reversely adapted to add variation to speech data. By changing a parameter, the vocal tract length warping technique alters speaker characteristics, allowing us to increase the number of speakers easily. Since the speaker embedding network aims to classify speakers, having a larger number of speakers enhances its robustness. Therefore, in this paper, we propose pseudo-speaker augmentation for speaker-embedding-based ASV by using the vocal tract length warping technique. In the experiments, we evaluated the effectiveness of the proposed pseudo-speaker augmentation with JTubeSpeech database [9]. The experimental results show that the best performance was obtained in the system with data augmentation for both the number of utterances and the number of speakers, and the effectiveness of speaker augmentation was confirmed.

The rest of the paper is organized as follows. Section 2 describes a general speaker embedding-based ASV system. Section 3 will show the conventional utterance number augmentation by adding noise and the proposed pseudo-speaker augmentation with VTLP. Section 4 gives the detailed experimental setup and results, and the paper is concluded in Section 5.

II. Speaker Embedding-based Automatic Speaker Verification

ASV is a binary classification task that determines whether the given voice is a registered speaker or not. Fig. 1 shows the framework of a speaker embedding-based ASV system, which has become mainstream in recent years. The system is constructed in the following flow:

First, a speaker embedding network is trained using a large amount of labeled data to extract features known as speaker embeddings, which represent the speaker's characteristics. The speaker embedding network is a neural network model trained for speaker classification and used as a feature extractor. The speaker embeddings are extracted from its embedding layer. Next, in the enrollment part, enrolled utterances are converted into acoustic feature vectors such as MFCC. Then, the features are fed into the trained speaker embedding network, and speaker embeddings are extracted. In the evaluation part, the speaker embeddings of test utterances are also extracted in the same manner. Subsequently, the similarity scores between the extracted speaker embedding vectors are computed, and the scores are used for determining the decision whether to accept or reject.

III. Pseudo-speaker Augmentation

A. Data augmentation using simulated noises

In most ASV systems in real environments, test utterances contain background noise. To construct a robust ASV system, it is necessary to include training data similar to the test environment. Also, a variety of training data is essential to build a more robust system that can adapt to different or unknown environments. However, it is very costly that collect large amounts of speech data recorded in many kinds of different environments. Data augmentation techniques are widely used in various tasks to increase simulated variation in training data and to improve the robustness of the trained model. Adding noise or background sounds to original data is a common data augmentation method Incorporating different types and levels of noise into the training data allows for better performance in real-world scenarios with varying acoustic conditions.

B. Pseudo-speaker augmentation using Vocal Tract Length Warping

There are various factors that cause different speakers' voices to have different acoustic features, one of which is called vocal tract length (VTL). If the vocal tract is modeled as a uniform tube, it is possible to scale the frequency axis of the spectra of two speakers with different vocal tract lengths using a warping factor. It is known that such differences

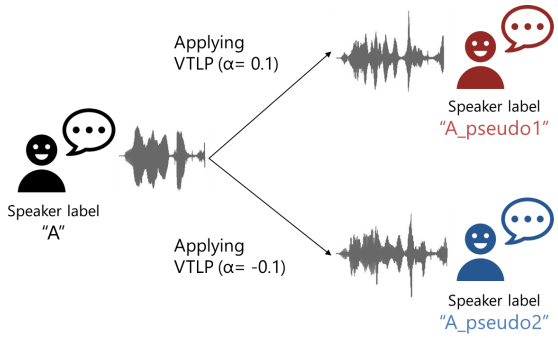

Fig. 2. Flow of making pseudo-speaker by VTLP

in vocal tract length affect recognition accuracy in speech recognition, and vocal tract length normalization (VTLN) [8] is used as a method to counteract this effect. VTLN removes inter-speaker variation by linearly warping the frequency axis of each speaker's spectrogram using the optimal warp factor for each speaker. A reverse adaptation of the VTLN method is the vocal tract length perturbation (VTLP) [10] approach, which adds variation to the input data by adding variation. In this paper, these frequency warping techniques are used as a data augmentation method to increase the number of speakers by attaching a different speaker ID to the processed speech than the original voice, like Fig. 2. If ω is the normalized frequency of the original voice and ω' is the frequency after augmentation and contraction, it can be expressed as:

$$\omega' = \omega + 2\arctan\frac{\alpha\sin(\omega)}{1-\alpha\cos(\omega)}, \tag{1}$$

where α is the VTL warping factor.

IV. Experiment

We conducted ASV experiments to show the effectiveness of the proposed pseudo-speaker augmentation using VTLP.

A. Database

JTubeSpeech [9] was used to train and evaluate the ASV systems. This is a database of mainly spoken Japanese speakers extracted from videos uploaded to YouTube. It is noted that since the videos are automatically collected, JTubeSpeech also includes other languages, such as English and Chinese. A dataset of JTubeSpeech is designed for ASV with a large number of speakers. In the experiments, we used the single-speaker dataset of the JTubeSpeech subset as the training dataset. The training dataset contains 502 hours of utterances from 1,795 speakers, and the development dataset contains 138 hours of utterances from 1,795 speakers. A total of 640 hours of utterances were used as the training dataset. The test dataset contained 20,976 trials by 92 speakers. The evaluation trials consist of 228 pairs with target speakers and 20,748 pairs with impostors. The speakers in the test set are all manually annotated as Japanese speakers.

MUSAN [11] was used for utterance augmentation. It contains 42 hours of music of various genres, 60 hours of

TABLE I
ARCHITECTURE OF CNN USED AS SPEAKER EMBEDDING EXTRACTOR

	Layer	Kernel size	Input x Output
1	Conv1d	5	40 x 128
2	Conv1d	3	128 x 128
3	Conv1d	3	128 x 128
4	Conv1d	3	128 x 64
5	Fc	-	(64x3) x 512
6	Fc	-	512 x (*n_classes*)

conversations in 12 languages, and more than 900 noise types. Noise type which contains approximately 6 hours of various types of noise, including mechanical, non-mechanical, and environmental sounds.

B. Experimental setup

The architecture of the convolutional neural network (CNN) used as the speaker embedding extractor is shown in Table I. The output vectors of the first fully connected layer in Table I were regarded as the speaker embedding vectors. The input features of CNN were a 40-dimensional MFCC with a frame length of 25 ms. The network was trained for 100 epochs with the Adagrad optimizer [12] and Cross-Entropy Loss.

For the JTubeSpeech training dataset, we applied both data augmentation increasing the number of utterances by adding noise and increasing the number of speakers by VTLP described in section 3. In this paper, we refer the noise-adding data augmentation as utterance augmentation. The comparison methods were shown as follows:

(A). None
No data augmentation was applied to the training data. This was referenced as the baseline system.

(B). Noise
For utterance augmentation, noise data was randomly selected from the MUSAN noise data set, and the signal-to-noise ratio (SNR) was randomly set from [-5, 0, 5, 10, 15]. We applied utterance augmentation by using different noises and SNRs for each utterance. In this condition, the number of utterances was augmented by a factor of three by adding two types of noise data.

(C). Noise (large)
The utterance augmentation was applied in the same manner as condition (B). To compare the performance of a larger amount of data expansion only by adding noise, the SNRs were set to all of [-5, 0, 5, 10, 15], and the number of utterances was augmented by a factor of six.

(D). VTLP (all)
The pseudo-speaker augmentation was applied to all speakers in the training data, and the number of speakers was augmented by a factor of three. The warping factor α for VTLP was set to -0.1 or +0.1 for all utterances.

(E). VTLP (select)
Pseudo-speaker augmentation was performed in the same manner as condition (D). Figure 3 shows the distribution of the degree of changing speaker characteristics before and after adapting VTLP. Therefore, we decided to select the pseudo-speakers whom can use as different speakers from the original one adequately. Finally, the number of speakers is about twice as large, which is a smaller number than in condition (D).

(F). VTLP (select) + Noise
To investigate the effectiveness of combining both utterance number augmentation and speaker number augmentation, almost the same number of utterance augmentation was applied to condition (E) as in condition (B).

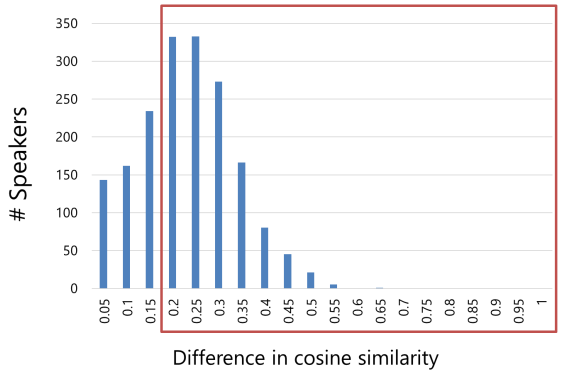

Fig. 3. Distribution of variation in speakability by VTLP

In creating pseudo-speakers, it is important that the individual characteristics after VTLP differ significantly from the original speaker. Therefore, we prepared condition (D) to test whether the degree of change in personal characteristics due to VTLP affects the accuracy of the ASV system. Specifically, we extracted the speaker embeddings of both the pseudo-speaker and the original speaker using one of our trained speaker classification models, and computed the average of the difference in the cosine similarity between them for each speaker. The average of the differences in similarity per speaker for a single warping factor is shown in Fig. 3. This confirms that the change in personal characteristics at a given value of the warping factor varies from speaker to speaker. For some speakers, however, the warping coefficients set in this study were not sufficient to treat the pseudo-speaker as a different speaker. Therefore, we used as VTLP (select) only pseudo-speakers with a difference in cosine similarity greater than 0.2. By implementing these conditions, we examined the usefulness of each data augmentation method in terms of the number of speakers and utterances. The amount of data in each condition is shown in the table II.

C. Evaluation metrics

To evaluate the comparison methods, we used two kinds of test trials provided in the JTubeSpeech dataset. One trial is defined as a core task, whose segments are set to under

TABLE II
DATA AMOUNT OF THE TRAINING DATASET IN EACH CONDITION

	Augmentation	# Speakers	Total hours
(A)	None	1,795	502.49
(B)	Noise	1,795	1,510.17
(C)	Noise (large)	1,795	3,014.90
(D)	VTLP (all)	5,385	1,506.32
(E)	VTLP (select)	3,681	957.59
(F)	VTLP (select) + Noise	3,681	2,875.49

TABLE III
EERS (%) FOR EACH AUGMENTATION METHOD.

	Augmentation	EER (%)	
		Core	Short
(A)	None	6.140	7.456
(B)	Noise	5.104	8.333
(C)	Noise (large)	5.104	8.333
(D)	VTLP (all)	7.018	9.211
(E)	VTLP (select)	6.579	7.822
(F)	VTLP (select) + Noise	**4.058**	**6.777**

five seconds, and another one is referenced as a short task, whose segments are set to under two seconds. These trials were released as the evaluation tasks of JTubeSpeech-ASV[1]. The evaluation metric was the equal error rate (EER) based on a comparison of cosine similarity between the speaker embeddings.

D. Experimental results

Table III shows the EERs under the core and short trials for each comparison condition. First, we discuss the results under the core trials. Comparing the results of (A) with (B) and (C) indicates that (B) and (C) improved performance compared to the baseline, attributed to the inclusion of utterance augmentation. On the other hand, when comparing (B) with (C), since only utterance augmentation was performed, the EERs were the same. Since both augmented data were generated by adding noise, the data diversity was limited, and it seems to lead to the saturated result. Comparing (D) with (E), both using the pseudo-speaker augmentation, the EER of (E) is 0.439 points better than that of (D). In both (D) and (E), pseudo-speaker augmentation was applied, and in (E), speakers were selected for which the change in their characteristics due to VTLP was significant. This indicates that when the speakers were chosen to apply VTLP, as in (E), VTLP can properly function as a data augmentation method. However, both (D) and (E) perform worse than the baseline. One reason for this result is that whereas the diversity of the speakers was increased, the number of utterance data for each speaker was not enough. (F) achieved the highest performance among all conditions. Especially comparing (F) with (C), while the EER of (C) seems saturated, the EER of (F) was 1.046 points better than that of (C) with almost the same amount of data. It denotes that the combination of utterance augmentation and pseudo-speaker augmentation contributes to expanding the data diversity, and it helps to improve performance. The short trials are challenging tasks, as stated in the Short-duration Speaker Verification Challenge(SdSVC) 2021[13]. In the results under these short trials, the performances were getting lower than the performances of the core trial. Comparing the results of (A) with those from (B) to (E), it appears that data augmentation is not effective in improving performance. However, comparing (E) with (B) and (C), the performance with the pseudo-speaker augmentation by VTLP(select) is better than the utterance augmentation. This trend is in contrast to the core trials. For short utterance trials, the speaker embedding quality is more important to represent speaker features accurately. The results suggest that the augmentation of the number of speakers may be effective in spreading the representation space of the speaker embedding. Consequently, the proposed pseudo-speaker augmentation was found to be effective when combined with the utterance augmentation in both the core and short trials.

V. CONCLUSIONS AND FUTURE WORK

In this paper, we proposed pseudo-speaker augmentation by using VTLP for robust ASV systems. Data augmentation by adding noise is basically used for the state-of-the-art speaker embedding models. On the other hand, the larger the number of enrollment speakers for the speaker embedding models, the more robust the performances. Therefore, the pseudo-speaker augmentation was performed by using VTLP. Additionally, we described that the pseudo-speaker selection was effective for the ASV systems. The experimental results showed that the best performance was obtained when both the pseudo-speaker augmentation and the utterance augmentation were applied simultaneously. In the future, we will investigate the effectiveness of the proposed method on state-of-the-art systems such as x-vector and ECAPA-TDNN.

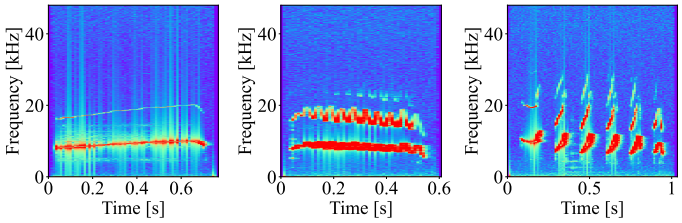
***Abstract*—In this study, we aim to automatically classify calls of autism model marmosets to analyze their vocal development. As a nonhuman primate model of autism spectrum disorder (ASD), valproic-acid-exposed (VPA) marmosets have recently been developed. This marmoset model has been shown to have abnormal vocal development similar to ASD symptoms compared with VPA-unexposed (UE) marmosets. Automatic classification of vocalizations and analysis of calls can be used to study the VPA marmosets. In the past, there have been no studies on the automatic classification of VPA marmoset calls. Therefore, we focus on classifying calls of both UE and VPA marmosets automatically and applying the automatic call classification to the analysis of their vocal development. We construct a call classifier based on deep learning, which distinguishes four types of marmoset call from audio signals. By experiment, we confirmed that the classifier trained on calls of UE marmosets could accurately classify two main classes of calls: 'phee' and 'twitter'. The classifier also worked well for VPA marmosets. Furthermore, we found that the classifier was also helpful for analyzing the vocal development of UE and VPA marmosets.**

I. Introduction



Autism spectrum disorder (ASD) is a developmental disorder characterized by symptoms such as social interaction and communication deficits. One notable symptom involves vocalization, which can exhibit specific features such as flat intonation and peculiar speech timing [1], [2]. To understand the pathogenic mechanisms of ASD and develop potential treatments, research has been conducted using animal models that replicate ASD-like pathologies and symptoms [3], as well as actual ASD diagnostic data [4]. Specifically, nonhuman primate models of ASD have attracted attention because they are more closely related to humans than rodent models [5].

As one of nonhuman primate model, an ASD marmoset model has been developed by administering valproic acid (VPA), which increases the risk of ASD in offspring, to the mothers of common marmosets (i.e., *Callithrix jacchus*) [6]. Common marmosets (hereafter simply referred to as marmosets) are small primates known for their ease of handling, small size, and high reproductive capacity, which provide several advantages for research purposes [7], [8]. Because of their high sociability and diverse calls used for communication, they have been extensively utilized in the field of psychiatric and neurological disorder research [9]–[11]. Consequently, marmosets are expected to be suitable for studying communication impairments in ASD. Indeed, VPA marmosets, which are marmosets exposed to VPA, exhibit anomalies in their calls [6], and they are expected to show abnormalities in their vocal development. Developing a system that efficiently and accurately captures call characteristics of the VPA and normal unexposed (UE) marmosets would aid in elucidating the mechanisms underlying communication impairments in ASD and would contribute to the development of treatments for ASD.

However, the classification of marmoset calls imposes a significant workload because it is performed manually by researchers. For this reason, we aim to classify marmoset calls automatically. Various methods have been proposed for this automatic classification, including signal-processing-based approaches, such as the threshold processing of the amplitude of acoustic signals [12], and deep-learning-based approaches [13]–[15] that demonstrate high efficacy for classification by considering relationships among short-time frames of acoustic signals. However, existing methods have primarily targeted UE marmosets and have not addressed the call classification of VPA marmosets.

Because of this situation, we construct a deep-learning-based call classifier for not only UE marmosets but also VPA marmosets. For training of the classifier, calls of VPA and UE marmosets are recorded, and the recorded signals are annotated by 12 different call types and two special classes, *unknown* and *no call*. Using the collected dataset, our classifier is trained to classify acoustic signals of marmoset calls into three main classes (*phee*, *trill*, and *twitter*) and two other classes (*other calls* and *no call*). For the architecture of our classifier, we

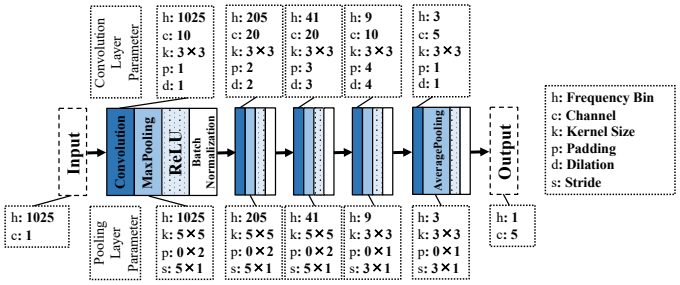

Fig. 3. Network architecture and hyperparameters of our classifier for marmoset call classification

use a convolutional neural network (CNN) because it will capture spectrotemporal characteristics of marmoset call signals in spectrograms obtained by short-time Fourier transform (STFT).

To objectively evaluate the classification accuracy of the proposed classifier, we conducted experiments using the data obtained from both UE and VPA marmosets. Experimental results show that the classifier can classify calls of VPA marmosets into the five classes with a high accuracy of 88.0 % in terms of the macro F1-score, even when trained only on calls of UE marmosets. Furthermore, we examined whether the trained classifier helps analyze the call changes observed during marmoset development.

II. Deep-learning-based Classification of Marmoset Calls

Aiming to analyze the vocal development of UE and VPA marmosets, we train a marmoset call classifier to distinguish call types of not only UE marmosets but also VPA ones. Here, we briefly summarize how to collect training data for the classifier. After that, we describe the problem statement for the marmoset call classification and the analysis method including the network architecture of our classifier.

A. Data Collection

To train the marmoset call classifier, we use a dataset of marmoset calls recorded and annotated by the Ichinohe group at the National Center of Neurology and Psychiatry. The following is the recording procedure. We collected calls of 37 marmosets including 24 UE, 11 VPA, and two other types of marmosets. The recordings were conducted for each marmoset from the first week to the 20th week after birth. During each recording, a marmoset was individually housed in a birdcage in a soundproof room, and its calls were monaurally recorded for approximately 5 min using a recording device (Olympus LS-100) placed in front of the birdcage. Marmoset calls include frequency components higher than human audible ones. Therefore, we set the sampling frequency to 96 kHz with a bit depth of 24 bits. The recorded audio signals include not only marmoset calls but also incidental noises, such as the sounds produced when the marmosets step on the pet sheet on the birdcage floor or grasp the wire mesh. For this reason, we classified the recorded marmoset calls into 12 different call classes (*phee, trill, twitter, tsik, ek, ek-tsik, cough, cry, chatter, breath, phee-trill,* and *trill-phee*) and two additional classes (*unknown* and *no call*). If calls were unidentifiable by annotators, they were labeled as *unknown*. If no marmoset call was included in a time segment, it was labeled as *no call*. The duration of each call was also annotated manually.

B. Problem Statement

The problem that we tackle in this study is detecting time segments including marmoset calls from audio signals in our dataset and classifying them into a number of classes.

Although 14 different labels are assigned to the signals in our dataset, as an initial study of VPA marmoset call classification, we focus on three main classes among them, *phee*, *trill*, and *twitter*, which are often analyzed in related studies. Figure 1 shows an example of spectrograms for calls of the three classes. Audio signals labeled as *phee-trill* or *trill-phee* are ignored because they are difficult to distinguish from *phee* and *trill*, and we also omit utterances labeled as unknown. We treat the other eight call classes as *other calls*. For signals that do not include any calls, we classify them as a *no call*. As a result, we consider a five-class classification problem in which audio signals are classified into one of the above classes.

C. Analysis Methods

The marmoset audio signals are fed into a deep neural network (DNN) to estimate the class for each short time frame of approximately 10 ms. The classification process is illustrated in Fig. 2.

We utilize the spectrogram obtained by applying the STFT to an input acoustic signal as an input feature. For the STFT, we use a frame length of 2048 samples, a frame shift of 1024 samples, and the Hamming window as the window function. As a result, the size of input feature matrices is the number of frequency bins (1025) $\times$ the number of time frames (N).

TABLE I
PERFORMANCE EVALUATION OF CALL CLASSIFICATION ON THE UE SET

other calls	72.69 %	84.94 %	78.34 %

TABLE II
PERFORMANCE EVALUATION OF CALL CLASSIFICATION ON THE VPA SET

	recall	precision	F1-score
no call	99.07 %	98.45 %	98.76 %
phee	97.59 %	97.28 %	97.44 %
trill	87.58 %	85.65 %	86.60 %
twitter	96.49 %	97.37 %	96.93 %
other calls	44.78 %	92.63 %	60.38 %

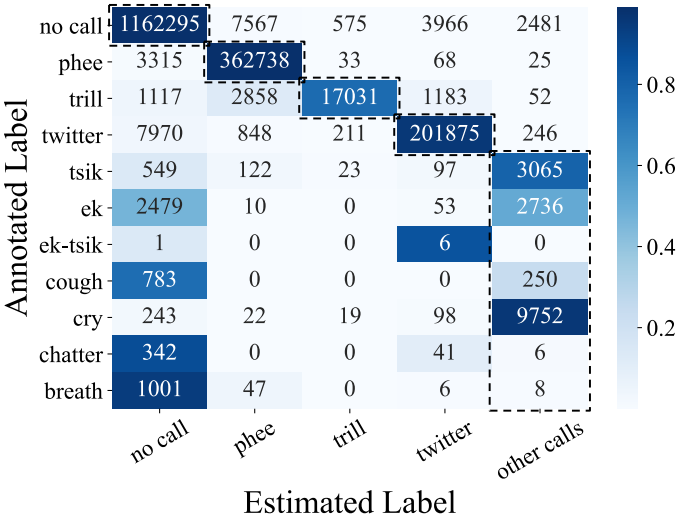

Fig. 4. Confusion matrix of classification results for the UE set (the estimated label of the *other call* class displayed the call types, *tsik, ek, ek-tsik, cough, cry*, and *chatter*, which belong to the annotated label)

The output of the classifier is a $5 \times N$ matrix, where the nth column in the matrix represents a call class as a five-dimensional one-hot vector for the nth short-time frame.

Since the marmoset call is generally longer than the length of the time frame, we employed a CNN. This network architecture can consider relationships among near-time frames. The CNN architecture and its hyperparameters are presented in Fig. 3.

A kernel size of 3×3 is utilized in the convolution layers, and three additional dilated convolution layers are employed to capture a wide range of temporal and spectral features. Furthermore, to enable framewise call classification, the network shown in Fig. 3 is designed to preserve the temporal size N of the feature maps. Specifically, the strides of the pooling layers are set to 1, and the padding widths of the convolution layers are determined on the basis of the kernel size and dilation rate, in order to maintain the output size.

III. EXPERIMENTAL EVALUATION OF CALL CLASSIFICATION

We conducted a numerical experiment to evaluate the performance of marmoset call classifiers that we trained. Here, we summarize the experimental conditions used and the results obtained.

A. Experimental Conditions

For the experiments, the dataset explained in Section II-A, consisting of UE marmosets recorded from the 3rd week to the 14th week of postnatal life, was divided into three subsets: training, validation, and test sets. The total signal lengths of the training, validation, and test subsets are 14 h 58 min 52 s, 3 h 20 min 2 s, and 5 h 24 min 27 s, respectively. Recordings and labels with deficiencies were excluded. The subsets consist of signals of 15, four, and five individuals, respectively.

The CNN model was trained using the training and validation subsets for learning analysis. To train the proposed CNN model, stochastic gradient descent was utilized as the optimization method, with an initial learning rate of 0.01 and a batch size of two. The model was trained for 100 epochs. Learning rate scheduling was also applied, which reduces the learning rate by a factor of 0.1 at the 50th and 75th epochs. The cross-entropy loss function was employed as the loss function.

To verify that the CNN trained only on the UE marmoset data can classify calls of VPA marmosets, the data from VPA marmosets (11 individuals, 11 h 21 min 13 s) were used solely for evaluation purposes.

B. Experimental Results

The performance of the proposed method on the UE set was evaluated using recall, precision, and F1-score, and the results are presented in Table I. Table I shows that the F1-scores for the *phee*, *trill*, and *twitter* classes are higher than that for the *other calls* class, which is 78.34 %.

Figure 4 displays the confusion matrix of the classification results on the UE set. The vertical axis represents the manually annotated labels, while the horizontal axis represents the labels estimated by the proposed method. Each element in the matrix represents the number of frames in which the label estimated by the proposed method corresponds to the annotated label. The background color of each element varies depending on the proportion it represents in each row. To examine the misclassification patterns in detail, the annotated labels are presented individually, without grouping *tsik, ek, ek-tsik, cough, cry, chatter*, or *breath* labels as *other calls*. The results show many correctly estimated frames along the diagonal, indicating accurate estimations for most frames.

Figures 5 and 6 show the spectrograms of a specific individual from the UE and VPA sets, along with the annotated and estimated labels for a 20 s segment. Although there are

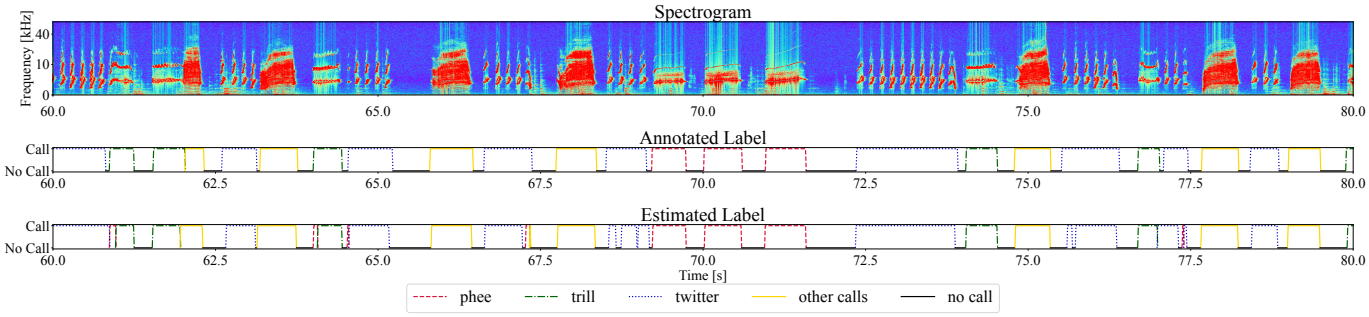

Fig. 5. Example of call classification results for the UE set (spectrograms of audio signals, annotated labels per time frame, and estimated labels)

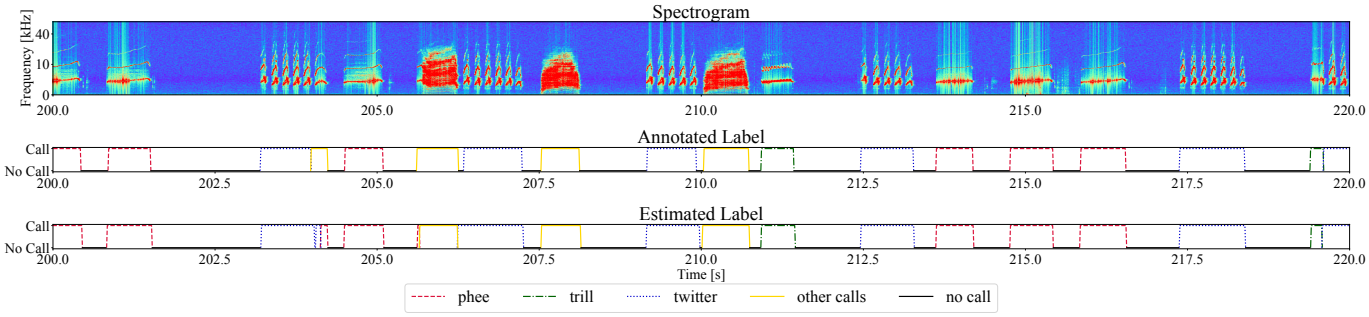

Fig. 6. Example of call classification results for the VPA set (spectrograms of audio signals, annotated labels per time frame, and estimated labels)

some misclassifications, it is evident that the classifications are generally accurate at the frame level.

The classification performance on the VPA set is presented in Table II. The results for the *phee*, *trill*, and *twitter* classes indicate that similar scores were achieved, as shown in Table I. This suggests that the proposed method can classify calls of VPA marmosets even when trained solely on the data of UE marmosets.

IV. Analysis of Vocal Changes Associated with Development

We examine whether our marmoset call classifier is helpful for analyzing changes in call proportions during marmoset development and for identifying differences between the calls of VPA and UE marmosets.

First, we analyze the changes in call patterns based on the annotated labels in the sets of UE and VPA individuals. The call labels considered here are the same as those described in Section III. Figure 7(a) represents the stacked bar graph of the proportion of each annotated label per frame over weeks for the UE Test individuals. Similarly, Fig. 7(b) shows the same graph for the VPA individuals. From Fig. 7(a) and Fig. 7(b), it can be observed that in both UE and VPA individuals, the proportion of *phee* calls increases with development. In contrast, *trill* and *twitter* calls tend to become less frequent. A comparison of UE and VPA data shows that VPA individuals have a higher proportion of *phee* calls than UE individuals. Furthermore, VPA individuals tend almost to cease *trill* calls with development.

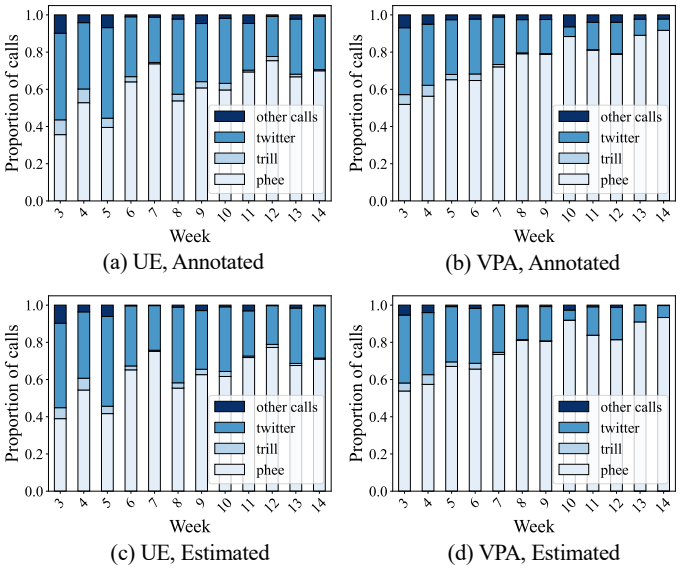

Fig. 7. Changes in proportion of calls for annotated and estimated labels by week (the UE set, the VPA set)

Figure 7(c) represents the stacked bar graph of the proportion of each estimated label per week for the UE Test individuals, obtained by applying the proposed method for call classification. Similarly, Fig. 7(d) shows the same graph for the VPA individuals. Comparing Figs. 7(c) and 7(d) with Figs. 7(a) and 7(b), we can see that even when using the proposed method to estimate call labels, the trends in call changes associated with development are still evident for both UE and

VPA individuals. This suggests that the proposed method will also be helpful for analyzing vocal development.

V. Conclusion

This study was aimed at developing a foundation for analyzing the developmental process of VPA marmosets by focusing on the automatic classification of marmoset calls. For marmoset call classification, marmoset audio signals were transformed into spectrograms by the STFT, and these spectrograms were used as acoustic features input to the CNN. The proposed method could classify four call types (*phee, trill, twitter*, and *other calls*) for each time frame by training the CNN on audio data from multiple individuals. Through objective evaluation experiments, high classification accuracy was confirmed.

Furthermore, it was found that even when training the deep learning model using only audio data from UE marmosets, high classification accuracy could still be achieved for the calls of VPA marmosets. Additionally, by comparing the annotated labels with the estimated labels for each developmental stage, it was determined that the proposed method will also be helpful for analyzing the vocal development of UE and VPA marmosets.

Future works include conducting individual-specific analyses of marmosets and exploring additional call labels not included in the current classification scheme, such as the *ek* and the *trill-phee* calls.

Cross-Domain adaptation in Distance Space for Speaker Verification

Lu YI and Man Wai MAK
The Hong Kong Polytechnic University, Hong Kong SAR, China
E-mail: lu-louisa.yi@connect.polyu.hk, enmwmak@polyu.edu.hk

***Abstract*—Significant performance degradation often occurs when a well-trained speaker verification system is applied to an unseen domain. Data augmentation and domain adaptation are two common approaches to tackling this problem. However, data augmentation would not be helpful when language mismatch rather than environment noise causes the domain shift. Domain adaptation also suffers from a label mismatch problem, making feature distribution alignment unreliable. We propose incorporating a distance metric space into model adaptation to address these issues. The idea is to align not only the embeddings across domains but also the distributions of their pairwise distances, resulting in embeddings tolerant to domain shift. To validate the idea, we used the non-Chinese utterances in VoxCeleb2 and the Chinese utterances in CN-Celeb2 as the source and target domain training data, respectively. Results show that the alignments reduce the EER on the CN-Celeb1 test set by 15.2%.**

Index Terms: Domain shift, speaker embedding, distance metric space, distance alignment

I. Introduction

Speaker verification (SV) has become a prevalent authentication method in remote services and financial transactions primarily because of its convenience and acceptable accuracy. However, the technology still has limitations under some practical scenarios. For example, an English system could fail when deployed to a Chinese environment, primarily due to the domain shift. Because collecting sufficient labeled data for all possible environments is time-consuming and labor-intensive, exploring more efficient and practical approaches to addressing domain shift is essential.

Domain mismatch and domain shift occur when speech data are collected from different acoustic environments or the speakers have various demography and speak different languages. Data augmentation can partly alleviate these problems. In particular, a wide variety of acoustic environments can be emulated by adding noise and reverberation to clean speech. However, if languages cause the domain shift, data augmentation would not be helpful. In this case, domain adaptation would be a better solution.

Most traditional approaches to domain adaptation adapt the PLDA models to fit the target data [1], [2]. However, the recent trend in speaker embedding is to train a speaker embedding network (the front end) and replace PLDA scoring with cosine distance scoring. Because the latter does not have any parameters for adaptation, all adaptations must be performed on the front-end network. Alternatively, we may adopt a training strategy that enables the network to find an embedding space that works well across different domains. Previous attempts in this line of thought align the embedding vectors across multiple domains by minimizing the inter-domain cosine distances or maximum mean discrepancy (MMD) [3], [4]. More recent research applied adversarial learning to extract domain-invariant features [5]–[7]. However, aligning the distributions of embedding vectors across domains without losing speaker discrimination requires the domains to have a common set of speakers (or at least many speakers have speech in all domains). Unfortunately, this requirement is not achievable in practice. To tackle this problem, Mekhazni et al. [8] proposed aligning the pairwise dissimilarity between domains for person re-identification. Inspired by this idea, Han and Song [9] found that within-speaker and between-speaker can be considered classes, eliminating the need for the source and target domains to share the same set of speakers. Then, the distributions of the within-speaker distances from different domains can be aligned, and similarly for the distributions of the between-speaker distances.

Motivated by [8] and [9], we propose incorporating the idea of aligning the within- and between-speaker distance distributions into the domain adversarial neural network (DANN) [10] and the domain separation and adaptation network (DSAN) [11]. The DSAN can disentangle the domain-specific and domain-invariant speaker features, ensuring that the domain-invariant features contain fewer redundant features. However, the original DANN and DSAN only focus on feature alignments, which may align speaker distributions instead of domain distributions, causing even higher speaker confusion. Different from [9], the extended DANN and DSAN in this paper align the feature distributions and the within- and between-class distance distributions, resulting in more robust and discriminative speaker embeddings. Our experimental results on the CN-Celeb dataset demonstrate the effectiveness of combining feature and pair-wise distance distribution alignments for domain adaptation.

II. Methodology

In speaker verification, aligning the feature distributions between multiple domains cannot produce domain-invariant speaker discriminative features because different domains have different speaker sets. The feature alignment may just be speaker alignment rather than domain alignment. To tackle this problem, we propose introducing pairwise-distance distribution

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

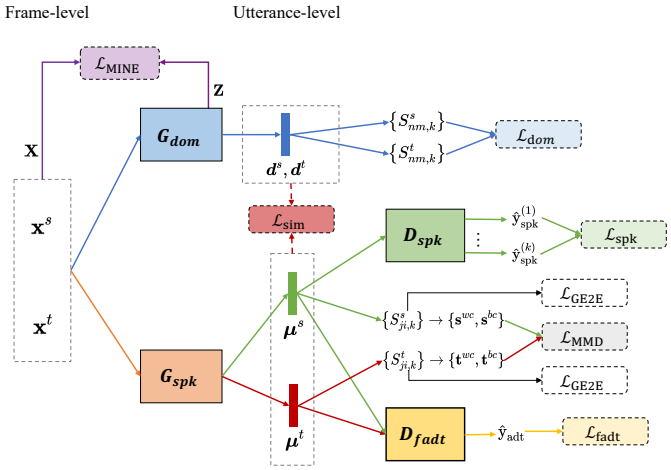

Fig. 1: Overview of the proposed domain separation and adaptation network (DSAN) with both feature distribution alignment and pairwise-distance distribution alignment.

alignment to the domain separation and adaptation network (DSAN) [11], as Fig. 1 shows.

Denote a labelled dataset from the source domain $\mathcal{D}^s$ as $\mathbf{X}^s = \{(\mathbf{x}_i^s, y_i)\}_{i=1}^{N_s}$, and an unlabelled dataset from the target domain $\mathcal{D}^t$ as $\mathbf{X}^t = \{\mathbf{x}_i^t\}_{i=1}^{N_t}$. The domain-specific features ($\boldsymbol{d}^s$ and $\boldsymbol{d}^t$) and domain-invariant features ($\boldsymbol{\mu}^s$ and $\boldsymbol{\mu}^t$) are extracted from the domain feature extractor G_{dom} and G_{spk}, respectively.

A. Domain-Invariant Speaker Features

To make the domain-invariant features speaker discriminative, AM-softmax loss [12] and generalized end-to-end (GE2E) loss [13] are adopted:

$$\mathcal{L}_{spk} = -\frac{1}{T}\sum_{i=1}^{T}\log\frac{e^{s\cdot\left(\cos\theta_{y_i}-m\right)}}{e^{s\cdot\left(\cos\theta_{y_i}-m\right)}+\sum_{c=1,c\neq y_i}^{C}e^{s\cdot\cos\theta_c}}, \tag{1}$$

where T denotes the batch size, s is the scaling factor, m is the margin, y_i denotes the speaker label of the i-th segment, and C is the total number of speakers from the source domain.

For the GE2E loss, we assume that each batch has $N^u \times M^u$ utterances, where N^u is the number of speakers and M^u is the number of utterances per speaker. Denote $\boldsymbol{\mu}_{ji}$ (which can be $\boldsymbol{\mu}^s$ or $\boldsymbol{\mu}^t$ in Fig. 1) as the domain-invariant features extracted from the i-th utterance of the j-th speaker. The centroids of the embedding vectors for the j-th speaker can be obtained by [13]:

$$\mathbf{c}_j = \frac{1}{M^u}\sum_{m=1}^{M^u}\boldsymbol{\mu}_{jm} \tag{2}$$

or

$$\mathbf{c}_j^{(-i)} = \frac{1}{M^u-1}\sum_{\substack{m=1\\m\neq i}}^{M^u}\boldsymbol{\mu}_{jm}. \tag{3}$$

Then, the similarity matrix between the embedding vectors $\boldsymbol{\mu}_{ji}$'s to all centroids is

$$S_{ji,k} = \begin{cases} w\cdot\cos\left(\boldsymbol{\mu}_{ji}, \mathbf{c}_j^{(-i)}\right)+b & \text{if } k=j \\ w\cdot\cos\left(\boldsymbol{\mu}_{ji}, \mathbf{c}_k\right)+b & \text{otherwise} \end{cases}, \tag{4}$$

where j and k index speakers and w and b are learnable parameters. Therefore, the GE2E loss is defined as:

$$L_{\text{GE2E}} = \frac{1}{N^u M^u}\sum_{j,i}\left(-S_{ji,j}+\log\sum_{k=1}^{N^u}\exp\left(S_{ji,k}\right)\right). \tag{5}$$

1) Feature Distribution Alignment: To explore the common features across multiple domains, we train G_{spk} adversarially to align the feature distributions. Specifically, the feature adaptation network D_{fadt} is trained to distinguish whether the speaker features come from the source domain or the target domain, while the speaker feature extractor G_{spk} is trained to produce domain-invariant features to confuse the D_{fadt}. Therefore, G_{spk} and D_{fadt} are trained with the following minimax loss:

$$\begin{aligned}\min_{G_{\text{spk}}}\max_{D_{\text{fadt}}}\mathcal{L}_{\text{fadt}} &= \mathbb{E}_{\mathbf{x}^s\sim\mathcal{D}^s}\left[\log D_{\text{fadt}}\left(G_{\text{spk}}\left(\mathbf{x}^s\right)\right)\right] \\ &+ \mathbb{E}_{\mathbf{x}^t\sim\mathcal{D}^t}\left[\log\left[1-D_{\text{fadt}}\left(G_{\text{spk}}\left(\mathbf{x}^t\right)\right)\right]\right].\end{aligned} \tag{6}$$

2) Pairwise Distance Distribution Alignment: As discussed in Section 1, only aligning the feature distributions may not truly learn domain-invariant features because of the label mismatch between the source and target domains. To address this problem, we also train G_{spk} to align the similarity matrices (Eq. 4) obtained from the source and target domains. Denote $\mathbf{s}^{wc}$ and $\mathbf{s}^{bc}$ as the source domain's within-class and between-class distance vectors, respectively. The elements of $\mathbf{s}^{wc}$ and $\mathbf{s}^{bc}$ are obtained from the first and second lines of Eq. 4, respectively, as Fig. 2 shows. Similarly, we denote $\mathbf{t}^{wc}$ and $\mathbf{t}^{bc}$ as the within-class and between-class distance vectors from the *target* domain. One advantage of using the similarity matrix (Eq. 4) is that it can save computation.

Given many similarity matrices (one for each utterance), we may consider the distance vectors as random vectors generated from some distributions. We use maximum mean discrepancy (MMD) [14] to measure the distance between the distributions from the source and target domains:

$$\begin{aligned}\text{MMD}(p(\mathbf{s}), p(\mathbf{t})) &= \frac{1}{{T_s}^2}\sum_{n=1}^{T_s}\sum_{m=1}^{T_s}k(\mathbf{s}_n, \mathbf{s}_m) \\ &+ \frac{1}{{T_t}^2}\sum_{n=1}^{T_t}\sum_{m=1}^{T_t}k(\mathbf{t}_n, \mathbf{t}_m) \\ &- \frac{2}{T_s T_t}\sum_{n=1}^{T_s}\sum_{m=1}^{T_t}k(\mathbf{s}_n, \mathbf{t}_m),\end{aligned} \tag{7}$$

where T_s and T_t are the numbers of samples from the source and target domains in a mini-batch, respectively, and $k(.,.)$ is a kernel. A mixture of radial basis function (RBF) kernels was

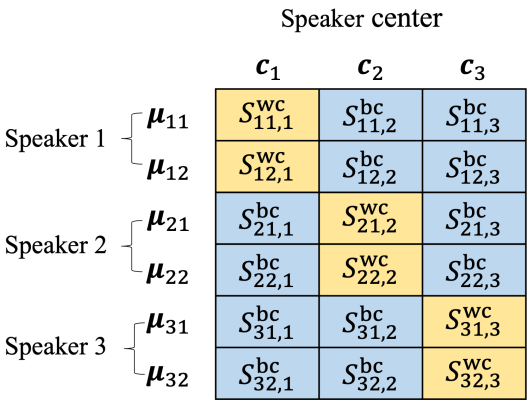

Fig. 2: Extracting $\mathbf{s}^{wc}$ and $\mathbf{s}^{bc}$ from the similarity matrix $\{S_{ji,k}\}$, where $j,k = 1,\ldots,3$ and $i = 1,2$, by stacking the gold and blue elements, respectively.

applied, i.e., $k(\mathbf{x},\mathbf{y}) = \sum_{q=1}^{K} \exp\left(-\frac{1}{2\sigma_q^2}\|\mathbf{x}-\mathbf{y}\|^2\right)$. Note that vectors $\mathbf{s}$ and $\mathbf{t}$ can be either within-class (wc) or between-class (bc) distance vectors. The loss function for distance distribution alignment is

$$\begin{aligned}\mathcal{L}_{\text{MMD}} = \text{MMD}(p(\mathbf{s}^{wc}), p(\mathbf{t}^{wc})) \\ + \text{MMD}(p(\mathbf{s}^{bc}), p(\mathbf{t}^{bc})).\end{aligned} \tag{8}$$

B. Domain-Specific Features

Instead of using a discriminator to distinguish the domain-specific features ($\mathbf{d}^s$ and $\mathbf{d}^t$ in Fig. 1), the proposed network leverages the similarity matrices in Eq. 4 to make these features distinguishable between domains. The loss has the same form as Eq. 5, except that G_{dom} is trained to produce domain-specific features close to the centroid of their respective domain and far away from the centroids of other domains.

Assume that there are $N^d \times M^d$ utterances in a batch, where the utterances are from N^d domains and each domain has M^d utterances. The feature vector $\mathbf{d}_{nm} (1 \le n \le N^d \text{ and } 1 \le m \le M^d)$ represents the domain-specific features extracted from the m-th utterance of the n-th domain. To extract domain-specific features, we train G_{dom} to minimize the loss:

$$\mathcal{L}_{\text{dom}} = \frac{1}{N^d M^d} \sum_{n,m} \left(-S_{nm,n} + \log \sum_{k=1}^{N^d} \exp\left(S_{nm,k}\right) \right), \tag{9}$$

where $\{S_{nm,k}\}$ are obtained by replacing $\boldsymbol{\mu}$ by $\mathbf{d}$ in Eq. 4 and replacing $\mathbf{c}$ and $\mathbf{c}^{(-1)}$ by the centroids of $\mathbf{d}$'s.

In addition, a mutual information neural estimator (MINE) is introduced, as proposed in [11], to maximize the mutual information between the frame-level domain features and the input acoustic features. The objective of adding MINE is to ensure that the domain-specific features $\mathbf{d}^s$ and $\mathbf{d}^t$ are meaningful, i.e., they learn useful domain information from speech. The MINE loss is defined as

$$\mathcal{L}_{\text{MINE}} = -\text{MINE}(\mathbf{X}, \mathbf{Z}), \tag{10}$$

where $\mathbf{X}$ and $\mathbf{Z}$ contain acoustic vectors and frame-level domain representation (before statistics pooling) of an utterance or a speech segment. Note that $\mathbf{X}$ and $\mathbf{Z}$ can be from the source or target domain.

MINE was initially proposed by Belghazi *et al.* [15] to approximate the information shared between random variables. However, we used a MINE based on the Jensen-Shannon divergence [16] instead of the KL divergence.

Apart from finding the domain-specific and domain-invariant features, we need to disentangle the domain-specific features from the speaker features. To achieve this, we introduce a constraint to make the speaker embeddings ($\boldsymbol{\mu}$) and the domain embeddings ($\mathbf{d}$) different, i.e., contain less mutual information. This goal can be achieved by minimizing a similarity loss:

$$\mathcal{L}_{\text{sim}} = \text{MINE}(\boldsymbol{\mu}^s, \mathbf{d}^s) + \text{MINE}(\boldsymbol{\mu}^t, \mathbf{d}^t), \tag{11}$$

where $\text{MINE}(a,b)$ is the MINE between the distributions of a and b [16]. G_{dom} and G_{spk} are trained to minimize $\mathcal{L}_{\text{sim}}$.

C. Overall Optimization

The overall objective of the proposed model is

$$\begin{aligned}\min_{G_{\text{dom}},G_{\text{spk}},D_{\text{spk}},T_\theta} \max_{D_{\text{fadt}}} \mathcal{L}_{\text{spk}} + \mathcal{L}_{\text{GE2E}} + \mathcal{L}_{\text{fadt}} + \lambda\mathcal{L}_{\text{MMD}} \\ + \mathcal{L}_{\text{dom}} + \mathcal{L}_{\text{MINE}} + \mathcal{L}_{\text{sim}},\end{aligned} \tag{12}$$

where T_θ is a MINE neural network parameterized by θ. λ is a hyper-parameter controlling the contribution of a sub-loss to the total loss, and we set it to 1 in the experiments. Noted that $\mathcal{L}_{\text{spk}}$ uses supervised learning, so only source domain data $\mathbf{x}_s$ is contributed to this loss.

III. Experimental Setting

A. Datasets

We used two datasets from different languages to perform domain adaptation. The source domain data comprises utterances from the development set of VoxCeleb2 [17], and the target domain data contains utterances from CN-Celeb2 [18]. There are 5950 speakers from the source domain, where most of the utterances are in English, and the Chinese utterances were removed. For the target domain data, around 1996 Mandarin speakers were used for training the domain adaptation models without using their speaker labels. Since CN-Celeb covers 11 genres, such as singing, speech, interview, movie, and so on, we considered them 11 domains when training the DSAN. In other words, we further divided the target domain data into 11 sub-domains according to the speech genres, i.e., $N^d = 11$ in Eq. 9. This division of domains is helpful in domain-specific feature extraction. No data augmentation was applied when training the domain adaptation models.

We evaluate the performance on the Voxceleb1 evaluation set [19] and the CN-Celeb1 evaluation set [20].

B. Data Preprocessing

For all audio files, 40-dimensional filter-bank features were extracted using Kaldi, with a 25ms window and 10ms frame shift, and the silence frames were removed using Kaldi's energy-based voice activity detector (VAD).

C. Implementation Details

Due to the complexity of the DSAN, we used a lightweight TDNN [21] instead of the bulky ECAPA-TDNN [22] as the backbone to reduce computation cost. G_{spk} has one fully-connected (FC) layer with 256 nodes after the statistics pooling layer, while D_{spk} comprises one FC layer with 64 nodes and a softmax output layer. The domain feature extractor G_{dom} shares the same layer structure and initial weights with G_{spk}. The adaptation network D_{fadt} has two FC layers with 256 nodes in each layer. The mutual information neural estimator (MINE) is a three-layer FC network with 512 nodes in each layer. The dimension of domain-specific embeddings $\mathbf{d}$'s is 64, while that of the speaker embeddings $\boldsymbol{\mu}$'s is 256.

The batch size is 1024, with 512 from the source domain and 512 from the target domain. Each batch has 128 speakers with four utterances per speaker from the source domain data. For the target domain data, each batch contains eight different genres with 16 utterances per genre and four chunks per utterance. Since we cannot access the speaker labels in the target domain, we considered segments sampled from the same utterance to be from the same speaker, and segments from different utterances to be from different speakers. As a result, the speaker classification in Eq. 5 was minimized in a self-supervised manner. For source domain data, we used Eq. 1 to compute the speaker classification loss.

A lightweight TDNN, which can be considered as the combination of G_{spk} and D_{spk}, was pre-trained using the source domain data (VoxCeleb2) with the additive margin softmax (AM-softmax) loss. The scaling factor s and the margin m in Eq. 1 are 30 and 0.2, respectively. The pre-trained model was then used to initialize G_{dom}, G_{spk}, and D_{spk}. An SGD optimizer with an initial learning rate of 0.01 was used to train the pre-trained and other models. For adversarial training (Eq. 6), we followed the training strategy in [10] by increasing the hyperparameter of the gradient reversal layer from 0 to 1 during training.

Probabilistic linear discriminant analysis (PLDA) [23] was used as the backend for scoring. Before PLDA training, LDA was applied to project the speaker embeddings onto a 150-dimensional space. We used the development set of VoxCeleb2 and the training set of CN-Celeb2 to train the PLDA backend, respectively. The former setting meets the condition of unsupervised domain adaptation (UDA), i.e., no access to the labels of the target domain. Although the latter setting slightly violates the UDA condition, it allows us to compare with the results of [24] and [25].

IV. Results and Discussions

We first compare the results of different models on the CN-Celeb1 evaluation set in the unsupervised setting, as Table I shows. The first four rows show the performance of the baseline models trained with different training sets. The front-end models trained with VoxCeleb2 perform better than the ones trained with CN-Celeb2, and data augmentation can help improve the performance slightly. The performance improved when training the front-end models with VoxCeleb2 and CN-Celeb2 (Rows 4 and 5). Row 5 shows the results obtained from a TDNN-based model trained with self-supervised fine-tuning using VoxCeleb2 and CN-Celeb2 as the training set. These promising results suggest that combining two different datasets extends the diversity of speech samples, encouraging the TDNN model to find more robust speaker embeddings.

The domain adaptation models, DANN and DSAN, were initialized using the parameters of the TDNN model from Row 1. Each DANN model comprises G_{spk}, D_{spk} and/or D_{fadt} in Fig. 1. If focusing only on the feature distribution alignment (Row 6), the performance is even worse than the baseline. This may be due to the negative transfer, meaning that the network cannot leverage the knowledge from the source domain to explore discriminative speaker features in the target domain. This result is consistent with our previous statement that only aligning the feature distributions would not be helpful in open-set domain adaptation. Row 7 shows the results from a DANN system that only considers the pairwise-distance distribution alignment. The results demonstrate the effectiveness of distance metric adaptation. However, the performance can be further improved when training the DANN with both kinds of alignments (Row 8). This suggests that with the constraint of distance metric alignment, the feature distribution alignment can bring a positive transfer from the source domain to the target domain.

Most domain adaptation techniques only focus on finding the common features while ignoring the domain-specific features. However, our results in Rows 9-11 demonstrate that finding the domain-specific features (Section II-B) is essential. Though the label sets of the source and target domains are different, robust speaker embeddings can be obtained by exploring the domain-specific features (the speech genres in our case). The performance is even better if we incorporate the pairwise distance distribution alignment into the DSAN models, as Row 11 shows. These positive results show that aligning the distance metrics across multiple target domains and considering the domain-specific features can help find more invariant and discriminative speaker features.

Although no domain adaptation is needed when the evaluation data are from the source domain, except for Row 8, the performance is even better after domain adaptation, demonstrating the robustness of the proposed DA method.

Table II demonstrates the performance of the CN-Celeb1 evaluation set in the supervised DA setting, i.e., using the target domain data (CN-Celeb2) to train the backend models. The DSAN with PDA can outperform the model with entirely supervised learning (Row 4). This further suggests that learning domain invariant speaker embeddings can enhance speaker verification. We also compare our results with other well-

TABLE I: Performance on the VoxCeleb1 evaluation set and CN-Celeb1 evaluation set in the unsupervised domain adaptation setting. For comparison, we also trained a DANN [10], which can be considered as the lower part of Fig. 1. The domain adaptation networks were trained to conduct feature alignment (FA) or/and pairwise distance distribution alignment (PDA).

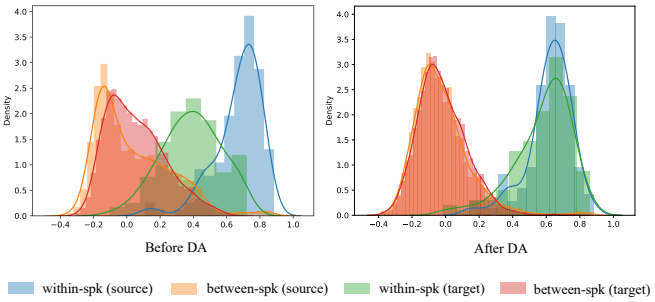

Fig. 3: Visualization of pairwise distance distributions.

established unsupervised domain adaptation baselines (Rows 6 and 7), which further demonstrate the effectiveness of our proposed DSAN model.

The basic assumption of applying the distance metric alignment is that the pairwise distance distributions will differ when employing a well-trained system on an unseen domain. We plot the distance distributions derived from a well-trained TDNN model (Row 1) to verify this assumption, as the left figure in Fig. 3 shows. It can be observed that the within-class distance distribution of the target domain is different from that of the source domain. There is a significant overlap between the within- and between-speaker distance distributions, indicating that the speaker vectors from different speakers are intertwined. After domain adaptation, the distributions of the target domain become similar to those of the source domain, as the right figure in Fig. 3 shows. The less overlapping between the within- and between-speaker distributions suggests that more discriminative speaker embeddings are produced.

V. Conclusions

In this paper, we propose aligning both feature and pairwise-distance distributions to produce domain-invariant speaker embeddings. We applied this idea to a domain adversarial neural network and our proposed domain adaptation and separation network. Our experiments demonstrate that the adaptation in a distance metric space helps find domain-invariant features for open-set domain adaptation tasks. The combination of feature distribution alignment and pairwise-distance distribution alignment can help find more speaker discriminative and domain invariant features.

***Abstract*— With the negative impact of noise pollution on human health and well-being, distributed wireless sensor network with edge devices like Jetson Nano as the centre of the network for noise data classification is an effective approach to urban noise monitoring. However, most classification systems were not developed for edge computing or did not include timing performance as a metric during development. The weaknesses can limit edge computing devices' real-time ability, stability, etc. This study addresses the weaknesses by proposing a classification system using MFCC and CNN-LSTM for Jetson Nano's low-latency computation. We consider both accuracy and timing performance as critical metrics in this study. The proposed approach is based on MFCC with a window length of 0.128 seconds and overlap of 50%, classified by a CNN-LSTM trained with 30% dropout probabilities, which has obtained an accuracy of 94.94% and an execution time of 35 ms to classify 6.144 seconds audio at an audio segment length of 1.024 seconds on a Jetson Nano. The experiment demonstrates that the proposed system has outstanding accuracy and timing performance compared to the existing urban sound classification systems.**

Keywords—CNN, Jetson Nano, LSTM, Sound Classification, Urbansound8k

I. INTRODUCTION

Urban noise monitoring, including noise classification, has become increasingly important due to the negative impact of noise pollution on human health and well-being. Excessive noise levels in urban areas can lead to hearing impairment, sleep disturbance, cardiovascular diseases, and other health problems [1]–[4]. Thus, monitoring and controlling noise levels in urban areas have become essential for maintaining a healthy living environment.

A distributed wireless acoustic sensor network (WASN) approach can be used in noise monitoring systems, where edge devices like the Jetson Nano can be deployed as the centre of the sensor network for classifying noise data from sensors. Jetson Nano is compact, low-power, and capable of processing data at low latency, making them ideal for monitoring noise levels in urban areas. Using machine learning algorithms and GPU acceleration, Jetson Nano can categorise noise at high speed.

Therefore, we propose a classification system based on the Mel-scale frequency cepstral coefficients (MFCC) feature and convolutional neural networks-long short term memory (CNN-LSTM) model for urban noise classification on Jetson Nano. The system is designed to provide low-latency noise classification, enabling quick responses to noise-related issues.

In this study, our main contributions include:

- A classification system based on MFCC and CNN-LSTM is proposed to give Jetson Nano a fast and highly accurate noise classification capability.
- Experiments and comparisons are conducted to evaluate the accuracy and timing performance of different feature extraction methods, classifiers, and parameters.

The work is organised as follows. Section II briefly introduces work related to our study. A detailed description of the dataset preparation, the proposed classifier, and the experiment settings are given in Section III. In Section IV, the experimental results are given. Finally, the paper is concluded in Section V.

II. RELATED WORK

Urban noise classification is a well-researched field, with researchers investigating various classification systems using different features and classifiers. Dong et al. achieved a 94.97% accuracy using log-Mel spectrogram and raw audio classified by 2D and 1D CNN, respectively, followed by network fusion [5]. Su et al. proposed a fused two-stream CNN network, called TSCNN-DS, to classify fused-feature input, which included MFCC, log-Mel spectrogram, chroma, spectral contrast, and Tonnetz. This system achieved 97.2% accuracy on the UrbanSound8k dataset [6]. Das et al. improved the accuracy to 98.81% using MFCC and chroma short-time Fourier transform (STFT) features classified by LSTM with data augmentation, and the result was 93.76% without augmentation [7].

However, the systems mentioned above with ultra-high accuracy were not explicitly designed for edge computing devices. Besides, some of them used fused features and/or models to achieve better accuracy, which may impose a computational burden on edge devices. Vidaña-Vila et al. used Raspberry Pi to classify the spectrogram by SqueezeNet18 and obtained 80.1% accuracy [8]. Shah et al. got 88% accuracy in classifying spectrogram from European Broadcast Union normalised audio with CNN on Raspberry Pi [9]. Furthermore, Maijala et al. classified MFCC by Artificial Neural Network using Raspberry Pi and obtained 93.8% accuracy [10]. These classification systems are more lightweight than the previously introduced systems for running on an edge device, with lower cost and classification accuracy.

Although these studies worked on running classification models with edge devices, they still considered accuracy the most critical metric but ignored the execution efficiency during

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

development. This renders their study insufficiently convincing, given that classification systems with higher accuracy rates are already available. In addition, few studies explored the effects of the different number of feature vectors included in each feature segment as classifier inputs on accuracy and classification timing performance. Therefore, it is necessary to develop a classification system for edge devices that considers the accuracy and timing performance as evaluation metrics and addresses the weaknesses mentioned above.

III. METHODOLOGY

A. Dataset

The most well-known datasets for noise classification include UrbanSound8K, ESC-50, and NoiseX92. UrbanSound8K contains 8732 labelled slices of audio in ten classes commonly found in urban areas; ESC-50 has 2000 slices of audio in 50 classes; NoiseX92 has fifteen audios, and each audio records a type of sound. Many studies, such as [7], have indicated that a more extensive dataset leads to a better result in deep learning models, so UrbanSound8K is the best of the three datasets totalling 8 hours and 45 minutes audio length, compared to ESC-50 with 2 hours 46 minutes and NoiseX92 with 57 minutes. Thus, we use UrbanSound8K for training and testing classification models. The ten classes in this dataset are air conditioners, car horns, children playing, dog bark, drilling, engine idling, gunshot, jackhammer, police sirens, and street music.

Audio slices in UrbanSound8K have a sampling rate of 44.1 kHz. Since the classification system running as a part of WASN samples sounds at 8 kHz, the dataset needs to be downsampled to match the system's real-world conditions. We concatenate the resampled UrbanSound8k audios according to classes in random order into ten audios, followed by manually seeking and removing the silence and wrong labelled segments. The corrected UrbanSound8K dataset has an audio length of 7 hours and 12 minutes. Then, the dataset is scaled using the following equation

$$x' = \frac{x}{\max(\mathrm{abs}(x))}, \tag{1}$$

where x is the raw audio waveform and x' is the new audio waveform. Hence, the maximum absolute value in this dataset is 1, which is consistent with the real scenarios. Then, each audio is segmented into the training, validation, and testing datasets in a ratio of 8:1:1. We normalise the training dataset using Z-score normalisation, as in

$$Z_{train} = \frac{x'_{train} - \mu_{train}}{\sigma_{train}}, \tag{2}$$

where x'_{train}, μ_{train}, and σ_{train} represent the training dataset, the training dataset's mean value, and the standard deviation, respectively. Finally, we obtain normalised validation and testing datasets using the following equation

$$Z_{validation/test} = \frac{x'_{validation/test} - \mu_{train}}{\sigma_{train}}. \tag{3}$$

B. Features Extraction

Considering the classification system is expected to run on a Jetson Nano which has a limited computation power, the feature extraction process should be less time-consuming, and the extracted features should be as abstract as possible. The more abstract feature can express sound information with fewer coefficients to reduce the burden on the classifiers. According to this guideline, spectrograms, including Mel and log-Mel spectrograms, are not considered as they usually have more than 128 coefficients in each feature vector. We select four static features that conducted good classification accuracy in previous studies, which are MFCC, perceptual linear prediction cepstral coefficients (PLPCC), Gamma-PLP cepstral coefficients (Gamma-PLPCC), and Gamma-cepst coefficients (Gamma-CC). Each window is represented by a 16-coefficient static feature vector.

Studies such as [11]–[13] have proven that using static features alone is not robust enough, especially with low-SNR sounds, compared to the combination of static features and dynamic features (first and second derivatives of the static features). The first derivative of a static feature vector is typically defined as

$$d_t = \frac{\sum_{k=1}^{K} k(c_{t+k} - c_{t-k})}{2\sum_{k=1}^{K} k^2}, \tag{4}$$

where d_t represents the t-th coefficient, c_t represents the t-th static coefficient, and K represents the maximum interval to consider, which is 2 in this paper. The second-derivative vector can be obtained by substituting the first-derivative feature vector back to (4). Thus, each window can be represented with a 48-

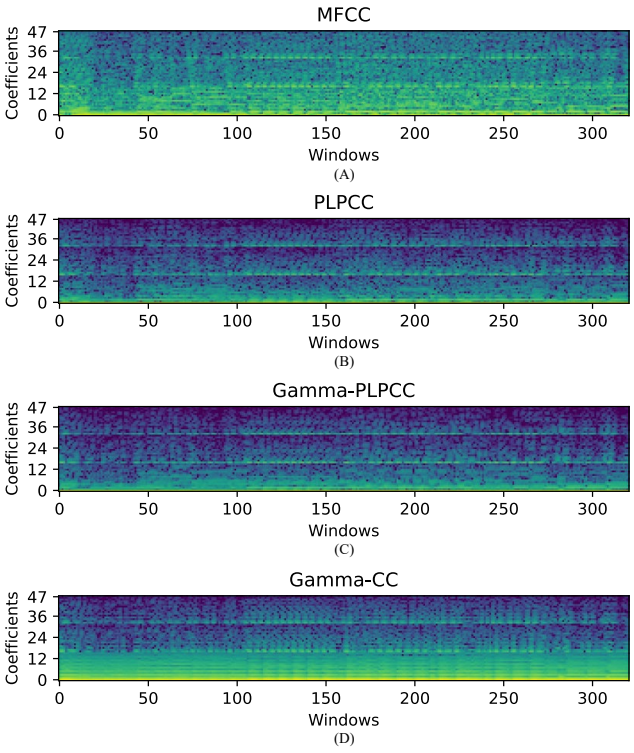

Fig. 1. Features extracted from dog-bark audio.

coefficient feature vector when the dynamic feature vector (first and second derivatives) is attached to the static feature vector.

1) MFCC (Fig. 1 (A)): MFCC is a popular and easy-to-calculate feature with good performance often used in speech recognition [14] by simulating the behaviour of human perception. Human perception of frequency is not linear and is more sensitive to low-frequency than high-frequency signals. Hence the Mel scale, a non-linear transformation of frequency, allows people to perceive signals with the same frequency difference almost equally well.

2) PLPCC (Fig. 1 (B)): Hermansky proposed PLP in 1990 based on LP because LP has the main flaw beyond 800 Hz where the spectral resolution disagrees with human hearing [15]. Unlike MFCC, which uses Mel scale filter banks, PLP uses Bark scale filter banks to simulate human hearing behaviours. Methods for computing PLPCC have been proposed in [16]–[18], which are by cepstral recursion based on the PLP results.

3) Gamma-PLPCC (Fig. 1 (C)) and Gamma-CC (Fig. 1 (D)): Gamma-PLP and Gamma-CC are proposed by Abdulla [19], which are based on Gammatone filter banks. When an external speech signal enters the cochlea's basilar membrane, it is decomposed according to frequency and produces a travelling wave vibration that stimulates the auditory receptor cells. Gammatone filters are a set of filter models that simulate the cochlea's frequency decomposition characteristics and simulate the acoustic performance of the human ear by modelling the cochlea and auditory stimuli [20]. Gamma-PLPCC is obtained from Gamma-PLP with cepstral recursion.

C. Classifiers

1) GMM: Gaussian mixture model (GMM) can be considered as a model consisting of a certain number of single Gaussian models, which are the mixture model's hidden variables. A mixture model can generally use any probability distribution, but the Gaussian distribution is chosen because it has good mathematical properties and computational performance. GMM can be described as a clustering algorithm where each cluster is modelled according to different Gaussian distributions, and any distribution with the corresponding probability may generate each data point.

2) ResNet18: We made some changes to ResNet18 to make it fit the features. Since each window is represented by a feature vector containing 48 coefficients that are highly abstract, we removed the max pool layer at the beginning of ResNet18 to ensure no coefficient is abandoned. Additionally, the convolutional layers are modified to work similarly to 1D layers along each feature vector (e.g., kernel size of (3, 1)) to process an input vector by vector. The average pool before the fully connected layer is kept for converting the data shape to 512*1*1.

3) ShuffleNetV2 1x: Similar to the modifications made on ResNet18, we removed the max pool layer and modified convolutional layers in ShuffleNet V2 for noise classification.

4) CNN-LSTM (proposed): Different to GMM and pure CNN models, CNN-LSTM considers the temporal relationship between feature vectors and has been proven by many studies to provide excellent classification accuracy. Since we use highly abstract features that barely include temporal information within each feature vector, the temporal relationship between vectors

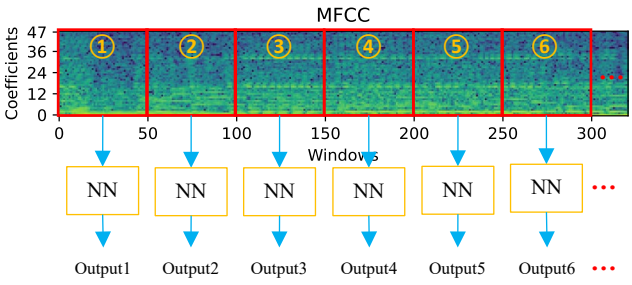

Fig. 3. Example of NNs inputs and outputs

can be critical for classification. Therefore, we propose a CNN-LSTM-based classifier (structure shown in Fig. 2) for classifying 48 coefficient-per-vector feature segments. The classifier contains 5 convolutional blocks, 2 LSTM layers, and a fully connected layer. TABLE I shows a detailed description of the classifier where "n" is the number of feature vectors in each input (feature segment) which should be greater than 1. The dropout probability at the dropout layer is set to 30% as the default unless otherwise stated.

D. Classifier Compilation in Training

1) Programming language and libraries: In its years of development, Python has provided convenient programming capabilities for numerous fields, including machine learning. Hence, we use Scikit-learn and PyTorch in Python to construct GMM and neural networks (NNs), respectively. We utilise the PyTorch with the GPU-supported version to speed up the NN computations to improve timing performance.

2) The Classifier inputs: The inputs for the classifiers, namely NNs like ResNet, ShuffleNet, and CNN-LSTM, are shaped as (1, 48, n), where "48" stands for the number of coefficients in each feature vector, and "n" represents the number of vectors in each feature segment. Fig. 3 illustrates an example of using MFCC, where each feature segment, shown by a red box, makes up 50 feature vectors representing 50 windows. Therefore, the inputs for NNs have a shape of (1, 48, 50).

The feature is calculated with a window length of 0.256 seconds and a hop length of 0.128 seconds. As a result, each feature segment is an audio segment of approximately 6.4 seconds, calculated as 0.128 seconds multiplied by 50. To represent audio segments of different lengths, we can calculate the number of vectors in each feature segment, denoted by "n", using the equation

$$n = \text{ceil}\left(\frac{L_s}{L_h}\right), \tag{5}$$

where L_s, L_h, and n represent the audio segment length, hop length, and number of vectors in each feature segment, respectively.

Unlike NNs, the GMM inputs are a sequence of independent feature vectors having a minimal number of coefficients to avoid problems such as the curse of dimensionality, computational complexity, and data sparsity. Therefore, each input in the GMM modelling is introduced by one feature vector, i.e., 48 coefficients.

3) Settings in NN training:

- Loss function: Cross entropy is used as the loss function, considering it can penalise a model more heavily for making larger errors in predicting the wrong class probabilities.
- Optimiser: We use Adam with 1e-4 weight decay as the optimiser. Adam can adjust learning rates adaptively to make changes on each parameter. We will use 1e-4 weight decay to balance the overfitting and accuracy of the models.
- Learning rate and decay: 1e-2 is set as an initial learning rate of Adam. Even though Adam can adjust the learning rate, we halve the learning rate manually when the validation accuracy is not increased for two epochs.
- Metric: We use accuracy as the evaluation metric during training. The following equation calculates accuracy:

$$\text{Accuracy} = \frac{N_{correct}}{N_{total}} \times 100\%. \tag{6}$$

- Training process: We train models using the training dataset and evaluate the models with the evaluation dataset in each epoch. The training process will terminate if the evaluation accuracy is not increasing for ten epochs. Then, the training and evaluation datasets are concatenated to train the model for one more epoch to get the final models for testing.

E. Experiment Environment and Methods

The advantage of choosing Jetson Nano over other edge devices in this study is that it supports GPU acceleration. To maximise the use of GPU acceleration, as much of the work as possible is scheduled to run using the GPU.

The classification process at edge devices should take as few computation resources as possible to avoid multiple issues, such as overheating, running out of memory, and system crashes. Hence, unlike the training process where accuracy is the only evaluation metric, we consider the execution time for classifying 6.144-second audio on a Jetson Nano as a critical metric in addition to accuracy. Detailed steps are as follows:

- Sampling a 6.144-second raw audio at 8 kHz.
- Pre-process the audio following the similar normalisation technique introduced in Section 3.1:

$$Z = \frac{x - \mu_{train}}{\sigma_{train}}, \tag{7}$$

  where x is the sampled audio, μ_{train} is the training dataset's mean value, σ_{train} is the training dataset's standard deviation, and Z is the normalised audio.
- Extract feature from the normalised audio.
- Segment the feature into feature segments.
- Classify the feature segments as input to the classifiers.

IV. Experiment Results

In this section, testing datasets are used to evaluate the classifiers. We start the experiment with an audio segment length of 4096 samples (0.512 seconds), a window length of 8192

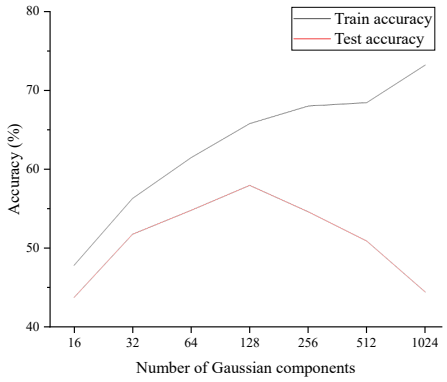

Fig. 4. Accuracy vs GMM component number

samples (1.024 seconds), and an overlap of 50%, so each input feature segment contains only one feature vector according to (5).

MFCC is used for exploring how many GMM components can provide the highest classification accuracy. Fig. 4 shows the result where 128-component GMM can provide the highest classification accuracy at 57.96%.

TABLE II. COMPARISON USING SINGLE-VECTOR INPUT

Classifiers		ResNet	ShuffleNet	GMM
MFCC	Accuracy (%)	88.47	89.78	57.96
	Time taken (ms)	104.05	88.57	-
PLPCC	Accuracy (%)	85.19	86.27	58.65
	Time taken (ms)	379.87	356.86	-
Gamma-PLPCC	Accuracy (%)	83.62	81.76	56.34
	Time taken (ms)	334.81	310.46	-
Gamma-CC	Accuracy (%)	81.09	84.49	61.42
	Time taken (ms)	109.09	88.4	-
Total NN parameters		3849034	1263422	-

Different combinations of features (MFCC, PLPCC, Gamma-PLPCC, and Gamma-CC) and classifiers (ResNet18, ShuffleNetV2 1x, and GMM) are tested, and the results are shown in TABLE II. The timing performance tests were not conducted with those combinations using GMM since GMM has significantly lower classification accuracy than ResNet18 and ShuffleNetV2. Results show that MFCC provides the highest accuracy for both NNs at around 89%. Considering the Jetson Nano's execution time and the numbers of NNs' parameters, the combination of ShuffleNetV2 1x and MFCC (highlighted) has more advantages than others.

Then, we keep the audio segment length at approximately 4096 samples and use MFCC to conduct more experiments. Multiple window lengths and overlaps are tested to determine which combination can produce better accuracy and timing performance.

TABLE III. Comparison using multiple-vector input

Window length (samples)	Overlap (%)	CNN-LSTM		ShuffleNet	
		Accuracy (%)	Time taken (ms)	Accuracy (%)	Time taken (ms)
1024	25	93.26	33.15	92.76	81.85
	50	94.21	36.91	92.55	83.29
	75	92.77	36.85	92.89	80.81
2048	25	91.96	41.82	92.08	81.9
	50	92.74	35.21	92.52	81.43
	75	93.39	32.99	91.83	83.61
4096	50	91.65	38.08	89.25	82.65
	75	92.64	43.94	92.47	89.98

CNN-LSTM can be tested since there are multiple vectors in each feature segment now. According to TABLE III, MFCC, with a window length of 1024 samples and an overlap of 50%, classified by CNN-LSTM, has the highest accuracy at 94.21%. At the same time, this combination has a short execution time, which is lower than half of those using ShuffleNetV2 1x, as shown in TABLE III. One of the reasons why CNN-LSTM has a much shorter computation time than ShuffleNet is that CNN-LSTM has 0.99M trainable parameters compared to 1.26M parameters in ShuffleNet.

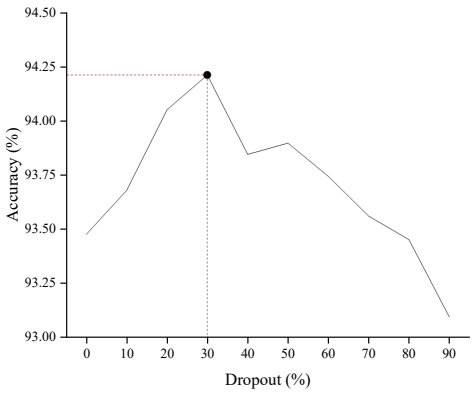

Fig. 5. Accuracy vs CNN-LSTM dropout probability

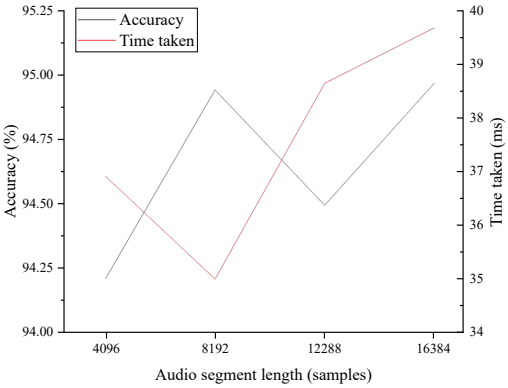

Fig. 6. Classification performance vs audio segment length

In addition, the proposed classifier, CNN-LSTM, with a dropout probability from 0% to 90%, is also tested using MFCC with a window length of 1024 samples, an overlap of 50%, and an audio segment length of 4096 samples. Results shown in Fig. 5 indicate that the classifier trained with a 30% dropout probability can obtain the highest classification accuracy at 94.21%.

Furthermore, audio segment lengths of 4096 samples (0.512 seconds), 8192 samples (1.024 seconds), 12288 samples (1.536 seconds), and 16384 samples (2.048 seconds) are tested using MFCC with a window length of 1024 samples and overlap of 50%, classified by CNN-LSTM. According to (5), each feature segment contains 8, 16, 24, and 32 feature vectors, corresponding

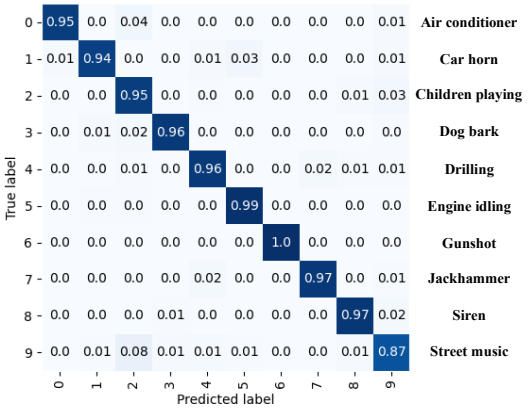

Fig. 7. Confusion matrix of the CNN-LSTM with 94.94% accuracy

to the audio segment lengths, respectively. Fig. 6 shows the results, where the execution time reaches the bottom at the audio segment length of 8192 samples. At the same time, the accuracy reaches a peak of 94.94%, and the highest accuracy of 94.966% is obtained at 16384 samples. Still, considering that the 0.026% improvement comes at the cost of a reduction in temporal resolution (e.g., to classify 49152-sample audio, 3 results are given with an audio segment length of 16384 samples versus 6 results with 8192 samples) and an increment in the execution time, we prefer the audio segment length of 8192 samples (1.024 seconds).

Fig. 7 is a normalised confusion matrix of CNN-LSTM trained with a 30% dropout probability, classifying MFCC with a window length of 1024 samples, an overlap of 50%, and an audio segment length of 8192 samples. 0 to 9 in the confusion matrix represent classes of air conditioner, car horn, children playing, dog bark, drilling, engine idling, gunshot, jackhammer, siren, and street music, respectively. Street music has the lowest accuracy at 87%, and it has an 8% chance of being classified into the class of children playing, which is the highest classification error rate.

TABLE IV. Proposed system vs previous systems

Network	Feature	Number of classes	Accuracy (%)	Used on edge devices
SqueezeNet 18 [8]	Spectrogram	10	80.1	Yes
ANN [10]	MFCC	10	81	Yes
D-2-DensNet [20]	MFCC + GFCC	10	84.83	No
ResNet-50 [21]	Log-Mel spectrogram	10	86.49	No
CNN [9]	Spectrogram	10	88	Yes
ShuffleNet [22]	Log-Mel spectrogram	2	93.1	No
LSTM [7]	MFCC + Chroma STFT	10	93.76	No
CNN [5]	log-Mel spectrogram + Raw audio	10	94.97	No
TSCNN-DS [6]	Chroma + Spectral Contrast + Tonnetz + Log-Mel spectrogram + MFCC	10	97.2	No
CNN-LSTM (ours)	**MFCC**	**10**	**94.94**	**Yes**

TABLE IV compares the proposed system and existing urban noise classification systems without data augmentation. Since some systems are not explicitly designed for edge devices, they may be computationally costly and low in timing performance. The proposed system has the second highest accuracy, but the highest one uses seven features and two stream CNN, which is inefficient to run on edge devices. Therefore, the proposed classification system has competitive accuracy with better timing performance.

V. CONCLUSION

This paper proposed a novel environmental noise classification system that targets running on Jetson Nano. We used a 7-hour-and-12-minute manually checked UrbanSound8K dataset to test different combinations of features, classifiers, window lengths, overlap, audio segment lengths, etc., using accuracy and timming performance as evaluation metrics, enabling the system to be accurate and efficient. The experiment results confirmed that the proposed system using MFCC with a window length of 1024 samples (0.128 seconds), overlap of 50%, and audio segment length of 8192 samples (1.024 seconds), classified by the CNN-LSTM that is trained with 30% dropout probabilities, can achieve an accuracy of 94.94% and an execution time of 35 ms for classifying a 6.144-second raw audio on a Jetson Nano. The proposed classification system shows outstanding accuracy in existing urban noise classification systems that do not use data augmentation.

***Abstract*—This study employs the random forest algorithm of Classification and Regression Trees (CART) to estimate soil water content (SWC) at shallow depths in a grassland terrain site. Leveraging meteorological parameters, the random forest model demonstrates efficient and effective SWC estimation in a 12-folds time series cross-validation. The results reveal distinct strategies employed by the CART model for different SWC depths, addressing seasonal variations and SWC sensitivity to precipitation. Additionally, the study highlights limitations of CART in extrapolating beyond training data, leading to misfit in certain scenarios. These findings contribute valuable insights for improved SWC estimation and agricultural practices.**

I. Introduction

Understanding and estimating soil water content (SWC) is crucial for various applications such as agriculture and green space management [1], [2]. Shallow Machine learning (ML) methods, such as decision trees and random forests, have been used for drought monitoring, irrigation management, and satellite-based SWC map enhancement [3]–[5]. Although deep learning (DL) methods have shown promise in numerical investigations and SWC modeling, tree-based shallow ML methods are preferred in scenarios where interpretability is important and when dealing with small datasets [6], [7].

In our previous study [8], the feasibility of using Classification and Regression Tree (CART) for SWC estimation is investigated. CART's feature selection ability allows for the inclusion of various meteorological parameters. The study uses data from a grassland terrain in Taiwan and demonstrates the effectiveness of CART in estimating SWC for agricultural irrigation and flood risk assessment.

In this study, we extend our investigation by employing a random forest of CART instead of a single tree to estimate SWC using the same dataset and feature sets. The emphasis is placed on understanding the role of rainfall, evapotranspiration, and soil texture in ML-based SWC estimation.

II. Data and Method

The study area is located at the Atmospheric and Hydrological Observatory site [9], characterized by a grassland terrain with specific meteorological and SWC measurements [10]. Meteorological data, including precipitation, air temperature, relative humidity, wind speed, atmospheric pressure, and solar radiation, were collected from various instruments. SWC was measured at different depths using specific sensors. The data covered the entire year of 2018 and underwent down-sampling and interpolation to fill in missing values.

In this study, we utilize a random forest of CART models for ensemble prediction of SWC. Each forest consists of 100 CART models, with a bagging ratio of 0.8. CART, a decision tree-based method, is a supervised machine learning algorithm that performs regression tasks by splitting the data based on features and thresholds. This splitting process is performed recursively, resulting in the creation of nested binary branches with the objective of minimizing the sum of squared errors (SSE) for each subset of data on the branch for every split [11]:

$$\min_{j,s}[\min_{c_L} \sum_{x_i \in R_L(j,s)} (y_i - c_L)^2 + \min_{c_R} \sum_{x_i \in R_R(j,s)} (y_i - c_R)^2]. \quad (1)$$

In this equation, x_i represents the input variables and y_i represents the target variable for the i_{th} observation. c_R and c_L represent the average responses (in this case, SWC) over the right and left subsets of data (R_R and R_L) respectively, after a binary split at a node using feature j with threshold s.

Table I presents the list of input and target features used for SWC estimation using CART. To incorporate the information of time points from the past, each meteorological parameter is shifted by a specific number of hours (0, -12, -24, -36, and -48). Models were trained using these shifted variants to estimate SWC at 5 depths for one hour ahead, and tested with 12-folds time-series cross validation (TSCV) as displayed in Fig. 1. The input and target features were listed in Table II;

it is important to note that only one target feature is used for training and validation at a time.

III. RESULTS AND DISCUSSION

In this study, we examine the impact of individual parameters on SWC estimation by utilizing ten parameter selection sets for the random forest model of CART. Fig. 4 presents the mean absolute error (MAE) loss of these sets in a 12-folds TSCV. The ten sets consist of variations that exclude a single parameter, exclude all AP parameters, use only AP and P parameters, and include all parameters, where AP denotes accumulated precipitation, P denotes precipitation and NP denotes non-precipitation parameters, as listed in Table II.

Results reveal that excluding a single NP or P parameter has minimal impact on the model's loss, suggesting the compensatory effect of other parameters. In contrast, removing all AP parameters significantly reduces the model's performance. Notably, the random forest model struggles to provide accurate SWC estimates without NP parameters, as demonstrated by the "only AP & P" set. Additionally, the findings indicate that AP parameters are crucial for estimating shallow SWC depths, while NP parameters play a vital role in estimating deeper SWC depths, as evident from the "w/o AP" and "only AP & P" results. In addition, the loss in MAE of the previous study [8] is demonstrated as the size of green hollow circles in the same plot for comparison. The results show a high consistency between the two studies, with ensemble prediction consistently bringing modest improvements for all parameter selection sets.

The fitting results of the 12-folds TSCV for different depths of SWC measurements are presented in Fig. 2. Overall, the trained models perform well, with MAE in general of less than 4% (v/v) except for the 3rd and 8th fold, as demonstrated in Fig. 3. In the case of the 3rd fold, the SWC of depths ≥ 50 cm reached historically low levels not present in the training data. Since the CART algorithm is intrinsically unable to give predicted values beyond the range of those in the training data, the misfit is high.

Hydrological factors also play a role. These factors are manifested in Fig. 2 from the 3rd to the 7th fold, where the responsiveness of SWC to non-intensive precipitation decreases at deeper depths. In contrast, SWC from the 8th to the 9th fold shows a clear response to precipitation at all depths. The different behavior in terms of the responsiveness of SWC to precipitation between deeper and shallow depths is a result of the evapotranspiration (ET) mechanism at this site. ET often reaches only to depth ≤ 50 cm, and only in relatively large or consecutive rainfall events can the precipitation reach a greater depth. Accordingly, during the 8th fold period, intense rainfall events result in a sudden change in the responsiveness of SWC to precipitation at deeper depths. As a consequence, the model trained with smaller rainfall amounts and more frequent drying periods gave erroneous predictions of SWC, leading to a distinctively larger misfit in this fold.

IV. CONCLUSION

In conclusion, our study demonstrates the effectiveness of random forest models based on the CART algorithm for estimating SWC at shallow depths in a grassland terrain in northern Taiwan. The random forest approach proves to be efficient in both training and prediction, yielding acceptable errors for agricultural purposes. The 12-fold TSCV analysis conducted throughout the entire year of 2018 reveals that the variation in misfit across TSCV can be attributed to the learning capabilities of the CART model in different layers and the characteristics of rainfall and evapotranspiration during different seasons. Notably, the CART model developed distinct strategies for estimating SWC at the shallowest depth (10 cm) and the deepest depth (100 cm). At 10 cm, the model relies more on AP parameters, while at 100 cm, it relies more on NP parameters. This accounts for the inconsistent sensitivity of SWC to precipitation between dry and wet seasons. These findings not only provide insights into the near-surface soil structure of the study area but also have

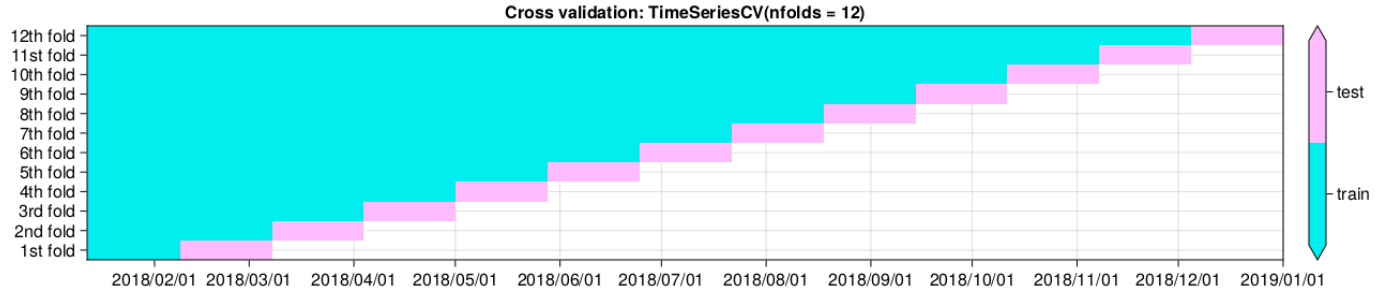

Fig. 1. Subsets of training-testing data for cross validation in this study.

implications for improving SWC estimation using other techniques beyond CART. Furthermore, our results exhibit a high level of consistency with the previous study, with ensemble predictions consistently showing modest improvements across various parameter selection sets.

Our work has resulted in the development of TWAISWCF.jl (Fig. 5 and Ref. [12]), a Julia package in early stage specifically designed for estimation of SWC in agricultural applications. In terms of the machine learning workflow, TWAISWCF.jl currently covers major stages such as data preprocessing, data splitting, and model training. It incorporates DecisionTree.jl [13] in the framework of MLJ [14] utilizing the CART algorithm based random forest strategy as the underlying foundation, and leverages the results of this study in processing the meteorological data. In terms of design pattern, TWAISWCF.jl stands out for its utilization of polymorphism through Julia's multiple dispatch mechanism, enabling a highly customizable and extensible API for integration with other collaborative applications. Furthermore, TWAISWCF.jl has been made freely available to the public, allowing researchers and practitioners to explore and experiment with the package for SWC estimation. We envision that its utilization will contribute to advancements in agricultural irrigation practices and enhanced flood risk assessment.

ACKNOWLEDGEMENT

The authors of the manuscript gratefully acknowledge the laboratories providing valuable data, namely the Surface Hydrology Lab., Aerosol and Cloud Lab., and Planetary Boundary Layer and Air Pollution Lab. of National Central University. The authors also would like to express their gratitude to the National Science and Technology Council (R.O.C) for providing funding for this research through grant number MOST 110-2634-F-008-008.

A Framework for Reusing Earth Science Data on Data and Model Marketplaces

Chung-I Huang, Jih-Sheng Chang, Chen-Kai Sun, Taichi Wang, Wei-Yu Chen, Hui Hung Yu, Wen-Yi Chang, Fang-Pang Lin
National Center for High-performance Computing (NCHC) ,Taiwan

Abstract: The AI-based Management Strategy for Earth and Environmental Disaster project proposes a framework for integrating AI technology into Earth environmental disaster prediction models. The project emphasizes the collaboration of multidisciplinary experts, such as information engineering and network engineering, to explore the effectiveness of AI technology in enhancing Earth environmental disaster prediction models. The project particularly highlights the concepts of data reuse and model reuse, combining the data marketplace and model marketplace platforms of the NCHC to establish a national-level data service platform. Through the data marketplace platform, data reuse is achieved, encouraging cross-disciplinary collaboration and fostering innovative applications and decision-making recommendations. Simultaneously, the model marketplace platform allows AI models from Earth science sub-projects to be launched, realizing model reuse and providing a strong reference for Taiwan's disaster response decision-making system, contributing to sustainable development.

Introduction: Natural disasters, such as earthquakes, typhoons, and floods, can have a significant impact on people's lives and the environment. The prediction and management of such disasters have become increasingly critical. The use of AI technology in disaster prediction models has shown great potential in improving accuracy and efficiency. This paper presents the AI-based Management Strategy for Earth and Environmental Disaster project, which aims to integrate AI technology into Earth environmental disaster prediction models and establish a framework for data and model reuse (1-4).

Several studies have shown the potential of AI technology in improving the accuracy and efficiency of disaster prediction models (5-7). These studies also suggest that collaboration among experts from different fields is crucial for enhancing the effectiveness of such models. The concept of data and model reuse has also been discussed in the literature, with several studies suggesting that it can improve resource utilization efficiency and promote the development of innovative applications (8-12).

Methods:

The research methodology for this project includes a literature review, case studies, and interviews with experts. The case studies focus on AI technology's application in Earth environmental disaster prediction models, while the interviews with experts explore their perspectives on the effectiveness of AI technology in enhancing such models and the importance of data and model reuse.

The concept of data and model reuse is a key aspect of this project. Data and model reuse helps avoid duplicative efforts in creating similar databases or models, saving time and economic costs while improving resource utilization efficiency. Sharing data and models enables experts from different fields to easily access the necessary resources, thus strengthening cross-disciplinary communication and collaboration and

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

promoting the development of innovative applications. By utilizing this framework, secondary innovations can be made based on existing foundations, leading to the development of new application services and decision-making recommendations, and promoting the advancement of relevant fields.

The data and model marketplace platforms of the NCHC will be crucial for achieving data and model reuse in this project. The data marketplace platform enables the sharing of diverse types of data, including meteorological data, geological data, and demographic data, among others. Through this platform, cross-disciplinary collaboration can be encouraged, and innovative applications and decision-making recommendations can be developed. The model marketplace platform, on the other hand, enables AI models from Earth science sub-projects to be launched, providing a strong reference for Taiwan's disaster response decision-making system. This model reuse can lead to significant improvements in the accuracy and efficiency of disaster prediction models.

In addition to data and model reuse, interdisciplinary collaboration is also a key aspect of this project. Collaboration among experts in Earth environmental research, information engineering, and network engineering will be crucial for enhancing the effectiveness of Earth environmental disaster prediction models. Through cross-disciplinary collaboration, new perspectives and innovative solutions can be developed.

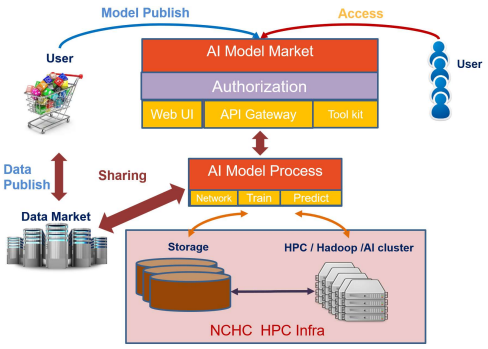

Fig.1 AI-based Management Strategy for Earth and Environmental Disaster Project Flowchart and Architecture

The flowchart and architecture of the AI-based Management Strategy for Earth and Environmental Disaster project highlights the importance of data and model reuse in disaster prediction models. Users can upload data to the data marketplace, and AI models can be launched on the model marketplace. The AI models can directly stream data from the data marketplace, and other authorized users can subscribe to the model marketplace to access the relevant data and models. This framework promotes cross-disciplinary collaboration and resource utilization efficiency, as users can easily access the necessary resources and develop innovative applications and decision-making recommendations. The data and model marketplace platforms of the NCHC enable data and model reuse and can significantly improve the accuracy and efficiency of disaster prediction models. By utilizing this framework, secondary innovations can be made based on existing foundations, leading to the development of new application services and decision-making recommendations, and promoting the advancement of relevant fields.

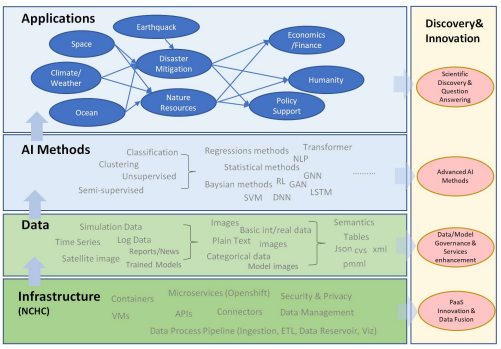

Fig.2 End-to-End AI-based Disaster Management System Infrastructure and Workflow

The "End-to-End AI-based Disaster Management System Infrastructure and Workflow" is a comprehensive framework for disaster prediction and management. The system includes multiple components, starting from the infrastructure, data, AI models, and application. The infrastructure component focuses on developing a robust and scalable system that can handle large amounts of data. The data component includes diverse types of data, including meteorological, geological, and demographic data, among others. The AI models component focuses on developing accurate and efficient models for disaster prediction and management, utilizing advanced machine learning algorithms. The application component includes a variety of innovative applications and decision-making recommendations, developed based on the outputs of the AI models. The end-to-end workflow of this system provides a comprehensive approach to disaster prediction and management, utilizing the latest technologies and promoting interdisciplinary collaboration. This framework has the potential to significantly improve the accuracy and efficiency of disaster prediction models, while promoting resource utilization efficiency and innovative applications.

Results: The results show that the integration of AI technology into Earth environmental disaster prediction models can significantly improve their accuracy and efficiency. The project's emphasis on data and model reuse is crucial for avoiding duplicative efforts in creating similar databases or models, saving time and economic costs while improving resource utilization efficiency. Sharing data and models enables experts from different fields to easily access the necessary resources, thus strengthening cross-disciplinary communication and collaboration and promoting the development of innovative applications. The AI-based Management Strategy for Earth and Environmental Disaster project's outcomes will comprehensively assess the impact on legislation, society, and humanities, ensuring that environmental protection and social equity and justice are considered while pursuing technological progress. The TWAI project will promote more breakthroughs in Earth environmental research and related fields in Taiwan, showcasing Taiwan's technical capabilities internationally. Through the implementation of this project, Taiwan will be able to establish a more robust disaster response decision-making system and enhance the nation's overall capacity in dealing with Earth environmental disasters. Additionally, the project's outcomes will benefit the research and development of related fields both domestically and internationally, making a significant contribution to Taiwan's sustainable development.

Conclusion: The AI-based Management Strategy for Earth and Environmental Disaster project proposes a framework for integrating AI technology into Earth environmental

disaster prediction models and establishing a framework for data and model reuse. The project emphasizes the collaboration of multidisciplinary experts to enhance the effectiveness of Earth environmental disaster prediction models. The results suggest that the integration of AI technology and the emphasis on data and model reuse can significantly improve the accuracy and efficiency of disaster prediction models, while promoting resource utilization efficiency and innovative applications. This project also underscores the importance of interdisciplinary collaboration, particularly among experts in Earth environmental research, information engineering, and network engineering. The project's outcomes will contribute to sustainable development and showcase Taiwan's technical capabilities internationally.

Abstract — **Developing an accurate air quality forecasting model with a lead time longer than 72 hours is important for predicting hazardous pollution events. An air quality forecasting system (AQF) conducted with the WRF-CMAQ numerical model has been developed. This study used the predicted $PM_{2.5}$ from AQF, observed $PM_{2.5}$, longitude, latitude, the land use index of the corresponding grid, and indexes of synoptic weather patterns to develop a forecasting model through the CNN algorithm to predict 72 hours of $PM_{2.5}$ concentrations at 75 surface air quality monitoring sites. The training dataset was from October 2019 to September 2021, and the data from October 2021 to September 2022 was divided into validation and test datasets in order of date. Since the $PM_{2.5}$ varies in a wide range, the weighted loss function was applied to improve the model performance. In general, the CMAQ-CNN models developed by this study show better performance than the AQF, especially during high pollution events when the CMAQ-CNN model utilizes the weighted loss function.**

I. Introduction

Previous research has demonstrated the adverse impacts of fine particular matter ($PM_{2.5}$) on human health, visibility, and global climate change. Developing a reliable air quality forecasting model with a lead time length longer than 72 hours is crucial for environmental agencies to predict severe pollution events in advance, control the concentration of ambient pollutants, and reduce the population's exposure to health dangers.

In recent years, various $PM_{2.5}$ forecasting models based on algorithms linked to machine learning have been developed. The convolutional neural network (CNN) contains one or several convolutional layers that can extract local characteristics from the input parameters. The forecasting model based on CNN with a large number of characteristic parameters through 1-D convolution could tackle the time-series data and showed better performance than using neural networks and a numerical model [1,2].

Since the machine learning algorithms are a statistical model, the developed models would highly depend on the training dataset. In the one-year data of each monitoring station, the observed high-level $PM_{2.5}$ concentration only accounts for a minor portion, which leads to a poor prediction of high concentration events. The weighted loss functions were often used to construct classification models with imbalanced input data. Ref. [3] applied the weighted loss function to solve the imbalanced rainfall levels and improve the precipitation nowcasting.

Considering the practical operation, this study develops a CMAQ-CNN forecasting model with as few auxiliary features as possible to avoid increasing the time cost of data preprocessing. Moreover, the impact of the weighted loss function in the air quality forecasting model will be discussed.

II. Data and Data Preprocessing

A. Observation datasets

The hourly $PM_{2.5}$ concentration observed at 75 surface air quality monitoring stations (Fig. 1) operated by the Taiwan Environmental Protection Agency (EPA) from October 2019 to September 2022 was collected. According to the characteristics of the emission and meteorological conditions, the EPA divided Taiwan into seven air quality zones (AQZs), which are: northern Taiwan (NT), the Chu-Miao area (CM), central Taiwan (CT), the Yun-Chia-Nan area (YCN), the Kao-Ping area (KP), the Yilan (YI), and the Hua-Dong area (HD) (refer to Fig 1). In this study, the YI and HD areas are combined into the Yi-Hua-Dong area (YHD), where the air quality tends

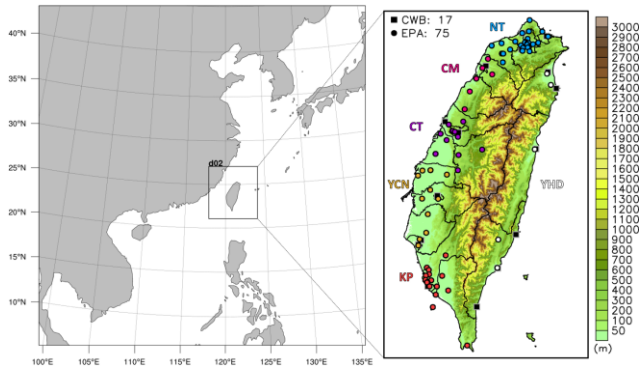

Fig. 1 The left panel displays the simulation domains. The locations of CWB and EPA surface monitoring stations are shown in the right panel. The shaded color is the elevation. The six AQZs (NT, CM, CT, YCN, KP, and YHD) are identified with different colors.

to be in good condition.

In addition, the meteorological parameters, including surface pressure, wind speed, and wind direction, were obtained from 17 surface weather stations (Fig. 1) developed by the Central Weather Bureau (CWB) in Taiwan. These daily data were used to identify the synoptic weather pattern of each day during the study period with the cluster analysis method [4].

This study objectively removed the abnormal values and outliers for each station to ensure the dataset's quality. The distribution of $PM_{2.5}$ concentration in each year would not be close to the normal distribution. After redistributing the data by taking the n-th root to make the absolute value of the skewness close to 0, we remove the data not in the interval of [$\overline{x}$-4*x_{std}, $\overline{x}$+4*x_{std}], where $\overline{x}$ and x_{std} are the average and standard deviation of one-year data, respectively. This quality assurance method was also applied to meteorological parameters.

B. Community Multiscale Air Quality forecasting system (AQF)

To forecast the concentration of ambient pollutants in Taiwan for a lead time of 96 hours, an air quality forecasting system (AQF) using Weather Research and Forecasting (WRF) version 3.8.1 [5] and Community Multiscale Air Quality (CMAQ) version 5.2 [6,7] was developed [8]. Two nested domains with resolutions of 15 km and 3 km are used to capture the synoptic weather pattern and background concentrations and long-range transported air pollutants in the coarse domain (d01) and local formation and transportation of air pollutants in the fine domain (d02) (Fig. 1). The biogenic and anthropogenic emissions are provided by the Model of Emissions of Gases and Aerosols from Nature (MEGAN) [9] in both domains and the Model Inter-Comparison Study for Asia (MICS-Asia) based on 2010 [10] in d01 and the Taiwan Emission Data System version 10 (TEDS10) based on 2016 [11] in d02, respectively. Besides, the CMAQ model executed with the Carbon Bond (CB05) [12] and aerosol module version six (AERO6) [13] chemical mechanisms.

The AQF is conducted with numerical models that are based on the atmospheric governing equations, and is able to predict the air pollutants concentrations. The prediction of 72-hr $PM_{2.5}$ concentration from d02 of the AQF during the study period were collected for developing the CMAQ-CNN forecasting model.

III. CMAQ-CNN Model

A. Input features

The input features can be split into time-dependent and time-independent components for each sample. The time-dependent elements include 24-hr observed $PM_{2.5}$ from the previous day and 72-hr predicted $PM_{2.5}$ from AQF.

For the time-independent parameters, the longitude and latitude of each air quality monitoring station are selected to depict the spatial variation of air pollutants. The land use (LU) index of the corresponding grid used in the AQF is also chosen to indirectly provide information on emission sources.

Ref. of [4] indicated that the synoptic weather pattern has a significant impact on air pollutant concentrations. The six synoptic weather patterns are identified with the cluster analysis method. This study replaced a substantial number of meteorological parameters with the synoptic weather patterns indexes. Four transformed indexes, including those for the previous day and the next three days (forecasting 1-24 hr: Day 1, 25-48 hr: Day 2, and 49-72 hr: Day 3), are included in the input sample to represent the changing pattern of the synoptic weather system.

The scales of input parameters vary in different ranges, which may lead to the misjudge of the importance of variables and also affect the efficiency of finding the best solution in the algorithms. Thus, the Min-Max normalization rescales each input feature to the range [0, 1].

B. Construction of model

Fig. 2 illustrates the structure of the model that was built to predict 72 hours of $PM_{2.5}$ concentrations at 75 surface air quality monitoring sites. Because the characteristics of concentration variations might differ in observation and simulation results, two datasets utilized various convolutional layers. The 1-D convolutional layers with a kernel size of 3 are used to address the time-varying properties of the air pollutants. Then, the convolutional layer outputs are combined with time-independent parameters. To capture the non-linear relationship

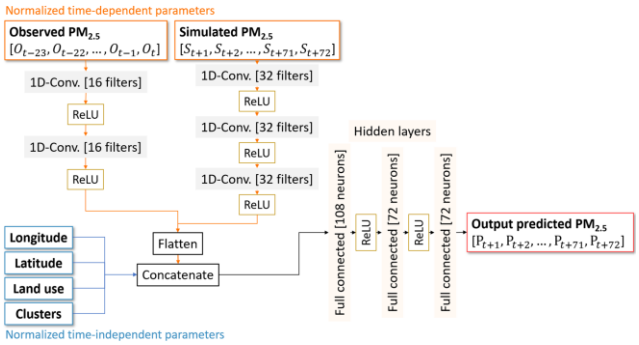

Fig. 2 The structure of the CMAQ-CNN forecasting model in this study.

between the input features and true $PM_{2.5}$ concentration, three full-connected layers, which had 108, 72, and 72 neurons with a Rectified Linear Unit (ReLU) activation function, were built.

The two-year data from October 2019 to September 2021 was used to train the CMAQ-CNN model, while the data from October 2021 to September 2022 was divided into validation and test datasets. The early-stopping was applied to avoid overfitting.

C. Experimental designs

This study constructed two CMAQ-CNN models: CNN_Cluster8 and CNN_Cluster8_WMSE. Table 1 shows the occurrence percentages of different $PM_{2.5}$ level in each AQZ. The occurrence frequency of high $PM_{2.5}$ concentrations is very low, which can degrade the performance of severe $PM_{2.5}$ events. As a result, the loss function of the Cluster8_WMSE experiment was applied with a weighted mean squared error as expressed by (1) and (2):

$$WMSE = \left(\sum_{i=1}^{72} W_i \times (P_i - O_i)^2\right)/72 \quad (1)$$

$$W_i(O_i) = \begin{cases} 1, & O_i < 20 \\ 1.5, & O_i \geq 20 \; and \; O_i < 30 \\ 2, & O_i \geq 30 \; and \; O_i < 40 \\ 3, & O_i \geq 40 \; and \; O_i < 50 \\ 4, & O_i \geq 50 \; and \; O_i < 60 \\ 5, & O_i \geq 60 \; and \; O_i < 70 \\ 6, & O_i \geq 70 \end{cases} \quad (2)$$

where P_i and O_i are the prediction and observation of i-th hour, respectively. The weight (W_i) of each forecasting hour is the function of observation value.

IV. Results and Discussions

varies from 7.63 to 14.36 μg/m^3, while the RMSE in eastern Taiwan is lower between 4.54 and 7.7 μg/m^3 due to the low air

The evaluation was conducted for the test datasets from two CMAQ-CNN models, and the AQF system. The RMSE of AQF predicted 72-hr $PM_{2.5}$ concentrations in western Taiwan

Table 1 The occurrence percentage (%) of hourly $PM_{2.5}$ concentration in each $PM_{2.5}$ levels for each AQZ from the training dataset.

Observed $PM_{2.5}$ (μg/m^3)	AQZ					
	NT	CM	CT	YCN	KP	YHD
<20	79.7	76.4	63.4	57.1	51.4	92.7
20–30	12.7	14.8	20.2	22.2	23.5	4.4
30–40	3.9	4.9	9.2	10.8	14.3	0.6
40–50	1.2	1.5	3.4	4.4	5.5	0.1
50–60	0.4	0.5	1.3	1.9	1.9	---
60–70	0.1	0.2	0.4	0.9	0.7	---
≥70	0.1	0.1	0.3	0.8	0.4	---

pollutants concentration (Fig. 3). The largest predicted bias exists in the KP AQZ and followed by the YCN AQZ. Both the CNN_Cluster8 and CNN_Cluster8_WMSE models had better performance than AQF, with the RMSE in western Taiwan ranging from 5.3 to 9.7 μg/m^3 and 5.88 to 12.07 μg/m^3, respectively. When the CNN model tends to focus on the high $PM_{2.5}$ level through the weighted loss function (Cluster8_WMSE experiment), it is prone to having larger biases. The spatial patterns of RMSE of the two CMAQ-CNN models are similar, which is higher in southern Taiwan than in northern Taiwan. The average RMSE from AQF is 10.48 μg/m^3, which can be reduced to 7.24 μg/m^3 by the CNN_Cluster8 and 8.3 μg/m^3 by the CNN_Cluster8_WMSE. Table 2 provides the performances of each model during different forecasting periods in each AQZ.

The AQF is based on the numerical model of atmospheric dynamic, physical, and chemical processes to describe the variations of air pollutant concentrations. Fig. 4 compares the mean RMSE and correlation coefficient (r) between AQF and two CMAQ-CNN models during 72 forecasting hours. The

Table 2 The RMSE of 72-hr, Day1 (1-24 hr), Day 2 (25-48 hr), and Day 3 (49-72 hr) forecasted hourly $PM_{2.5}$ concentration of each model in each AQZ and also the average of all stations. The number in the brackets represent the amount of monitoring stations in that area. Unit: μg/m^3.

Model	Period	AQZ						ALL
		NT (26)	CM (6)	CT (11)	YCN (11)	KP (16)	YHD (5)	(75)
AQF	72-hr	9.33	9.26	11.86	11.35	12.66	5.91	10.48
	Day 1	9.37	9.27	12.18	10.66	12.04	5.79	10.29
	Day 2	9.46	9.41	11.79	11.86	13.16	5.82	10.70
	Day 3	9.17	9.10	11.60	11.54	12.80	6.10	10.44
CNN_Cluster8	72-hr	6.15	6.67	8.09	8.69	8.53	4.45	7.24
	Day 1	5.66	6.28	7.29	7.59	7.49	4.17	6.52
	Day 2	6.42	6.91	8.45	9.28	8.96	4.51	7.59
	Day 3	6.38	6.83	8.54	9.22	9.13	4.67	7.61
CNN_Cluster8_WMSE	72-hr	6.71	7.55	9.62	10.24	10.00	4.80	8.30
	Day 1	6.14	7.02	8.17	8.48	8.30	4.33	7.19
	Day 2	7.05	7.82	10.2	10.94	10.77	4.77	8.79
	Day 3	6.95	7.80	10.50	11.29	10.92	5.29	8.91

mean RMSE of AQF falls between 8.79 and 12.33 μg/m^3 and exhibits significant diurnal variation with higher value in the early morning and lower value in the afternoon for each forecasting day. This variation allowed the application of only one weight-sharing convolutional layer to cover the entire 72 hours rather than independently building the convolutional layers for each forecasting day. For the Cluster8 experiment, the mean RMSE gradually increases from 4.93 to 7.12 μg/m^3, during the first 12-hr forecasting time, then remains stable at around 7.5 μg/m^3 (varying from 6.77 to 8.33 μg/m^3) during the next 60-hr forecasting hours. The Cluster8_WMSE experiment has a higher RMSE than the Cluster8 experiment, with the mean RMSE increasing from 5.66 to 7.96 μg/m^3 during the first 12-hr prediction time and falling between 7.44 to 9.83 μg/m^3 during the next 60-hr prediction time.

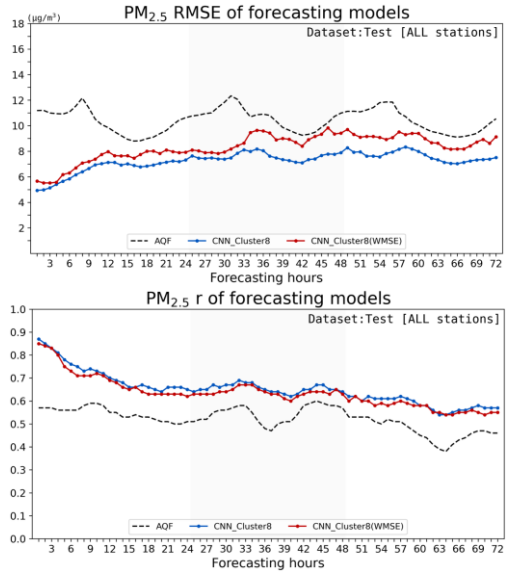

Fig. 4 The comparison of mean RMSE (top) and r (bottom) of all stations during 72-hr forecasting time between the AQF (black), CNN_Cluster8 (blue), and CNN_Cluster8_WMSE (red) models.

For the correlation coefficient (r) between observed and predicted concentration from AQF during 72 forecasting hours, it ranges from about 0.38 to 0.60 and has smaller r in Day 3 (49-72 hr). On the other hand, both CMAQ-CNN models show high correlation during the first 12-hr forecasting time ($r \geq 0.7$) and the average r of all sites exceed 0.54 during the 72-h forecasting time. These findings demonstrate that the CMAQ-CNN model has the ability to predict the variations of air pollutant concentrations up to 72 hrs.

To discuss the impact of the weighted loss function for high $PM_{2.5}$ event day (with daily mean $\geq$ 35 μg/m^3), this study developed two CMAQ-CNN models with different loss

functions. For each forecasting day, we collected the samples that meet the criteria from the test dataset and calculated the average of observed and predicted daily concentration and RMSE in each AQZ (Fig. 5). The YHD area does not have high $PM_{2.5}$ events during the study period. Instead, more than 57% of the high $PM_{2.5}$ events are found in the KP region, with 22% found in the YCN region. Under the influence of the northeasterly monsoonal flow, the YCN and KP AQZs are located in the leeside of the mountain, which exhibits stagnant and stable atmospheric conditions [8]. Moreover, the northerly wind might transport the air pollutants from the NT, CM, and CT areas toward the YCN and KP areas, deteriorating the air quality in southwestern Taiwan.

Overall, the AQF underestimates the $PM_{2.5}$ concentration in all AQZs for each forecasting day, especially in the YCN and KP areas. Both CMAQ-CNN models have worse performance than AQF in the NT area due to the relatively small sample sizes. The CNN_Cluster8 underestimates the

$PM_{2.5}$ concentrations during the high $PM_{2.5}$ events, but has significantly better performance than the AQF in southern Taiwan, with the average RMSE of Day 1 reducing from 13.59 to 8.33 μg/m^3. The overall performance of the high $PM_{2.5}$ events is enhanced with the use of the weighted loss function. The predicted $PM_{2.5}$ concentration from the CNN_Cluster8_WMSE is close to the observation for each of the three forecasting days.

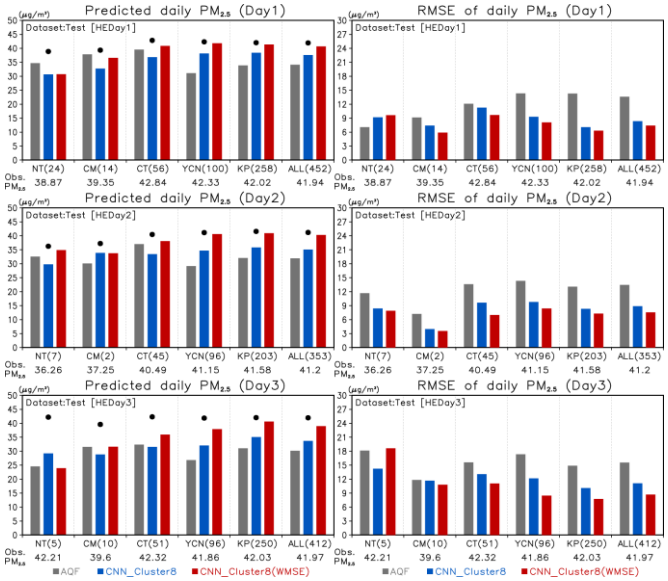

Fig. 5 The observed (black dots) and forecasted (bar) daily $PM_{2.5}$ concentration from the AQF (gray), CNN_Cluster8 (blue), and CNN_Cluster8_WMSE (red) models in each AQZ when Day 1, Day 2, and Day 3 are high pollution events (left panels, from top to bottom row). The right panels display the RMSE in each AQZ and also the average of all samples. The number in the brackets represent the sample size of high pollution events in that area.

V. Conclusions

This study utilized the predicted $PM_{2.5}$ from a numerical AQF system conducted with WRF-CMAQ and other auxiliary features to develop two forecasting models through CNN algorithm (CMAQ-CNN). The indexes of synoptic weather patterns were used in place of the meteorological parameters to decrease the number of input features and to increase the computing efficiency for air quality forecasting operations. To solve the problem of an imbalanced $PM_{2.5}$ concentration value, one of the CMAQ-CNN models (CNN_Cluster8_WMSE) utilized the weighted loss function to put more weight to high-level $PM_{2.5}$ conditions.

Overall, the CMAQ-CNN models perform better than the AQF system. The mean RMSE of all stations for the predicted 72-hr $PM_{2.5}$ from the AQF, Cluster8 experiment and Cluster8_WMSE experiment are 10.48, 7.24, and 8.3 μg/m^3, respectively. For each of the 72 forecasting hours, the RMSE of both CMAQ-CNN models slightly increases during the first 12-hr forecasting time, and the r is larger than 0.7.

According to the comparison of predictions for high pollution events (daily average of $PM_{2.5} \geq 35$ μg/m^3), the AQF underestimated the concentration, while the predicted $PM_{2.5}$ from the Cluster8_WMSE experiment was close to the observation for each of the three forecasting days. The mean RMSE of all sites from the AQF, Cluster8 experiment, and Cluster8_WMSE experiment are 13.59, 8.33, and 7.4 μg/m^3 in Day 1, 13.44, 8.89, and 7.56 μg/m^3 in Day 2, and 16.56, 11.09, and 8.68 μg/m^3 in Day 3, respectively. These results confirm that the weighted loss function has certain capabilities to solve the problem of imbalanced input features.

***Abstract*—Dementia is a severe cognitive impairment that affects the health of older adults. This paper analyzes diverse speech-based features extracted from spoken languages and selects the most discriminative ones for dementia detection. We propose a two-step feature selection method to handle the circumstance where the feature dimension is far larger than the number of training samples. Recently, the performance of dementia detection has been significantly improved by utilizing Transformer-based models that automatically capture the linguistic properties of spoken languages. We combine features extracted from BERT with selected speech-based features to enhance dementia detection performance. We propose a novel strategy to model the transcriptions and their phonemes using BERT and phoneme-BERT. The proposed method is evaluated on a Cantonese dataset called CU-Marvel, which contains 185 healthy older adults, 98 older adults having minor neurocognitive disorders (minor NCD), and 26 older adults suffering from major NCD. Experimental results show that simultaneously fine-tuning the BERT and phoneme-BERT can leverage information from the recognized phonemes and make the detection performance robust to automatic speech recognition errors. Simultaneous fine-tuning of the BERT and phoneme-BERT models results in a 6% improvement in F_1 scores, compared to fine-tuning the BERT model alone.**

Index Terms: Dementia detection, feature selection, phoneme-BERT

I. Introduction

Dementia is a severe cognitive impairment that may seriously affect the health and daily lives of the afflicted individuals. The most common form of dementia is Alzheimer's Disease (AD). According to a report from the World Health Organization,[1] more than 55 million people live with dementia worldwide, and there are nearly 10 million new cases every year. The disease has a huge impact on the quality of life of not only the patients but also their families and caretakers. Fortunately, with effective detection of early dementia, disease-modifying medications and interventions are possible [1].

A. Related Works

Recently, automatic detection of dementia through speech and language analyses has gathered attention in the research community. Some studies investigated different types of speech-based features for dementia detection. For example, Haider *et al.* [2] compared different types of paralinguistic features – including the Geneva Minimalistic Acoustic Parameter Set (eGeMAPS) [3], ComParE 2013 [4], Emobase [4], and MRCG [5] – for dementia detection. Because the paralinguistic features are high-dimensional, Pearson's Correlation (PeaCorr) tests were performed to reduce the feature dimensions.

In addition to speech-based features, transcription-based features have also been used for dementia detection [6–8]. For example, Qiao *et al.* [8] combined disfluency and linguistic complexity features with features extracted from Transformer-based models for AD detection. In [8], BERT [9] and ERNIE [10] models were fine-tuned to capture the language characteristics of the AD patients. The Transformer-based models were also extensively investigated by Syed *et al.* [6].

More recently, the fully-automatic assessment of dementia from spontaneous speech has gathered more attention as it does not require labor-intensive annotations or manual transcriptions. In such a case, an automatic speech recognition (ASR) system is utilized to transcribe the patients' speech. However, the erroneous transcriptions produced by the ASR system could lead to high detection errors. To mitigate the errors in ASR systems, the research community has developed three strategies:

- *Adapting ASR systems.* In the Alzheimer's Dementia Recognition through Spontaneous Speech only (ADReSSo) challenge [11], the conventional Kaldi-based ASR system was adapted using multiple datasets containing spontaneous speech [12]. Pappagari *et al.* [13] first used a pre-trained ASpIRE model from Kaldi to transcribe target domain data. To improve transcription quality, they interpolated the language model (LM) of ASpIRE with an LM trained on automatic transcriptions of the target domain.
- *Utilizing ASR lattices.* An ASR lattice can provide time alignments, recognized words, and confidence scores for different hypotheses. Usually, we only consider the best hypothesis that has the highest confidence score.

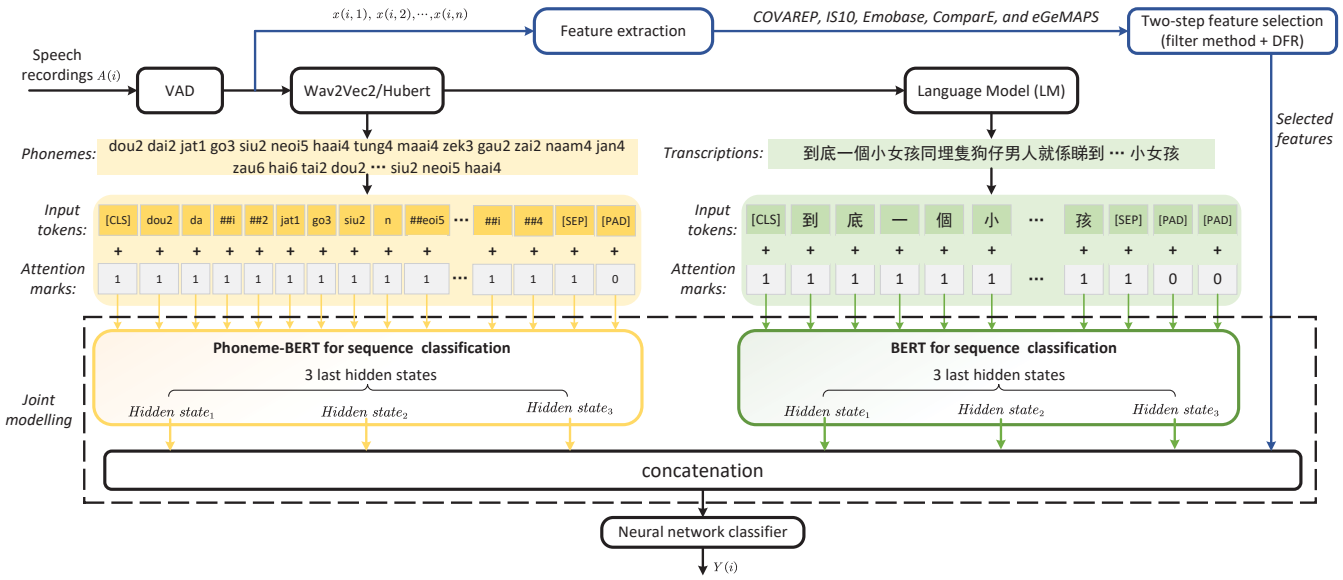

Fig. 1. The architecture of our system for detecting dementia of Cantonese speakers. The recording $A(i)$ is segmented using voice activity detection into n segments. A two-step FS method identifies the most discriminative speech-based features. BERT and phoneme-BERT are jointly fine-tuned on ASR transcriptions and their corresponding phonemes and are combined with the speech-based features to screen dementia patients. We concatenated the last three hidden states of the BERT model, the last three hidden states of the phoneme-BERT model, and the selected features. The neural network classifier was adopted for classification.

However, in addition to the best hypothesis, Pan *et al.* [12] used multiple hypotheses to augment the input of BERT to recognize AD patients. More importantly, they concatenated the confidence scores and hidden states of the BERT model, where the confidence scores were used as a proxy measure of accuracy to inform the classifier about the transcription quality.

- *ASR correction.* To extract more robust linguistic features to distinguish AD patients, the transcribed words with low confidence scores can be removed from the automatic transcriptions [14]. In [12], the automatically transcribed words with the confidence scores lower than 0.87 were replaced by the unknown token <unk>.

B. Modeling Approach

The modeling approach presented in this paper is based on the key insights from the above studies. Importantly, it combines the most discriminative speech-based features and the features extracted from Transformer-based models for fully-automatic dementia screening. To overcome the data sparsity problem, we propose a two-step feature selection (FS) method to identify the most discriminative speech-based features. Additionally, to mitigate the errors in ASR systems, we propose a new strategy to jointly model the ASR transcripts and their corresponding phonemes using the Transformer-based models. The whole architecture is shown in Fig. 1. The proposed system is evaluated on a Cantonese corpus called CU-Marvel. The main contributions of this work are summarized as follows:

1) We propose a two-step FS method to identify the most discriminative speech-based features to screen dementia patients.
2) Extensive experiments are conducted to explore the possibilities of modelling phonemes using phoneme-BERT to detect dementia. Results show that information underlying the ASR phonemes is also indicative of dementia.
3) We jointly model transcriptions and phonemes using BERT and phoneme-BERT. Experimental results show that simultaneously fine-tuning the BERT and phoneme-BERT models can leverage information from the recognized phonemes, making the dementia classifier more robust to ASR errors.

II. Methods

A. Selection of Speech-based Features

While various types of features have been used for dementia detection, it is still unclear which features or their combinations are more effective. We built on key insights from the previous studies and utilized FS methods to find the most effective speech-based features for dementia detection. The extracted speech-based features are as follows.

- *INTERSPEECH 2010 Paralinguistic Challenge Features (IS10).* IS10 [15] is a feature set for emotion recognition and bipolar disorder recognition. In addition to the 32 low-level descriptors (LLDs) in INTERSPEECH 2009 Emotion Challenge, 44 LLDs were added to IS10, including PCM loudness, eight log Mel-frequency bands, eight line-spectral frequency pairs, fundamental frequency (F0) envelope, voicing probability, jitter, and shimmer. Twelve statistics (minimum, maximum, mean, range, etc.) of the LLDs were computed, leading to a 1582-dimensional feature vector per recording. IS10 was adopted as the

baseline feature set for the AD2021 Alzheimer's Dementia Recognition Challenge.[2]

- *COVAREP.* COVAREP [16] provides comprehensive acoustic features, which include prosodic features (F0 and voicing), voice quality features, and spectral features. We extracted COVAREP features at 100Hz; for each recording, the mean, maximum, minimum, median, standard deviation, skew, and kurtosis of the features were computed, leading to a 518-dimensional feature vector per recording. Rohanian *et al.* [17] used the COVAREP features for cognitive impairment detection.
- *eGeMAPS.* The eGeMAPS [3] contains 88 features that are selected based on their potential for characterizing physiological changes in voice production.
- *ComParE 2013.* The ComParE 2013 [4] feature set was adopted as a baseline feature set for AD detection in the ADReSS [18] and ADReSSo [11] challenges, which contains energy, spectral, mel-frequency cepstral coefficients (MFCC), and voicing related LLDs.
- *Emobase.* The Emobase feature set [4] comprises MFCC, F0, F0 envelope, line spectral pairs, etc. Wang *et al.* [19] used the Emobase feature set in multi-modal attention network for AD detection.
- *MRCG.* The MRCG features are multi-resolution cochleagram features, which were used by Haider *et al.* [2] to identify AD patients.

We combined all the feature listed above and adopted a two-step FS approach to selecting dementia features. When the feature dimension is very high, filter methods are indispensable for obtaining a reduced feature set for the expensive FS methods. Therefore, in Step 1, filter methods are utilized to pre-screen the original features. Three filter methods were evaluated in the experiments: Fisher's discriminant ratio (FDR) [20], PeaCorr tests, and mutual information (MutInfo). In Step 2, a deep-learning-based feature ranking method called dual-net feature ranking (DFR) [21] is applied to rank the remaining features. Features with high feature importance were then selected. DFR utilizes a dual-net architecture, where two networks (called operator and selector) are trained to simultaneously perform FS and dementia detection. Specifically, the selector is trained to find multiple subsets of features with minimal cardinality to predict the operator's performance, and the operator uses these feature subsets to minimize classification errors. DFR uses all of the selector's parameters to determine the contribution of individual features to the selector's predictions. DFR shows good performance on a dementia-related Cantonese dataset called JCCOCC-MoCA [22].

B. Automatic Speech Recognition

In order to build a fully-automatic dementia screening system, ASR was used for transcribing speech. Wav2vec 2.0 [23] (denoted as Wav2vec2 from now on) and HuBERT [24] are self-supervised pre-trained models that can be utilized for end-to-end ASR. They can also learn powerful representations from a large amount of unlabeled speech data. By fine-tuning the models on a small amount of transcribed speech, they can achieve similar performance as the traditional fully-supervised ASR systems [23]. As there is no Cantonese pre-trained version of Wav2vec2 or HuBERT, we adopted multilingual and Chinese pre-trained versions of Wav2vec2 and HuBERT from the Transformer Python library, including *Wav2vec2-large-xlsr*,[3] *Wav2vec2-large-Chinese*,[4] and *Hubert-large-Chinese*.[5]

The Cantonese version of Common Voice Speech dataset [25] (common-voice-zh-HK) was used for fine-tuning. The PyCantonese library was utilized to convert the transcriptions to corresponding phonemes.[6] The acoustic models were end-to-end fine-tuned on phone-level using connectionist temporal classification loss. The fine-tuned acoustic models were tested on common-voice-zh-HK test data. The phone error rate for *Wav2vec2-large-xlsr*, *Wav2vec2-large-Chinese*, and *Hubert-large-Chinese* were 0.087, 0.145, and 0.148, respectively. Therefore, *Wav2vec2-large-xlsr* was selected for producing phonemes using the CU-Marvel corpus as inputs. To generate the ASR transcriptions, the phonemes were decoded using a beam search decoder with a 4-gram KenLM trained on common-voice-zh-HK.[7]

C. Modelling with Optimal Features

The BERT models were pre-trained on a large amount of transcriptions using masked language modeling (MLM) as the pre-training objective. As there is no pre-trained version of BERT on Cantonese phonemes, we pre-trained our phoneme-BERT using the common-voice-zh-HK Cantonese phonemes. To form a better representation of the phonemes, we first trained a Word Piece Encoder (WPE) with a vocabulary that consists of 600 sub-word units[8] using the common-voice-zh-HK phonemes. The WPE was shown to work well on the Cantonese phonemes. The trained WPE was then utilized to encode the phonemes into multiple WPE-tokens. In our pre-training settings, the token embeddings of WPE-tokens were randomly initialized and the default configuration of the original BERT was adopted. Following the pre-training regime of BERT, we randomly masked 20% of WPE-tokens using `[MASK]`. Finally, we pre-trained our phoneme-BERT using the masked WPE-tokens as inputs and MLM as the learning objective.

After pre-training our phoneme-BERT, we combined it with a well pre-trained BERT model[9] from the Transformer library. We followed the strategy in [12] and concatenated the last three hidden states of the BERT model with the last three hidden states of the phoneme-BERT model, see

TABLE I
CHARACTERISTICS OF THE CU-MARVEL DATASET.

Variable	HCs ($n = 185$)	Dementia ($n = 124$)
No. of Female	122	70
No. of Male	63	54
Age (years)	70.0 (66.0, 75.0)	78.0 (68.8, 83.0)
Education (years)	7.0 (6.0, 11.0)	6.0 (2.0, 9.25)
MoCA scores	23.0 (21.0, 26.0)	19.0 (15.0, 21.0)
Language	Cantonese	
Task	Rabbit-story picture description	
Manual transcriptions	No	

HCs: healthy older adults; MoCA: Montreal Cognitive Assessment.
The values are presented as *median (interquartile range)*.

Fig. 1. To utilize information from the speech, we combined the concatenated hidden states with the selected speech-based features. Note that the selected speech-based features were normalized to make them compatible with the characteristics of the hidden states. A fully-connected neural network (FCNN) classifier was built on top of the concatenated hidden states and the selected features. Finally, the phoneme-BERT and BERT were end-to-end fine-tuned on the ASR transcriptions and their corresponding phonemes.

III. DATASETS AND EXPERIMENTAL SETTINGS

A. The CU-Marvel Cantonese Corpus

Cantonese is one of the major Chinese dialects that has over 80 million native speakers in Southern China. The CU-Marvel corpus was collected for the research on the screening and monitoring of neurocognitive disorders based on spoken language technologies. A series of cognitive tests, including Montreal Cognitive Assessment (MoCA) tests and picture description tests, were given to each participant for assessing the mild cognitive impairment and dementia in older adults. According to the assessment results, 309 participants were divided into three groups: 185 healthy older adults (HCs), 98 older adults having minor neurocognitive disorders (minor NCD), and 26 older adults suffering from major NCD. For detecting dementia, we combined minor NCD and major NCD into one category called "possible dementia". A rabbit story picture description task was selected for the experiments. Table I shows the corpus's characteristics.

B. Implementation Details

The phoneme-BERT was pre-trained on the common-voice-zh-HK phonemes with a batch size of 512 for 3,000 steps. We observed an increase in the validation loss when the number of steps exceeded 3,000. 10-fold cross-validation (CV) was applied to the CU-Marvel dataset to determine the performance of dementia detection. For each fold, we fine-tuned the models with a batch size of 4 for 10 epochs. The maximum length for word tokens and phoneme tokens was set to 512. This setting aims to cover as many words and phonemes as possible because most participants spoke a lot.

TABLE II
DETECTION PERFORMANCE (F_1 SCORES) ON THE CU-MARVEL. THE NUMBERS IN THE BRACKETS ARE FEATURE DIMENSIONS.

Feature set	SVM	DT	KNN	LDA	FCNN
IS10 (1582)	0.521	0.559	0.528	0.517	0.590

Mean	0.540	0.549	0.539	0.531	***0.603***

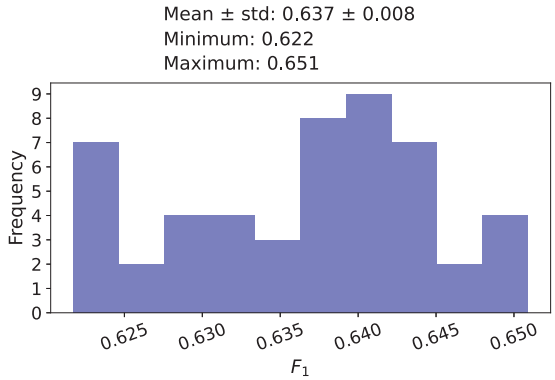

Fig. 2. Variation in detection performance across the repeated CVs.

IV. RESULTS AND DISCUSSIONS

A. Performance of Different Feature Types

We first evaluated the recognition performance of all the feature sets *before* FS. Five classifiers were adopted, including k-nearest neighbor (k-NN) classifier ($k = 1$), linear support vector machines (SVM, box constraint $= 0.1$), decision trees (DT, leaf size $= 20$), linear discriminant analysis (LDA), and FCNN classifier.[10] We ran 50 repetitions of the 10-fold CV based on different data splittings and averaged the performance (F_1 scores). The corresponding results are reported in Table II. Table II shows that the FCNN classifier achieves the best classification performance among all classifiers, that is, it achieves the highest averaged F_1 scores. Therefore, subsequent experiments adopted the FCNN classifier.

We then combined all of the features to form the *combined features*, which are 10317-dimensional vectors. When conducting 10-fold CV on the combined features, large variation in detection performance across the repeated CVs was observed, as illustrated in Fig. 2. The variation is caused by applying random splitting on a small dataset for each CV, inducing significantly different training partitions (TR) for each run. To reduce the variation, we propose using an ensemble procedure to stabilize the detection performance. Specifically, we ran 10 repetitions of CV based on different data splittings.

[10]Except for the FCNN classifier, all other classifiers were adopted from [2]. FCNN classifier settings: network architecture 'feature_dimension–128–32–2", batch size $= 4$, and epochs $= 10$.

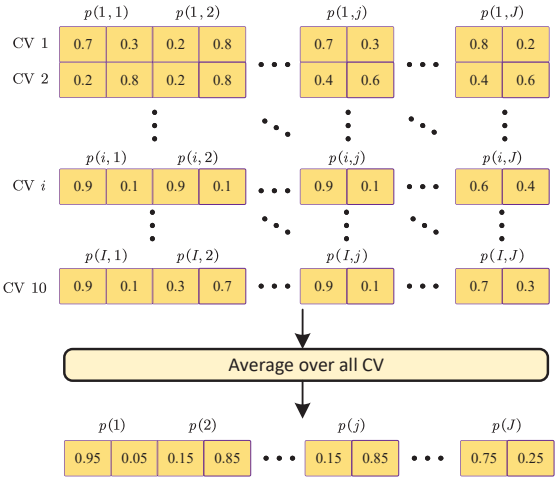

Fig. 3. The ensemble procedure to stabilize the classification performance estimated by CV. We ran I repetitions of CV based on different data splittings and averaged the predicted scores $p(i,j)$ over all the CV for each of the J subjects.

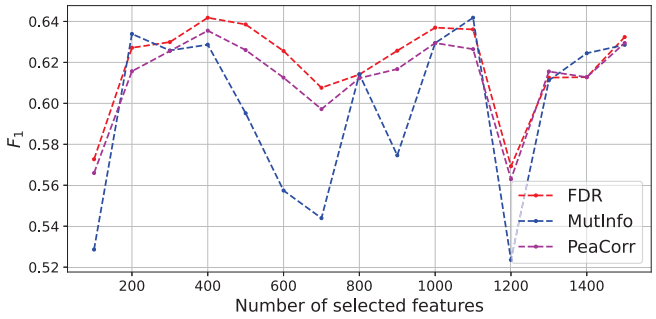

Fig. 4. Classification performance of the filter methods.

We then produced the predicted scores $p(i,j)$ for subject j in CV i, as shown in Fig. 3. Finally, we averaged the predicted scores $p(j) = (1/10)\sum_{i=1}^{10} p(i,j)$ over all the 10 CV for each of the J subjects. After utilizing the ensemble procedure, we obtained 0.670 accuracy (ACC) and 0.645 F_1 scores, which boosts the minimum F_1 scores from 0.622 (Fig. 2) to 0.645. Therefore, the subsequent experiments adopted the ensemble procedure to stabilize classification performance.

B. Performance of Two-step FS

We followed the procedure described in Section II-A to evaluate the performance of the filter methods (FDR, PeaCorr, and MutInfo) on the combined features (10317-dimensional vectors). On the TR of individual folds, we applied the filter methods to reduce the feature dimension to $n = \{100, 200, 300, 400, \ldots, 1500\}$, as shown in Fig. 4. It shows that FDR achieves the highest F_1 scores (0.645) when the feature dimension was reduced to 400. We then applied DFR on the remaining 400 features to further select more discriminative features, as shown in Table III. It shows that when we reduced the feature dimension from 400 to 300, we further improved the ACC. This two-step procedure

TABLE III
CLASSIFICATION PERFORMANCE OF TWO-STEP FS. *ACC*: ACCURACY; *PRE*: PRECISION; *REC*: RECALL.

	Dimension	10-fold CV ACC	PRE	REC	F_1
FDR + DFR (Step 1 + Step 2)	150	0.650	0.634	0.631	0.632
	200	0.663	0.648	0.626	0.627
	250	0.628	0.623	0.628	0.622
	300	***0.680***	***0.668***	***0.643***	***0.645***
	350	0.634	0.622	0.624	0.623
	400	0.663	0.648	***0.643***	***0.645***

significantly reduces the feature dimension and outperforms the combined features.

C. Performance of Fine-tuning

We evaluated the performance on fine-tuning BERT, phoneme-BERT, and the combination of BERT and phoneme-BEET, as shown in Table IV (Row 2 to Row 4). Row 3 shows that fine-tuning phoneme-BERT on ASR phonemes is beneficial to dementia detection. This indicates that some abnormal information (e.g., phoneme disorder, phoneme repetition, phoneme scarcity, and phoneme deficiency) in the patients' ASR phonemes is also indicative of dementia. Row 2 and Row 3 show that fine-tuning phoneme-BERT is better than fine-tuning BERT. This maybe due to the insufficient training of the LM. If we adapt the LM with an elderly corpus containing similar picture description tasks, we may reduce the ASR errors and improve detection performance.

Row 4 shows that it is better to fine-tune the phoneme-BERT and BERT models jointly instead of fine-tuning the BERT model only, indicating that the recognized phonemes contain useful information for dementia detection. Our ASR system produces phonemes, which are subsequently decoded into words using a 4-gram KenLM. In Cantonese, a single set of phonemes may correspond to multiple words, i.e., homophones. Despite the ASR system producing the correct phonemes, in some instances, these phonemes are misinterpreted, resulting in erroneous words. Though the ASR system decodes some erroneous words, simultaneous fine-tuning of BERT and phoneme-BERT enables the system to leverage the corresponding correct phonemes, enhancing its overall robustness to ASR errors.

D. Fine-tuning with Optimal Features

Finally, we fine-tuned BERT, phoneme-BERT and the combination of phoneme-BERT and BERT with the optimal features selected in Section IV-B. Table IV (Row 5 to Row 7) shows that fine-tuning with the optimal features can improve performance, no matter on which model. This strategy leverages the optimal features to enhance the inputs to the classifier. Row 7 shows that with the optimal feature set, simultaneously fine-tuning the phoneme-BERT and BERT models achieves the best detection performance.

TABLE IV
CLASSIFICATION PERFORMANCE ACHIEVED BY FINE-TUNING DIFFERENT MODELS. *ACC*: ACCURACY; *PRE*: PRECISION; *REC*: RECALL.

Row	FDR + DFR	Fine-tuning		10-fold CV			
		BERT	Phoneme-BERT	ACC	PRE	REC	F_1
1	✔	✘	✘	0.680	0.668	0.643	0.645
2	✘	✔	✘	0.608	0.591	0.591	0.591
3	✘	✘	✔	0.650	0.635	0.634	0.634
4	✘	✔	✔	0.667	0.654	0.655	0.654
5	✔	✔	✘	0.693	0.680	0.666	0.669
6	✔	✘	✔	0.683	0.670	0.671	0.671
7	✔	✔	✔	***0.696***	***0.685***	***0.687***	***0.686***

V. CONCLUSIONS

We proposed a two-step feature selection method to identify the most effective speech-based features to screen Cantonese-speaking dementia patients. Fine-tuning Transformer-based models with the selected speech-based features improved performance further. We also fine-tuned BERT and phoneme-BERT on transcriptions and their corresponding phonemes, which made the dementia classifier more robust to ASR errors. Fine-tuning both the BERT and phoneme-BERT models together resulted in a 6% improvement in F_1 scores, compared to fine-tuning the BERT model alone.

***Abstract*—Automatic speech recognition (ASR) systems which involve the use of multiple ASR models, known as "system combination" approaches, have been confirmed by many studies to be effective for improving speech recognition performance. In this study, we propose a system combination method using multiple end-to-end (E2E) ASR models trained under different conditions (i.e., using data from different source domains), in order to perform ASR on an unknown target domain without the need for additional, expensive model training. In order to efficiently adapt existing ASR models to the target domain, we exploit a density ratio approach (DRA), and experimentally demonstrate that by combining ASRs trained with multiple types of acoustic information with an external language model for the target domain, i.e., the standard DRA, our method can more robustly perform ASR for an unknown target domain than a single ASR model trained under one domain condition.**

I. Introduction

Combining the outputs of multiple automatic speech recognition (ASR) systems has been shown to be an effective technique for improving ASR performance. For example, the NIST Recognizer Output Voting Error Reduction (ROVER) method integrates the output of multiple Large Vocabulary Continuous Speech Recognition (LVCSR) systems using a voting module [1], [2]. Other methods integrate the outputs of multiple LVCSR systems in a machine-learning manner, e.g., using a Support Vector Machine [3], [4]. These multiple model ASR systems have outperformed single model ASR approaches, demonstrating the effectiveness of this approach. Robust acoustic models have also been created by integrating large-scale acoustic models, acoustic models trained with speech recorded in noisy environments, and acoustic models trained with data containing different styles of speech, in a Gaussian mixture model (GMM) space [5]. Researchers have also proposed integrating a hybrid ASR model and an end-to-end (E2E) ASR model at the hypothesis level to improve recognition performance [6], while other investigators have integrated ASR models with completely different model architectures, such a hybrid ASR model and a GMM-HMM ASR model [7].

In contrast, only a few studies have explored combining multiple E2E ASR models [8]. This is because it is generally believed that the vast training parameters of a single E2E ASR model allow a sufficient degree of freedom to process speech data from a variety of domains, including speech data containing noise and multiple styles of speech, and thus there is no need to combine multiple ASR models. While the recognition performance of large-scale E2E ASR models has improved over the years, researchers have also explored the use of E2E ASR models in combination with external language models. Shallow Fusion (SF) is a method frequently used to integrate an ASR model and an external language model [9]–[12], allowing easy integration without the need for retraining, unlike other integration methods such as Deep Fusion [13], Cold Fusion [14], and Component Fusion [15]. The Density Ratio Approach (DRA) [16], [17], which is a stochastic improvement of SF, is a more recently proposed integration method which considers the "implicit language information" contained inside the trained ASR model. It has been reported that the language information contained in English [16], [17], Spanish, Italian [18], and Japanese [19] ASR models can be approximated by external language models using DRA, which separates the acoustic and language information acquired by the ASR model.

Therefore, in this study, we combine the acoustic information contained within multiple existing ASR models with language information from an external language model for the target domain using DRA, under the assumption that there may be situations in which it is not feasible to create a large E2E ASR model for a particular target domain. By combining acoustic information from multiple existing E2E ASR models with language information from the target domain language model, we thought it might be possible to create an ASR model that is acoustically robust for the target domain, improving speech recognition performance. Therefore, our proposed method extracts multi-domain acoustic information from multiple E2E ASR models and combines it with knowledge about the target domain obtained from the external language model.

Multiple E2E ASR and language models are combined also in [8]. The authors conduct their experiments in one domain scenario. In contrast, we conduct our experiments in a domain adaptation scenario.

II. Language model fusion methods

A. Shallow fusion

The standard method used to integrate information from an ASR model and an external language model is called shallow fusion (SF). The output probabilities of the ASR model

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

are added with those of the external language model in the logarithmic domain follows:

$$\hat{y} = \underset{y}{\operatorname{argmax}}\{\log P(y|x) + \lambda \log Q(y)\}, \tag{1}$$

where $P(y|x)$ is the output probability of the ASR model, i.e., the probability of inferring symbol label y when acoustic feature x is given, and where $Q(y)$ is the prior output probability of the external language model. When using the SF method, the external language model is only used during inference. Note also that the language and ASR models are trained independently.

B. Density ratio approach (DRA)

More recently, research have attempted to estimate the "implicit language information" contained with ASR models to facilitate integration with external language models [20], [21]. The original DRA is presented below.

The density ratio approach (DRA) is one of the method s proposed. The original DRA method is similar to SF, but DRA also takes this implicit language information into account during inference. Conventional ASR models attempt to infer sequence $\hat{y}$ as follows:

$$\hat{y} = \underset{y}{\operatorname{argmax}}\{\log P_{\mathrm{src}}(y|x)\}, \tag{2}$$

where $P_{\mathrm{src}}(y|x))$ is the probability of output sequence y obtained from the ASR model for the source domain when given input sequence x. Here, "source domain" refers to the task being performed when the speech data used for model training was recorded, e.g., dialog speech, presentation speech, etc. Output probability $P_{\mathrm{src}}(y|x)$ from the ASR model can be expanded using Bayes' rule as follows:

$$\log P_{\mathrm{src}}(y|x) = \log P_{\mathrm{src}}(x|y) + \log P_{\mathrm{src}}(y) - \log P_{\mathrm{src}}(x), \tag{3}$$

where $P_{\mathrm{src}}(x)$ is a term commonly calculated for all y and does not affect the relative relation of the probability. Therefore (3) can be expressed as follows:

$$\log P_{\mathrm{src}}(y|x) = \log P_{\mathrm{src}}(x|y) + \log P_{\mathrm{src}}(y) + \mathrm{Const}. \tag{4}$$

On the right side of (4), we can see that the ASR model includes the acoustic information term $P_{\mathrm{src}}(x|y)$ and the language information term $P_{\mathrm{src}}(y)$, the letter of which represents the "implicit language information" refereed to above, i.e., the statistics of language obtained from the speech data used for training the ASR model. This "implicit language information" is considered to be approximately the same as the language information that would be possessed by a language model trained in the same domain, i.e., $P_{\mathrm{src}}(y) \approx Q_{\mathrm{src}}(y)$.

ASR models take advantage of implicit language information to improve decoding when the test data domain is the same as the training domain. But if the test domain differs from the training domain, this implicit language information can degrade the ASR model's decoding performance. When using DRA, this implicit language information can be removed by subtracting the output probability of the language model from the output probability of the ASR model for the source domain, and then adding the output probability of the target domain language model as follows:

$$\begin{aligned}\log P_{\mathrm{src}}(y|x) &- \lambda_{\mathrm{sub}} \log Q_{\mathrm{src}}(y) + \lambda_{\mathrm{add}} \log Q_{\mathrm{tgt}}(y) \\ &\approx \log P_{\mathrm{src}}(x|y) + \lambda_{\mathrm{add}} \log Q_{\mathrm{tgt}}(y) + \mathrm{Const} \\ &\propto \log P_{\{\mathrm{src,tgt}\}}(y|x),\end{aligned} \tag{5}$$

where $Q_{\mathrm{tgt}}(y)$ is the probability of the external language model for the target domain, and λ_{add} is an addition weight. The DRA assumes that the source domain acoustic information $P_{\mathrm{src}}(x|y)$ is roughly equal to target domain acoustic information $P_{\mathrm{tgt}}(x|y)$. Therefore, $P_{\{\mathrm{src,tgt}\}}(y|x)$ in (5) indicates that the acoustic information is the source domain and the language information is the target domain. It can also be said that $P_{\{\mathrm{src,tgt}\}}(y|x)$ is the ASR model, where the acoustic information is the source domain and the language information is the target domain. By using (2) to (5), we can successfully replace only the ASR model's language information allowing the create of an ASR model for any target domain simply by preparing text data for that domain. Furthermore, DRA integrates the external language model and ASR model only at the time of inference, as in SF.

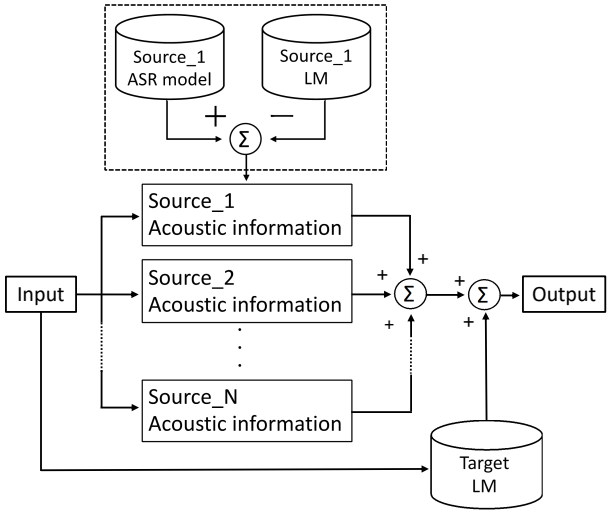

Fig. 1. Overview of the proposed method.

III. Proposed method

In this study, we assumed that only pure acoustic information remains in the E2E ASR model when the implicit language information is removed, and that it is possible to construct a ASR model for the target domain by combining acoustic information from multiple source domains with language information from the target domain. By integrating the acoustic information extracted from multiple ASR models, it should be possible to enhance the acoustic information even when the ASR models are trained with only a small amount of data.

We first extract acoustic information from multiple E2E ASR models at each decoding step, using the process shown

in (6):

$$\log \tilde{P}_{\mathrm{src}}(x|y) \approx \sum_{i=1}^{N} \{\log P_{\mathrm{src_}i}(y|x) - \lambda_{\mathrm{sub_}i} \log Q_{\mathrm{src_}i}(y)\}, \tag{6}$$

where N is the number of E2E ASR models used, $P_{\mathrm{src_}i}(y|x)$ is the i-th source domain ASR model, and $Q_{\mathrm{src_}i}(y)$ is the i-th source domain language model. The acoustic information for each domain is extracted using the external language model's language information for each domain, which is then subtracted from the E2E ASR models for those domains. We then add extracted acoustic information $\tilde{P}_{\mathrm{src}}(x|y)$ and external language model information for the target domain $Q_{\mathrm{tgt}}(y)$, as shown in (7) below, confirming in theory that a target domain ASR model can be created with acoustic information obtained from multiple E2E ASR models and language information from an external language model trained with a large amount of target domain text data.

Figure 1 provides an overview of our proposed method. We integrated the acoustic information from each E2E ASR model with the language information from the external language model during the beam search step as follows:

$$\hat{y} = \underset{y}{\mathrm{argmax}} \{\log \tilde{P}_{\mathrm{src}}(x|y) + \lambda_{\mathrm{add}} \log Q_{\mathrm{tgt}}(y)\}. \tag{7}$$

We expect that our proposed method will be more acoustically robust due to the use of acoustic information from multiple, existing E2E ASR models, potentially improving ASR performance while reducing development cost. Since our method does not require re-training, such as fine-tuning the existing ASR model, this type of ASR system can be easily developed without incurring the cost of dataset construction (e.g., pairing speech data with its transcription). We only need to prepare an external language model trained with text data for the target domain.

IV. Experiment

A. Setup

We evaluated the performance of the proposed method experimentally using an ASR task, and compared its recognition accuracy with results when using E2E ASR models with SF, DRA, and an without external language model. The speech recognition accuracy for each method was evaluated using character error rates (CER) for the test set.

We used data from the Corpus of Spontaneous Japanese (CSJ) dataset [22], the Mainichi Shimbun (MS) dataset, the Japanese Newspaper Article Sentences (JNAS) dataset [23], and Corpus of Everyday Japanese Conversation (CEJC) [24] dataset in our experiments. Table I shows the details of the datasets used in the experiment. Two domains were used from the CSJ dataset: Academic Presentation Speech (APS), which includes presentations on the subjects of engineering, humanities, and sociology, and Simulated Public Speech (SPS), which did not contain academic terminology. The APS and SPS domain consist of 214 and 257 hours of speech data, respectively. These speech data was randomly divided into a training set (Train-set) and a development set (Dev-set), representing the training and development data used when training the E2E ASR models. The Dev-set was used to monitor learning, and early stopping was applied to prevent overfitting with the patience value set to 3. We expanded the training datasets using speaking speed perturbation, adding voice data converted to 0.9 and 1.1 times the speed of the original voice data. The MS dataset is a text dataset consisting of 58 million characters from 11 years of Japanese newspaper articles (1991 to 2002), and was only used for training the external language models. The JNAS dataset was created by having speakers read excerpts from daily newspaper articles aloud, thus the JNAS speech data is from the same domain as the MS text data. The JNAS corpus was used for the Dev-set and Test-set. The Dev-set was used when selecting hyperparameters for the model integration methods, while the Test-set was used to evaluate the proposed method and the other integration methods. The CEJC dataset contains natural daily conversations in various situations by speakers of a wide range of ages. This data was divided into a Train-set, Dev-set, and Test-set. Train-set was used for training the external language model, and Dev-set and Test-set were used for the same purposes as JNAS.

TABLE I
Details of the data sets used in the experiment.

Domain	Split	Speakers	Utterances	Characters	Duration
APS (CSJ)	Train	889	139,396	5,041,328	206h
	Dev	49	5,272	195,416	8h
SPS (CSJ)	Train	1,555	221,994	5,503,402	245h
	Dev	80	8,612	258,651	12h
MS	Train	—	—	64,864,516	—
JNAS	Dev	23	500	230,821	0.9h
	Test	23	500	238,717	0.9h
CEJC	Train	—	—	2,792,530	—
	Dev	279	1,161	30,567	1h
	Test	279	1,161	30,396	1h

As our E2E ASR models, we used both the hybrid CTC/attention architecture [25] and the joint CTC/Attention Transformer [26] provided by ESPnet (version: v.202205) [27], [28]. We prepared three versions of the E2E ASR models: E2E ASR models trained with the CSJ's APS domain, E2E ASR models trained with CSJ's SPS domain, and E2E ASR models trained with both the APS and SPS domain of the CSJ. We also prepared five external language models, which were trained with APS transcription data, SPS transcription data, both APS and SPS transcription data, MS text data, and CEJC transcription data, respectively. The vocabulary size of dictionary used for training the ASR and language models was set to 3,262, which is the total number of characters in the CSJ.

Based on the theoretical foundation established in (6) and (7), we first extracted the acoustic information for the APS and SPS speech data from the APS E2E ASR and SPS E2E ASR models, respectively, using the method shown in (8). The extracted acoustic information was then integrated with the MS

trained external language model, as shown in (9):

$$\log P_{\{\mathrm{APS,SPS}\}}(x|y) \approx \log P_{\mathrm{APS}}(y|x) - \lambda_{\mathrm{sub_1}} \log Q_{\mathrm{APS}}(y) + \log P_{\mathrm{SPS}}(y|x) - \lambda_{\mathrm{sub_2}} \log Q_{\mathrm{SPS}}(y), \quad (8)$$

$$\hat{y} = \underset{y}{\mathrm{argmax}} \{\log P_{\{\mathrm{APS,SPS}\}}(x|y) + \lambda_{\mathrm{add}} \log Q_{\mathrm{MS}}(y)\}, \quad (9)$$

where $\hat{y}$ represents the most probable character sequence obtained using a beam search with the beam size set to 20. $\lambda_{\mathrm{sub_1}}$ and $\lambda_{\mathrm{sub_2}}$ in (8) correspond to the subtraction weights of the APS and SPS language models, respectively. λ_{add} in (9) corresponds to the addition weight of the MS language model. These parameters were selected from grid search with values from 0.1 to 1.1 by 0.2 increments, and the most optimal parameters for the Dev-set were used. The weights of the language models used with the SF, DRA, and proposed methods were tuned by grid search. In addition, we conducted an experiment using CEJC as another target domain, and this is formulated as follows:

$$\hat{y} = \underset{y}{\mathrm{argmax}} \{\log P_{\{\mathrm{APS,SPS}\}}(x|y) + \lambda_{\mathrm{add}} \log Q_{\mathrm{CEJC}}(y)\}. \quad (10)$$

B. Training

Following ESPnet's CSJ recipe, the ASR and language models were trained under the following conditions.

1) CTC/Attention model based BLSTM: The hybrid CTC/Attention architecture is an RNN-based speech recognition model that utilizes the advantages of both Connectionist Temporal Classification (CTC) and an Attention mechanism during training and inference for E2E ASR. The acoustic features of the input speech for the ASR models were processed using Mean and Variance Normalization (MVN) with an 80 mel-scale filter bank. The ASR model consisted of an encoder with VGGnet and four Bidirectional Long Short Term Memory (BLSTM) layers, and an Attention-based decoder with one Long Short Term Memory (LSTM) and a linear layer. A CTC module-based decoder was also used as an auxiliary, in which case the weight of the CTC decoder was set to 0.3. We trained the entire ASR model end-to-end using the Ada-delta optimizer with a batch size of 24.

2) CTC/Attention model based Transformer: The joint CTC/Attention Transformer is a Transformer-based ASR model that combines CTC and Attention, as in the hybrid CTC/Attention architecture described above. The model first performs SpecAugment (time contraction, time masking, and frequency masking) [29] and MVN when acoustic features are input. The model consisted of 18 Transformer encoders, 6 Transformer decoders and a CTC module-based decoder with the weight set to 0.3. The number of Multi-Head Attention heads used by each encoder and decoder was set to 8. We then trained the entire model end-to-end using Adam.

TABLE II
PERPLEXITIES FOR EACH LANGUAGE MODEL AND TEST SET.

Language Model	Perplexity for Test Set				
	APS	SPS	APS+SPS	JNAS	CEJC
APS	17.33	33.37	24.23	147.66	43.07
SPS	34.79	17.38	24.39	100.64	32.07
APS+SPS	15.78	16.77	16.28	80.53	29.06
MS	95.82	56.58	73.18	33.43	50.78
CEJC	99.15	49.51	69.50	208.29	23.80

3) RNN language model: The character-based RNN language model consisted of an embedding layer, two LSTM layers, and a linear layer. The input to the embedding layer was a one-hot vector of characters. The batch size was 256 and stochastic gradient descent (SGD) was used as the optimization function.

C. Results

1) Perplexity: To compare the differences in the language information of each domain, we calculated the perplexities of the external language models for each domain, which are shown in Table II. The APS and SPS test sets consist of 117,252 and 121,465 characters, respectively, and the APS + SPS test set is simply a combination of these two sets of text data. The perplexities shown in Table II confirm that the language information of each domain is different. In particular, we can confirm that there is a large difference between the language information in the MS and CEJC domains and that in the APS and SPS domains.

2) CERs with CTC/Attention model based BLSTM: Using the ASR and language models obtained after training in each domain, we compared and evaluated the performance of the proposed method with that of the conventional integration methods.

First, the results of our comparative experiment when using MS as the target domain are shown in Table III. where, we used RNN-based models as the ASR model. These results reveal that the proposed method outperformed the single ASR model methods (ASR models without an external language model, ASR models using SF or DRA). Results when using the APS+SPS E2E ASR models, which are relatively large-scale E2E ASR models trained with both the APS and SPS datasets, were CERs of 18.9% without the external language model, 16.6% with SF, 15.9% with DRA. The CER when using the proposed method was 16.3%, which was slightly higher than the CER when using the DRA, however our proposed method achieved comparable performance without the need to train the ASR model with the APS and SPS speech data. The relative difference between the CER of the proposed model and the collective CER of the large-scale E2E ASR model was only 2.45%. Despite its higher CER, we believe the proposed method is very effective given the fact that it can integrate multiple existing E2E ASR models without re-training. On the other hand, when comparing the CERs of the proposed method with those of the integrated methods using two domains (APS and SPS) for acoustic information, the

TABLE III
CERs (%) FOR EACH METHOD WHEN USING RNN-BASED ASR MODELS WITH JNAS AS THE TARGET DOMAIN.

ASR Model	N	Integration method			
		w/o LM	SF (λ_{add})	DRA (λ_{sub} / λ_{add})	Proposed ($\lambda_{\mathrm{sub_1}}$, $\lambda_{\mathrm{sub_2}}$ / λ_{add})
APS	1	26.3	23.9 (0.5)	22.4 (0.3 / 0.3)	—
SPS	1	22.0	21.7 (0.5)	19.9 (0.3 / 0.3)	—
APS+SPS	1	18.9	16.6 (0.5)	**15.9** (0.3 / 0.5)	—
APS, SPS	2	19.4	17.9 (0.7)	—	**16.3** (0.5, 0.3 / 0.9)

TABLE IV
CERs (%) FOR EACH METHOD WHEN USING RNN-BASED ASR MODELS WITH CEJC AS THE TARGET DOMAIN.

ASR Model	N	Integration method			
		w/o LM	SF (λ_{add})	DRA (λ_{sub} / λ_{add})	Proposed ($\lambda_{\mathrm{sub_1}}$, $\lambda_{\mathrm{sub_2}}$ / λ_{add})
APS	1	42.7	42.1 (0.3)	41.1 (0.3 / 0.5)	—
SPS	1	38.9	38.4 (0.1)	38.3 (0.1 / 0.3)	—
APS+SPS	1	36.6	36.2 (0.3)	**36.2** (0.1 / 0.3)	—
APS, SPS	2	35.4	35.3 (0.1)	—	**35.1** (0.5, 0.1 / 0.7)

TABLE V
CERs (%) FOR EACH METHOD WHEN USING TRANSFORMER-BASED ASR MODELS WITH JNAS AS THE TARGET DOMAIN.

ASR Model	N	Integration method			
		w/o LM	SF (λ_{add})	DRA (λ_{sub} / λ_{add})	Proposed ($\lambda_{\mathrm{sub_1}}$, $\lambda_{\mathrm{sub_2}}$ / λ_{add})
APS	1	21.5	17.5 (0.5)	15.7 (0.3 / 0.7)	—
SPS	1	14.7	12.9 (0.3)	11.6 (0.5 / 0.7)	—
APS+SPS	1	12.8	11.0 (0.5)	**10.5** (0.3 / 0.5)	—
APS, SPS	2	15.2	13.2 (0.7)	—	**11.6** (0.7, 0.3 / 1.1)

proposed method achieved higher ASR accuracy. Therefore, we can confirm that the DRA is effective even when multiple E2E ASR models are used together.

Next, the experimental results when the target domain was CEJC is shown in Table IV. We can see that the CER achieved by the proposed method is 35.1%, which outperformed the single ASR model methods. On the other hand, unlike when using MS as the target domain, the accuracy was higher than APS+SPS. We assumed that when a single model is trained, the probability distribution converges to fit to the source domains, but when multiple models are integrated, multiple distributions are combined to form an abstract representation. This distribution covers the feature space robustly and improves recognition performance in the domains different from the source domains. Therefore, it indicates that the proposed method is effective even when the speech styles of the source and target domains are different.

3) CERs with CTC/Attention model based Transformer: Experimental results when using Transformer-based ASR models are shown in Table V. We can see that the CER achieved by the proposed method is 11.6%, which is much better than that of the RNN-based version (16.3%). However, the relative relationship between the performance of the proposed and conventional methods remained almost the same. The accuracy of DRA methods with SPS and that of the proposed method were the same however, which is presumably because the performance of the Transformer model is already very high, and is not improved by the combination of multiple ASR models. But these results show that the proposed method achieved performance comparable to that of the best performing conventional model, regardless of which type of ASR model was used.

V. CONCLUSION

In this study we proposed a method of combining multiple E2E ASR models using a density ratio approach. We used subtraction through DRA to extract pure acoustic information from multiple existing E2E ASR models, and then integrated the extracted acoustic information with an external language model for the target domain to create an ASR model for the target domain. The proposed method achieved better performance than most of the conventional methods using a single E2E ASR model. By using two different, existing ASR models in our proposed method, we have successfully created an acoustically robust ASR model for the target domain without the need to retrain the ASR model.

In our comparative experiment, we only combined two E2E ASR models in our proposed method, but in future work we would like to evaluate the effectiveness of using three or more models for acoustic information. We would also like to compare our method's performance with ROVER, a conventional combination method. Furthermore, we plan to conduct experiments using ASR models trained with noisy data and with data containing multiple speech styles.

Speech-Emotion Control for Text-to-Speech in Spoken Dialogue Systems Using Voice Conversion and x-vector Embedding

Shunichi Kohara*†, Masanobu Abe* and Sunao Hara*
* Okayama University, Okayama, Japan
† E-mail: pdaepw2@s.okayama-u.ac.jp

***Abstract*—In this paper, we propose an algorithm to control both speaker individuality and emotional expressions in synthesized speech, where the most important feature is the controllability of intensity in emotional expressions. An aim of the proposed algorithm is to generate various responses including emotions in text-to-speech (TTS) for spoken dialogue systems (SDS), which results in making the system more human-like. An idea is to control emotion and its intensity in line with the user's utterances. For example, when a user happily talks to SDS, the agent of the SDS responses with happy voice. Generally, voice quality of a user and the agent are different. Therefore, the proposed algorithm consists of two steps: (1) voice conversion to change speaker individuality including emotional expressions and (2) TTS with x-vector acting as an embedding vector to mainly control speech quality related to the intensity of emotions. Evaluation experiments are carried out using a scenario of a spoken dialogue system, where a teacher system of TTS encourages or cheers up students according to students' utterances. The experiment results showed that TTS can successfully reproduce the emotion and its intensity that are extracted from students' utterances, while maintaining the teacher's speaker individuality.**

I. Introduction

Spoken dialogue systems (SDS) are systems that accomplish a range of tasks using speech, and consist of speech recognition, dialogue processing, and speech synthesis. Important features of SDS is the function to appropriately synthesize speech that conveys rich information such as focus and emotions, and generate various responses according to situations. Monotonous speech responses makes the systems boring, and repetitions of the same sentences are not interesting to use. To address these problems, several methods are proposed such as the usage of linguistic and/or prosodic contexts of dialogue history [1], [2], and the modeling of speaking styles [3], [4].

In this paper, in terms of expressing emotional information, we propose a different approach, i.e., to reproduce emotion and its intensity in synthesized speech to match the user's utterances. Figure 1 shows examples of dialogues. When a user uttered a sentence with sad, happy, and very happy emotions, the agent of SDS responds with the same emotion, sad, happy, and very happy, respectively.

For emotional speech synthesis, extensive studies have been carried out using deep neural networks(DNN) [5]–[7] which showed that emotional IDs work well to control emotional information in DNN. Since emotional IDs are categorical feature vectors, it is not always suitable to control the intensity of emotions. [8] reported that emotional information can be represented by utterance-level x-vectors [9] that were originally proposed to extract features of speakers. In addition, x-vectors can be applied to emotion recognition [10]. [11] proposed an embedding vector called global style tokens (GST) and showed that GST are related to emotional information. Although x-vectors or GST is suitable to control the level of intensity unlike emotional IDs, it is difficult to disentangle the feature representation from the emotion and speaker's individuality.

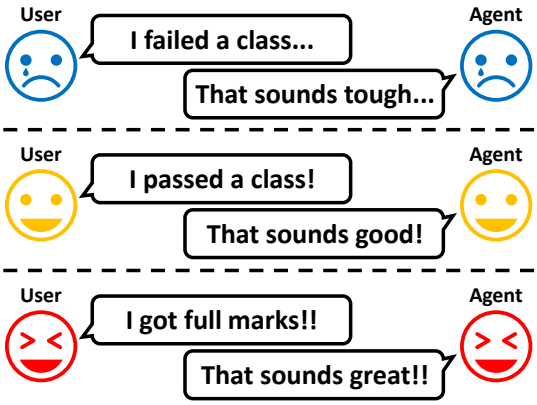

Fig. 1. Examples of dialogues. Our SDS aim to generate response speech in line with the user's speech taking into account nonverbal information, especially emotion, in the user's speech.

In this paper, we propose an algorithm to control both speaker individuality and emotional expressions in synthesized speech; the most important feature is the controllability of intensity in emotional expressions [12]. A promising usage of the proposed algorithm is to generate responses in line with the user's emotions in spoken dialogue systems which makes it possible to generate various responses with emotions and its their intensity making the system interesting or pleasant. This strategy might not always work in SDS systems, but occasionally be reasonable. The proposed algorithm consists of two steps: (1) voice conversion to change speaker individuality including emotional expressions and (2) TTS with x-vector extracted from the converted speech as the embedding vector

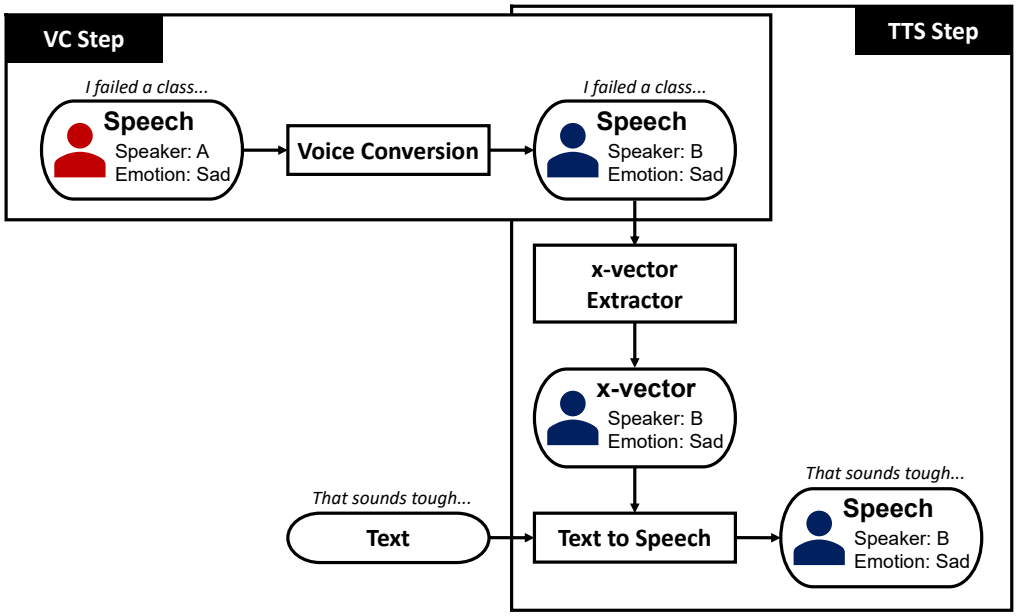

Fig. 2. Outline of the proposed algorithm. The proposed algorithm consists of a VC Step and a TTS Step.

to control the speech quality of the emotion and its intensity.

The rest of this paper is organized as follows: Section 2 describes the outline of the proposed algorithm, Section 3 explains the setup for carrying out evaluation experiments of the proposed algorithm, Section 4 presents the experiment methods and evaluation results, and Section 5 discusses our conclusions and suggests avenues for future work.

II. Proposed Algorithm

Figure 2 shows the outline of the proposed algorithm, which consists of 2 steps: 1. VC Step and 2. TTS Step.

A. Training Procedure

1) VC Step: In the VC Step, we train the multi-speaker setting VITS[13][1] as a voice conclusion model. VITS architecture can apply many-to-many voice conversions, so we use this architecture to convert the speaker's individuality. The speakers of multi-speaker VITS are controlled by speaker ID. At this time, we assume that voice conversion changes the speaker's individuality by inheriting emotional expressions.

2) TTS Step: In the TTS Step, we train a single-speaker (an agent of SDS) TTS model using VITS with x-vector (X-VITS) on ESPnet2-TTS [14][2]. The training data of the speaker contains various instances of emotional speech, and we expect it to express emotion and its intensity by conditioning x-vectors extracted from various instances of emotional speech. The x-vector extractor is trained by ECAPA-TDNN [15] architecture, using large-scale multi-speaker datasets VoxCeleb [16] by SpeechBrain[17].

[1]VITS: https://github.com/jaywalnut310/vits
[2]ESPnet: https://espnet.github.io/espnet/

B. Inference Procedure

1) VC Step: In the VC Step, we convert the speaker individuality of input speech to the TTS model (the agent of SDS). A process of voice conversion by VITS is formulated as follows;

$$z \sim \quad q_\phi(z \mid x_{lin}, s) \tag{1}$$

$$e = \quad f_\theta(z \mid s) \tag{2}$$

For a given speaker identity s and an utterance of the speaker, VITS needs a linear spectrogram x_{lin} from the corresponding utterance. VITS can transform x_{lin} into a speaker-independent representation e through the posterior encoder and the normalizing flow [18] in the prior encoder. Then, the converted speech $\hat{y}$ of a target speaker identity $\hat{s}$ from the representation e is synthesized through the inverse transformation of the normalizing flow f_θ^{-1} and decoder G:

$$\hat{y} = G(f_\theta^{-1}(e \mid \hat{s}) \mid \hat{s}). \tag{3}$$

The speech converted speaker individuality as inheriting emotional expressions.

2) TTS Step: In the TTS Step, we synthesize speech conditioned x-vectors extracted from the converted speech at the VC Step. x-vectors trained with large-scale multi-speaker datasets can encode information such as speaker individuality and emotion and its intensity. Therefore, the TTS conditioned with x-vectors can synthesize the agent of SDS speech including a variety of emotions.

III. Experiments Setup

A. Dataset

The dataset used in evaluation experiments of this paper is STUDIES [19]. STUDIES is the Japanese emotional speech

TABLE I
SEVERAL UTTERANCES BY EMOTION LABEL (WITHOUT PHONETICALLY-BALANCED SENTENCES SPEECH).

Speaker	Neutral	Happy	Sad
Teacher	1796	615	212
M-student	351	381	329
F-student	300	417	340

corpus and contains speech by three voice actors (one male and two female). This dataset consists of simulated dialogue speech between a female teacher who is an agent of SDS in this paper (hereinafter called the Teacher) and a male student (hereinafter called the M-student) and between the Teacher and a female student (hereinafter called the F-student). Also, STUDIES has speech of phonetically-balanced sentences of Japanese, ITA corpus[3], by the Teacher. All audio data are 48kHz/16bit wav files and consist of the attached text, monophone labels, and full-context labels with phoneme alignments.

Each utterance is annotated with emotion labels of four types: Neutral, Happy, Sad, and Angry. In evaluation experiments in this paper, we evaluate three emotions: Neutral, Happy, and Sad, because the Angry utterances are less necessary for our proposed dialogue strategy. Table I shows the number of utterances by emotion label. As a result, the total number of hours for each speaker is approximately 5.6 hours for the Teacher, 1.3 hours for the M-student, and 1.5 hours for the F-student. In this paper, we treat the Teacher of STUDIES as a agent of SDS and the M-student and the F-student as users of SDS.

B. Training Models

We trained each of the models for evaluation experiments, for which speech was down-sampled to 22.05 kHz in advance. Also, 80% of each speaker's utterances and each emotion of the dataset were allocated to the training data, and the remaining 20% to the validation and evaluation data.

In the VC Step, we trained a VITS models for the three-speakers (the Teacher, the M-student, and the F-student) and assigned speaker ID to the three speakers of STUDIES. As a side note, the speech of each speaker contains all emotions. For training multi-speaker VITS, phonemes are derived from full-context labels of the dataset, and we used the method of Kurihara et al. [20] to obtain prosody symbols. The model was trained for 20k epochs using the AdamW optimizer [21] with $\beta_1 = 0.8$, $\beta_2 = 0.99$ and weight decay $\lambda = 0.01$. Settings of networks like hyperparameters are not changed from official implementation[4].

In the TTS Step, we trained a X-VITS of the Teacher, which can control emotions by x-vectors. The phoneme and prosody symbols are obtained in the same way as in the VC Step. This model was trained for 20k epochs using the AdamW optimizer with $\beta_1 = 0.8$, $\beta_2 = 0.99$ and weight decay $\lambda = 0.01$. The settings of networks, like hyperparameters, conform to the VCTK dataset[5] Recipe of ESPnet. Also, to compare with the proposed algorithm, we trained a VITS of the Teacher using one-hot emotional ID as a multi-emotion model. All conditions without one-hot settings are the same as in the X-VITS model.

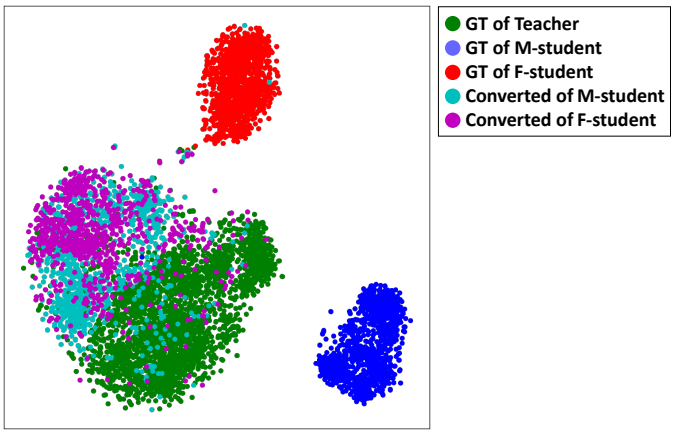

Fig. 3. Distribution of x-vectors. • is x-vector extracted from one utterance. "Converted M-student" and "Converted F-student" are converted speech from the Studnets to the Teacher.

IV. EVALUATION EXPERIMENTS

A. Analysis of VC Step

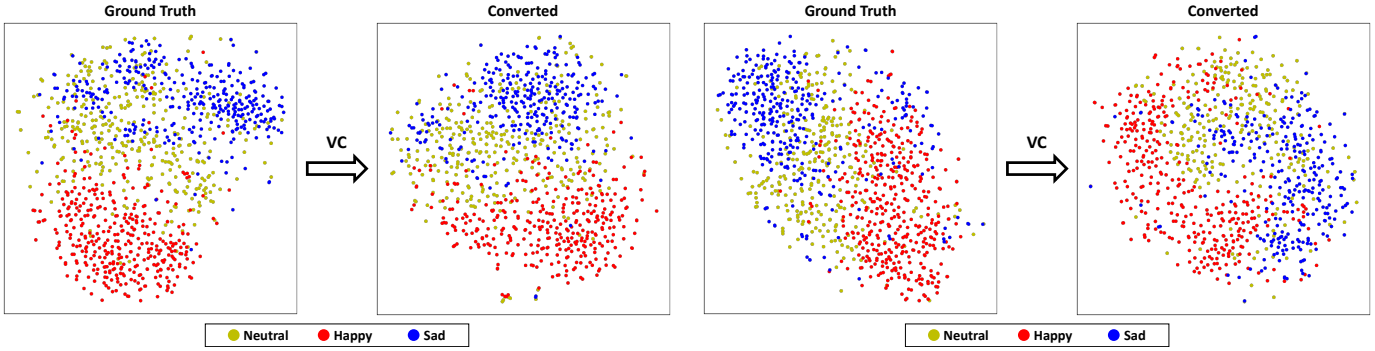

Figure 3 shows the distribution of x-vectors extracted from the ground truth of three speakers in STUDIES and the converted speech of the M-student and the F-student to the Teacher. In this figure, • means each x-vector extracted from one utterance. The dimensions of the x-vectors were reduced by t-SNE [22]. Although the converted speech of the M-student and the F-student are not exactly same as the Teacher's speech itself, this figure shows that the converted speech of the M-student and the F-student are closer to the characteristics of the Teacher than the ground truth of the M-student and the F-student.

To examine emotions in detail, Figure 4 shows the distributions of x-vectors for the M-student and the F-student before and after applying voice conversion. In the figure, • means the x-vector extracted from one utterance. About ground truth, this figure shows that the happy speech of both of the M-student and the F-student is far from Neutral and Sad, and Neutral and Sad are distributed nearby. These relationships are also generally inherited for the converted speech. To summarize voice conversion, the conversion to the speaker individuality while retaining emotional expressions, was adjudged successful.

B. Subjective Evaluation Experiments

As subjective evaluation experiments of the proposed algorithm, we carried out emotional identification tests and paired-comparison experiments using synthesized speech, and these experiments were conducted in a soundproofed room (background noise level: 25 dB) using Sony CD900ST headphones.

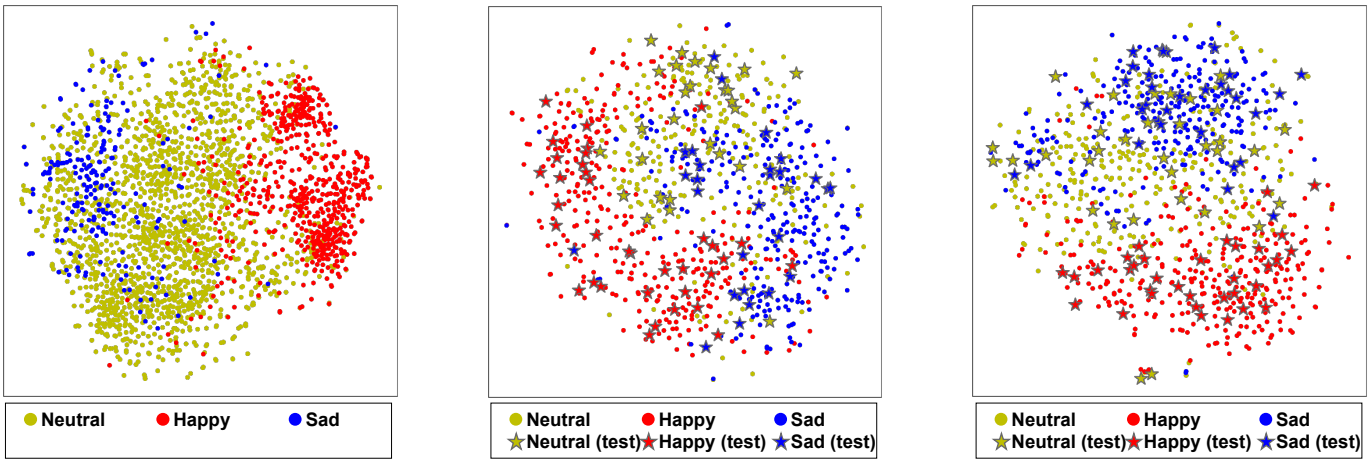
(c) M-student-Converted

	Neutral	Happy	Sad
precision	0.699	0.971	0.851
recall	0.860	1.000	0.630

(d) F-student-Converted

	Neutral	Happy	Sad
precision	0.530	0.932	0.727
recall	0.870	0.960	0.240

The participants are ten native Japanese speakers. Note that examples of generated speech can be found on our webpage[6].



1) Emotion Identification Tests: We asked participants to listen to synthesized speech and select an emotion representing each stimulus from Neutral, Happy, and Sad, and the speech was synthesized under the following four conditions.

1) The Teacher model with one-hot emotional ID (OneHot-EmoID)
2) Averaged x-vectors extracted from the ground truth of the Teacher (Teacher-GT)
3) Averaged x-vectors extracted from the converted speech of the M-student (M-student-Converted)
4) Averaged x-vectors extracted from the converted speech of the F-student (F-student-Converted)

In these conditions, OneHot-EmoID means the very basic emotional speech control algorithm by one-hot ID, and Teacher-GT, such that synthesized speech with x-vectors extracted from the Teacher's ground truth, denotes the ideal conditions for using x-vectors. Compared with the ideal condition for the ground truth of the Teacher, we verify how much control is possible with x-vectors extracted from the converted speech. Incidentally, x-vectors of the Teacher-GT are the mean of "all" data of the Teacher and x-vectors of the M-student-Converted and the F-student-Converted are the mean of "test" data of each converted speech. For each condition, 15 stimuli (3 emotions $\times$ 5 texts) were generated. In terms of texts for TTS, sentences with neutral emotion were selected from the J-set of ATR Japanese speech database [23]. In total, 60 stimuli were presented to the participants in random order. Each stimulus was presented twice.

Table II shows the confusion matrices of the emotion recognition experimental result. About Table II, the rows show the correct emotions, while the columns show subject-perceived emotions.

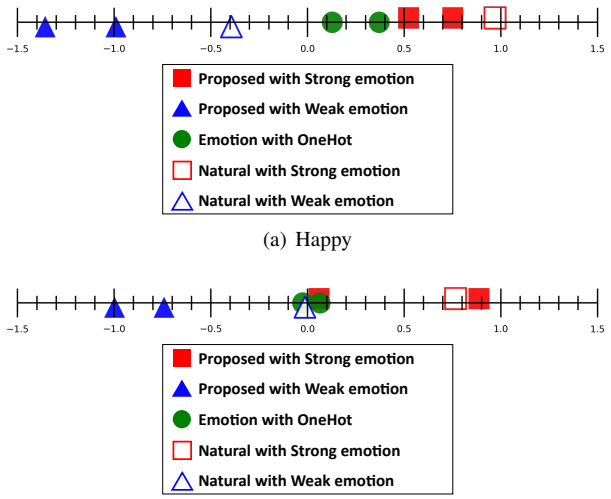
(a) Teacher-GT (b) M-student-Converted (c) F-student-Converted

Fig. 5. Distributions of x-vectors used to calculate averaged x-vectors. Note that ★ of (b) and (c) means x-vectors extracted from "test" data, are used to calculate averaged x-vectors.

First of all, compared with OneHot-EmoID and the Teacher-GT, the Teacher-GT is not less than OneHot-EmoID, so speech-emotion control by x-vectors seems valid. Second, compared with the Teacher-GT and the proposed algorithm, the M-student-Converted and the F-student-Converted, the identification rate of Neutral and Happy in the proposed algorithm is almost the same as the Teacher-GT, but that of Sad is inferior. Table III shows precision and recall, however, the precision of Sad at M-student-Converted and F-student-Converted is over 70%, which suggests that the proposed algorithm can express Sad itself.



The identification rate of the F-student-Converted's Sad has only 24%, and this might come from the averaged x-vectors used in synthesis. So, we plot x-vectors used to calculate averaged x-vectors in Figure 5. Judging from this figure, the boundary between Neutral and Sad is blurred by the order of the Teacher-GT, MStudent-Converted, and FStudent-Converted, and the identification rate of Sad in each condition is the same as the order. Therefore, we can say that x-vectors caused poor judgments in Sad. At the same time, we have to pay attention the fact that there is little differences in grand truth utterances between Neutral and Sad as shown in Figure 4.

2) Paired-Comparison Experiments: Paired-comparison experiments are carried out to evaluate whether the proposed algorithm can express the emotion's intensity. First, we selected four utterances from the M-student utterances; strong-Happy, weak-Happy, strong-Sad and weak-Sad. Those are assumed to be input utterances to a SDS. Then, as response utterances of the SDS, the proposed algorithm synthesized following two types of speech.

1) Using x-vectors extracted from converted speech with strong emotion
2) Using x-vectors extracted from converted speech with weak emotion

As references, we also prepared following synthesized speech.

3) The synthesized speech generated by OneHot-EmoID

(a) Happy

(b) Sad

Fig. 6. Thurstone's Case V scale of experimental results. Outlined square and outlined triangle indicate natural speech uttered by the M-student with strong emotion and with weak emotion.

Moreover, we used following natural speech for comparisons.

4) Ground truth uttered by the M-student with strong emotion
5) Ground truth uttered by the M-student with weak emotion

In terms of emotions, we evaluated for Happy and Sad, and listening tests were carried out separately using Happy stimuli and Sad stimuli. As response texts of synthesized speech, for Happy and Sad, two sentences are used. As stimuli pairs, all combinations of the five types of speech are used. Participants were asked to select an utterance with stronger emotions from presented pair. The total number of the pairs was 28, and each pair was presented twice.

Figure 6 shows the values of Thurstone's Case V scale calculated from the results of paired-comparison, where larger

values indicate a stronger emotional expression. In Figure 6, outlined square and outlined triangle indicate natural speech uttered by the M-student with strong emotion and with weak emotion, respectively.

First of all, in Figure 6, OneHot-EmoID is always placed in the similar position, which indicates that participants consistently judged the emotional intensity of the OneHot-EmoID. This is quite reasonable. In the results for Happy, it is clearly observed that the proposed algorithm can control intensities of the emotion as good as the natural speech. In the results for Sad, although performance is inferior to the case of Happy, the same tendencies are observed. Judging from these results, we can say that the proposed algorithm can successfully control the intensities of the emotion.

V. Conclusions

In this paper, we proposed a algorithm to control speech-emotion including the intensity of emotions to fit the emotions of input speech in SDS using voice conversion and x-vector embedding. First, the proposed algorithm converts the speaker individuality of input speech to the TTS model speaker including emotional expressions, and second, a TTS model synthesizes speech with x-vectors extracted from the converted speech to add emotions and their intensities. In evaluation experiments, the results showed speech-emotions are controllable by the proposed algorithm and its intensity is expressed appropriately against input-speech.

In future, we have a plan to evaluate that the proposed algorithm makes a SDS system interesting or pleasant by generating various responses with emotions and its their intensity. We also need to investigate a voice conversion method that uses a small amount of the source speaker's data to enlarge the area of the proposed algorithm and to carry out a listening experiment about the speaker individuality of speech synthesized by the proposed algorithm. In addition, we would like to investigate to use a categorical classification of emotions for controlling the emotional intensity instead of VC steps and to compare the proposed algorithm with TTS that can be controlled by speaker and emotion IDs.

Narrow-edged Acoustical Beamforming Utilizing Phase Inversion for Frequency Modulation-based Parametric Array Loudspeaker

Yuting Geng*, Masato Nakayama† and Takanobu Nishiura*

***Abstract*—Parametric array loudspeakers (PALs) can achieve narrow directivity with the straightness of ultrasonic waves. However, the acoustic beam formed by small-scale PALs has a tendency to spread easily. We have previously proposed a narrow-edged beamforming based on phase inversion for common amplitude modulation-based PALs; however, it decreased the sound pressure significantly when forming a narrow acoustic beam. In this study, we focus on frequency modulation-based PALs, in which a modulated wave has a constant envelope and can hold more energy in a limited amplitude. The phase inversion strategy is discussed to use phase cancellation in both ultrasound and audible sound for a narrow beam. The experimental results show that the proposed method can achieve narrow-edged acoustical beam while reducing the decrease in sound pressure.**

I. Introduction

Commonly, loudspeakers are used to reproduce acoustic signals. A typical electro-dynamic loudspeaker emits audible sound directly; therefore, the sound it reproduces has a wide directivity. In contrast, a parametric array loudspeaker(PAL) [1], [2], [3] emits ultrasounds and reproduces an audible sound indirectly; as a result, the reproduced audible sound inherits the straightness of the emitted ultrasounds and achieves a sharp directivity. One basic principle of the PAL is the nonlinearity of air, which causes the generation of new frequency components, including the sum frequency and difference frequency of emitted components [4], [5]. This phenomenon can be exploited to reproduce an audible component at frequency f_{d} by emitting a pair of ultrasonic components at frequencies f_{c} and $f_{\mathrm{c}} - f_{\mathrm{d}}$. The emission signal for the PAL can be generated by modulating an ultrasonic carrier wave at frequency f_{c} with target sound at frequency f_{d}. Here, the audible sound generated as the difference frequency of the emitted ultrasounds can be called demodulated sound [6].

A typical PAL, which consists of dozens of ultrasonic transducers, can be regarded as a piston source under the conditions that the number of transducers is sufficiently large and the interval is adequately small. Because the demodulated sound inherits the straightness of emitted ultrasounds, PALs have been used in many applications [7], [8], [9], [10]. In contrast, small-scale PALs tend to suffer the problem that the beam of reproduced audible sound spreads widely. Directivity control methods for PAL's reproduced sound have been proposed based on transducer configuration [11], [12], [13] and array signal processing [14], [15], [16]. Moreover, in the study of phase cancellation excitation [17], it is reported that phase cancellation in ultrasounds can widen the directivity of the demodulated sound of a PAL. In the study of length-limited PALs [18], [19], [20], it is reported that the phase cancellation of audible sound limits the acoustic beam in the length direction.

In our previous works [21], [22], we focused on controlling the acoustical beam in the width direction, to form a narrow-edged acoustical beam. Based on the phase cancellation in both ultrasounds and audible sound, we have proposed narrow-edged beamforming using individual phase inversion in amplitude-modulated waves for PALs [21], [22]. In this method, the transducers are divided into interior and exterior zones. Either the carrier or the sideband is phase inverted in the signal fed to the exterior transducers, while all components hold their original phase in the signal fed to the interior transducers. Both numerical and experimental results demonstrated that a narrower beam can be formed with this method [22]. However, this conventional method suffers from two main drawbacks: one is the trade-off between the directivity and the sound pressure, and the other is the occurrence of side lobes in directivity.

Our goal is to form a narrow-edged acoustical beam with less degradation of the sound pressure, which is the solution to the first drawback of the conventional method. The conventional method was proposed for the amplitude modulation (AM) methods for PAL, whose modulated wave has a simple spectral structure consisting of a carrier wave and only one or two sideband wave(s). In this paper, we focus on the frequency modulation (FM) method for PAL [23], which has a complicated spectral structure consisting of a carrier wave and multiple sideband waves. We propose a narrow-edged acoustical beamforming method using phase inversion for FM-based PAL. This proposed method shares part of the theoretical basis with the conventional method [22], and keeps the same division of transducers as in the conventional method. However, the phase inversion strategy is re-discussed

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

based on the characteristics of FM for PAL. Experimental evaluation was carried out to demonstrate the effectiveness of the proposed method.

II. Principle of frequency modulation-based parametric array loudspeaker

A. Basic Principles of Parametric Array Loudspeakers

The PAL is an application of a parametric array [24] for audible sound reproduction in the air. In the simplest case, the signal emitted from a PAL consists of two ultrasonic components and can be expressed as

$$p(t) = \sum_{n=1,2} P_n \cos\left(2\pi f_n t\right), \tag{1}$$

where t denotes time and P_n and f_n denote the initial pressure and frequency of the ultrasound, respectively. The emitted ultrasound observed at distance r on the propagation axis can be expressed as

$$p_r(t) = \sum_{n=1,2} P_n e^{-\alpha_n r} \cos\left(2\pi f_n t - k_n r\right), \tag{2}$$

where α_n and k_n denote the attenuation rate and wavenumber of the ultrasound, respectively.

Based on Westervelt's theory, virtual sources are generated as frequencies $2f_1$, $2f_2$, $f_1 + f_2$ and $|f_1 - f_2|$. Considering the demodulation process of the ultrasound emitted from PAL, we focus on the difference frequency $f_\mathrm{d} = |f_1 - f_2|$, whose intensity can be expressed as

$$q_\mathrm{d}(t) = \frac{2\pi\beta P_1 P_2 f_\mathrm{d}}{\rho_0^2 c_0^4 e^{(\alpha_1+\alpha_2)r}} \sin(2\pi f_\mathrm{d} t - k_\mathrm{d} r), \tag{3}$$

where β, ρ_0 and c_0 denote a nonlinear coefficient, the density and the speed of sound in the air, respectively, and k_d denotes the wavenumber of the difference frequency.

The demodulated sound observed in the far field can be expressed as a volume integral of virtual sources at difference frequency f_d, and can be further approximated into a line integral along the propagation axis as follows

$$\begin{aligned} p_\mathrm{d}(t) &= \frac{\rho_0}{4\pi} \int_V \frac{e^{-jk_\mathrm{d}R}}{R} \frac{\partial q_\mathrm{d}(t)}{\partial t} \mathrm{d}V \\ &\approx \frac{\rho_0 S_0}{4\pi} \int_0^{l_0} \frac{e^{-jk_\mathrm{d}R(r)}}{R(r)} \frac{\partial q_\mathrm{d}(t)}{\partial t} \mathrm{d}r, \end{aligned} \tag{4}$$

where $R(r)$ denotes the distance from the virtual source at distance r. Here, the integral interval is approximated as a cylinder with volume V, base area S_0 and height l_0.

The signal emitted from the PAL can be generated by modulating an ultrasonic carrier $c(t)$ with the target sound $s(t)$. In the case of AM methods, which are widely used for PAL, the amplitude of the carrier wave holds the information of the amplitude of the target sound. For example, the modulated wave of double sideband (DSB) modulation [1], [6], [25] can be given as

$$u_\mathrm{DSB}(t) = \left(1 + m_\mathrm{DSB} s(t)\right) c(t), \tag{5}$$

where $m_\mathrm{DSB} (0 < m_\mathrm{DSB} \leq 1)$ denotes the modulation factor. In general, the carrier wave $c(t)$ can be expressed as

$$c(t) = A_\mathrm{c} \cos\left(2\pi f_\mathrm{c} t\right), \tag{6}$$

where A_c and f_c denote the amplitude and frequency of the carrier wave, respectively. When the target sound $s(t)$ is a pure tone, it can be given as

$$s(t) = A_\mathrm{s} \cos\left(2\pi f_\mathrm{s} t\right), \tag{7}$$

where A_s and f_s denote the amplitude and frequency of the target sound, respectively.

Substituting (6) and (7) into (5), it can be derived that the DSB-modulated wave $u_\mathrm{DSB}(t)$ contains three frequency components: carrier wave f_c, upper sideband wave $f_\mathrm{c} + f_\mathrm{s}$, and lower sideband wave $f_\mathrm{c} - f_\mathrm{s}$. Because the difference frequency between the carrier wave and either sideband wave is the same as that of the target sound, the target sound at frequency f_s is expected to be generated with a self-demodulation process.

B. Frequency Modulation for Parametric Array Loudspeaker

In the case of FM, the instantaneous frequency of the carrier wave holds the amplitude information of the target sound. A frequency-modulated wave [23], [26], [27] can be given as

$$u_\mathrm{FM}(t) = A_\mathrm{c} \cos\left(2\pi f_\mathrm{c} t + 2\pi f_\mathrm{f} \int_0^t s(\tau)\mathrm{d}\tau\right), \tag{8}$$

where f_f denotes the frequency fluctuation. The instantaneous frequency $f_\mathrm{ins}(t)$ varies with time and can be derived as

$$f_\mathrm{ins}(t) = \frac{1}{2\pi}\frac{\mathrm{d}}{\mathrm{d}t}\left(2\pi f_\mathrm{c} t + 2\pi f_\mathrm{f} \int_0^t s(\tau)\mathrm{d}\tau\right) = f_\mathrm{c} + f_\mathrm{f} s(t). \tag{9}$$

Substituting (7) into (9), derives the instantaneous frequency $f_\mathrm{ins}(t)$ as sinusoidal with bias f_c and amplitude $A_\mathrm{s} f_\mathrm{f}$. In this case, the frequency-modulated wave $u_\mathrm{FM}(t)$ can be expanded with Bessel functions of the first kind, which can be expressed as

$$\begin{aligned} u_\mathrm{FM}(t) &= A_\mathrm{c} \cos\left(2\pi f_\mathrm{c} t + \frac{A_\mathrm{s} f_\mathrm{f}}{f_\mathrm{s}} \sin(2\pi f_\mathrm{s} t)\right) \\ &= A_\mathrm{c} \sum_{i=-\infty}^{\infty} J_i(m_\mathrm{FM}) \cos\left(2\pi\left(f_\mathrm{c} + i f_\mathrm{s}\right) t\right), \end{aligned} \tag{10}$$

where $J_i(\cdot)$ denotes the i-th order Bessel function of the first kind and m_FM denotes the modulation factor of FM which is defined as

$$m_\mathrm{FM} = \frac{A_\mathrm{s} f_\mathrm{f}}{f_\mathrm{s}}. \tag{11}$$

It is known that $J_{-i}(\cdot) = (-1)^i J_i(\cdot)$ holds for Bessel functions; therefore, (10) can be further expanded as

$$\begin{aligned} u_\mathrm{FM}(t) = {} & A_\mathrm{c} \sum_{i=1}^{\infty} J_i(m_\mathrm{FM}) \cos\left(2\pi\left(f_\mathrm{c} + i f_\mathrm{s}\right) t\right) \\ & + A_\mathrm{c} \sum_{i=1}^{\infty} (-1)^i J_i(m_\mathrm{FM}) \cos\left(2\pi\left(f_\mathrm{c} - i f_\mathrm{s}\right) t\right) \\ & + A_\mathrm{c} J_0(m_\mathrm{FM}) \cos\left(2\pi f_\mathrm{c} t\right). \end{aligned} \tag{12}$$

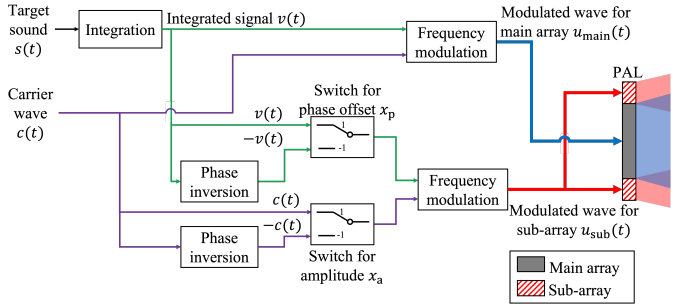

Fig. 1. Overview of the proposed method.

It is obvious from (12) that the first term indicates multiple upper sideband components, the second term indicates multiple lower sideband components, and the last term indicates a carrier component.

When the modulation factor m_{FM} is a very small value, for example, when $f_{\mathrm{f}} \ll f_{\mathrm{s}}$, the energy of high-order components ($|i| > 1$) can be approximated to zero. In this case, the frequency-modulated wave $u_{\mathrm{FM}}(t)$ has a spectral structure similar to that of the DSB-modulated wave $u_{\mathrm{DSB}}(t)$. In contrast, if the above condition does not hold, the high-order components cannot be ignored, and the frequency-modulated wave $u_{\mathrm{FM}}(t)$ will have a complicated structure. However, in both cases, the target sound at frequency f_{s} can be demodulated as the difference frequency between the carrier component and sideband component.

III. Proposed Narrow-edged Beamforming Using Phase Inversion for Frequency Modulation

A. Overview of the Proposed Method

Fig. 1 gives an overview of the proposed method. The proposed method uses phase cancellation in both ultrasounds and audible sounds by inverting the phase of components in the frequency-modulated wave. The PAL is divided into a main array in the interior and a sub-array in the exterior. The modulated wave for the main array is generated by common FM, as expressed in (8). First, the target sound $s(t)$ is integrated by the time index into signal $v(t)$ which can be given as

$$v(t) = \int_0^t s(\tau)\mathrm{d}\tau. \tag{13}$$

The integrated signal $v(t)$ is then used to determine the phase offset for a sinusoidal carrier wave at frequency f_{c}, and the output signal can be expressed as

$$u_{\mathrm{main}}(t) = A_{\mathrm{c}} \cos\left(2\pi f_{\mathrm{c}} t + 2\pi f_{\mathrm{f}} v(t)\right). \tag{14}$$

The modulated wave for the sub-array is generated by FM with phase inversion. The output signal can be expressed as

$$u_{\mathrm{sub}}(t) = x_{\mathrm{a}} A_{\mathrm{c}} \cos\left(2\pi f_{\mathrm{c}} t + 2\pi f_{\mathrm{f}} x_{\mathrm{p}} v(t)\right), \tag{15}$$

where we set two phase inversion switches x_{a} and x_{p} ($x_{\mathrm{a}} = \pm 1$, $x_{\mathrm{p}} = \pm 1$), which indicate whether the corresponding component is phase-inverted.

In the case of $x_{\mathrm{a}} = 1$ and $x_{\mathrm{p}} = 1$, (15) becomes equivalent to (14), which indicates that the same signal is fed to the main array and sub-array. In other cases, the signal for the sub-array differs from that for the main array, because the phase of some components is different in these two signals. To realize narrow-edged beamforming, the values of phase inversion switches should be determined properly. Detailed discussion on the determination of phase inversion switches is given in Section III-B.

B. Phase Inversion Strategy for Frequency Modulation

As shown by (15), the proposed method has two phase inversion switches: x_{a} controls the sign of the amplitude in signal $u_{\mathrm{sub}}(t)$, and x_{p} controls the sign of the phase offset in signal $u_{\mathrm{sub}}(t)$. The phase inversion patterns can be categorized into four cases: one case is regarded as a reference; one case can form a wider beam; and the other two cases can form a narrower beam, which correspond to our goal in this paper. A detailed description is as follows:

1) Reference – inverting none of the components ($x_{\mathrm{a}} = 1$, $x_{\mathrm{p}} = 1$): As described in Section III-A, the signal for sub-array $u_{\mathrm{sub}}(t)$ is equivalent to the signal for main array $u_{\mathrm{main}}(t)$ in this case, and can be expanded into the same expression with (10). The instantaneous frequency of signal $u_{\mathrm{sub}}(t)$ can be expressed with (9). This case can be regarded as a common FM-based PAL emitting the same frequency-modulated wave from all transducers. Therefore, this case is the reference case for comparison.

2) Inverting only the amplitude ($x_{\mathrm{a}} = -1$, $x_{\mathrm{p}} = 1$): In this case, the signal for the sub-array can be expanded as

$$\begin{aligned} u_{\mathrm{sub}}^{\mathrm{A}}(t) &= -A_{\mathrm{c}} \cos\left(2\pi f_{\mathrm{c}} t + 2\pi f_{\mathrm{f}} v(t)\right) \\ &= -A_{\mathrm{c}} \sum_{i=1}^{\infty} J_i(m_{\mathrm{FM}}) \cos\left(2\pi \left(f_{\mathrm{c}} + i f_{\mathrm{s}}\right) t\right) \\ &\quad - A_{\mathrm{c}} \sum_{i=1}^{\infty} (-1)^i J_i(m_{\mathrm{FM}}) \cos\left(2\pi \left(f_{\mathrm{c}} - i f_{\mathrm{s}}\right) t\right) \\ &\quad - A_{\mathrm{c}} J_0(m_{\mathrm{FM}}) \cos\left(2\pi f_{\mathrm{c}} t\right). \end{aligned} \tag{16}$$

Note that all the frequency components are phase-inverted compared with signal $u_{\mathrm{main}}(t)$, but the instantaneous frequency is the same as expressed (9). Based on the related studies [17], [22], we can predict that the beam will become wider than that in the reference case.

3) Inverting only the phase offset ($x_{\mathrm{a}} = 1$, $x_{\mathrm{p}} = -1$): In this case, the signal for the sub-array can be expanded as

$$\begin{aligned} u_{\mathrm{sub}}^{\mathrm{P}}(t) &= A_{\mathrm{c}} \cos\left(2\pi f_{\mathrm{c}} t - 2\pi f_{\mathrm{f}} v(t)\right) \\ &= A_{\mathrm{c}} \sum_{i=1}^{\infty} (-1)^i J_i(m_{\mathrm{FM}}) \cos\left(2\pi \left(f_{\mathrm{c}} + i f_{\mathrm{s}}\right) t\right) \\ &\quad + A_{\mathrm{c}} \sum_{i=1}^{\infty} J_i(m_{\mathrm{FM}}) \cos\left(2\pi \left(f_{\mathrm{c}} - i f_{\mathrm{s}}\right) t\right) \\ &\quad + A_{\mathrm{c}} J_0(m_{\mathrm{FM}}) \cos\left(2\pi f_{\mathrm{c}} t\right). \end{aligned} \tag{17}$$

Note that only the sideband components of the odd-number order are phase-inverted compared with signal $u_{\mathrm{main}}(t)$. More-

over, the instantaneous frequency becomes the following expression:

$$f_{\mathrm{ins}}^{\mathrm{P}}(t) = f_{\mathrm{c}} - f_{\mathrm{f}} s(t). \tag{18}$$

This case can be regarded as only inverting the sideband component in an amplitude-modulated wave when the high-order sideband components are ignored. Based on the conclusion in our previous work [22], this case is expected to form a narrower beam than that of the reference case.

4) Inverting both the amplitude and the phase offset ($x_{\mathrm{a}} = -1$, $x_{\mathrm{p}} = -1$): In this case, the signal for the sub-array can be expanded as

$$\begin{aligned} u_{\mathrm{sub}}^{\mathrm{AP}}(t) &= -A_{\mathrm{c}} \cos\left(2\pi f_{\mathrm{c}} t - 2\pi f_{\mathrm{f}} v(t)\right) \\ &= -A_{\mathrm{c}} \sum_{i=1}^{\infty} (-1)^i J_i(m_{\mathrm{FM}}) \cos\left(2\pi \left(f_{\mathrm{c}} + i f_{\mathrm{s}}\right) t\right) \\ &\quad - A_{\mathrm{c}} \sum_{i=1}^{\infty} J_i(m_{\mathrm{FM}}) \cos\left(2\pi \left(f_{\mathrm{c}} - i f_{\mathrm{s}}\right) t\right) \\ &\quad - A_{\mathrm{c}} J_0(m_{\mathrm{FM}}) \cos\left(2\pi f_{\mathrm{c}} t\right). \end{aligned} \tag{19}$$

Note that the sideband components of the even-number order and the carrier component are phase-inverted compared with signal $u_{\mathrm{main}}(t)$. Moreover, the instantaneous frequency becomes the following expression:

$$f_{\mathrm{ins}}^{\mathrm{AP}}(t) = f_{\mathrm{c}} - f_{\mathrm{f}} s(t). \tag{20}$$

This case can be regarded as only inverting the carrier component in an amplitude-modulated wave when the high-order sideband components are ignored. Based on the conclusion in our previous work [22], this case is expected to form a narrower beam than that of the reference case.

We here introduce a comparison of the time-domain waveforms in the above four cases in Fig. 2. The parameters are set as $A_{\mathrm{c}} = 1$, $A_{\mathrm{s}} = 1$, $f_{\mathrm{c}} = 40$ kHz, $f_{\mathrm{s}} = 4$ kHz, and $f_{\mathrm{f}} = 2$ kHz. The instantaneous frequency can be estimated using the Hilbert transform [28], and the analysis results are given in Fig. 3. The spectra were also estimated and the results are shown in Fig. 4. In Fig. 4, red dashed lines show the estimated amplitude spectra while blue solid lines show the estimated phase spectra. It can be noticed from the amplitude spectra that the frequency-modulated waves consist of carrier component and sideband components as expressed in (12), (16), (17) and (19). In the estimation of the phase spectra, circular-shift is carried out to prevent the original phase from being affected by the window function [29]. Although Fig. 3 shows several analysis errors, it can be seen that the analytical results on phases of components correspond to the theoretical expansion in (12), (16), (17) and (19).

IV. Experiments and Results

A. Experimental Setup

We conducted experiments to demonstrate the effectiveness of the proposed method. We used a prototype PAL with a column-wise configuration of piezoelectric ultrasound transducers (MURATA, MA40S4S), which consists of 15 channels in total, as shown in Fig. 5. As in previous work [22], we assigned $M = 2$ or 3 channels on each side for the sub-array, and the remaining 11 or 9 channels on the interior for the main array. The PAL was set on a pan-rotation unit (Manfrotto, 300 N), by which the direction of the PAL could be rotated manually with an interval of 5 degs. to measure the directivity characteristics. Other conditions and equipment are shown in Table I and Table IV-A, respectively.

1 to 8 kHz were used as target signal $s(t)$ in the experiments. The signal fed to the main array was generated based on (14), while the signal fed to the sub-array was generated based on (15). The parameters were set as $f_{\mathrm{c}} = 40$ kHz, and $f_{\mathrm{f}} = 2$ kHz. As discussed in Section III-B, the four cases of phase inversion for the signal fed to the sub-array, are case Ref., case A, case P and case A/P, respectively. Cases P and A/P were expected to form a narrower beam than that of case Ref.

The directivity of demodulated sound is known to depend on the frequency of the target signal [31], so we measured the frequency-dependent directivity in the experiments. The observed TSP signals were convolved with the inverse TSP signal to estimate the impulse response of demodulated sound in each direction. Analyzing with Fourier transform, we derived sound pressure $p_{\mathrm{idx}}(f_{\mathrm{s}}, \theta)$ in the θ direction when the target frequency was f_{s}, where idx = Ref., A, P, or A/P denotes the cases index. The on-axis ($\theta = 0$ deg.) sound pressures were expected to be different among the comparison cases [22]. Moreover, a PAL holds a frequency-dependent response of +12 dB/octave in theory [1]. To eliminate the influence of these factors, we calculated the frequency-dependent directivity by normalizing the sound pressure at each frequency, which can be given as:

$$d_{\mathrm{idx}}(f_{\mathrm{s}}, \theta) = p_{\mathrm{idx}}(f_{\mathrm{s}}, \theta) - p_{\mathrm{idx}}(f_{\mathrm{s}}, 0). \tag{21}$$

B. Experimental Results and Discussions

Figs. 6 and 7 show the measured frequency-dependent directivity characteristics when $M = 2$ and 3, respectively. It can be seen that cases Ref. and A achieved significantly

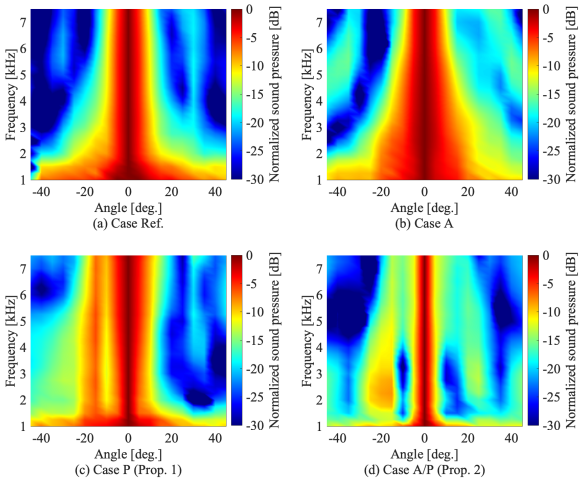

Fig. 6. Measured frequency-dependent directivity characteristics (M=2).

frequency-dependent directivity, the beam becoming narrower as frequency f_{s} increased. In contrast, cases P and A/P achieved an almost constant beamwidth in the main lobe, despite having larger side lobes. It can be derived that the proposed method (cases P and A/P) has an advantage over the reference (case Ref.) when target frequency f_{s} is lower, because the proposed method can form a much narrower beam than can the reference case. However, when target frequency f_{s} increased, the difference in beamwidth became smaller between the proposed method and the reference case. Comparing Fig. 6 with Fig. 7 shows that the beam of case A becomes wider as M increases. In the results of cases P and A/P, the main lobe remains the same or becomes narrower while the side lobes increase as M increases.

The results of the reference case correspond to the theoretical model of Westervelt's directivity [24], [32], [31], while the others can be explained by the phase cancellation in ultrasound and audible sound. Especially, phase cancellation as used in the proposed method contributes to a narrow beam at low-frequencies.

Fig. 8 shows the measured directivity characteristics when the target frequency f_{s} is 2 kHz. Table III shows the corresponding measured results at a beamwidth of -6 dB. It can be easily observed that cases P and A/P achieved a much narrower main lobe than did case Ref., while case A achieved a wider beam than did case Ref. However, cases P and A/P achieved more significant side lobes than did case Ref. Comparison of Fig. 8(a) with (b) shows that the directivity of the proposed method (cases P and A/P) becomes narrower while the sound pressure becomes lower as M increases.

The above conclusions generally correspond to those of phase inversion for AM-based PAL [22] and can be explained by the enhancement of phase cancellation because more channels are assigned to the sub-array.

The on-axis ($\theta = 0$ deg.) relative sound pressures of these results are listed in Table IV, where case Ref. was set as 0

dB. It can be derived that the phase inversion for FM-based PAL decreases the sound pressure by a very small amount. The phase inversion for AM-based PAL causes a decrease in sound pressure of over 10 dB at 2 kHz [22], while the proposed phase inversion for FM-based PAL only causes a decrease of about 3 dB. Therefore, our results demonstrate that the proposed method can achieve an equivalent level of narrow directivity with a much lower reduction of sound pressure compared with that of the phase inversion for AM-based PAL.

V. CONCLUSIONS

In this paper, we propose a narrow-edged beamforming method based on phase inversion for FM-based PAL. The phase inversion strategy is developed to realize phase cancellation in both ultrasound and audible sound, aiming to form a narrow beam of demodulated sound. The experimental

results demonstrated the effectiveness of the proposed method, which shows that the proposed method can achieve a level of narrow directivity equivalent to that of the phase inversion for AM-based PAL. Moreover, the decrease of sound pressure is mitigated significantly, which is one of the main drawbacks of the phase inversion for AM-based PAL. In the future, we will work on the elimination or the exploitation of the side lobes for the proposed method.

***Abstract*—This study explores automatic speech recognition (ASR) for the deaf and hard-of-hearing. Despite the recent progress in ASR for dysarthric speakers, existing research primarily focuses on people with motor speech disorders. Thus, the effect of speech diversity on the performance of ASR is not considered for ambiguous deaf speech owing to a lack of auditory feedback. Therefore, we compiled a corpus of speech of many profoundly deaf speakers to compare the ASR performance with that of normal-hearing speakers. The performance analysis is reported through a set of phoneme recognition experiments. Furthermore, we show that additional phonological features that reflect deaf speakers' articulation can improve performance in phoneme recognition for deaf speech.**

I. Introduction

In communication between normal-hearing and deaf or hard-of-hearing people, accessibility supports, such as written conversation, sign language, and automatic speech recognition (ASR), are commonly used. Notably, it has been reported that only 25 % of deaf people in Japan use sign language daily, and more than half of them communicate using spoken language. Moreover, smartphones and tablets have recently diversified the applications of ASR, such as through interactive information retrieval and the control of electrical appliances through Internet of Things (IoT) devices. Hence, in addition to considering the disparity in ASR-based operations as an urgent social issue, considering accessibility and inclusion for deaf people is necessary.

In recent years, many ASR studies have been on atypical speakers, such as those with speech disorders [1]–[6]. Many such studies deal with motor speech disorders; as part of these studies, hearing impairment is often included as a subject. In [1], [2], the ASR performance was improved by multitask learning of voice conversion from disorders of a normal-hearing speaker and ASR of speech of people with disorders. In [3], [4], the authors employed articulatory motion data collected using electromagnetic articulography. Then, they combined acoustic and articulatory features to improve ASR performance. Because it is generally difficult to collect a large amount of speech data from people with speech disorders, data augmentation methods have been proposed to improve performance [5], [6].

Many studies mentioned above have focused on dysarthric people, i.e., people with motor speech disorders caused by amyotrophic lateral sclerosis (ALS) and other disorders. These studies focused on various speech disorders but have not intensively analyzed the speech of deaf people. It is challenging to focus on ASR for deaf speakers because of their small population. This means the details of the ASR performance of deaf speech remain unclear. This study first attempts to construct a corpus to examine the ASR performance for deaf speakers. The differences in performance caused by the diversity of their speech were clarified through a series of phoneme recognition experiments. From a phonological perspective, segmental units, such as phonemes, can be further classified based on features like articulation. For example, [7] showed that deaf speakers' articulation has different phonological characteristics than normal-hearing people. If neural networks can capture such characteristics of deaf speakers, ASR performance would be significantly improved.

II. Deaf Speech and Corpus

A. Deaf Speech

A review of deaf speech based on phonetics and phonology, particularly concerning articulation errors, can be found in [8]. [8] reported that substitutions, deletions, and insertions of phonemes are frequently observed in deaf speakers' articulation, especially as substitutions in place and manner of articulation for consonants. In a recent study [7], the speech of cochlear implant users was analyzed and compared with that of normal-hearing speakers for use in rehabilitation. Similar substitutions are observed in front- and close-vowels. The vowel space of the deaf speaker is generally narrower than that of normal-hearing speakers, and the formants (F_1, F_2) that characterize vowels tend to fluctuate significantly [9]. The cause of these errors is the difficulty in acquiring articulation owing to a lack of auditory feedback [10].

B. Deaf Speech Corpus

It is essential to construct a speech corpus for deaf speakers. A corpus targeting deaf speakers was described in [11], which gives a set of detailed metadata, including hearing abilities and communication methods in addition to speech. However, [11] is a corpus for analysis from a phonetic perspective and is not designed for spoken language processing.

In the field of spoken language processing, there are many speech corpora for individuals with normal-hearing. Even for the Japanese, there are many widely used corpora, such as the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

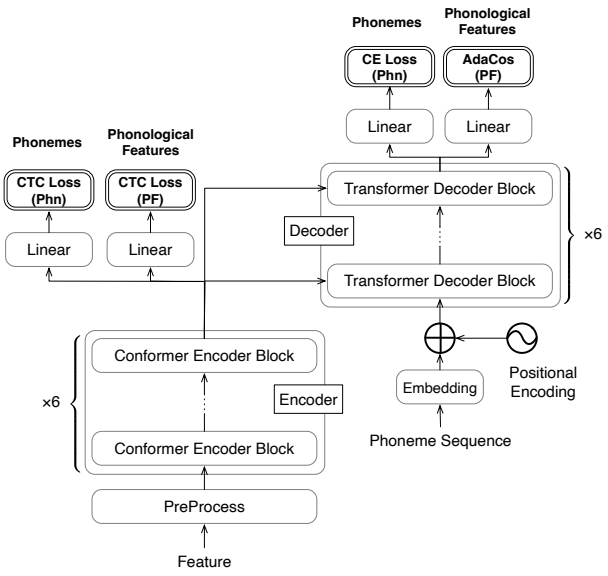

Fig. 1. Neural network and loss functions

Corpus of Spontaneous Japanese (CSJ) [12], ASJ Continuous Speech Corpus for Research [13], and Japanese Newspaper Article Reading Corpus (JNAS) [14]. Some of these corpora contain a set of phoneme-balanced sentences, which is the de facto standard for Japanese spoken language processing. Thus, we must develop a corpus that can compare ASR performance with normal-hearing while collecting standard sentences spoken by deaf speakers. Therefore, the authors are eager to collect a variety of utterances from deaf speakers [15]. The corpus includes phoneme-balanced sentences, utterances from JNAS newspaper articles, and spontaneous speech as conversations. During compilation, the corpus comprised the speeches of 46 deaf students.

III. Phonological Features

A. Phonemes and Articulation

A phoneme is the smallest unit used to distinguish a word from others; hence it is convenient for investigating the error tendency in deaf speech. Alternatively, each phoneme can be characterized by articulation in terms of phonology. Phonological features are smaller units than phonemes used to capture features spanning among the phonemes. For example, comparing the phonemes /s/ with /z/, both are alveolar fricatives but are in conflict for voicing. For example, phonological features have often been introduced when evaluating the pronunciation of L2 speakers [16], [17]. Therefore, using phonological features allows phonemes to be evaluated from other measures and, as a result, may provide robust discrimination of phonemes in ambiguous deaf speech.

B. Phonological Features

The phonological features in this study are defined as multiple classes that characterize phonemes. Therefore, phonemes and classes representing phonological features are output symbols in a neural network that performs phoneme recognition using articulation features. First, phonological features are divided into five groups; any feature in an opposing relationship within a group is output. However, if none of the features in the group are activated, the symbol none is output. The five groups of articulatory features are as follows:

i. Voice activity features
   This group includes three classes—vowels, consonants, and silence.

ii. Voicing features
   This group includes two categories—voiced and unvoiced.

iii. Vowel features
   This group includes the following three categories
   a. Rounding features
      This group represents the degree of lip rounding, i.e., rounded and unrounded.
   b. Height features
      This group represents the height of vowels or tongue. The group has four categories: close, close-mid, open-mid, and open. These are defined by the International Phonetic Association (IPA) [18].
   c. Backness features
      This group represents the position of the tongue. This group has three categories: front, central, and back tongue. The IPA also defines these categories.

iv. Consonant features
   The following two groups characterize consonants:
   a. Place-of-articulation features
      This group represents the 13 places of articulation of consonants, e.g., bilabial, dental, alveolar, velar, uvular, and alveolo-palatal.
   b. Manner-of-articulation features
      This group represents the nine manners of articulation for consonants, e.g., nasal, plosive, tap/flap, fricative, and affricate.

v. Other features
   These features include palatalization and devoicing.

Since the phoneme environment is affected by coarticulation, it is impossible to determine the articulatory features uniquely. However, in this study, one typical feature is used for simplicity.

C. Loss Functions

For phonological features defined as multiclass, the loss functions of the encoder/decoder of the neural network are determined. As described later, we employ a network structure based on the conformer–transformer model. We use the CTC loss functions [19] for the encoder outputs and AdaCos for the decoder outputs. AdaCos[20] is a function employed in deep metric learning. Therefore, it can effectively improve

performance while correcting the discriminative hyperplanes among phonemes with phonological features.

IV. Experiments

In the experiments, we used a relatively small-scale neural network with conventional structures to investigate the differences in ASR performance between normal hearing and deaf speakers in a preliminary study. The deaf speech was first evaluated using a neural network trained with only normal-hearing speech, referred to as the *NH network*. Then, the NH network parameters were fine-tuned using deaf speech to evaluate the speech, referred to as the *DF network*.

A. Training and Test Data

To evaluate deaf speech, we used 699 phonetically balanced sentences spoken by 14 students (nine males and five females) from the Tsukuba University of Technology. Specifically, the B set, composed of 50 sentences from ATR phonetically-balanced sentences, was used[21]. For comparison, 5,996 phonetically-balanced sentences from 120 normal-hearing speakers from JNAS were used. 77.9k (123.7 h) balanced sentences of normal-hearing from ASJ, JNAS, and ATR multispeaker speech databases were used to train the NH network. As the fine-tuned DF network, we used 3,525 balanced sentences (6.3 h) spoken by the abovementioned 14 students.

B. Neural Networks

We employed encoder-decoder networks with a Conformer [22] as the encoder and a Transformer [23] as the decoder (see Fig. 1). The encoder comprised six conformer blocks with 512 input dimensions, eight heads of multi-head attention for convolution modules, and 1024 dimensions for feed-forward modules. The kernel size of the depth-wise convolution block was set to 31. The decoder comprised six transformer blocks with similar configurations for input dimensions, number of heads, and dimensions for feed-forward modules. Convolution layers for preprocessing were prepended to the encoder, reducing the temporal length to 1/4, similar to [22]. We used four convolution layers, and their kernel sizes were set to 3 for 256 channels. The Adam optimizer was used to train the network, and 50 epochs were configured with a learning rate of 4.0e-5.

We conducted experiments with different configurations of the four loss functions listed in Table I for the ablation studies.

TABLE I
Network configurations

	Encoder Loss		Decoder Loss	
	CTC (Phn)	CTC (PF)	CE (Phn)	AdaCos (PF)
Baseline			✓	
CTC	✓		✓	
Proposed-A			✓	✓
Proposed-B		✓	✓	✓
Proposed-C	✓		✓	✓
Proposed-D	✓	✓	✓	✓

TABLE II
Overall results for normal-hearing on NH networks (%)

	PER	Sub.	Del.	Ins
Baseline	8.9	5.4	1.7	1.8
CTC	7.3	4.5	1.3	1.5
Proposed_A	7.5	4.6	1.5	1.4
Proposed_B	7.7	4.8	1.8	1.1
Proposed_C	7.1	4.6	1.4	1.1
Proposed_D	**6.0**	**4.0**	**1.2**	**0.9**

TABLE III
Overall results for deaf speech on NH networks (%)

	PER	Sub.	Del.	Ins.
Baseline	41.6	24.4	4.9	12.3
CTC	38.8	**23.2**	5.0	10.6
Proposed_A	37.9	23.6	4.9	9.5
Proposed_B	39.9	24.5	4.3	11.1
Proposed_C	37.5	23.5	4.8	9.2
Proposed_D	**36.9**	23.6	**4.2**	**9.0**

C. Evaluation on normal-hearing(NH) Network

First, we conducted experiments on NH networks trained with only normal-hearing data. Table II lists the phoneme error rates (PERs) for 120 normal-hearing subjects, and Table III lists the PERs for the 14 deaf subjects. The tables include the substitution, deletion, and insertion rates. As shown in Table II, for the normal-hearing, **Proposed_C** and **D** reduced the PERs against **CTC**, with relative reduction rates of 2.7 % and 17.8 %. According to the matched-pair test, these were statistically significant ($p < 0.05$). However, **Proposed_A** and **B** that were trained without CTC loss did not achieve **CTC** results. The results show that the CTC loss of phonemes for the encoder is effective for gaining performance and that the loss functions of phonological features play supplemental roles in network training.

Table 2 shows that the reduction in PER for deaf speakers is limited, while it is statistically significant at $p < 0.05$ for **Proposed_C** and **D**. It is because deaf speech differs significantly from normal-hearing speech. The detailed results show that insertion errors are reduced, whereas substitution errors are not reduced. We found fewer vowel insertions in the results. Introducing phonological features would lead to robustness in suppressing articulatory fluctuations of vowels.

D. Evaluation on deaf(DF) Network

Next, we conducted experiments employing DF networks, whose parameters were fine-tuned to those of NH networks with deaf speech. The DF network parameters were updated with the speech of 13 speakers so that the evaluated speakers were excluded, i.e., in a *leave-one-speaker-out* manner. Therefore, the PER of the evaluated speaker would be reduced if the neural network reflected the speech characteristics common to deaf speakers. Table IV lists the PERs. In the configuration of **Baseline**, only a small error reduction from its counterpart of the DF network was achieved. When adding CTC loss functions, PER was reduced from 38.8 % (NH) to 34.1 %, achieving a 12.3 % relative reduction. The additional CTC

TABLE IV
OVERALL RESULTS FOR DEAF ON DF NETWORK (%)

	PER	Sub.	Del.	Ins.
Baseline	41.0	23.9	9.8	7.3
CTC	34.1	21.5	7.0	5.6
Proposed_A	35.2	22.2	6.9	6.1
Proposed_B	35.6	22.6	6.7	6.3
Proposed_C	33.7	21.7	6.5	5.5
Proposed_D	**31.4**	**20.2**	**6.3**	**4.9**

TABLE V
VOWEL/CONSONANT ERROR RATES ON DF NETWORK (%)

	Vowels	Consonants
CTC(NH)	30.7	47.1
CTC(DF)	25.4	43.2
Proposed_A	26.6	44.1
Proposed_B	26.1	45.4
Proposed_C	24.6	43.0
Proposed_D	23.0	40.1

loss on the encoder effectively improved the performance for deaf speech and normal-hearing [24]. **Proposed_D**, which is a network using all loss functions, reduced the PER from 36.9 % to 31.4 %, achieving a 14.9 % relative reduction. The network reduced the substitution errors, which were difficult to achieve in its counterpart NH network.

The PERs for the vowels and consonants are listed in Table V. Compared with the **CTC(DF)** results, the error reduction rate for vowels in **Proposed_D** was 9.4 %, whereas that for consonants was 7.2 %. Generally, vowels are less complicated to articulate than consonants, even for deaf speakers. Thus, the phonological features compensated for the narrowness of their vowel space to reduce vowel errors.

Next, we investigated error reduction for consonants. Table VI lists the top five error-reduction rates for consonant errors, comparing **CTC(NH)** and **CTC(DF)**. The table shows that nasal /N/ achieved the highest reduction rate. Nasalization is one of the characteristics of deaf speech and commonly appears within it. /w/ and /y/ are approximants and close to vowels in articulation, so they probably benefit from error reduction, similar to vowels.

Comparing **CTC(DF)** and **Proposed_D**, the voiced plosive /b/achieved the highest error reduction (Table VII). This reduction is because the confusion with the nasal /m/ is resolved. The nasal /n/ and approximants /w/ and /y/ were also recovered from errors.

V. CONCLUSION

We described automatic speech recognition for deaf speakers. We showed that phonological features could capture characteristics common to deaf speakers and significantly reduce phoneme errors.

The corpus is still being developed due to the difficulty of collecting deaf speech, especially from communication with deaf people. In the future, we intend to assemble more speech recordings, including spoken dialogues from over 100 deaf speakers, and to make them widely available to the public.

TABLE VI
TOP-5 ERROR-REDUCED CONSONANTS: CTC(NH) TO CTC(DF)

	CTC(NH)	CTC(DF)	reduction
/N/	51.2	37.4	26.9
/w/	32.8	24.4	25.7
/y/	66.0	50.5	23.5

***Abstract*—Automatic chord recognition is a task of recognizing and transcribing chords from music data such as popular music. Manual chord transcription requires highly technical knowledge and great effort. A chord is a typical musical feature. Realization of automatic chord recognition can enable their use for many purposes such as musical notation and structural analysis. For this reason, automatic chord recognition has become a major research task in the field of music information retrieval. In recent years, automatic chord recognition has widely used deep learning models. Convolutional Recurrent Neural Network (CRNN) and Transformer have achieved high accuracy. For this study, we focus on the differences in feature extraction approaches used by CRNN and Transformer, and propose an ensemble learning method using the two models. Additionally, we adopt an original overlap inference method to improve their accuracy by complementing the lack of temporal information. Results show that we achieved average accuracy of 78.92% under the traditional evaluation metrics, which are, respectively, 1.64% and 2.43% higher than those of CRNN and Transformer.**

I. INTRODUCTION

When playing a musical instrument, a chord is essential information: a symbol expressing the musical scale used in each section. In recent years, chord information for various musical pieces has become accessible on the internet, but in many cases, chord information for new music or independent music is not publicly available. Although transcribing chords from the music by oneself is necessary, this process requires highly technical knowledge and great effort. Therefore, the task of automatic chord recognition (ACR), which recognizes and transcribes a series of chords from music data, has been studied actively in the research field of music information processing. A chord is a typical musical feature. Chord information obtained by ACR is useful for many purposes such as music notation and music structure analysis.

Most traditional ACR systems consist of feature extraction and chord sequence decoding. Among input features, chromagram [3, 4, 5] is widely used: it reflects the 12 different pitch classes. Other attempts at handcrafted features have been made, such as chroma vectors and tonnetz [6]. The most common sequence decoding method is based on Hidden Markov Model (HMM) [7, 8]. Dynamic Bayesian Network (DBN) is also used for decoding [3, 5].

Recently, deep learning has been developed and used in various fields [9]. In ACR, Convolutional Neural Network (CNN) [10, 11] and Recurrent Neural Network (RNN) [12, 13] have been used particularly. Moreover, Vaswani et al. proposed Transformer, which is based solely on Attention mechanisms, dispensing entirely with recurrence and convolutions [14]. Transformer was first proposed for application to a machine translation task, but in recent years, it has been applied to various domains because of its high performance and the very low training costs. In the field of music, Huang et al. applied it to a music generation task and obtained state-of-the-art results [15].

In the dataset used for this study, Jiang et al. used the Convolutional Recurrent Neural Network (CRNN) [1] and recorded 67.09% in tetrads. Park et al. used Transformer [2] and recorded 66.00% in tetrads. A tetrad is an evaluation metric that targets all chords. However, it is not easy to infer chords that theoretically include more than 4,000 types. Therefore, some room remains for improving accuracy.

For this study, we focus on the differences of feature extraction approaches between CRNN with convolutional filter and Transformer with Self-Attention mechanism, and propose an ensemble learning method using these two models and our own neural network (NN) model. Additionally, we adopt an original overlap inference method to improve accuracy by complementing the lack of temporal information in inference.

The remainder of this paper is organized as follows: Section 2 explains chords in the field of music. Section 3 introduces two earlier studies. Section 4 presents a description of ensemble learning and overlap inference proposed herein. Section 5 presents results of experiments using the proposed method. Finally, the conclusion is given in Section 6.

II. CHORD

In the field of music, a chord is a sound that is formed by multiple and different overlapping notes. Generally, a chord comprises three or more notes. However, some notes might be omitted. Chords might consist of two or fewer notes.

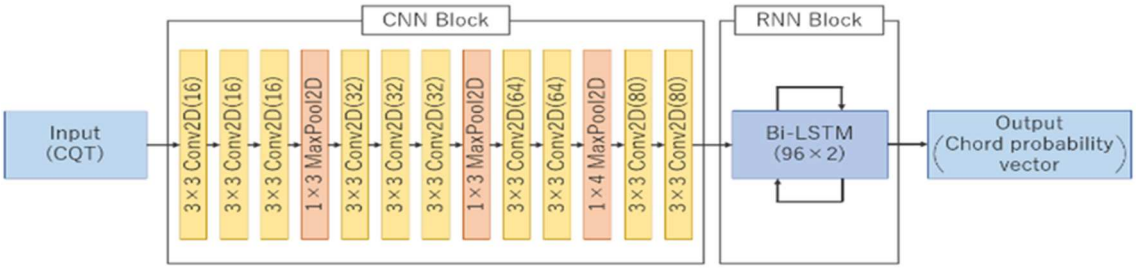

Fig. 1 Model architecture of the CRNN by Jiang et al. [1].

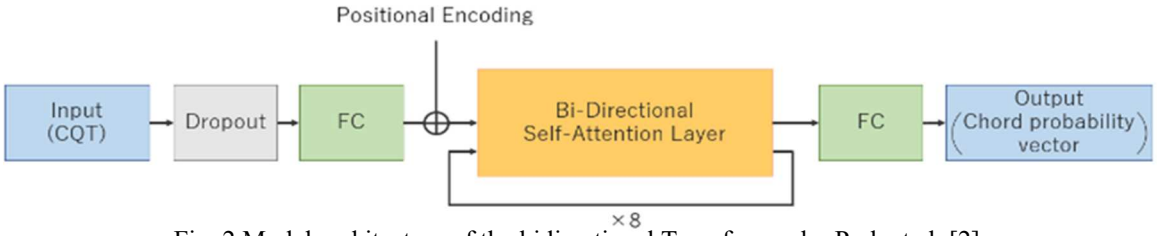

Fig. 2 Model architecture of the bidirectional Transformer by Park et al. [2].

Table 1 Pitch and the classification in the music theory

Semitones	Pitch	Classification
0	P1, 12	Root
+1	11, m2	-
+2	M2, 13	-
+3	12, m3	Third
+4	M3, 14	Third
+5	13, P4	-
+6	14, 15	Fifth
+7	P5, 16	Fifth
+8	15, m6	Fifth
+9	M6, 17	Sixth, Seventh
+10	16, m7	Seventh
+11	M7, 18	Seventh
+12	17, P8	(Root)

A chord consists of a single note (Root) over multiple notes (Quality). Various variations exist for chords, such as triads and tetrads. Each note in the Quality is interpreted in terms of its musical distance relative to the Root, based on the pitch relations shown in Table 1. The type of chord is determined by the pitch relations of all notes in the chord. In popular music, chords called triads or tetrad are mainly used. In this paper, ACR discriminates evaluation metrics of seven types.

A triad is a chord made up of one note from the Root, Third, and Fifth in the classification shown in Table 1, which is a predetermined combination. For example, the major chord consists of P1 (Root), M3 (Third), and P5 (Fifth). The minor chord consists of P1 (Root), m3 (Third), and P5 (Fifth).

A tetrad is a chord made by depositing a single note classified as a Sixth or Seventh on the Triad. For example, the M7 chord consists of P1 (Root), M3 (Third), P5 (Fifth), and M7 (Seventh). The m7 chord consists of P1 (Root), m3 (Third), P5 (Fifth) and m7 (Seventh).

III. RELATED WORK

Actually, ACR is a task that has been studied for more than two decades. Various methods have been proposed [16]. For most recent work, ACR systems based on deep learning models have been used. This section introduces two earlier studies using deep learning models [1, 2] because we use them in proposed ensemble learning.

A. ASR with CRNN

As a deep learning model for ACR, Jiang et al. used CRNN, a combination of CNN and RNN. It consists of the CNN part with convolutional and pooling layers, and the RNN part with Long Short-Term Memory (LSTM) or Gated Recurrent Unit (GRU).

Fig. 1 portrays the model architecture of the CRNN as described by Jiang et al. The input is the fixed-length Constant-Q Transform (CQT) spectrogram extracted from a musical piece, which is a widely used two-dimensional feature in music analysis. The horizontal axis represents time. The vertical axis is the strength of each music scale, as calculated using CQT transformation at each time. The output is the probability vectors of each chord for the same frame as the input. Jiang et al. used 10 convolutional layers and three pooling layers with optimization in the CNN part. The RNN part uses Bi-directional LSTM (Bi-LSTM).

B. ASR with Transformer

Park et al. used bidirectional Transformer, a model based on the Attention mechanism, which is used widely in natural language processing fields. The Attention mechanism computes the output vector using three vectors obtained from the input: Query, Key and Value. In a sequence task, Query corresponds to a specific element of the target sequence, whereas Key and Value correspond to an element of the source sequence. The output vector is a weighted sum of Values. The weights are calculated using Query and Key. When Query, Key, and Value are obtained from the same input, it is called

the Self-Attention mechanism. Transformer is a model with the Self-Attention mechanism.

Fig. 2 shows the model architecture of the bidirectional Transformer for ACR by Park et al. Similarly to CRNN, the input is a fixed-length CQT spectrogram. The output is probability vectors of each chord for the same frame as the input. In the middle, the process called positional encoding is performed before the bidirectional Self-Attention layer to consider temporal information.

IV. PROPOSED METHOD

Because it has a convolutional filter, CRNN can capture local features, whereas the self-attention mechanism of Transformer enables it to capture global features. For this study, we aim to improve the ACR discrimination accuracy by performing ensemble learning using two models having different feature extraction approaches. We also propose a novel overlap inference method to resolve the lack of temporal musical information at the beginning and end of clips during inference.

Because the source chord of the CRNN model is not publicly available for one earlier study [1], we reproduced it based on descriptions in the report of that study. Considering the pre-experiments, we used CRNN without the normalization process. We used the Transformer model source chord published by its authors [2].

First, ensemble learning is explained. Then an overlap inference method is described.

A. Ensemble learning

Ensemble learning, a machine learning method, uses each output value of multiple models. For this study, we use the stacking method, which can deal with probability sequences. In stacking, the output values obtained in the training process of multiple models (lower models) are used to create datasets for training upper models. By constructing upper models that capture the tendency of each lower model, we can expect to improve the accuracy. For this study, we use the full-connected NN as upper models, for which the inputs and outputs are sequences. Fig. 3 shows a training flow for the lower and upper models. Regarding lower models, the input is a CQT spectrogram (F in the frequency direction × T frames in the time direction). The output is a sequence of chord probability vectors (chord classes C × T frames). N_Train is the number of spectrograms used for training.

The model is trained by application of k-Fold Cross-Validation, by which 1/k of the training data are used as validation data. The rest are used as training data. Training is performed k times. For this study, the number of Folds for the lower and upper models is set as five. K-Fold Cross-Validation is generally used to verify generalization performance accurately. However, it also creates datasets for training upper models of stacking. At the end of model training for each Fold of lower models, the output values for validation data are stored as input features for upper models. As the result of 5-Fold, five trained lower models and output values for the validation data are obtained for each fold.

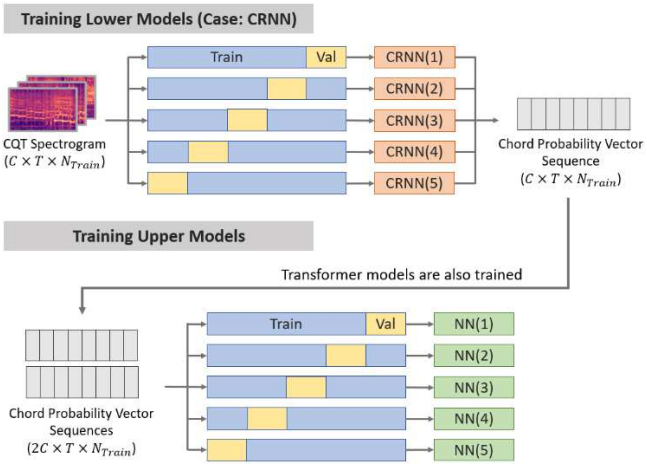

Fig. 3 Training flow for the lower and upper models.

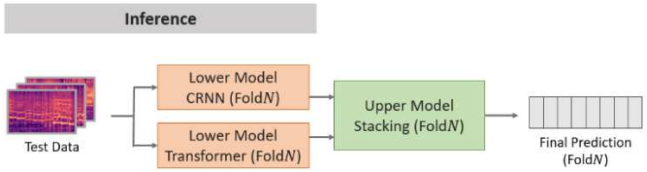

Fig. 4 Inference flow.

The sequence of chord probability vectors, which is the output value obtained in training lower models, CRNN and Transformer, is input to upper models as two-dimensional features (2 × C × T). The upper models are also trained with k-Fold Cross-Validation because of the inference described later. Therefore, five trained upper models are obtained.

Fig. 4 shows the inference flow. Along with the training, the CQT spectrogram is input to each lower model. The obtained two sequences of chord probability vectors are used to infer upper models. The lower and upper models used are of the same Fold.

B. Overlap inference

Both the earlier research models and the proposed models use the fixed-length spectrogram as input. For earlier studies [1, 2], the target music piece was divided into short audio data (clip) before input to the model. The predicted chord sequences obtained for each inference were arranged and treated as inference results for the entire piece. In this case, as presented in Fig. 5, the beginning and end of each clip often lacks the former and the latter part of temporal musical information, resulting in unstable inference. To resolve this difficulty, we adopt an original overlap inference method. An overview of overlap inference is presented in Fig. 6. The music is divided into clips with overlap. The middle parts of each inference result, shown as green in Fig. 6, are used as a result of the entire song. Presumably, this method generates stable inference results overall and engenders improved accuracy.

Our experiments compare two types of overlap inference method. Hereinafter, N_Test is the number of clips in T frames. In Pattern 1, the clips are overlapped by 1/2T and inference is

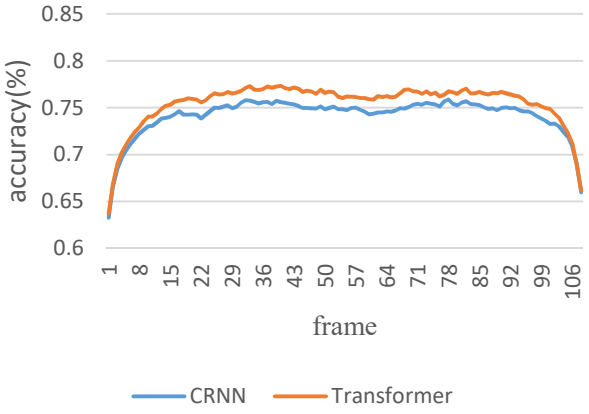

Fig. 5 Average accuracy per frame for validation data.

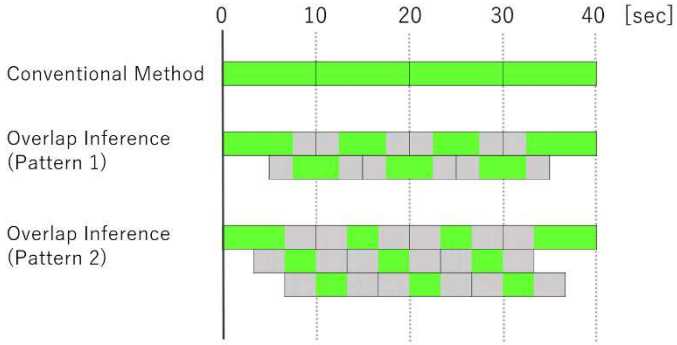

Fig. 6 Overview of overlap inference.

performed. Then the central 1/2 part of the inference result is extracted. Considering the non-overlapped part, the first clip is the 0 to 3/4T frame part of the inference result, each second to N_Test-1 clip is the 1/4T to 3/4T frame part of the inference result, and the N_Test clip is the 1/4T to T frame part of the inference result, are extracted and used as inference results of the entire song. In Pattern 2, the clips are overlapped by 2/3T; the central 1/3 part of the result is extracted. Considering the non-overlapped part, the first clip is the 0 to 2/3T frame part of the inference result, each second to N_Test-1 clip is the 1/3T to 2/3T frame part of the inference result, and the N_Test clip is the 1/3T to T frame part of the inference result, are extracted and used as inference results of the entire song.

V. EXPERIMENTS

This section presents comparison of the proposed model with CRNN [1] and Transformer [2], which are the earlier research models, with verification of the effectiveness of overlap inference. To make fair comparisons, experiments are conducted under the common conditions of input–output format and dataset used.

A. Dataset

For this study, we use 390 songs for model training and testing (80% for training and 20% for testing) as shown in

Table 2 Dataset used

Dataset	Annotated by	No. songs
Beatles	Isophonics [19]	180
Queen	Isophonics [19]	20
Zweieck	Isophonics [19]	18
Carole King	Isophonics [19]	7
Robbie Williams	Bruno et al. [20]	65
RWC POP [18]	MARL [21]	100

Table 2. Each annotation datum includes the type of chord that appears in the song, the start time, and the end time.

B. Pre-processing

We use the CQT spectrogram as an input feature for the lower models in ensemble learning. Because the input of the lower model must have fixed length, each piece of music is divided into clips of short duration. The number of seconds in each clip was set as 10 s (overlap 5 s), which preserves sufficient temporal information and which can be extracted efficiently from the music. We extract the CQT spectrogram from the audio by Librosa [17], with a sampling rate of 22,050 Hz, an analysis window length of 2,048 sampling points (approximately 0.093 s), and a scale of 8 octaves from C1 and 24 bins per octave. The analysis window is shifted without overlap so that each clip is a two-dimensional feature of 108 frames and 192 frequency bins.

We applied data augmentation using the 11-step pitch shift operation (from -5 semitones to -1 semitone and from +1 semitone to +6 semitones) on the training set to avoid overfitting. Annotation data corresponding to the music data generated by this extension process are also created and used.

Chords in the annotation data are based on 170 labels (Root{C, C#, D, D#, E, F, F#, G, G#, A, A#, B} × Quality{maj, min, dim, aug, sus2, sus4, maj6, min6, maj7, minmaj7, min7, hdim7, dim7} + No Chord + Unclassified) and are assigned to each frame of the feature to obtain the correct data.

C. Model training

We trained the CRNN, Transformer, and NN used for ensemble learning under the conditions shown in Table 3. If the validation loss did not improve by more than 0.001 in three epochs, then we decreased the learning rate by 80%.

Table 3 Training conditions

Model	CRNN	Transformer	NN
Programming language	Python 3.8.10		
Framework	Pytorch 1.10.0		
Input dim	108 × 192		108 × 340
Output dim	108 × 170		
Batch size	128		
Loss Function	Categorical CrossEntropy		
Optimizer	Adam [22]		
Initial learning rate	0.0001		

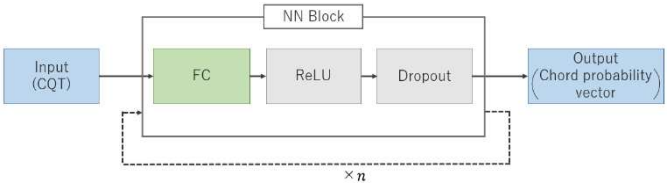

Fig. 7 NN model structure.

Table 4 NN model details

Model name	No. units	No. NN blocks	No. parameters
NN256_1	256	1	130,986
NN256_2	256	2	196,778
NN512_1	512	1	261,802
NN512_2	512	2	524,458
NN1024_1	1024	1	523,434
NN1024_2	1024	2	1,573,034

D. Upper model structure

The NN structure used as upper models is portrayed in Fig. 7. The chord probability vector output by the lower model (CRNN, Transformer) is used as input. The probability of each chord per frame is output after passage through the intermediate block consisting of the full-connected layer, ReLU function, and the dropout layer (rate 0.2). For this study, we trained several models with different numbers of units in full-connected layers and intermediate blocks for experiments. Table 4 presents the models used in experiments.

E. Comparative results

We evaluate the performance of an ensemble learning and an overlap inference. We use seven evaluation metrics: root only, root and thirds, major–minor chords, triads, sevenths, tetrads, and MIREX (more than three correct notes between reference and estimated chords). All evaluation metrics are calculated as the number of correct frames out of the total number of frames. They are calculated using the python library mir_eval [23].

First, we compare the results obtained for the six proposed models without overlap inference shown in Table 4 with CRNN and Transformer, the earlier research models. Table 5 shows inference results of each model. The proposed model (NN1024_1), compared to CRNN, improves the accuracy by 0.87% on average. Compared to Transformer, the proposed model improves accuracy by 1.66%. It confirms that an ensemble learning model in ACR is effective for improving the accuracy because the upper NN model was able to incorporate consideration of the tendency of the CRNN flexibly, which is strong for local features, and Transformer, which is strong for global features. In the case of model comparisons without overlap, neither increasing the number of full-connected layer units nor increasing the number of intermediate blocks improved accuracy in many cases. Most information had already been processed by the lower model. The upper model needs only to judge the accuracy of the information: it needs no large network structure.

Table 5 Results of the earlier studies' model and the six proposed NN models without overlap inference

NN1024_2	83.86	**81.83**	**82.61**	**80.30**	**71.72**	**68.84**	82.79

Next, we compare the results of overlap inference. The Pattern 1 and Pattern 2 results are presented, respectively, in Table 6 and Table 7. In Pattern 1, NN1024_2 had the highest average accuracy of 78.92% for all indicators. In Pattern 2, NN1024_2 had the highest average accuracy of 78.85%. Apparently, the inference performance in overlap inference depends on the number of parameters. Comparison of Pattern 1 and Pattern 2 shows that Pattern 1 had higher accuracy. Pattern 1 is a long interval extraction. Therefore, less discrepancy exists in the integration of each inference result.

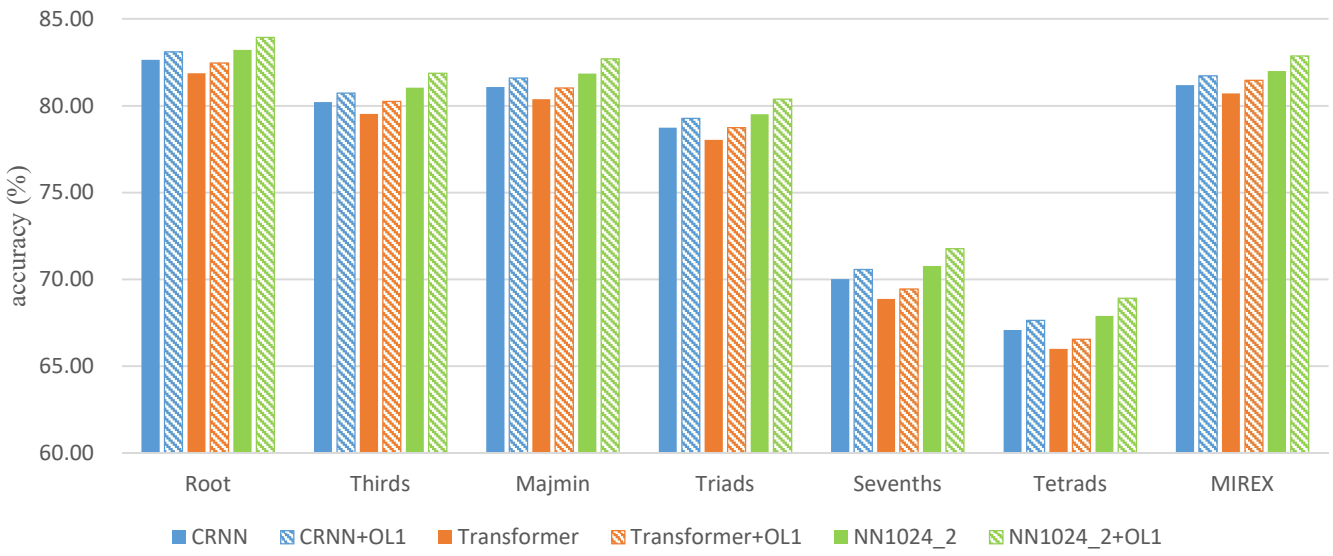

Fig. 8 Results of proposed NN model compared to CRNN and Transformer.

We confirmed the effectiveness of overlap inference (Pattern 1).

Finally, we compare the results obtained using the NN model (NN1024_2), which has the highest average accuracy with overlap inference with CRNN and Transformer. Fig. 8 presents the inference results obtained using each model. Pattern 1, which shows the greatest improvement in average accuracy, was used for overlap inference for all models. For inference without overlap, the NN model (green) improved the average accuracy by 0.77% and 1.56%, respectively, compared to the CRNN (blue) and Transformer (orange). Particularly Tetrads, the most difficult evaluation metric, showed the greatest improvement, respectively, of 0.81% and 1.90%. When we used overlap inference, CRNN (shaded blue) and Transformer (shaded orange) improved the average accuracy by 0.52% and 0.64%, respectively, compared to the same models without overlap inference. The NN model with overlap inference (shaded green) improved the average accuracy by 0.87% compared to the same model without overlap inference. It also improved the average accuracy by 1.64% and 2.43%, respectively, compared to the CRNN (blue) and Transformer (orange) without overlap inference and improved the average accuracy by 1.12% and 1.79%, respectively, compared to the CRNN (shaded blue) and Transformer (shaded orange) with overlap inference. We confirmed ensemble learning effectiveness and the overlap inference proposed in this study.

VI. Conclusions

As described in this paper, we propose ensemble learning models for automatic chord recognition, particularly addressing differences in feature extraction approaches: The CRNN has a convolutional filter, which can capture local features. By contrast, Transformer has a Self-Attention mechanism, which can capture global features. We also proposed original overlap inference methods to solve unstable inference because of the lack of temporal musical information in the inference of each clip.

In the inference without overlap, the NN model with 1024 full-connected layer units and one intermediate block had the highest average accuracy of 78.15%, which are 0.87% and 1.66% higher, respectively, than the CRNN and Transformer. In the overlap inference (Pattern 1), CRNN and Transformer improved the average accuracy by 0.52% and 0.64%, respectively, compared to inference without overlap. The NN model with 1024 full-connected layer units and two intermediate blocks in the overlapped inference caused the highest average accuracy of 78.92% among all models.

This study confirmed the effectiveness of ensemble learning and an overlap inference proposed in this study. In future studies we plan to improve the accuracy further by increasing the number of intermediate blocks and the number of full-connected layer units of the proposed NN model, improving the model structure, and adopting multi-task learning and Conditional Random Fields (CRF) used with other methods.

Construction of Automatic Speech Recognition Model that Recognizes Linguistic Information and Verbal/Non-verbal Phenomena

Nagito Shione, Yukoh Wakabayashi and Norihide Kitaoka
Toyohashi University of Technology, Japan

***Abstract*—This study addresses an automatic speech recognition (ASR) model that simultaneously recognizes linguistic information and various verbal/non-verbal (VNV) phenomena: fillers, laughter, interrogative ascending tones, end of speech, pronunciation errors, word fragments, etc. Although ASR technology has rapidly advanced in recent years, most ASR systems can only recognize linguistic information and can still not VNV phenomena. Recognition of VNV phenomena is important because speakers often convey their intentions during spontaneous speech using these types of utterances. We achieve VNV recognition by annotating VNV phenomena tags on learning transcribed text when the ASR model is trained. Our experimental results revealed that the accuracy of speech recognition is improved by also recognizing VNV phenomena. The ASR model in which the VNV phenomena tags appeared before the linguistic information in the transcribed text showed the best performance when using data from the Corpus of Everyday Japanese Conversation.**

I. Introduction

In recent years, conversational AI assistants like Apple's Siri and Google Assistant have been widely installed in smartphones and smart speakers, and have become increasingly popular for helping people in their daily lives. These conversational AI assistants have been realized through the use of Automatic Speech Recognition (ASR), which is used to interpret user commands. With the rise of End-to-End (E2E) models, ASR performance has surpassed that of the previously dominant Deep Neural Network-Hidden Markov Model (DNN–HMM) approaches in terms of recognition accuracy. However, conversational speech often includes fillers like "uh" and "um", missing words, repetitions, and other disfluencies, which degrade speech recognition [1] since ASR models are typically trained using fluent speech. Furthermore, conversational speech includes not only verbal phenomena, such as fillers, but also non-verbal phenomena, such as laughter, changes in intonation and variations in voice intensity, which can play an important role in communication. For example, fillers are used to give the speaker additional time when choosing words, or to organize one's thoughts [2]. Laughter is used to soften the meaning of the previous utterance or to express emotions such as happiness or discomfort [3]. Thus, speakers try to communicate their intentions to others by using not only verbal information but also verbal/non-verbal (VNV) phenomena, and therefore it is important to be able to recognize VNV phenomena in speech.

Several studies on recognizing VNV phenomena in speech have been previously conducted. Kaushik *et al.* built an ASR model that could detect fillers and laughter in speech by combining a DNN, a Convolutional Neural Network (CNN), and a Low-pass filter (LPF) [4]. Chatziagapi *et al.* built an ASR model to detect fillers in both speech and linguistic information by combining a CNN and a Recurrent Neural Network (RNN) [5]. However, these studies only focused on recognizing VNV phenomena in speech, and not on recognizing the linguistic information, which is our primary method of understanding conversation. Therefore, it is important to recognize both language information and VNV phenomena simultaneously in order to understand a speaker's intended message.

Some studies on simultaneously recognizing linguistic information and verbal phenomena have been conducted. Mendelev *et al.* built an ASR model to simultaneously recognize linguistic information and hesitations in speech using a RNN Transducer (RNN-T) [6]. Horii *et al.* proposed an ASR model capable of simultaneously recognizing linguistic information, fillers and hesitations in speech using a Joint/CTC Attention Transformer [7], and reported that the simultaneous recognition of linguistic information and along with fillers and hesitations improved the accuracy. These studies suggest that the simultaneous recognition of verbal phenomena and linguistic information improves the accuracy of speech recognition. However, these studies only made use of fillers and hesitations as verbal phenomena. In order to better understand natural human speech, it will be necessary to recognize a wider variety of VNV phenomena. Therefore, in this study we propose an ASR model that simultaneously recognizes linguistic information and multiple types of VNV phenomena. To achieve this, the proposed ASR model is trained using a conversational corpus containing spontaneous utterances with VNV phenomena. The proposed model can more accurately interpret user intentions by simultaneously recognizing linguistic information and a wide variety of VNV phenomena

II. Corpus of Everyday Japanese Conversation

The Corpus of Everyday Japanese Conversation (CEJC) [8] is spontaneous speech corpus which contains 200 hours of audio, 577 conversations, and approximately 2.4 million words uttered by 1675 speakers. It includes everyday conversations occurring in a variety of situations, such as a conversation with a friend at a restaurant, and a meeting at work, etc. Unique characteristics of the CEJC are that it includes natural everyday conversations which occur in daily life, and that audio and video are both recorded. It also contains tagged transcriptions of the utterances, identifying VNV phenomena as well as other phenomena. There are 24 types of VNV phenomena which are tagged in the CEJC in total, a list of which is shown in Table I. As shown, the CEJC supplements linguistic information with tags for verbal phenomenon, such as fillers (F) and pronunciation errors (W), as well as tags for non-verbal phenomenon tags, such as laughter (L) and interrogative ascending tones (?), and other phenomenon tags such as uncertain hearing or word judgment (U) and pseudonyms and foreshadowing related to personal (R). In the CEJC, the VNV and other information phenomenon tags are generally added before the linguistic information, as a supplement to the linguistic information, but some VNV phenomenon tags and other phenomenon tags are handled differently. For example, (W), which indicates pronunciation errors, is transcribed with the linguistic information of the mispronunciation and the language information of the correction. The tag (L), which indicates laughter, is transcribed as (L) if there is only a laugh.

TABLE II: Positions of the VNV phenomenon tags

Positions of VNV tags	Example of transcription
Before	まず (D ソ) 何を (L 目的にするか)。
After	まず (ソ D) 何を (目的にするか L)。
Enclosing	まず (D) ソ (/D) 何を (L) 目的にするか (/L)。

III. Proposed method

In this study, we propose an ASR model that simultaneously recognizes linguistic information and 9 types of VNV phenomenon tags. In addition, we investigate the effect on speech recognition accuracy of changing the position of VNV phenomenon tags. The proposed method is described below.

A. Recognition of verbal and non-verbal phenomena

The VNV phenomena that we recognize in this study are fillers (F), laughter (L), interrogative ascending tones (?), end of speech (。), pronunciation errors (W), word fragments (D), small voice (T), speech related to the flow of conversation (<>) and speech in dialects or foreign languages (O). Of the twenty-four types of phenomena listed in Table I, the nine VNV phenomena tags with the largest number of occurrences were selected as recognition targets. By simultaneously recognizing not only linguistic information but these nine types of VNV phenomena, we can build an ASR model that is able to use a richer amount of information for recognition than conventional ASR models.

B. Changing the position of VNV phenomenon tags

In this study, the positions of the VNV phenomenon tags in the transcription were changed, and a different ASR model constructed for each variation. The three tag position protocols used for the VNV phenomena tags are shown in Table II. These are before, after, and enclosing the targeted linguistic information. Within the CEJC, the end of speech (。), interrogative ascending tones (?) and voice, speech related to the flow of conversation (<>) are not supplementary to the linguistic information, and are assigned independently. Therefore, the positions of these three types of VNV phenomenon tags were not changed under any of the three conditions. By building and evaluating ASR models under each of these three tag position conditions, we can clarify the effect of the position of the VNV phenomenon tags on speech recognition.

IV. Experimental settings

We used the CEJC as the dataset to implement the proposed ASR method. We excluded from the dataset utterances that contained unrecognized VNV phenomenon tags, and other phenomenon tags other than the nine we selected. Because the CEJC take place daily in a variety of settings, some of the speech is relatively clean (daily conversation in a staff room), while other conversations contain considerable noise (daily conversation in a restaurant). In fact, the CEJC contains more noisy than clean audio, therefore we performed speech enhancement on all of the speech samples using the Conv-TasNet model [9] which was pre-trained with CHiME [10] as provided by ESPnet [11]. This process denoised somewhat. The dataset was divided into three sets: a Train set for training data, a Dev set for development data and an Eval set for evaluation data. Details of the datasets used in this study are shown in Table III.

We used ESPnet to conduct the experiments in this study. ESPnet is an open source toolkit for speech processing which is specialized for E2E ASR models. An ASR model used in this study is the Joint CTC/Attention Transformer model provided by ESPnet, which is a Transformer Encoder–Decoder model that combines Attention and Connectionist Temporal Classification (CTC) [12]. Speed Perturbation (SP) [13] was applied to the speech in the training set to create additional speech data, converted at 0.9x and 1.1x the speed of the original speech data. The input acoustic features were log-mel spectrograms calculated using 80 mel-scale filter banks. The input acoustic features were further augmented with Spec Augment [14], and then Mean and Variance Normalization (MVN). Next, embedding and positional encoding were performed to convert the features into feature vectors with embedded positional information. This data is then input to the Transformer Encoder, which consisted of 18 layers, with each layer consisting of 2 sub-layers; a Multi-Head Attention layer and a Feed-Forward Network layer. Each sub-layer was followed by residual connection and normalization. The output of the last layer was input to the Transformer Decoder and the CTC Decoder, the latter of which has a fully-connected layer. The Transformer Decoder consisted of six layers, each of which consisted of 3 sub-layers; a Masked Multi-Head Attention layer, a Multi-Head Attention layer and a Feed-Forward Network layer. Each sub-layer was followed by residual connection and normalization, like the Encoder. For Multi-Head Attention, the number of heads in the Encoder and Decoder was 8. We trained the model using the Adam optimizer. For inference, the output of the Transformer Decoder and the output of the CTC Decoder were used to output the sequence of label $\hat{y}$, which was obtained as follows:

$$\hat{y} = \underset{y}{\operatorname{argmax}} \{\lambda \log p_{\mathrm{ctc}}(y|x) + (1-\lambda) \log p_{\mathrm{tf}}(y|x)\}, \quad (1)$$

where $\log p_{\mathrm{ctc}}(y|x)$ and $\log p_{\mathrm{tf}}(y|x)$ are the output probabilities of the CTC Decoder and the Transformer Decoder, respectively, that output the sequence of label y when input acoustic features x are input, and λ is the weight of the CTC Decoder. In this study, λ was set to 0.3, which is the ESPnet default.

We used Character Error Rate (CER) and Slot Error Rate (SER) [15] to evaluate and compare the performance of the ASR models as measures. CER was used to evaluate speech recognition accuracy for linguistic information while SER was used to evaluate VNV phenomenon tag detection accuracy. SER is the ratio of the total number of deletion errors, insertion errors, and substitution errors divided by the total number of VNV phenomenon tags correctly detected, as shown in Eq. (2). SER is obtained as follows:

TABLE III: Details of the datasets used in this study

Dataset	Number of utterances	Duration	Number of VNV tags								
			(W)	(D)	?	(T)	(L)	<>	(F)	。	(O)
Train	476590	116:04:57	12743	25140	34654	8786	46917	169	13308	374066	16
Dev	59529	15:55:41	1855	3702	3466	1222	4737	54	1819	46450	15
Eval	60618	16:15:26	1775	4048	2809	1711	7289	27	2284	44937	209

$$\text{SER} = \frac{\text{\# of insertion errors + \# of deletion errors + \# of substitution errors}}{\text{\# of target VNV phenomenon tags}}. \quad (2)$$

SER is greater than 100% if the total number of targeted VNV phenomenon tags that were correctly detected is less than the number of insertion errors.

V. Experimental results

We built three different ASR models by changing the position of the VNV phenomenon tags in the training data, as described in Sec. Ⅲ-B, and obtained the CER of the linguistic information and SER for tag detection. The results are shown in Table IV. We can see that the ASR model for the "enclosing" VNV tag condition produced a higher CER than the other two ASR models. This is because the number of characters to be recognized was larger. For example, the "before" and "after" tag conditions require estimation of four characters because "(" and ")" is one character when the recognition target is (D ソ) or (ソ D). On the other hand, the "enclosing" tag condition requires estimation of eight characters when the recognition target is (D) ソ (/D). Therefore, there is a difference in the number of characters even if the recognition target is the same. As a result, the "enclosing" tag condition had a larger negative impact on the CER when mis-estimation occurred, compared to the other ASR models. Table IV also shows that the SERs for speech related to the flow of conversation (<>) and for the speech in dialects or foreign languages ((O)) were greater than 100% in all conditions. This was due to a lack of sufficient data for training. However, the SERs for interrogative ascending tones (?) and small voice (T) were also high, even though the number of utterances used for training. For (T), this was because the input acoustic feature is a non-verbal phenomenon (the loudness of a sound). Since we only used the log-mel spectrogram as the acoustic features input, we did not use a feature related to the loudness of the sound, so the SER of (T) was high. In future work, we will add features that are sensitive to changes in sound intensity, such as power features. The log-mel spectrogram used as input acoustic features contains information on pitch although the SER for (?) was also high. It is highly possible that the change in pitch due to (?) was not captured by the spectrogram. In future work, we will add features that are more sensitive to changes in pitch, such as F0 features. The SERs for pronunciation errors (W) and word fragments (D) were much higher than fillers (F) even though these three are the same verbal phenomena. This is because VNV phenomenon tags contain a variety of linguistic information; (F) contains a limited variety of linguistic information, such as (F あの) and (F その) while both (W) and (D) both include a huge variety of linguistic information unlike (F). As a result, recognition of the (W) and (D) tags was not successful.

Table IV shows that the SERs were different for each VNV tag position condition, so the position of the VNV phenomenon tags effected VNV phenomena detection in the CEJC data. The Transformer model uses self-attention mechanisms to calculate the relationships between tokens within an input sequence. Since the tag indicates positional information, so the model takes that positional information into account. For example, when tag is placed before tokens, the model is more likely to associate them with the preceding tokens. Therefore, the position of tags can be considered to alter the importance of positional information, potentially leading to differences in accuracy. The ASR model trained under the "before" tag condition achieved a lower CER and SERs than those trained under the other tag conditions. Therefore, the best ASR model for the CEJC data was the one that recognizes linguistic information by prefixing it with a VNV phenomenon tag.

We also evaluated ASR performance when only linguistic information was used for recognition, in order to compare the performance of our proposed method with that of a standard ASR model that does not use VNV tag information. To perform this comparison, we built an additional ASR model trained without VNV tags as a baseline model. The training conditions and architecture of the baseline model were the same as those of the other models, as described in Section Ⅳ, except no VNV tags were used. To compare performance of the proposed methods with the baseline model, we post-processed the recognition results of the proposed ASR models by removing the VNV phenomenon tags, and then obtained CERs when using only linguistic information.

The flow of VNV phenomenon tag removal is shown in Fig. 1. Performance results for each model are shown in Table V. We can see that the CERs achieved by the proposed ASR models were lower (i.e., better) compared to the baseline model. Therefore, the proposed ASR modeling method improves speech recognition accuracy by simultaneously recognizing not only linguistic information but also VNV phenomena tags in the CEJC.

VI. Conclusion

In this study, we proposed an ASR model that simultaneously recognizes linguistic information and a wide variety of VNV phenomena, in contrast to conventional ASR models that only recognize linguistic information. We also investigated the effect of changing the position of the VNV phenomenon tags on speech recognition accuracy, and on the accuracy of VNV phenomena detection, as well as the effect of simultaneously recognizing VNV phenomena and linguistic information on

TABLE IV: Character Error Rates (%) and Slot Error Rates (%) when VNV tags are located in various positions. CER was calculated by including the VNV phenomenon tags as characters to be recognized.

Enclosing	24.1

the accuracy of speech recognition. Our experimental results showed that the best performing ASR model for CEJC data was one that recognizes linguistic information by prefixing it with VNV phenomenon tags. We also demonstrated that simultaneous recognition of linguistic information and VNV phenomena improves the accuracy of speech recognition, in comparison to a conventional ASR method using only linguistic information. In the future, we would like to investigate methods of improving both the speech recognition accuracy and VNV phenomena detection accuracy of the proposed method by using it in combination with a language model, F0 features and power features.

***Abstract*—With the growing amount of musical data available, automatic instrument recognition, one of the essential problems in Music Information Retrieval (MIR), is drawing more and more attention. While automatic recognition of single instruments has been well-studied, it remains challenging for polyphonic, multi-instrument musical recordings. This work presents our efforts toward building a robust end-to-end instrument recognition system for polyphonic multi-instrument music. We train our model using a pre-training and fine-tuning approach: we use a large amount of monophonic musical data for pre-training and subsequently fine-tune the model for the polyphonic ensemble. In pre-training, we apply data augmentation techniques to alleviate the domain gap between monophonic musical data and real-world music. We evaluate our method on the IRMAS testing data, a polyphonic musical dataset comprising professionally-produced commercial music recordings. Experimental results show that our best model achieves a micro F1-score of 0.674 and an LRAP of 0.814, meaning 10.9% and 8.9% relative improvement compared with the previous state-of-the-art end-to-end approach. Also, we are able to build a lightweight model, achieving competitive performance with only 519K trainable parameters.**

I. Introduction

Music is an essential part of our lives. Nowadays, online music streaming services such as Apple Music and Spotify enable us to access an abundance of music recordings much more easily than before. At the same time, the massive amount of data brings new challenges: how can we find the music we want efficiently? Music Information Retrieval (MIR) has emerged as a research field that focuses on extracting and inferring meaningful features from music, indexing music using these features, and developing various search and retrieval methods to make the world's vast store of music easily accessible by individuals [1].

As one of the important problems in MIR, instrument recognition shows great potential to contribute to real-world music applications, such as music recommendation and source separation [2]. Though the past 30 years have seen great progress in the automatic classification of monophonic phrases or isolated notes, the task of instrument classification for polyphonic multi-instrument music, where the sound mixture becomes more complex but similar to the real-world scenario, remains rather difficult. In this work, we tackle predominant instrument recognition, which focuses on identifying the main instruments in a given polyphonic music segment.[1]

Generally speaking, training a robust statistical model for classification requires a large amount of high-quality annotated data. However, in the field of predominant instrument recognition, a lack of such annotated polyphonic musical data has been a constraint for training a robust classifier. First, domain knowledge is necessary for annotation in polyphonic musical mixtures, especially for complex ones. Second, well-produced music recordings help generalization but have copyright issues. On the contrary, monophonic sounds and isolated notes require relatively less effort to collect and label. But in terms of timbral characteristics, these are far from the music we listen to daily, which is consecutive, melodic, polyphonic, and not as "clean" as the isolated samples. Therefore, it would be interesting to discuss how monophonic musical data can help instrument recognition in a polyphonic setting.

Some studies have touched on this. Bosch *et al.* [3] made an early attempt by using source separation as a pre-processing step to divide polyphonic music signals into stems, and classified each stem through a separate model. Kratimenos *et al.* [4] experimented with four random mixing augmentation methods using the IRMAS training set [3], which contains monophonic samples and polyphonic samples but all labeled with one predominant instrument, to improve the polyphonic instrument recognition system.

In this paper, we look into this topic from another perspective. We investigate the effectiveness of using isolated musical notes as pre-training data for improving the predominant instrument recognition system. We adapt the model proposed in [5] to classify instrument classes from raw musical waveforms and experiment with various data augmentation techniques to bridge the domain gap between isolated notes and polyphonic music. Furthermore, we investigate a weight-sharing method [6] for reducing the parameters of our instrument encoder.

The remainder of the paper is structured as follows: Section II gives a non-exhaustive review of the relevant research in the

[1] In this paper, "polyphonic" means both polyphonic and multi-timbral, following the literature in this field.

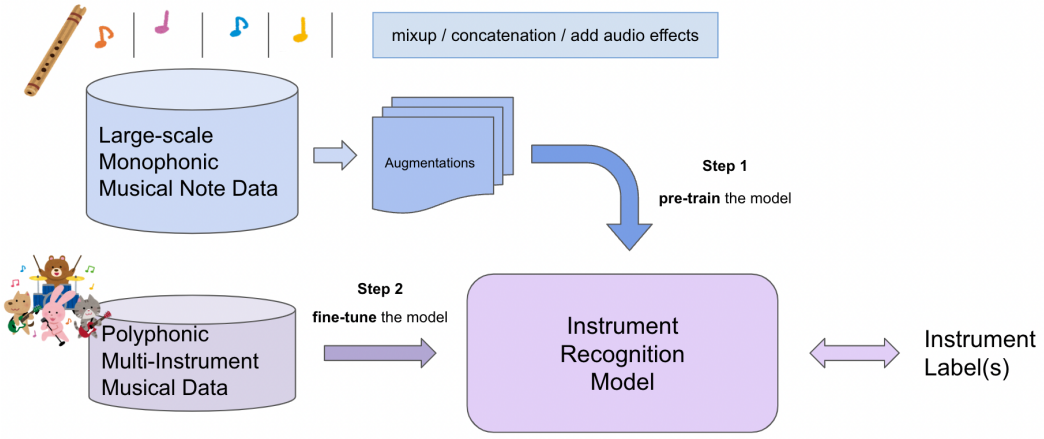

Fig. 1. Overview of the proposed method.

field of instrument recognition. Section III describes the model architecture and data augmentation pipeline. Section IV introduces the details of our experiment settings. Section V presents our experimental results. Finally, Section VI summarizes this work.

II. Related Work

Automatic classification of musical instruments has been studied since the mid-1990s. In 1995, Kaminsky & Materka [7] trained instrument classifiers for four instruments in isolated notes. Eggink & Brown [8][9] conducted two consecutive studies on instrument classification in polyphonic mixtures with models trained on monophonic audio. Livshin & Rodet [10] developed a real-time solo instrument classifier and also applied it directly to performance duets, demonstrating that the solo instrument classifier has the potential for multi-instrument classification.

As the automatic classification of isolated musical notes has been considered a solved problem [11], and monophonic music is not very applicable to real-world scenarios, more and more attention has shifted to instrument recognition in a polyphonic context. Fuhrmann *et al.* [12][13] took the first step towards the problem of predominant instrument recognition in polyphonic music by collecting a database and using hand-crafted features and support vector machines (SVM) to classify the music segments. Bosch *et al.* [3] extended this research by using source separation as a pre-processing step. The dataset used in their research, the IRMAS (Instrument Recognition in Musical Audio Signals) dataset, later became the benchmark for predominant instrument recognition.

Recently, deep learning techniques have fostered more and more advances in polyphonic instrument recognition. In the task of predominant instrument recognition, Han *et al.* [14] continued the research on the IRMAS dataset by using VGG-styled convolutional neural networks (CNNs), and their system outperformed the previous SVM methods, marking a pioneering work in deep models for predominant instrument recognition. Pons *et al.* [15] made an attempt to modify the neural network structures based on domain knowledge, achieving similar scores to previous work with much fewer model parameters. Yu *et al.* [16] extended the CNN-based predominant instrument recognizer by combining additional spectral features and a multi-task approach based on instrument groups. Reghunath and Rajan [17] applied Swin-Transformers to this task, and their input incorporates images of Mel-spectrograms as well as phase and tempo features. With an ensemble voting technique, a micro F1-score of 0.66 was achieved. Kratimenos *et al.* [4] proposed to randomly mix monophonic audio clips as augmented data samples to train neural networks for polyphonic instrument recognition. Avramidis *et al.* [18] compared different architectures in an end-to-end fashion, using raw waveforms as model input. Zhong *et al.* [19] investigated a cross-modal transfer learning approach for predominant instrument recognition using an ImageNet pre-trained vanilla ResNet-50 model.

III. Methodology

A high-level scheme of our proposed method is presented in Fig. 1. The training pipeline is as follows: First, we augment the monophonic musical note data by mixing, concatenating, and adding effects, to alleviate the domain gap between isolated notes and polyphonic recordings. The augmentations are done on-the-fly during the training process. Then we use the augmented data to pre-train the instrument recognition model. Finally, we fine-tune the pre-trained model for predominant instrument recognition using polyphonic, multi-instrument musical recordings. An overview of the instrument recognition model is shown in Fig. 2. We will give a detailed explanation of the model and the augmentation methods in the following section.

A. Model Architecture

We adapt the instrument encoder proposed by Shi *et al.* in [5] as the main backbone. It consists of a learnable front-end, a CNN feature extractor, and a learnable pooling layer. The components of the backbone are described next.

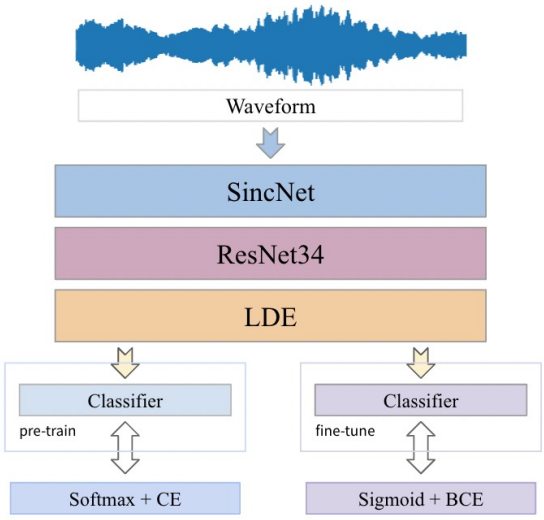

Fig. 2. Model Architecture.

A SincNet [20] layer is used as the trainable front-end to extract the low-level features from the raw waveform. SincNet is implemented as a 1-D CNN layer. Instead of learning all the elements of the kernels, SincNet constrains its kernels to be a set of sinc functions in the time domain. Suppose g is one SincNet kernel; then the operation is written as:

$$g[n, f_1, f_2] = 2f_2 \,\mathrm{sinc}(2\pi \mathrm{f}_2 \mathrm{n}) - 2\mathrm{f}_1 \,\mathrm{sinc}(2\pi \mathrm{f}_1 \mathrm{n}), \quad (1)$$

where $\mathrm{sinc}(\mathrm{x}) = \sin(\mathrm{x})/\mathrm{x}$. Then its Fourier transform is a rectangular bandpass filter in the frequency domain, which can be described as the difference between two low-pass filters:

$$G[f, f_1, f_2] = \mathrm{rect}(\frac{\mathrm{f}}{2\mathrm{f}_2}) - \mathrm{rect}(\frac{\mathrm{f}}{2\mathrm{f}_1}), \quad (2)$$

where $\mathrm{rect}(\cdot)$ is the rectangular function. For such a parameterized filter, the only parameters to learn are f_1 and f_2, which are the low and high cutoff frequencies, respectively. Although in [5], a constant Q transform (CQT)-initialized SincNet provided better results, we did not find results showing improved polyphonic instrument recognition performance. Thus, the SincNet layer is initialized using the Mel-scale cutoff frequencies in our experiments, following the original SincNet paper.

We then use 34-layer residual convolutional networks (ResNets) [21] to encode the low-level acoustic features to meta-level feature vectors. ResNets are CNNs which have identity mapping by shortcuts in every few stacked layers.

Finally, we use a learnable dictionary encoding (LDE) layer [22] to aggregate CNN-encoded features as the instrument embeddings. In a nutshell, LDE learns a dictionary as a set of clustering centroids based on the weighted distance between every frame-level feature and every centroid.

B. Data Augmentation

We use the following three data augmentation strategies at the pre-training stage:

1) Concatenation: Some instruments cannot produce sustained notes. Thus, following [5], we randomly concatenate trimmed samples of the same instruments. By doing so, we also introduce note changes within an instrument in the generated samples, which is common in real-world recordings.

2) Mixup: Since multiple instruments may play at the same time in multi-timbral polyphonic music, in the pre-training phase, we adopt a mixup style training process [23] [24], which trains the networks on convex combinations of pairs of examples and their labels. This process can be described as:

$$x_{mix} = \lambda x_i + (1 - \lambda) x_j, \quad (3)$$

$$y_{mix} = \lambda y_i + (1 - \lambda) y_j, \quad (4)$$

where x_i and x_j are two randomly selected audio waveforms of the same length, y_i and y_j are their labels respectively, $\lambda \in [0, 1] \sim \mathrm{Beta}(\alpha, \alpha)$ is the random mixing ratio, x_{mix} is the generated waveform, and y_{mix} is the corresponding mixed label. In our implementation, we randomly select the audio samples regardless of the instrument class for mixing. Before combing the samples, we normalized them to the same Loudness Units relative to Full Scale (LUFS) level [25][2]. LUFS is a weighted loudness measure mimicking the relative sensitivity of the human ear to different frequencies in terms of perceived loudness.

3) Audio effects: As in reality, professionally-produced music often involves different kinds of audio effects such as reverb, delay, etc., we apply audio effect augmentation, including adding noise, delay, reverb, gain, pitch shift, and high-low pass for pre-training[3]. According to [26], augmentation with audio effects commonly used in electronic music production improves the instrument recognition accuracy in both processed and unprocessed test sets.

C. Fine-tuning for Polyphonic Multi-instrument Recordings

Pre-training uses augmented monophonic note data, and its optimization criterion is to select only one most plausible instrument among multiple instruments. We therefore update the model with the softmax layer based on the cross-entropy loss with corresponding instrument labels.

The criterion of the final task, on the other hand, is to select one or more principal instruments in a segment of the input polyphonic multi-instrument music recording, which is different from the pre-training criterion. Hence, for fine-tuning, we replace the softmax layer with a Sigmoid layer where each dimension corresponds to a probability for each instrument class and compute an element-wise binary cross-entropy loss so that more than one class may be predicted by setting a threshold value for the predicted probability of each instrument class.

TABLE I
SUMMARY OF THE NSYNTH DATASET AND THE IRMAS DATASET

Dataset	NSynth	IRMAS - train	IRMAS - test
# Instruments	1,006	11	11
# Samples	305,979	6,705	2,874
Duration per sample	4 seconds	3 seconds	5 - 20 seconds
Total duration	340.0 hours	5.6 hours	13.5 hours

IV. EXPERIMENTS

A. Data Preparation

In our experiments, we pre-train our models on the NSynth dataset [27], fine-tune the models with the IRMAS training data [3], and perform the evaluation on the IRMAS testing data. Table I shows a summary of the two datasets.

1) NSynth: The NSynth dataset is a collection of 305,979 audio snippets in 16 kHz, each lasting 4 seconds, containing an isolated monophonic musical note. Each note was held for the first 3 seconds, and for the last second, it was allowed to decay. Every note is different in instrument, pitch, or velocity and generated using one of 1,006 instruments from a commercial sample library. These 1,006 instrument labels are fine-grained, and each belongs to one of 11 instrument families: bass, brass, flute, guitar, keyboard, mallet, organ, reed, string, synth lead, and vocal. Since not all instruments play a full range of 88 pitches, NSynth contains an average of 65.4 pitches per instrument. However, in NSynth, some notes contain a pitch unusual for the particular instrument, thus producing nearly silent sounds that are hazardous to the classification. We therefore filter out these notes by applying an energy threshold before pre-training. NSynth was released with an official split of train, validation, and test sets, and the instruments in the train set do not overlap with the ones in the validation set or test set. In our work, we formulate the pre-training process as a multi-class classification task in which the labels of samples in the validation set should be seen in the training phase. So we combine the train and validation sets in the official splits, resulting in a new train set with all 1,006 instruments. Then, 4% of the new train set is separated as a new validation set.

2) IRMAS: We use the IRMAS dataset to fine-tune and evaluate our instrument recognition model. This dataset consists of stereo recordings of professionally produced music excerpts with a sampling rate of 44.1 kHz, featuring varying instrumentation, playing styles, genres, audio quality, and production styles. Every sample in the dataset contains the segment-wise label of eleven pitched instruments, specifically cello (cel), clarinet (cla), flute (flu), acoustic guitar (gac), electric guitar (gel), organ (org), piano (pia), saxophone (sax), trumpet (tru), violin (vio), and human singing voice (voi). Note that the human voice was labeled as one of the instruments, while bass, drums, and percussion instruments were not annotated. Synthesizers, now essential ingredients in popular music, are not included in the annotations, either. IRMAS provides an official split of the dataset into training and testing sets. The training set comprises 6,705 3-second audio files, some are monophonic and others are polyphonic. But they all have only one predominant instrument label. The testing set includes 2,874 audio files, each lasting from five to twenty seconds and labeled with one or more predominant instruments. All the samples in the IRMAS dataset are downsampled to 16 kHz and converted to mono by taking the mean of the two stereo channels. Then, they are normalized to -12 LUFS.

We use the raw waveform signals as the input to our model. In the pre-training phase, only the first second of each sample in the augmented NSynth dataset is used as the fixed-length input for training and validation. There are two main reasons for doing so: first, as found in previous research [14], a 1-second duration is sufficient for the CNNs to capture the features of the instruments involved, and it was also found to be the optimal setting; second, in our preliminary experiments, we found that longer duration produced worse results. In the fine-tuning phase, for the IRMAS dataset, every 3-second audio sample in the training set is divided into three 1-second clips, resulting in 20,115 training samples. 15% of the training samples are separated to form a validation set. However, the 3-second samples in the IRMAS training set are from 2,000 distinct songs. Obviously, within each song, the samples share similar timbral characteristics. So, in creating a validation set, we make sure that there are no overlaps with songs in the training split.

B. Training Configuration

In this study, all experiments are implemented with the PyTorch framework. The source code is available online[4].

1) Pre-training: The models are pre-trained using vanilla categorical cross-entropy loss on 2 GPUs with synchronized batch normalization [28]. We set the mini-batch size to 128 and trained the model for 30 epochs. We use Adam optimizer [30], and a weight decay of 0.0005. The maximum value of the learning rate is set to 0.001. In training, the learning rate increases linearly from zero to the maximum value for the first three epochs and decreases to zero following a cosine curve. We set label smoothing [29] to 0.05. Mixup is applied with a probability of 0.5 and $\alpha = 0.3$. Concatenation augmentation was applied with a probability of 0.5, and we sliced the first second of the generated samples as the input. The effect augmentation ratio was set to 0.3. We use the model weights of the last epoch as the starting point for fine-tuning.

2) Fine-tuning: We fine-tune the models with the IRMAS training data. We use binary cross entropy loss and Sigmoid as the final activation. This is because our testing samples have one or more than one instrument labels. We set the mini-batch size to 64 and trained the model for 40 epochs on a single GPU. We use Adam optimizer and a weight decay of 0.0005. The maximum value of the learning rate is set to 0.00025. To examine the effects of pre-training, we also train models from scratch for comparison. For the models trained from scratch, we set the learning rate to 0.0035, which is the optimal setting based on the results of the preliminary experiments. We

[4]https://github.com/nii-yamagishilab/predominant-instrument-recognition

believe this leads to a fairer comparison. Again, the "warm-up" training strategy is adopted: the learning rate increases linearly from zero for the first five epochs and decreases following a cosine curve. No data augmentations were implemented during fine-tuning since we didn't observe any improvements using augmentations. We use the model weights of the last epoch for evaluation.

C. Evaluation Methodology

We use the IRMAS testing set to evaluate our model, following the evaluation settings of previous works [14][4][18]. The testing samples in the IRMAS dataset are of varying lengths. To handle this, we divide each of them into 1-second fixed-length clips with 50% overlap and take the average of clip-wise logits as the sample-wise predictions. As previously mentioned, there can be one or more predominant instrument labels, so generally, predominant instrument recognition is formulated as a multi-class multi-label classification task. We use the F1-score and Label Ranking Average Precision (LRAP) as evaluation metrics, consistent with previous research.

1) F1-score: F1-score is a commonly used metric in the field of instrument recognition. For each instrument label, F1-score is defined as the harmonic mean of precision and recall:

$$F1 = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}, \tag{5}$$

and the corresponding precision and recall values for each instrument label are defined as:

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}, \quad \text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}, \tag{6}$$

where TP is true positive, FP is false positive, and FN is false negative.

We calculate the averaged metrics over the 11 instrument labels to evaluate the overall model performance. To obtain the binary outputs, we compute the scores under a range of thresholds and report the optimal ones. The sample-wise predictions that exceed the threshold will be binarized as ones, i.e., the active labels. Since the label distribution of the IRMAS dataset is not balanced, both macro and micro-averaged metrics are calculated:

$$\text{P}_{macro} = \frac{1}{L}\sum_{l=1}^{L}\frac{\text{TP}_l}{\text{TP}_l + \text{FP}_l}, \tag{7}$$

$$\text{R}_{macro} = \frac{1}{L}\sum_{l=1}^{L}\frac{\text{TP}_l}{\text{TP}_l + \text{FN}_l}, \tag{8}$$

$$\text{P}_{micro} = \frac{\sum_{l=1}^{L}\text{TP}_l}{\sum_{l=1}^{L}(\text{TP}_l + \text{FP}_l)}, \tag{9}$$

$$\text{R}_{micro} = \frac{\sum_{l=1}^{L}\text{TP}_l}{\sum_{l=1}^{L}(\text{TP}_l + \text{FN}_l)}, \tag{10}$$

where l denotes the index of each label, and L denotes the number of labels. respectively, The macro and micro averaged F1-scores are defined as:

TABLE II
TRAINING WITH RANDOM INITIALIZATION *vs.* WITH NSYNTH PRE-TRAINING

Initialization	F1-micro	F1-macro	LRAP
Random	0.634 ± 0.0075	0.536 ± 0.0127	0.780 ± 0.0057
NSynth	0.674 ± 0.0068	0.584 ± 0.0068	0.814 ± 0.0020

$$F1_{macro} = \frac{2 \cdot \text{P}_{macro} \cdot \text{R}_{macro}}{\text{P}_{macro} + \text{R}_{macro}}, \tag{11}$$

$$F1_{micro} = \frac{2 \cdot \text{P}_{micro} \cdot \text{R}_{micro}}{\text{P}_{micro} + \text{R}_{micro}}. \tag{12}$$

The macro average considers each class to have the same weight, whereas the micro average treats each instance as having equal weight, thus assigning more weights to the classes with more samples.

2) LRAP: Proposed in [31], LRAP is a metric for multi-label classification, and it was introduced to the instrument activity detection task by Gururani *et al.* [32]. Suppose we have N samples and M labels. Given ground truth labels $y \in \{0,1\}^{N\times M}$ and predictions $\hat{f} \in \mathbb{R}^{N\times M}$, it is defined as:

$$LRAP(y,\hat{f}) = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{||y_i||_0}\sum_{j:y_{ij}=1}\frac{|\mathcal{L}_{ij}|}{\text{rank}_{ij}}, \tag{13}$$

where $\mathcal{L}_{ij} = \left\{k : y_{ik} = 1, \hat{f}_{ik} \geq \hat{f}_{ij}\right\}$ and $\text{rank}_{ij} = \left|\left\{k : \hat{f}_{ik} \geq \hat{f}_{ij}\right\}\right|$. $|\cdot|$ computes number of elements of the set and $||\cdot||_0$ computes the number of nonzero elements in a vector. The intuition of this metric is that our model should assign a higher score to the true labels than the other ones. Thus, LRAP does not require a threshold to have binary outputs as F1-score does.

V. EXPERIMENTAL RESULTS

We present the evaluation results on the IRMAS testing set. Note that we run each experiment three times with the same configuration except for the random seed, and report the mean value and standard deviation.

1) Effects of NSynth Pre-training: To examine the effects of NSynth pre-training, we train models from scratch with only the IRMAS training data. The comparison is shown in Table II. From this table, we can see that NSynth pre-training strongly improves the performance of downstream task, i.e. predominant instrument recognition (from 0.634 to 0.674 for F1-micro). After analyzing the average performance over all the labels, we visualize the instrument-wise micro F1-score to get more insights into how the NSynth pre-training weights benefit predominant instrument recognition. As shown in Fig. 3, NSynth pre-training boosts the system's performance in almost all the instruments except for the violin.

NSynth itself is a large dataset, and its monophonic samples share similarities with polyphonic music data to a certain extent. Thus, we are interested to see how the effectiveness changes with the amount of the IRMAS training data used

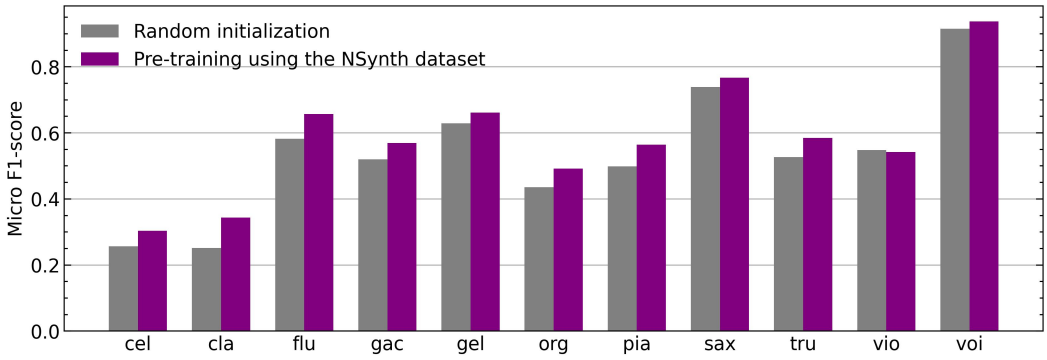

Fig. 3. Instrument-wise analysis: Training from random initialization *vs.* with NSynth pre-training.

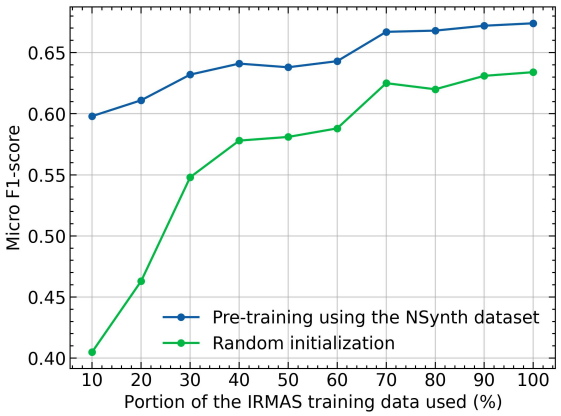

Fig. 4. Portion of the IRMAS training data used in the fine-tuning phase *vs.* evaluation results on the IRMAS testing data.

in the fine-tuning phase, in order to explore the effect of NSynth pre-trained weights a step further. Again, we report the results on the IRMAS testing set. Fig. 4 shows the micro F1-score obtained with respect to the amount of training data. Overall, the model benefits from NSynth pre-training regardless of the training data volume. The gap between pre-trained and randomly-initialized models is enlarged as the training data volume decreases. Surprisingly, with NSynth pre-trained weights and 10% of the IRMAS training data, we can train a model that is reasonable for predominant instrument recognition.

2) Effects of Data Augmentations: Next, we ablate the data augmentation methods during the pre-training phase to examine their individual contributions to the results. The ablation results are shown in Table III. While all augmentation techniques contribute to better performance, mixing two samples with soft labels has the most impact (by removing it, the micro F1-score drops from 0.674 to 0.657). And by pre-training without mixup and audio effects, the micro F1-score drops to 0.642.

3) Single Predominant Instrument Identification: As in [14], we also analyze the model's ability to identify the "most" predominant instrument of the music segment. Here we report

TABLE III
ABLATIONS OF PRE-TRAINING AUGMENTATION METHODS

Augmentations	F1-micro	F1-macro	LRAP
All	0.674 ± 0.0068	0.584 ± 0.0068	0.814 ± 0.0020
- mixup	0.657 ± 0.0029	0.560 ± 0.0045	0.804 ± 0.0040
- audio effect	0.671 ± 0.0031	0.576 ±0.0055	0.812 ± 0.0030
- both[a]	0.642 ± 0.0050	0.535 ± 0.0031	0.791 ± 0.0037
- concatenation	0.670 ± 0.0012	0.576 ± 0.0015	0.813 ± 0.0013

[a] Without mixup and audio effects

our results of the last epoch on the validation set. Note that we select the validation set to avoid similarity to the training split, so we believe that these results properly reflect the upper bound of our model's generalization ability. The overall identification accuracy is 72.6%. We present the confusion matrix in Fig. 5, and t-SNE visualization [33] of the neural embeddings, explicitly the output of the penultimate layer, in Fig. 6. From the results we can see that our model is prone to confuse the timbre of violin, flute, and clarinet with others.

4) Parameter Reduction: In the field of predominant instrument recognition, designing a reduced, lightweight model has been a research direction recently [15] [18]. In our research, considering the potential applications of our system in DAW (Digital Audio Workstation) software, we want to reduce the parameters of the model, because when producing or mixing music on our local machines, we do not want the tagging system to take up too much of the limited hardware resources.

To reduce the parameters, we run experiments with backbones that are more shallow and further adopt a shared residual block strategy (ShaResNets) proposed in [6] in consecutive residual blocks between two spatial downsampling layers. Fig. 7 presents the testing micro F1-score with respect to the models' number of parameters. We use $\{d_1, d_2, d_3, d_4\}$ to denote the number of repetitive residual blocks in n-th section in ResNet. In this figure, ResNet34 is the model we start with, ResNet28 reduces the residual layers of backbone to $\{3, 3, 4, 3\}$ and ResNet18's backbone has residual layers of $\{2, 2, 2, 2\}$. Previous works are plotted as dots for comparison. The best performance is achieved by our base model, ResNet34. Using shared blocks, we can reduce its number of parameters to 836K (64%) with 0.011 (1.6%) reduction in the

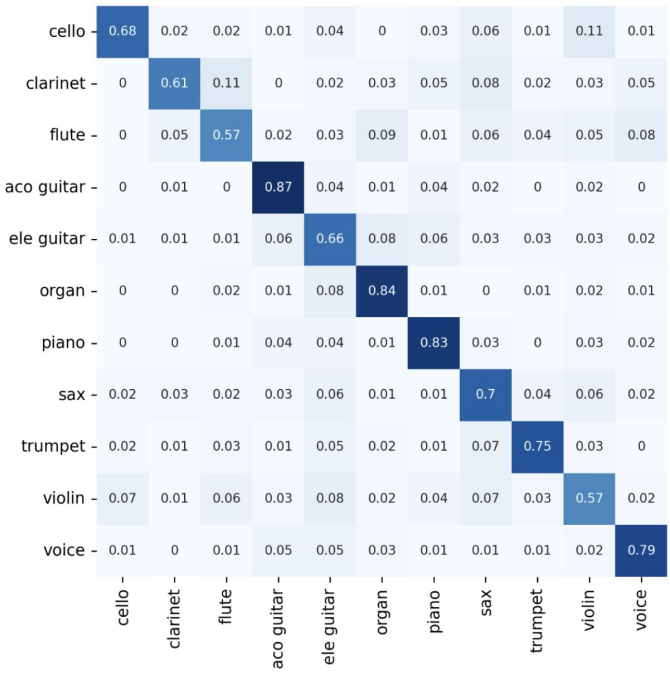

Fig. 5. Confusion matrix of single predominant instrument identification. The columns are predictions and the rows are groun truth labels. Here, "aco guitar" and "ele guitar" stand for acoustic guitar and electric guitar, respectively.

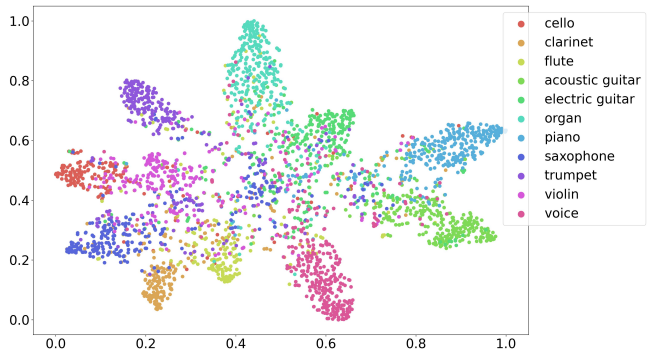

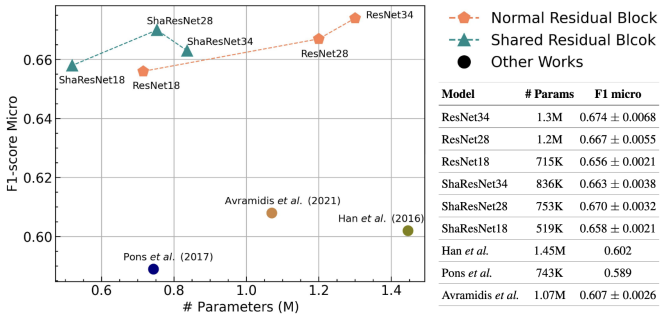

Fig. 6. t-SNE visualization of the embeddings of the validation set.

F1 score. For ResNet28 and ResNet18, sharing the weights achieves even higher performance than the original structures. ShaResNet28, which has 753K parameters, almost the same number of parameters as Pons's model in [15], has a competitive performance to our best model. Our smallest model, ShaResNet18, which only has 519K parameters, achieves a micro F1-score of 0.658, a surprising score considering its small size. Besides, from this figure, we can see a trend that as the number of parameters grows, the performance of normal residual networks grows, too. Thus we can infer that there is still room for improvement if we add more parameters to the model.

5) Comparison with Other Works: Table IV shows the micro-averaged F1-score, macro-averaged F1-score, and LRAP achieved by our proposed method and previous approaches.

Model	# Params	F1 micro
ResNet34	1.3M	0.674 ± 0.0068
ResNet28	1.2M	0.667 ± 0.0055
ResNet18	715K	0.656 ± 0.0021
ShaResNet34	836K	0.663 ± 0.0038
ShaResNet28	753K	0.670 ± 0.0032
ShaResNet18	519K	0.658 ± 0.0021
Han *et al.*	1.45M	0.602
Pons *et al.*	743K	0.589
Avramidis *et al.*	1.07M	0.607 ± 0.0026

Fig. 7. Comparison of evaluation performance between previous work and our reduced models.

TABLE IV
COMPARISON OF EVALUATION RESULTS ON THE IRMAS TESTING DATA

Methods	Features	F1-micro	F1-macro	LRAP
This work	Waveform	0.674	0.584	0.814
Avramidis *et al.* [18]	Waveform	0.608	0.543	0.747
Kratimenos *et al.* [4]	CQT	0.647	0.546	0.805
Zhong *et al.* [19][a]	Mel	0.680	0.600	0.818
Reghunath & Rajan [17]	Mel[b]	0.66	0.62	-
Yu *et al.* [16]	Mel	0.661	0.569	-
Pons *et al.* [15]	Mel	0.589	0.516	-
Han *et al.* [14][c]	Mel	0.619	0.513	-

[a] Here we show the results of single model. For the model ensemble in this work, the results were 0.688, 0.606, and 0.826 for F1-micro, F1-macro and LRAP respectively.
[b] They fused Mel-spectrogram with modgdgram and tempogram as features.
[c] Here we show their results in publication, but in preprint, the results were 0.602 and 0.503, for F1-micro and F1-macro respectively.

For all three evaluation metrics, the performance of our system produced the second best results. Our method, as an end-to-end classification approach that takes raw music data as input, outperforms the previous end-to-end system by 0.066 in micro F1-score, a 10.9% relative improvement, which is noteworthy taking into account the difficulties of this task. Also, for all three metrics, our method shows a better performance than most of the previous methods that take time-frequency representations as inputs. [19] obtained a micro F1-score of 0.680 with a vanilla ResNet-50 whose number of parameters is 25.5M. But note that in this work, the best model only has 1.3M parameters, which is no more than 5.1% of the former. Overall, this result indicates great potential in such end-to-end instrument recognition systems with trainable frontends.

VI. CONCLUSION

In conclusion, our study demonstrates the effectiveness of an end-to-end predominant instrument recognition system for polyphonic multi-instrument music. The key contributions of our research can be summarized as follows:

- A pre-training and fine-tuning approach utilizing monophonic musical note data proves effective in predominant instrument recognition.
- Data augmentation techniques during pre-training help bridge the gap between monophonic data and real-world

polyphonic music, contributing to the robustness of our model.

- Our best model achieves a micro F1-score of 0.674 and an LRAP of 0.814, marking a significant improvement of 10.9% and 8.9% relative to the previous end-to-end approach.
- A lightweight model with only 519K trainable parameters can still deliver competitive performance, demonstrating the potential for efficient deployment in various applications.

For future work, we will continue this research focusing on both model architecture as well as the challenges inherent in the data. First, we will improve the model performance by increasing the number of parameters, since the largest models we tested have only 1.3M parameters. Second, we would like to experiment with synthesized music rendered from MIDI scores as pre-training data. Moreover, we are also interested to explore this polyphonic instrument recognition problem in a zero-shot way.

ACKNOWLEDGEMENTS

We would like to thank Ms. Xuan Shi from the University of Southern California for her useful comments. This study is supported by JST CREST Grant Number JPMJCR18A6 and by MEXT KAKENHI grant 21K11951.

***Abstract*—We propose two methods to improve the quality of extracted speech signals utilizing the out-of-focus areas in video captured with a rolling-shutter camera. A rolling-shutter camera exposes and reads pixels from the top row of an image to the bottom, but when capturing an object that is vibrating due to speech, image distortion occurs due to the different exposure start times. The conventional method extracts a speech signal from a phase variation calculated from an image distortion. Here, we consider a case where out-of-focus areas arise in the captured video. In this case, the phase variation is not calculated correctly, which is expected to cause quality degradation of the speech signal extracted from the video. Our first proposed method weights the phase variation and the second one removes the out-of-focus areas. Experimental results show that our first method improves the quality of extracted speech signal and the second one reduces the time complexity.**

I. Introduction

In speech recording, an air-conduction microphone is typically used for converting speech signals into electrical signals when sound waves arrive at its diaphragm. As a result, the microphone acquires not only the target speech but also background noise. To solve this problem, methods [1], [2] have been proposed for extracting a speech signal from a video of an object vibrating due to speech by capturing an object with a consumer-level camera. These methods extract the speech signal by using only the captured video images. While this approach prevents the extracted speech signal from being affected by the noise near the camera, the speech recorded by the air-conduction microphone includes the noise near the microphone.

Many consumer-level cameras come equipped with complementary metal oxide semiconductor (CMOS) image sensors [3], [4] and a rolling-shutter system. The rolling-shutter system exposes and reads pixels from the top row of an image to the bottom which means that image distortion can occur due to the different exposure start times when capturing an object that is vibrating due to speech. The speech extraction method proposed in [1] utilizes this distortion by extracting a speech signal from a phase variation in each row of captured images. Here, we consider the case where out-of-focus areas arise in the captured video. Out-of-focus areas are blurred compared to an in-focus area. Therefore, when out-of-focus areas of the captured video are used for speech extraction, the phase variation cannot be calculated correctly, which degrades the quality of the extracted speech signal.

In this paper, we propose two speech extraction methods that focus on out-of-focus areas. The proposed methods calculate the weights based on the partial derivative in the captured images and process out-of-focus areas using the calculated weights. Specifically, the first method weights the phase variation to reduce the contribution rate of the out-of-focus areas and extracts the speech signal. The second method removes out-of-focus areas and extracts the speech signal. We evaluate the quality of the extracted speech signal based on short-time objective intelligibility (STOI) [5] and log-spectral distance (LSD) [6].

II. Speech Extraction Method from Rolling-Shutter Video

This section describes the conventional method [1] for speech extraction by the rolling-shutter video, which is shown in Fig. 1. This method captures RGB video of an object that is vibrating due to speech, converts it to a grayscale video $I(x, y, t)$, and then extracts a speech signal $u(n)$ from $I(x, y, t)$, where x and y are the column and row indices, t is the frame index, and n is the time index. The speech signal $u(n)$ is calculated on the basis of the phase variation of the captured video $I(x, y, t)$. The phase variation is calculated using a complex steerable pyramid [7], [8] for the captured video $I(x, y, t)$. The complex steerable pyramid consists of sub-band images for each scale r and orientation θ. Hence, $I(x, y, t)$ can be transformed by the complex steerable pyramid as

$$S(r, \theta, x, y, t) = A(r, \theta, x, y, t)e^{j\phi(r,\theta,x,y,t)}, \tag{1}$$

where j denotes the imaginary unit, $A(r, \theta, x, y, t)$ denotes the amplitude of the sub-band video, and $\phi(r, \theta, x, y, t)$ denotes its phase. $S(r, \theta, x, y, t)$ is obtained by repeating Gabor filter convolution and downsampling on $I(x, y, t)$. As the conventional method uses the phase variation of each row in each video frame, the orientation θ is fixed to 0. Therefore, $S(r, x, y, t)$, which is the decomposition of $I(x, y, t)$, is given by

$$S(r, x, y, t) = A(r, x, y, t)e^{j\phi(r,x,y,t)}, \tag{2}$$

where $S(r, x, y, t)$ is downsampled from the original resolution by 2^{-r} times the resolution for each scale r. Then, the numbers of columns and rows in the captured video $S(r, x, y, t)$ for each scale r are given by

$$W_r = 2^{-r}W, \tag{3}$$

$$H_r = 2^{-r}H, \tag{4}$$

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

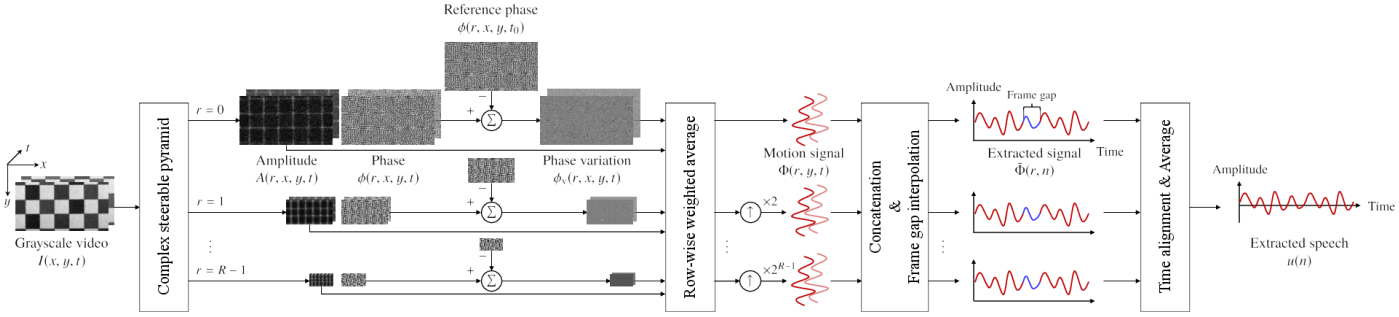

Fig. 1. Overview of speech extraction from rolling-shutter video.

where W and H denote the number of columns and rows in $I(x, y, t)$. By using the phase $\phi(r, x, y, t)$ of each row in each video frame, it is possible to extract the speech signal, as the vibration of an object will cause a phase variation [9], [10], [11]. The first step is to calculate the phase difference $\phi_v(r, x, y, t)$ from the reference frame $\phi(r, x, y, t_0)$, as

$$\phi_v(r, x, y, t) = \phi(r, x, y, t) - \phi(r, x, y, t_0), \tag{5}$$

where t_0 denotes the index representing the reference frame.

The next step is to obtain one value per row as the amplitude of the speech signal. We calculate the row-wise weighted average $\Phi(r, y, t)$ of the phase difference $\phi_v(r, x, y, t)$. Here, the square of the amplitude is used as a weight, since the phase can be accurately estimated for pixels with large amplitude. The row-wise weighted average $\Phi(r, y, t)$ is calculated as

$$\Phi(r, y, t) = \sum_{x=0}^{W_r - 1} A^2(r, x, y, t)\phi_{\mathrm{v}}(r, x, y, t). \tag{6}$$

As the length of $\Phi(r, y, t)$ is H_r for each r, the signal length H_r is aligned to H through upsampling by a factor of 2^r for each r. Here, $\Phi(r, y, t)$ for each r is a two-dimensional signal. Therefore, the averaged phase difference is transformed to a one-dimensional signal $\tilde{\Phi}(r, n)$ for each r, as

$$\tilde{\Phi}(r, n) = \Phi(r, y, t), \tag{7}$$

$$n = y + (H + N_{\mathrm{seg}})t, \tag{8}$$

where N_{seg} is the number of samples in a frame gap. The missing segment arises due to the characteristics of rolling-shutter cameras [3]. Therefore, an autoregressive model [12] is utilized to interpolate the missing segments between frames of the captured video.

The final step is to enhance the speech signal. $\tilde{\Phi}(r, n)$ from different r are synchronously added. For each scale r, a delay $d(r)$ between the reference signal $\tilde{\Phi}(r_0, n)$ and $\tilde{\Phi}(r, n)$ is calculated by

$$d(r) = \underset{m \geq 0}{\operatorname{argmin}}\ \tilde{\Phi}(r_0, n)^{\top}\tilde{\Phi}(r, n + m), \tag{9}$$

where r_0 denotes the index representing the reference scale and $\top$ denotes the transpose operator. For different r, the signals $\tilde{\Phi}(r, n)$ are added and averaged after synchronization by

$$u(n) = \frac{1}{R}\sum_{r=0}^{R-1} \tilde{\Phi}(r, n + d(r)), \tag{10}$$

where R is the number of scales of the complex steerable pyramid.

The conventional method performs speech extraction without handling out-of-focus areas. Since out-of-focus areas are blurred compared to the in-focus area as shown in Fig. 2, it is not able to correctly calculate phase variation in out-of-focus areas. In this paper, we propose methods to solve this problem.

III. SPEECH EXTRACTION METHODS UTILIZING OUT-OF-FOCUS AREAS

In this section, we propose two methods: one that weights the phase variation to reduce the contribution rate of the out-of-focus areas, and one that removes the out-of-focus areas from the captured video and extracts the speech signal.

A. Method 1:Weighted Phase Variation

As mentioned in Section Ⅱ, when out-of-focus areas of a captured video are used for speech extraction, the phase variation cannot be calculated correctly and the quality of the extracted speech signal degrades. Therefore, it is required to reduce the effect of out-of-focus area by weighting phase variation in each area. Since the absolute value of the partial derivative of an image brightness value is large at the edge of an image, weighting by the absolute value of the partial derivative leads to an emphasis on the phase variation at the edge. First, a weight $M(x, y)$ can be calculated as the absolute value of the partial derivative as

$$M(x, y) = |G_{\mathrm{X}}(x, y)|, \tag{11}$$

where $G_{\mathrm{X}}(x, y)$ is the partial derivative with respect to x and is calculated as

$$G_{\mathrm{X}}(x, y) = K(x, y) * I(x, y, t_0), \tag{12}$$

where $*$ denotes convolution and $K(x, y)$ denotes 3×3 Sobel filter in the row direction. Next, as in Section II, the phase variance $\phi_{\mathrm{v}}(r, x, y, t)$ is calculated using (1)–(5), and (6) is replaced with (13) to weight $M(x, y)$ to $\phi_{\mathrm{v}}(r, x, y, t)$. Finally,

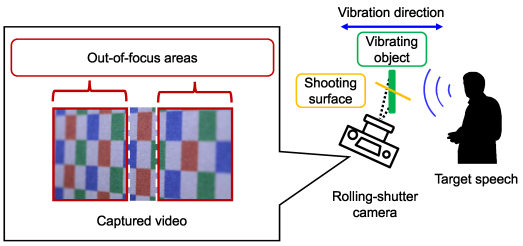

Fig. 2. Out-of-focus areas of captured video.

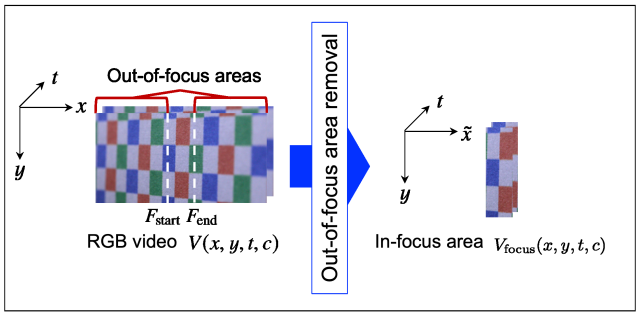

Fig. 3. Overview of out-of-focus area removal.

as in Section II, the extracted speech signal is obtained by (7)–(10).

$$\Phi(r, y, t) = \sum_{x=0}^{W_r - 1} M(x, y) A^2(r, x, y, t) \phi_{\mathrm{v}}(r, x, y, t). \quad (13)$$

B. Method 2:Removing Out-of-Focus Areas from Captured Video

As mentioned in Section Ⅱ, the phase variation cannot be calculated correctly in out-of-focus areas, thus the speech signal is extracted from the in-focus area only. When video is captured as shown in Fig. 2, the captured video is divided into in-focus area and out-of-focus areas, as shown in Fig. 3. In this case, pixels in the same column are considered to have the same weight. In addition, based on the relationship between focal length and depth of field, out-of-focus areas are composed of multiple adjacent columns. On the basis of the above, we perform out-of-focus area removal for the captured video.

First, $M(x, y)$ is calculated for each pixel of the captured video using (11) and (12). The column mean of $M(x, y)$ is calculated as

$$\bar{M}(x) = \frac{1}{H} \sum_{y=0}^{H-1} |M(x, y)|. \quad (14)$$

Next, we define a set $\boldsymbol{F}$ of column indices x such that $\bar{M}(x)$ is larger than the threshold value $\bar{M}_{\mathrm{th}}$ as

$$\boldsymbol{F} := \{x \mid \bar{M}(x) \geq \bar{M}_{\mathrm{th}}\}, \quad (15)$$

$$\bar{M}_{\mathrm{th}} = \frac{\alpha}{W} \sum_{x=0}^{W-1} \bar{M}(x), \quad (16)$$

where $\bar{M}_{\mathrm{th}}$ is calculated as α times the row means of $\bar{M}(x)$. The effect of removing out-of-focus areas can be amplified by increasing this α. Next, the column indices indicating the start point F_{start} and end point F_{end} of the in-focus region are calculated as

$$(F_{\mathrm{start}}, F_{\mathrm{end}}) = \left(\min_{x \in \boldsymbol{F}} x, \max_{x \in \boldsymbol{F}} x \right). \quad (17)$$

Finally, we remove the out-of-focus areas from the RGB video $V(x, y, t, c)$ and calculate the video $V_{\mathrm{focus}}(x, y, t, c)$ in the in-focus area as

$$V_{\mathrm{focal}}(\tilde{x}, y, t, c) = V(\tilde{x} + F_{\mathrm{start}} - 1, y, t, c), 1 \leq \tilde{x} \leq \tilde{W}, \quad (18)$$

$$\tilde{W} = F_{\mathrm{end}} - F_{\mathrm{start}} + 1, \quad (19)$$

where c denotes the index representing R, G, and B channels, $c = 0, 1$, and 2 are for the R, G, and B channels of the video, and $\tilde{W}$ denotes the number of columns in the in-focus region video. The speech signal is extracted by applying the method described in Section II to the obtained $V_{\mathrm{focus}}(x, y, t, c)$.

IV. Evaluation Experiments

We conducted evaluation experiments to investigate the effectiveness of the proposed methods. First, we show the experimental conditions for speech extraction from videos captured by a rolling-shutter camera. Next, we describe the quantitative experimental conditions and evaluation metrics for speech extraction and discuss the results. Finally, we describe the speech extraction results for one sample selected from a speech corpus [13].

A. Experimental Conditions for Speech Extraction

Figs. 4–6 respectively show the experimental setup, the equipment arrangement, and a paper with a printed pattern used as the vibrating object. Moreover, Tables I and II list the experimental conditions and equipment. As shown in Figs. 4 and 5, a paper placed in front of a loudspeaker was captured with a rolling-shutter camera, and the speech signal was extracted from the captured video. The videos were taken at an angle of 30° to the paper so that the vibrations in the row direction would be large. The pattern shown in Fig. 6 was printed on paper from the Salzburg Texture Image Database (STex) [14], which is a database of textures. In addition, we used a floodlight for illumination so that we could accurately capture the paper's vibration when the shutter speed was high. We used 50 sentences comprising five sentences for each of the ten speakers (five women, and five men) selected from the TIMIT Acoustic-Phonetic Continuous Speech Corpus [13].In this experiment, we set $t_0 = 0$ in (6) and (11), and used the initial frame taken in silence as the reference frame. We set $r_0 = 0$ in (9), with the lowest level of the complex steerable pyramid used as a reference scale. Since the speech extraction method using captured videos is based on the vibration of the object, vibration caused by non-speech elements introduces noise into the extracted speech signal. We suppressed this noise

in these experiments using the minimum mean-square error short-time spectral amplitude (MMSE-STSA) method [15].

Loudspeaker amplifier	BOSE 1705II
Floodlight	GOODGOODS GDGDS-WL02 (10000 lm)

B. Quantitative Experiments

We evaluated the quality of extracted speech by short-time objective intelligibility (STOI) [5] and log-spectral distance (LSD) [6]. STOI is a measure to evaluate the intelligibility of noise-suppressed speech. It takes a score from 0 to 1 with a higher score indicating higher intelligibility of evaluated speech. LSD is a difference between spectral envelope of a clean speech and that of an evaluated speech. The lower the LSD score, the smaller the difference between the clean speech and the evaluated speech, indicating that the evaluated spech is closer to the clean speech.

First, we evaluated the extracted speech signal extracted which by the weighted phase variation method. Figs. 7 and 8 show the results of evaluating the intelligibility of the extracted speech evaluated by STOI and the quality of the extracted speech evaluated by LSD, where the STOI and LSD values are the average scores of 50 sentences. Error bars indicate the standard deviation of each score. Paired-sample t-tests [16] on the STOI and LSD scores for the conventional and proposed methods at a significance level of 5% revealed no significant differences between the STOI scores, but significant differences between the LSD scores. In addition, the LSD score of the proposed method was on average 0.089 dB smaller than that of the conventional method, as shown in Fig. 8. This finding demonstrates that the quality of extracted speech can be improved by using the proposed method compared to the conventional method.

Next, we evaluated the speech signal extracted by the out-of-focus area removal method. In this experiment, we evaluated the cases $\alpha = 0.0, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0$, and 3.5 in (16). $\alpha = 0.0$ is the case where the speech is extracted from the captured video without out-of-focus area removal. As shown in Figs. 7 and 8, both the STOI scores and LSD scores of the proposed and conventional methods were comparable for all α. Paired-sample t-tests [16] on the STOI scores for the conventional and proposed methods at a significance level of 5% revealed no significant differences and similar results were obtained for the LSD scores. This finding demonstrates that the quality of the extracted speech is not improved by the removal of out-of-focus areas.

C. Time Complexity

Table III shows that the number of columns of captured videos decreases as α increases. By reducing the number of columns, the number of convolutions between the captured images and the Gabor filter in the speech extraction process is reduced, and thus the time complexity can be reduced. Specifically, the processing time for 50 sentences of the conventional method takes about 70 minutes using MATLAB on a computer with Intel(R) Core(TM) i9-11950H @2.60GHz and 32 GB of RAM. On the other hand, the processing time for 50 sentences of the proposed method under $\alpha = 1.5$ takes about 20 minutes in the same environment as the conventional method. These results indicate that the method of out-of-focus area removal reduces the time complexity without degrading the quality of the extracted speech signal.

TABLE III
NUMBER OF ROWS OF VIDEO IN EACH α

α	0.0 (Original)	0.5	1.0	1.5	2.0	2.5	3.0	3.5
In-focus area $\tilde{W}$	1920	1910	1052	326	232	201	123	48

D. Experimental Results of Speech Extraction

As a final evaluation, we examined one sample picked up from the speech corpus [13]. Spectrograms of the clean speech, the speech extracted by the conventional method, and the

(e) Proposed method (Out-of-focus area removal) $\alpha = 3.0$

Fig. 9. Spectrograms of speech.

speech extracted by the method of weighted phase variation are shown in Fig. 9. As we can see in Fig. 9 (c), the speech extracted by the proposed method contains more harmonic components in the high-frequency band than the conventional method. These results demonstrate the difficulty of measuring high-frequency vibrations in the out-of-focus areas. In Figs. 9 (d) and (e), the structure of the extracted speech in each α is generally the same, even though the number of video columns W varies depending on the method used. These findings demonstrate that the method of out-of-focus area removal can reduce the time complexity without degrading the quality of the extracted speech.

Overall, experimental results show that proposed method 1 improves the speech quality of extracted speech signal and proposed method 2 reduces the time complexity.

V. Conclusion

In this paper, we proposed two speech extraction methods that focus on out-of-focus areas to improve the quality of the extracted speech. The first method weights the phase variation, thereby reducing the contribution of the out-of-focus areas, and the second method removes the out-of-focus areas of the captured video and extracts the speech signal. Our experimental findings demonstrate that utilizing the out-of-focus areas in speech extraction is effective in improving sound quality or reducing time complexity. In future work, we aim to improve the method of weight calculation in the proposed method to achieve even higher speech quality.

E-mail: geniusturtle6174@gmail.com, {yuchun.lin, pooh.hsu, jang}@mirlab.org

***Abstract*—This paper proposes to use both audio input and subject information to predict the personalized preference of two audio segments with the same content in different qualities. A siamese network is used to compare two inputs and predict the preference. Several different structures for each side of the siamese network are investigated. The baseline structure which uses only audio information involves using a pretrained audio encoder followed by fully connected layers. In several different proposed structures, the approach of concatenating subject information with audio embedding before feeding it into fully connected layers outperforms the baseline model the most, resulting in an increase in overall accuracy from 77.56% to 78.04%. Experimental results also demonstrate that utilizing the complete set of subject information, which includes age, gender, and headphone/earphone specifications such as impedance, frequency response range, and sensitivity, is more effective than using a subset of this information.**

I. Introduction

Automatic audio quality measurement can be applied in many different audio related tasks, including detecting fake-quality audio [1], monitoring speech quality for online conference [2], or assessing the naturalness of synthesized speech [3]. Besides, since many people use mobile phones in their daily life, and the quality of audio playback is one of the considerations of choosing mobile phones [4], measuring the quality of audio playback for mobile phones would also be one of the important tasks.

On the other hand, while some research focused on predicting the mean score of users[5], methods that aimed to make personalized predictions have also been studied. Saquil et al. classified users into different categories and used the categorical labels as one of the inputs of their network to rank the preference of different video segments [6]. Xu et al. added personal information and personality test results of subjects to the input features to their models to predict the preference of sad music [7].

While Saquil et al. [6] and Xu et al. [7] focused on predicting the preference of different audio or video content, Leng et al. [8] and Hunag et al. [9] focused on predicting the preference for the same content across different qualities. Leng et al. proposed mean-bias network (MBNet), which was composed of a MeanNet accepting only audio spectrum to predict the mean opinion score (MOS), and a BiasNet in parallel with MeanNet accepting both audio spectrum and subject's ID to predict the possibly biased scores judged by individual subjects [8]. To improve MBNet, Hunag et al. [9] proposed listener-dependent network (LDNet), which used an encoder-decoder structure to predict the listener-dependent score, where the encoder accepted the input speech, and the decoder accepted the encoded vector and the subject's ID to output the listener-dependent score. However, the largest limitation of their methods is that the input of the subject's information is simply their ID, thus the subjects cannot be unseen at the inference stage.

To our best knowledge, despite the impact of subject information on listening tests has been discussed [10], there is no research focused on adding subjects' personal information to the prediction model for audio quality preference. In this paper, we aim to predict the personalized preference of two audio segments played by different mobile phones, i.e. preference of two audio segments with the same content in different qualities. Model performance of using several network structures and types of personal information are investigated. The rest of this paper is organized as follows. Section II describes the process of dataset collection, Section III describes our proposed methods, Section IV shows the experimental setting and results, and Section V concludes this paper and addresses future work.

II. Dataset

To obtain audio clips of different qualities, we select some song segments and use some devices to play the segments, and record them. In this study, seven song segments selected from English, Mandarin, Japanese, and Korean pop songs are used for playback by five mobile phones with different brands. Each song segment is about 10 to 15 seconds long and is played by each mobile phone with two different volumes. The first volume is each individual phone's max volume, which is about 78 to 84 dB for different phones. The second volume is called normal volume, which is about 70 to 75 dB for different phones. A 3DIO Free Space XLR binaural microphone and an ART USB Dual Pre Project Series computer interface are used for recording. Configurations for recording, including the distance between mobile phone and microphone and volume gain, are kept the same for all song segments and all mobile phones.

The recorded files are then used to make questionnaires. The five recorded audio files of each volume of each song segment form ten pairs, where each of the two audio files in one pair corresponds to different mobile phones, and the actual order of the two audio files in the questionnaire is randomly assigned. Therefore, each of the two volumes has 70 pairs. These 70 pairs are divided into five questionnaires, where each questionnaire contains 14 pairs corresponding to the seven different songs.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Since the preference of two audio files with similar qualities may be difficult to judge but the preference of two audio files with dissimilar qualities may not, we try to balance the total difficulties of questionnaires by dividing the 70 pairs carefully. The five files are first sorted based on the prejudged order of qualities of their corresponding mobile phones. After that, the 70 pairs can be viewed as a composition of 28, 21, 14, and 7 pairs respectively with distances of 1, 2, 3, and 4, where the 28 pairs are assumed to be the most difficult ones, and the 7 pairs are assumed to be the easiest ones. For each difficulty, the corresponding pairs are assigned into questionnaires as balanced as possible. Finally, each questionnaire contains at least 1 pair belonging to the easiest group, and at most 6 pairs belonging to the most difficult group.

In each audio pair of each questionnaire, subjects will choose which one is better according to their own preference. The preference score is originally an integer in the range of [1, 5], where 1 and 2 indicates that the subject prefers the first audio, 3 indicates that no preference for any one of the two audio files, and 4 and 5 indicates that the subject prefers the second audio. For convenience, we will translate the scores to the range of [-2, 2] for further description and analysis, where -2 and -1 indicates that the subject prefers the first audio, 0 indicates that no preference for any one of the two audio files, and 1 and 2 indicates that the subject prefers the second audio.

Finally, 31 subjects joined the test, including 27 males and 4 females. Their ages range from 21 to 46 years, where 21 of them are between the ages of 21 and 25. The total number of questions answered by subjects is 2,856. Beside, subjects are asked to provide the brand and model of headphones or earphones they used for this test, and the specifications of headphones or earphones, including impedance, lower and upper bound of frequency response, and sensitivity will be collected from the internet. After removing the data of subjects where more than half of the specifications of headphones or earphones they used cannot be found, and the questions of which preference score were answered as 0 (i.e. no preference for any one of the two audio files), the number of remaining subjects is 23, and the number of preference of audio pairs being answered is 2,000. The number of answers of ± 2 and ± 1 are respectively 936 and 1,064. The whole dataset is public available[1].

III. Methods

Since the primary objective of this study is to predict the preference between two audio segments, using a network with two input audio segments is not feasible. This is because the output preference may not remain consistent when the order of inputs is changed. Therefore, we employ the siamese network structure to ensure that the output preference remains the same, regardless of the order of input. Fig. 1 (a) shows the overall structure of the siamese network, where the inputs are passed through two networks sharing the same weights, and the outputs of the two networks are concatenated together,

[1]https://zenodo.org/record/8293869

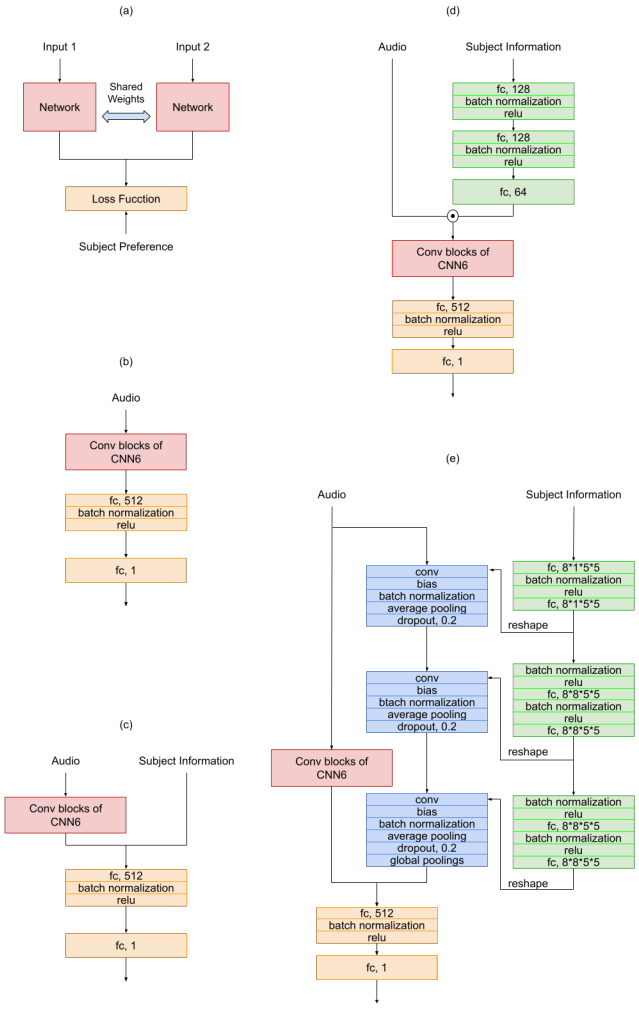

Fig. 1. Model structure. (a) Siamese network. (b) The network uses audio input only (**AO**). (c) The network uses both audio input and subject information, fused later than the CNN6 (**A+S-L**). (d) Audio input and subject information fused earlier than the CNN6 (**A+S-E**). (e) Subject information is used as the kernels of convolution to process audio input in parallel with CNN6 (**A+S-P**).

passed through a softmax function, and used for further loss calculation. For the two sides of the siamese network, the side with the larger output means that the corresponding input audio is preferred by a subject. Note that the network is trained to predict the preference of qualities of two audio segments for one subject, thus the audio segment input to the two sides are in different qualities, but the subject information input to the two sides are the same.

Fig. 1 (b) shows the baseline network which uses only audio features on each side. The pretrained model "CNN6" in PANNs [11], which accepts a log-mel spectrogram of 64 mel bins as input, is used as the basic structure. The original fully-connected layers of CNN6 were replaced with a multi-layer perceptron (MLP) block containing a linear layer with 512 output nodes (denoted by "fc, 512"), a batch normalization layer, an activation function of ReLU, and a linear layer with one output node (denoted by "fc, 1"). We name this structure

AO in this paper.

Fig. 1 (c) shows the first network using both audio input and subject information on each side. The subject information contains one dimension of age, one dimension of gender, and four dimensions of specifications of headphones or earphones, i.e. impedance, lower and upper bound of frequency response, and sensitivity. The value of -1 will be used for missing values of specifications of headphones or earphones. The six-dimensional vector is concatenated with the output of the convolutional block of CNN6, and fed into consequent layers together. Not that this network can be viewed as an LDNet with CNN6 as the encoder and an MLP block as the decoder, except that the input subject information is not only their ID, and this network will be combined with another identical one and viewed as a siamese network. We name this structure **A+S-L** (L for late fusion) in this paper.

To investigate the possibility of different methods for using both audio input and subject information, two more structures of networks are introduced in this paper. Fig. 1 (d) and Fig. 1 (e) respectively show the second and the third network using both audio input and subject information on each side. In the network in Fig. 1 (d), the subject information is passed through an MLP block, multiplied with audio input, and then fed into remaining parts. In this network, the subject information acts like an equalizer for the corresponding audio signal. We name this structure **A+S-E**, where E is for early fusion. In the network in Fig. 1 (e), the subject information is also passed through some MLP blocks (light green blocks in the figure), but the output of these MLP blocks are reshaped and used as the convolution kernel for input audio, and the convolutional blocks (light blue blicks in the figure) are designed to be similar to that of CNN6. This path is in parallel with the original CNN6, and the outputs of this path and CNN6 will be concatenated together for further processing. We name this structure **A+S-P**, where P is for parallel.

The sample rate of audio files are originally 44.1 kHz and are reampled to 32 kHz for the use of CNN6. Frame size and hop size are respectively 32 ms and 10 ms. SpecAugment [12] is applied for the training data online during the training process for data augmentation, where the number of stripes for both time and frequency axes is 2, and the maximal drop widths are 64 for the time axis and 4 for the frequency axis. The negative log-likelihood is used as the loss function, and the ADAM optimizer is used to optimize the network. The initial learning rate is 5×10^{-5} and will be decreased by a factor of 0.95 after each epoch. The batch size is 64. In all of the models, the CNN6 will be fine-tuned.

IV. Experimental Results

A. Experimental Setup

To test the ability of predicting the preference for unseen subjects, we divide all the 23 subjects into 7 folds. All the subjects are sorted by their age, and when the subjects of index k are used for testing, the subjects of index $k+1 \ mod \ 7$ are used for validation, and the remaining subjects are used for training. The number of epochs for training is 50, and the training process will be early-stopped if the validation loss does not achieve a new lower value for consequently 10 epochs. The evaluation metric is accuracy, which is defined by the number of pairs of which the preferences are correctly predicted divided by the total number of test pairs.

Experiments are conducted in a container running on a machine with Intel(R) Xeon(R) Gold 6154 CPU, occupying 4 CPU cores, 90 GB of host memory, and a Tesla V100-SXM2 GPU.

B. Results

We first compare the performances of different model. The test accuracies of the 7 folds and the overall accuracies are shown in Table I, where the results of each model in each fold are the average of 21 runs, and the overall accuracies are calculated by the weighted average of accuracies of all the folds. As shown in the table, **A+S-L** performs better than **AO** on average, where the accuracy grows from 77.56% to 78.04%. For individual folds, higher mean values are achieved in 5 out of the 7 folds, lower standard deviations are achieved in 6 out of the 7 folds, and mean values are higher and standard deviations are lower in 4 out of the 7 folds. On the other hand, performance of **A+S-E** is significantly lower than other models, and **A+S-P** achieves similar mean values to **AO** and **A+S-L**, but the standard deviations are higher, which is possibly due to that the network is more complex but the amount of data is not very large. We do not compare to other LDNet structures which use different encoders and decoders because the amount of data is currently not very large, thus may not be suitable for training more complex network structures.

To observe the importance of both audio input and subject information, the weight matrices of the linear layers of the last MLP block of **A+S-L** and **A+S-P** are respectively multiplied, and the mean absolute values are shown in Fig. 2, where the first 512 values are for audio information processed by CNN6, and the remaining 6 or 8 values are for raw subject information in **A+S-L** or subject information convolved with audio information in **A+S-P**. For **A+S-L**, the first 512 values are around 0.4, and the remaining values are around 0.02. This difference of scales may simply be due to the fact that the values of audio information processed by CNN6 are normalized but the values of raw subject information are not. Therefore the importance of audio and subject information may be similar. For **A+S-P**, both audio and subject information are normalized, but the mean absolute values of multiplied weight matrices are at different levels (0.03 for audio and 0.01 for subject information), so the subject information may not be utilized very well in **A+S-P**, but collecting more data to train a more complex model may improve the accuracy.

Test accuracies of **A+S-L** using different subsets of subject information are shown in Table II. When using only age and gender as the subject information, the model performs slightly worse than that of using other subsets of subject information in most of the folds. On the other hand, when

using all specifications of headphones or earphones as the subject information, the accuracies are slightly higher than that of using all the available subject information, but the standard deviations are also slightly higher. Above results suggest that the model performs more stable when all the available subject information is used. However, using only specifications of headphones or earphones may also be a good choice when age and gender information of subjects is not available.

V. CONCLUSIONS AND FUTURE WORK

This paper proposes to make personalized prediction of the preference of two audio segments with the same content but are in different qualities using both audio input and subject information. Siamese network is used to compare two sets of input, and the side with larger output indicates that the corresponding input audio is preferred. For each side of the siamese network, the performances of several different structures are investigated, and concatenating subject information with audio embedding in between audio encoder and fully connected layers outperforms a baseline model using only audio input the most, where the overall accuracy grows from 77.56% to 78.04%. The effectiveness of different types of subject information is also investigated, and using all the available subject information, including age, gender, and the specifications of headphones or earphones, is found to be the most stable.

Since currently the ages of most subjects concentrate in a small range and most of the subjects are male, recruiting more subjects with different ages and genders in the future may help with a better discussion of the effectiveness of age and gender to predict the personalized preference of audio quality. Besides, since the environment and other information for listening devices including life and power of headphones or earphones may also affect the audio preference, collecting such information may also help predict the audio preference better.

VI. ACKNOWLEDGEMENTS

This work was supported by the ASUSTek Computer Inc. We also thank the National Center for High-performance Computing (NCHC) for providing computational and storage resources.

***Abstract*—Voice, as input, has progressively become popular on mobiles and seems to transcend almost entirely text input. Through voice, the voice search (VS) system can provide a more natural way to meet user's information needs. However, errors from the automatic speech recognition (ASR) system can be catastrophic to the VS system. Building on the recent advanced lightweight autoregressive retrieval model, which has the potential to be deployed on mobiles, leading to a more secure and personal VS assistant. This paper presents a novel study of VS leveraging autoregressive retrieval and tackles the crucial problems facing VS, viz. the performance drop caused by ASR noise, via data augmentations and contrastive learning, showing how explicit and implicit modeling the noise patterns can alleviate the problems. A series of experiments conducted on the Open-Domain Question Answering (ODSQA) confirm our approach's effectiveness and robustness in relation to some strong baseline systems.**

***Index Terms*—Voice search, Information retrieval, Autoregressive information retrieval, Contrastive learning**

I. Introduction

Compared to desktop and laptop computers, flourishing with recent advances in speech technology, voice-based input is gradually replacing text input as the primary method of interaction between humans and machines on small-screen mobile devices [1]. Through voice inputs, how to provide users with an effective mechanism to access the content they want in an overwhelming amount of information available on the Internet, viz. voice search (VS), has gained a place with other spoken language technologies at the center of the stage. VS is related to, but distinct from spoken document retrieval (SDR) [2], [3]. Compared to SDR, in which text queries are given to the system and need to search for relevant spoken documents meanwhile facing essential issues, the queries are usually too short to conveying the information needs. VS searches for relevant text documents using a more natural modality, viz. voice, that lead to longer queries, thus better-expressing information needs [4].

Over the years, many efforts have been devoted to investigating deep neural network-based retrieval methods, showing good promise in many IR and SDR tasks. These models can be applied to various VS scenarios. Recently, dense retrieval models have become the primary neural-based document retrieval approach, complementary to sparse retrieval models such as TF-IDF [5] and BM25 [6], that matches keywords efficiently with an inverted index. Dense retrieval models [7], [8] leverage the pre-trained language models to encode information in latent semantic space, thus better capturing the semantic relationships between queries and documents. A typical dense retrieval construct of a dual encoder contains two independent neural networks optimized for embedding the queries and documents. The advantage of the dual encoder design is that the entire corpus can be encoded and indexed offline. At the inference time, the score of a query-document pair can be efficiently computed as the inner product of the corresponding query and document embeddings.

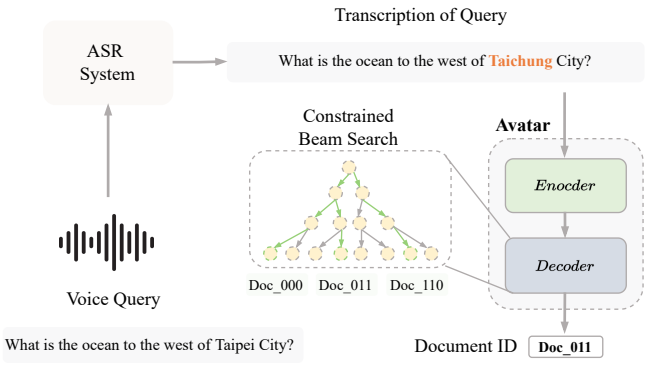

Fig. 1. Flow diagram of our proposed Avatar VS system. Given a voice query, Avatar first uses an ASR system to obtain a text query (errors generated from the ASR system were denoted in orange). Then, an autoregressive retriever directly generates the ranked list of relevant document ID (docid) through constrained beam search.

Recently, another novel autoregressive retrieval approach orthogonal to the dual encoder models dubbed Differentiable Search Index (DSI)[9] has been proposed. DSI first encodes all the information about the corpus into a single transformer model's parameters space, on top of which DSI can generate the relevant document identities (docids) in an autoregressive manner in response to a user query. DSI has many advantages over the dual encoder models: 1) It avoids using only dot products, which could miss the fine-grained interaction between the query and the document meta information. 2) It lowers memory requirements; storing dense vectors for the whole corpus requires a large memory footprint. Although

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

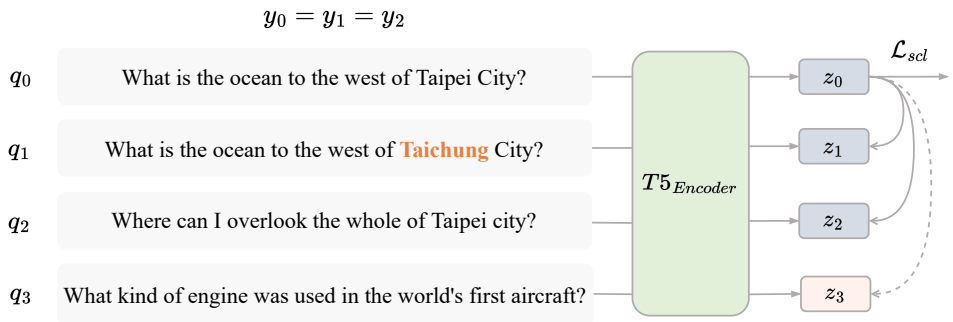

Fig. 2. Pre-training: supervised contrastive learning (SCL). SCL takes data of the same class as positive samples and consists of three query types: queries from the original dataset, pseudo queries generated from the query generation model, and augmented queries.

with the benefits mentioned above, DSI suffers serious data distribution problems during the model training and inference phase. [10]. Specifically, DSI learns to build connections between long document texts and their docids, but at inference time, relatively short queries are input into the model to retrieve their relevant docids. Differentiable search index with query generation (DSI-QG) [10] migrates this problem using another query generation model to generate relevant pseudo queries from documents. It uses these short pseudo queries instead of long text documents to build the connection with their docids in the training phase. After incorporating these pseudo queries [11], the autoregressive retrieval model has become effective while requiring less memory footprint and has potential to be deployed on the mobile or edge device, making it a more secure and personal retrieval system.

Nevertheless, as far as we are concerned, the autoregressive retrieval model has not been sufficiently and systematically studied in neither ad-hoc information retrieval (IR) nor VS, and its retrieval effectiveness is mostly unknown. Based on this background, we present an empirical VS evaluation that sheds light on the efficacy of the autoregressive retrieval model in this paper. Further, we address one of the critical problems with VS, viz. noises in the query caused by the ASR system has an enormous impact on the retrieval model [12], [13], by means of explicitly modeling the ASR noise pattern using data augmentation and implicitly teaching the model to distinguish the features invariant to noise using contrastive learning. A series of experiments conducted on the Open-Domain Spoken Question Answering dataset (ODSQA) [14] confirm our approach's effectiveness and robustness in relation to some strong baseline systems.

II. Methodology

In this paper, we propose Avatar, a robust voice search engine leveraging **a**utoregressive retrie**va**l and con**t**rastive le**ar**ning. Figure 1 shows the main workflow. Given a voice query, Avatar first uses an ASR system to transcribe voice queries into a text query. Then, an autoregressive retriever built from standard transformer architecture directly generates the relevant docids through constrained beam search. In this section, we first introduce autoregressive retrieval and then demonstrate our approach to robust the model.

A. Autoregressive Retrieval

Unlike classic retrieval techniques, autoregressive retrieval methods use a sequence-to-sequence (seq2seq) language model for encoding all the corpus information into the model's parameter space. After receiving the user query, beam search is used to generate the rank list of docids. Specifically, the autoregressive retriever ranks each document $d \in D$ in the corpus by computing a score with an autoregressive formulation:

$$score(d|q) = p_\theta(y|q) = \prod_{m=1}^{M} p_\theta(y|y_{1<m}, q), \tag{1}$$

where q is the query entered by the user, y is the set of M tokens in docid of d, and θ represents the parameters of the model. Original DSI models suffer from data distribution problems during the model training and inference phase. To migrate this problem, we follow the DSI-QG to use the pseudo queries generated from a seq2seq query generation model and incorporate them into the model training phase. In other words, we generate pseudo queries Q_{qg} from their relevant documents using a query generation model. Following that we combine them with the original queries Q_{sup} from the training data to form the new training sets $q \in Q_{seq} = \{Q_{sup} \cup Q_{qg}\}$. After that, we train the model by the general seq2seq training objective and teach forcing:

$$\mathcal{L}_{seq}(\theta) = -\sum_{q \in Q_{seq}} \log p_\theta(y|q). \tag{2}$$

A well-built docid must be able to identify the different documents while reflecting their semantic information. Since exploring different docids is not the focus of this study, we adopt the semantic docid proposed in DSI and leave the extension of docids for future work. At first, semantic docid

uses a BERT language model [15] to encode all the documents in the corpus to obtain the semantic vectors. Second, the hierarchical clustering algorithm is employed to cluster the semantically similar documents in the same group in a hierarchical fashion. Finally, we can assign each document the identifier by group number by traversing the hierarchical tree. The docids generated by the beam search do not necessarily exist in the corpus. Inspired by [16], we use the constrained beam search to guide the decoder to search in a limited tokens space for each step to generate the valid docids. Concretely, we define constraints based on a prefix tree built on all docid strings.

B. Explicit: Data Augmentation

Data augmentation (DA) is a simple and effective method often used to strengthen models by explicitly exposing them to data containing ASR noise and clean data so that model learning remains invariant to noise. Specifically, we generate three random augmentations for each query in Q_{seq}: $Q_{da} = Aug(Q_{seq})$, where $Aug(\cdot)$ is a data augmentation module similar to [17], we generate random substitution, deletion, or insertion errors. For substitution, we use similar phonological words to substitute them. Finally, we train the model using the training sets consisting of $Q = \{Q_{seq} \cup Q_{da}\}$.

C. Implicit: Contrastive Learning

Contrastive learning (CL) can help the model distinguish the invariant features in the ASR noise and clean text query. Firstly, we pre-train the model's encoder to bring the original queries closer to the augmented queries and push the others away. By closely looking into the autoregressive retrieval model, we find that it's fundamentally similar to the sequence classification task. Thus bringing the same class close together in the latent space can benefit the classification task later.

Supervised Contrastive Learning (SCL)[18] takes data of the same class as positive samples and pulls their embeddings closer together. In the end, representations from the same class form a clustering effect and discriminate different classes by the margins created between them. It is more suitable to use SCL for the autoregressive retrieval model to enhance its robustness against ASR errors. Given a min-Batch of N queries, random sample from the Q training sets, $B = \{(q_i, y_i)\}_{i=1..N}$. We first obtain the representation of each query through the model's encoder $Enc(\cdot)$ and use the $Proj(\cdot)$ projection network, $z = Proj(Enc(q))$ to obtain the sequence-level representation. Let $i \in I = \{1, ..., N\}$ be the index of B. The following equation can describe our SCL objective:

$$\mathcal{L}_{scl} = -\sum_{i \in I} \frac{1}{|S(i)|} \sum_{s \in S(i)} \log \frac{\exp(z_i \cdot z_s)}{\sum_{a \in A(i)} \exp(z_i \cdot z_a)} \quad (3)$$

Here $\cdot$ denotes inner product operations, $A(i) = I \setminus \{i\}$ is the set of index I minus i, $S(i) = \{s \in A(i) : y_s = y_i\}$ is the index of all positive samples of index i, and $|S(i)|$ is its cardinality. The process is illustrated in Figure 2.

TABLE I
DATA STATISTICS OF ODSQA-TEST. WE EMPLOY THREE DIFFERENT ASR SYSTEMS TO UNDERSTAND BETTER THE INFLUENCES CAUSED BY DIFFERENT WER-LEVEL AND ENTITY ERROR RATES (EER).

		ODSQA(Test)	
ASR Model	**Train Sets**	**WER**	**EER**
iFLYTEK	-	10.61%	19.75%
Conformer Mask-CTC	In-house	15.06%	42.68%
Conformer	Aishell	23.89%	50.87%

D. Combine

Combining the above Explicit and Implicit approaches makes our proposed Avatar model more robust when encountering ASR noises. Overall, we first use SCL Eq. (3) to pre-train the model's encoder and then use DA with general seq2seq objective Eq. (2) to fine-tune the model further.

III. EXPERIMENTS

A. Experimental Setting

Dataset and Evaluation. We used Open-Domain Spoken Question Answering (ODSQA) for our experiments. ODSQA consists of 30,461 query-document pairs, whose the queries are natural language, and the 2,051 documents are from Delta Reading Comprehension Dataset (DRCD) [19]. Since ODSQA only releases 1,465 query audios equipped with official ASR transcriptions from the ODSQA-test, we adopt these as our testing set and the remaining 28,996 query-document pairs as our training set. To observe the influences on the model caused by different WER-level and Entity Error Rates (EER), in addition to official ODSQA ASR transcriptions, we apply another two ASR systems to obtain the testing set's transcriptions. Specifically, we used a Conformer Mask-CTC ASR system trained on In-house Data and a Conformer ASR system on Aishell [20]. Detail summarized in Table I.

Like the original DSI, we utilize Hits@1 and Hits@10 to evaluate the effectiveness of the baselines and the model. This metric reports the proportion of the correct docid ranked in the top 1 and top 10 predictions.

Baselines. We compare Avatar with the following baselines: 1) Okapi BM25: A classic sparse retrieval method bases on the inverted index. 2) DPR: A dual encoder dense retriever that trained with contrastive loss and hard negatives. 3) DSI: An autoregressive retrieval method that uses document texts as input for indexing. 4) DSI-QG: An improved version of DSI that mitigates the data distribution mismatch problems by using generated queries as inputs for indexing.

Implementation details In this study, we use two multilingual T5(mT5)[21] base models provided by huggingface for our system, one as the Avatar model and the other as the Query Generation model. We apply the same training method as that of DSI-QG for the query generation model and generate three relevant pseudo queries for each document. For the Avatar model pre-training, we employ the same

$MeanPooling$ as that of [22] to obtain the sequence-level represents. We utilize the same mT5 model as a fair comparison for all the learning-based models in the baseline. Since the document length in the corpus is too long for the model to accommodate, we only keep the document title and the first 100 tokens as the model's inputs.

B. Main Results

The evaluation performance is presented in Table 3. Based on term matching, we find that the BM25 model has the lowest performance among all models, showing the importance of assessing the semantic information. By looking at DSI-QG, incorporating the pseudo queries can effectively improve the model's retrieval ability compared to the autoregressive DSI model. Moreover, the noise caused by the ASR system can cause catastrophic impacts on all the baselines model, including the strong DPR model. The magnitude of the drop also rises with the increase of WER. Through data augmentation and supervised contrastive learning, our proposed Avatar can alleviate the influences from the imperfection of the ASR transcriptions and not only keep the performance in a clean environment but also simultaneously increase the retrieval ability in contrast to other strong baseline systems.

C. Ablation Study

Study of different WER. We now focus on evaluating the effectiveness of different ASR noise-robust methods in the model and show the performance in Table III. Not surprisingly, explicit modeling of the noise pattern, viz. data augmentation, has the biggest effect on the model's performance. Through implicitly teaching the model to distinguish the invariant features between the ASR noise and clean query text, viz. pre-trained with SCL objective, we can further enhance the model's robustness, after combine these two, the model's performance increases vastly.

Study of different EER. The entities mentioned in the query significantly impact the success of retrieving the relevant documents. To further test our proposed Avatar's robustness, we split the testing sets into two subsets, one contains the ASR noise in the entity mentioned in the queries, and the other includes the noise in the non-entity position, results shown in Table 4. First, the model's retrieval effect is dramatically reduced when ASR noise occurs in Entity queries, which illustrates the importance of the entities mentioned in the query for retrieval. We find that adding data augmentation and contrastive learning improves the effectiveness of our model.

IV. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented a novel robustness method to improve the performance of the autoregressive retrieval model when exposed to noisy ASR transcriptions, whose effectiveness has also been validated and analyzed through a series of empirical experiments. The proposed model Avatar sheds light on the potential of an on-device VS engine, which can bring more convenience, security, and personal experience. In future work, we intend to first tackle the more intensive tasks which are entities error caused by ASR system and second extend the model to a large scale that requires designing the autoregressive retrieval with more capacity.

***Abstract*—We propose an end-to-end regression-based semi-supervised approach to the problem of sound event detection (SED) in this paper. As a segment-level method, the proposed approach to SED treats the prediction of the temporal location of acoustic events as a regression problem. It alleviates issues with classification-based approaches based on frame-level classification followed by smoothing operation. Treating SED as a regression problem, we design machine-learning systems to learn the relation between onset, duration, and acoustic features. To leverage unlabeled data in model training, we propose a simple and effective training process with a mean-teacher framework to improve the utilization of training data. We implemented two regression-based SED systems with CRNN and VGGSK models. On the validation set of Domestic Environment Sound Event Detection Dataset, the regression-based systems achieve respectively the event-based F1 scores of 0.480 and 0.523, and the intersection-based F1 scores of 0.673 and 0.728. Both systems outperform the classification-based systems using the same backbone network with event-based F1 scores of 0.429 and 0.463 and intersection-based F1 scores of 0.643 and 0.704.**

I. Introduction

Sound event detection (SED) aims to identify acoustic event classes and locate the corresponding time boundaries within audio clips. SED can be used for acoustics-based applications, e.g. smart homes/speakers, where systems detect acoustic events and take appropriate actions.

Detection and Classification of Acoustic Scenes and Events task 4 (DCASE Task 4), which focuses on semi-supervised learning in SED, has been one of the major contests in recent years. Most participants in this task have adopted classification-based approaches [1]. Such approaches are based on frame-by-frame classification, in which the core machining-learning problem is to predict the event-wise probability in each frame. One issue with such approaches is that oscillatory predictions occur when the probability is near the threshold. Smoothing operations such as median filtering are often necessary to stabilize system outputs.

To locate sound events directly, we propose a regression-based approach for sound event detection. Inspired by the You-Only-Look-Once (YOLO) object detection algorithm [2], sound events are detected via bounding boxes. The proposed approach utilizes an end-to-end model which predicts frame-by-frame bounding boxes in the frame. Each bounding box prediction conveys temporal and prominent information for sound events. As onset is more distinct than center in acoustic events, bounding boxes are designed to convey the onset time and duration time. Since regression based on anchor boxes can stabilize the localization of object boundaries [3]–[6], the duration is determined with reference to anchor box priors. Furthermore, since DCASE Task 4 involves semi-supervised learning for SED, we also implement a training framework using the mean teacher framework [7]. During training, we employ a teacher-student model architecture. The teacher model is in charge of providing pseudo-labels, which are used in supervising the student model. By minimizing the difference between the outputs of the teacher and student models, we effectively leverage the unlabeled data.

SED based on a regression approach has attracted attention in recent years. You Only Hear Once (YOHO) [8], [9] is an end-to-end regression-based supervised SED system that performs well on TUT [10] and UrbanSound [11] datasets. SEDT [12] is a DETR-based [13] SED system for DCASE Task 4, which locates the temporal center and duration of sound events through regression. The semi-supervised SEDT (SS-SEDT) utilizes a teacher-student architecture with exponential moving average (EMA) updates. The training process of SS-SEDT consists of two phases: the burn-in phase and the teacher-guided phase. In the burn-in phase, SEDT is trained with labeled data. In the subsequent teacher-guided phase, the trained SEDT is duplicated into two models, and maintains consistency training on unlabeled data. Compared to YOHO, SEDT and SS-SEDT, our proposed approach has the following novelties. First, our approach is based on anchor box regression to respond to sound events with varying duration. Second, the semi-supervised training process is simpler compared to SS-SEDT, as it requires only one-stage training. Lastly, the approach is flexible and compatible with CRNN, which is the mainstream architecture in DCASE Task 4.

The rest of this paper is organized as follows. We introduce our methods in Section II. We describe the datasets and the experiment setting in Section III. The experiment results are shown in Sections IV. The concluding remarks are summarized in Section V.

II. METHODS

We introduce classification-based and regression-based approaches for SED. They are followed by the description of the loss functions, neural-network models, and the post-processing methods that are used in our systems.

A. Classification-based Detection

In the common classification-based approach, the output prediction $\hat{Y}$ is of size $N \times C$, where N is the number of frames and C is the number of event classes, and $\hat{y}_{i,c} \in [0,1]$ represents the probability of class c at frame i. After binarizing the prediction with a threshold and smoothing it with a median filter, the event classes and the corresponding temporal boundaries can be generated by finding consecutive active frames. Additionally, the clip-level prediction $\hat{y}_w$ can be derived by aggregating the frame-level prediction in $\hat{Y}$. A common method is attention pooling [14], where the probability of event class $\hat{y}_w(c)$ is weighted average of $\hat{Y}$

$$\hat{y}_w(c) = \frac{\sum_{i=1}^{N} w_{i,c}\hat{y}_{i,c}}{\sum_{i=1}^{N} w_{i,c}} \tag{1}$$

where $w_{i,c} \in [0,1]$ is a learnable attention weight for $\hat{y}_{i,c}$.

B. Regression-based Detection

In our regression-based approach, we replace the frame-level classification with bounding box prediction. An one-dimensional bounding box is considered a basic event prediction unit for a sound event. Each frame is assigned B hypothetical bounding boxes. Duration prediction is specified via anchor box priors. The prediction $\hat{y}_{i,j}$ for bounding box j with onset in frame i consists of the following components.

- $\hat{y}_{\text{conf}}$: confidence score in $[0,1]$. A bounding box is considered as a candidate event only if $\hat{y}_{\text{conf}}$ exceeds a threshold τ_{conf} (set as 0.5 in this paper).
- $\hat{y}_s, \hat{y}_d$: output variables for the onset and duration of a bounding box. Specifically

$$\hat{y}_s = i + \sigma\left(\hat{t}_s\right), \ \hat{y}_d = p_j e^{\hat{t}_d}. \tag{2}$$

  That is, $\hat{y}_s$ is specified by offset to frame index i and $\hat{y}_d$ is specified by anchor box prior p_j.
- $\hat{y}_{\text{cls}}$: probability for each event class.

Thus, the size of the output prediction is $N \times B \times (3+C)$ for an input of N frames.

During training, each bounding box in prediction $\hat{y}$ is specified as foreground, background, or ignored case. For a ground-truth event with onset in frame i, the bounding box j with maximum Intersection-over-Union (IoU) is assigned as a foreground case. The confidence score and the class probability are set to 1. The onset and duration are set by Eq. (2). The other bounding boxes are assigned as background cases and their confidence scores are set to 0. To alleviate the imbalance between the foreground and the background cases, the background cases with a specified condition will be ignored. When the IoU between the background case and the foreground case reaches a threshold τ_{ignored} (set as 0.7 in this paper), the background case would not calculate the loss. For inference, we only consider the bounding boxes with confidence score larger than τ_{conf}, i.e. the candidates.

As with classification-based SED systems, our regression-based systems can also produce clip-level predictions $\hat{y}_w$. We apply max pooling to aggregate classification scores of all bounding boxes. The equation is as follows:

$$\hat{y}_w(c) = \max_{i \in N, j \in B} \hat{y}_{c,i,j}. \tag{3}$$

C. Loss Functions

The total loss consists of the supervised loss, weak-supervised loss and the consistency loss

$$L_{\text{total}} = L_{\text{supervised}} + L_{\text{weak-supervised}} + L_{\text{consistency}}. \tag{4}$$

The supervised loss $L_{\text{supervised}}$ is based on the YOLO loss

$$L_{\text{supervised}} = L_{\text{coord}} + L_{\text{conf}} + L_{\text{cls}} \tag{5}$$

where $L_{\text{coord}}, L_{\text{conf}}$ and L_{cls} denote the coordinate loss, confidence loss and classification loss, respectively. We modify the coordinate loss term L_{coord} to adapt to the one-dimensional localization scenario. Given a set of strong annotated labels Y and a bounding box prediction $\hat{Y}$, the coordinated loss is

$$L_{\text{coord}} = \sum_{i=1}^{N}\sum_{j=1}^{B} \mathbb{1}_{ij}^{obj}[(\hat{y}_{s,i,j} - y_{s,i,j})^2 + (\hat{y}_{d,i,j} - y_{d,i,j})^2]. \tag{6}$$

The remaining terms L_{conf} and L_{cls} are the same as in YOLO, i.e., L_{conf} is the mean-square error (MSE) of confidence scores

$$L_{\text{conf}} = \sum_{i=1}^{N}\sum_{j=1}^{B} \mathbb{1}_{ij}^{obj}(\hat{y}_{c,i,j} - y_{c,i,j})^2, \tag{7}$$

L_{cls} is the binary cross entropy (BCE) of classification scores

$$L_{\text{cls}} = \sum_{i=1}^{N}\sum_{j=1}^{B} \mathbb{1}_{ij}^{obj} \sum_{c \in C} \text{BCE}(\hat{y}_{c,i,j}, y_{c,i,j}), \tag{8}$$

where $\mathbb{1}_{ij}^{obj}$ is an indicator with value 1 when bounding box j in frame i is a foreground case and 0 otherwise. The weak-supervised loss $L_{\text{weak-supervised}}$ is based on the weak clip-level labels. Specifically,

$$L_{\text{weak-supervised}} = \text{BCE}(\hat{y}_w, y_w) \tag{9}$$

where $\hat{y}_w, y_w$ are model prediction and ground-truth label. To utilize the unlabeled data, the system is implemented with the mean teacher framework. We employ two identical models during training, referred to as the teacher model θ' and the student model θ. The parameter of the teacher model is updated by the student model with an exponential moving average, i.e.

$$\theta_t^{'} = \alpha\theta_{t-1}^{'} + (1-\alpha)\theta_{t-1} \tag{10}$$

where t represents the training step and α is a weight in $[0,1]$. The consistency loss $L_{\text{consistency}}$ depends on student/teacher model prediction via

$$L_{\text{consistency}} = L_{\text{pos}} + L_{\text{neg}} + L_{\text{weak-consistency}}. \tag{11}$$

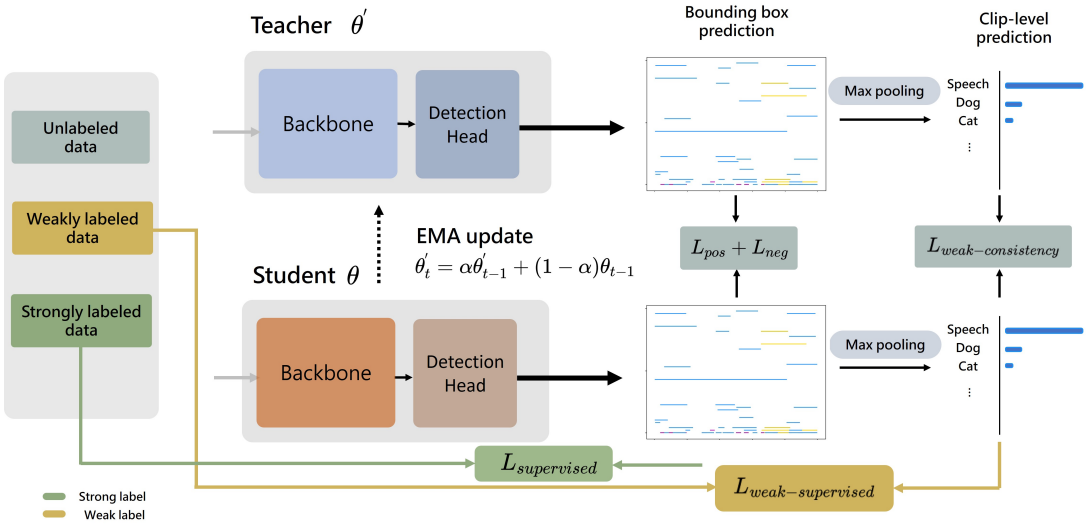

Fig. 1. The training process for the regression-based system: The parameter of the teacher model is updated by the student model with an exponential moving average. During training, teacher model is in charge of providing reliable predictions for unlabeled data, and student model is trained. The consistency loss is the difference between the predictions of the two models.

To mitigate the impact of low-quality pseudo labels, the bounding boxes produced by the teacher model are divided into positive/negative cases based on confidence threshold $\tau_p = 0.8$. For the positive cases, L_{pos} is the MSE between the model predictions for all confidence, coordinate and classification. For the negative cases, L_{neg} is the MSE for only the confidence scores. $L_{\text{weak-consistency}}$ is the BCE of the clip-level predictions. The training process is illustrated in Figure 1.

D. Model Architecture

Our regression-based SED network is composed of a backbone and a detection head. The former extracts features from input data, and the latter produces bounding boxes for each frame. In this paper, we implement two regression-based models with different backbones. One is CRNN [15], the baseline model for DCASE 2022 Task 4, that consists of a convolution neural network followed by a recurrent neural network. The other is VGGSK [16], a popular system on DCASE Task 4, that uses selective kernel units [17] to enhance performance.

E. Post-processing

The set of candidate events (bounding boxes with high confidence scores) often contains redundancy. De-duplication is necessary for regression-based systems. How to effectively select the correct bounding boxes dramatically affects performance. Non-maximum suppression (NMS) algorithm is commonly used in image object detection [18], [19] to eliminate redundant bounding boxes. However, in our system we did not apply NMS directly due to the polyphonic situation.

We propose two approaches to properly select bounding boxes for sound event detection. The first approach is called bounding box mutual exclusion, in which we select the bounding box with the highest score for each class. The second approach is called bounding box union, in which we concatenate bounding boxes with high classification scores for each class. This is shown in Figure 2.

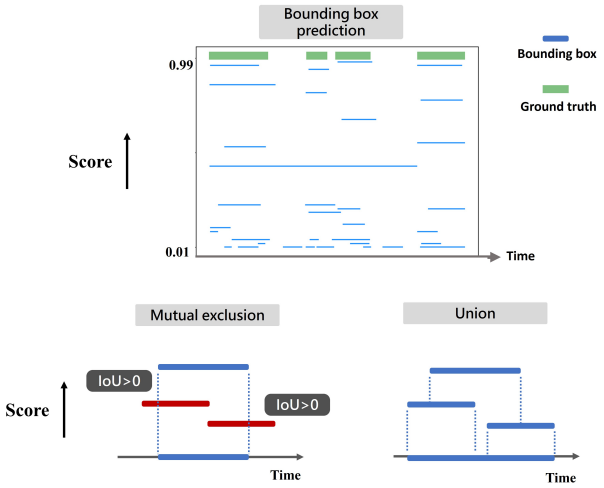

Fig. 2. Bounding box mutual exclusion and bounding box union for post-processing candidate events. The upper of the figure presents an example of a regression-based system inferring an audio clip. Bounding box mutual exclusion discards other overlapping bounding boxes. Bounding box union concatenates overlapping bounding boxes.

F. Data augmentation

We apply mixup data augmentation [20]. Artificially labelled data points created through linear combination, i.e.

$$\begin{aligned} \hat{x} &= \lambda x_i + (1-\lambda)x_j \\ \hat{y} &= \lambda y_i + (1-\lambda)y_j \end{aligned} \tag{12}$$

where x_i, x_j are randomly sampled data, y_i, y_j are the corresponding labels, and $\hat{x}, \hat{y}$ are generated data and label.

III. EXPERIMENT SETUP

A. Datasets and Model Training

We use Domestic Environment Sound Event Detection (DESED) dataset [22], with 10 classes of sound events in home environments, for training and evaluating the proposed SED methods. The training set consists of a strongly annotated set of 10,000 clips, a weakly annotated set of 1,578 clips, and an unlabeled set of 14,412 clips. In addition, an additional strongly labeled dataset with 3,470 clips provided by DCASE 2022 task 4 is used in the training. The duration time of each audio clip is 10 seconds. We evaluated the performance of the systems on the DESED validation set, which consists of 1,168 clips with strongly annotated labels.

All experimental results in this paper are based on the same settings. Each model is trained for 200 epochs with ADAM optimizer. The maximum learning rate is 0.001. The learning rate is initially set to a minimum value and increased gradually to maximum by a warm-up schedule during the first 50 epochs.

B. Pre-processing

Each audio clip in the dataset is resampled to 16kHz and mono due to the inconsistency in audio format. Mel-spectrogram is extracted from audio clip using short-time Fourier transform with window size of 2048, hop length of 256 then applied 128 mel-scale filters. As a result, the input acoustic feature is represented with 626 frames and 128 frequencies.

C. Evaluation Metrics

We use collar-based F1 (CB-F1), intersection-based F1 (IB-F1) [23] and PSDS [24] to evaluate the systems. For the collar-based and intersection-F1 metrics, the systems were evaluated with a threshold fixed at 0.5. For PSDS, two different scenarios were measured, namely PSDS1 with $\rho_{\text{DTC}} = \rho_{\text{GTC}} = 0.7, \rho_{\text{CTTC}} = 0$ and PSDS2 with $\rho_{\text{DTC}} = 0.1, \rho_{\text{GTC}} = 0.1, \rho_{\text{CTTC}} = 0.3$. These two scenarios were evaluated on 50 thresholds linearly distributed between 0.01 and 0.99.

IV. EXPERIMENTAL RESULTS

We compare the performance of implemented SED systems based on different approaches. Furthermore, we analyze the effect of different post-processing methods.

A. Comparison of Different SED Approaches

In Table I, we show the results of SED systems using different detection approaches described in Section II,. We also compare them with FDY-CRNN, SEDT and SS-SEDT. The results of SEDT, SS-SEDT and classification-based CRNN (rows 2-4) are obtained from DCASE 2022 Task 4 technical reports, and the remaining results are re-produced from open-source code under the same configuration and training process.

TABLE II
RESULTS OF SED SYSTEMS USING ANCHOR-FREE AND ANCHOR-BASED DETECTION APPROACHES. THE NUMBER OF BOUNDING BOXES B IS 5.

	Anchor boxes	K-means	IoU	CB-F1	IB-F1	PSDS1	PSDS2
CRNN			-	0.399	0.645	0.252	**0.569**
	✓		0.590	0.424	0.641	0.288	0.553
	✓	✓	**0.835**	**0.480**	**0.673**	**0.384**	0.562

TABLE III
RESULTS OF REGRESSION-BASED SED SYSTEM USING DIFFERENT NUMBERS OF BOUNDING BOXES B.

	B	CB-F1	IB-F1	PSDS1	PSDS2
CRNN	3	0.457	0.670	0.323	**0.570**
	4	0.470	0.670	0.359	0.565
	5	**0.480**	**0.673**	**0.384**	0.562
	6	0.476	0.653	0.362	0.548
	7	0.457	0.630	0.353	0.549

As shown in the table, SED systems using our proposed approach outperform classification-based systems on almost all metrics. One of the reasons is that in the post-processing of the classification-based approach, the window size of the median filter is manually adjusted and is static. This can affect performance because the continuity of sound events is various in practice. On the other hand, our proposal provides a finer resolution and a more automated process to fit sound events. Furthermore, SED systems using our approach only require two weights to convey time boundaries for a sound event: the start time and the anchor box scaling factor. It improves the continuity of the time boundary, resulting in an increase on both CB-F1 and IB-F1. In contrast, the classification-based system requires all frames within the target period to be predicted as active. This may cause breakpoints when encountering non-distinctive parts of acoustic features. We compared the class-wise CB-F1 scores of the regression-based and classification-based CRNN in Figure 3. From the results, regression-based CRNN has improved significantly for long-duration classes such as frying, running water and vacuum cleaner. Here we give an instance in Figure 4 to illustrate the improvement. For PSDS, our approach does not improve significantly. PSDS comprehensively evaluates performance over a wide range of thresholds. However, predictions at a specific threshold are dependent on high-scoring bounding boxes according to our de-duplicate strategy. Therefore, when high-scoring bounding boxes are incorrect, there would be a knock-on effect. This results in a large number of false positives, as shown in Figure 5.

B. Number of Bounding Boxes in Regression-Based Systems

The number of bounding boxes B indicates the maximum number of sound event predictions for input data. Table III shows the results of systems with different numbers of bounding boxes. From the table, the system with $B = 5$ has better performance than other settings. A larger B allows the system to generate more predictions in each frame, which can reduces false negative cases. However, too large B might cause

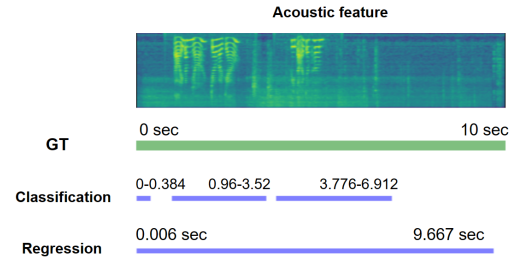

Fig. 4. An instance of CRNN inferences a 10-second audio clip with a 10 second "Frying" class in the DESED validation set: The green lines indicate the time period of events, and the blue lines are the predictions of the systems. The classification-based approach is prone to discontinuity in predicting duration, resulting in two breakpoints in this example. The regression-based approach, on the other hand, is able to overcome this problem.

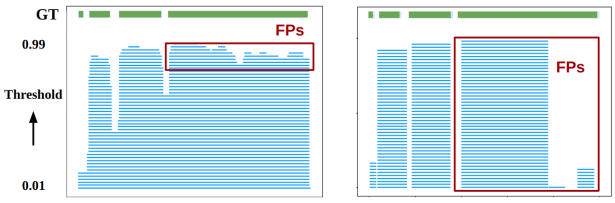

Fig. 5. The difficulties of the regression-based system in computing PSDS: The output of the segmentation-based system and the regression-based system at each threshold (0.01 - 0.99) is shown on the left and right of the figure, respectively. The vertical axis is the predicted result for each threshold. Due to the post-processing approach, when the predictions with high scores of the regression-based system is incorrect, it will significantly affect the results of other thresholds as well.

the system to produce too many false positive predictions. In our experiments, regression-based CRNN with $B = 5$ is the optimal setting for bounding box numbers.

C. Impact of Regression Based On Anchor Boxes

Anchor-free systems estimate the offset of object boundaries directly, and anchor-based systems estimate it based on predefined anchor boxes. For determining the prior lengths of anchor boxes, we first select B different lengths linearly distributed within the maximum audio length (10 sec in our training data) as the initial lengths. Next, we optimize the anchor boxes using K-means to fit the distribution of ground-truth events. Table II shows the results of SED systems using anchor-free and anchor-based detection approaches. From the table, the anchor-based systems are better than the anchor-free systems. This is because ground-truth labels are explicitly assigned to anchor-based systems based on maximum IoU during training. Anchor-free systems are prone to generate too many positive samples due to label assignment instability. After applying K-

TABLE IV
RESULTS OF THREE DIFFERENT POST-PROCESSING APPROACHES: THE TABLE COMPARES THE EFFECT OF USING DIFFERENT POST-PROCESSING APPROACHES FOR THE REGRESSION-BASED CRNN.

De-duplicate	CB-F1	IB-F1	PSDS1	PSDS2
NMS	0.362	0.511	0.325	0.457
Union	0.422	0.649	0.321	**0.564**
ME	**0.480**	**0.673**	**0.384**	0.562

means, the average IoU between the anchor boxes and the training data improved from 0.593 to 0.843, and anchor-based systems further improved performance.

D. Comparison of De-duplicate strategies

As mentioned in section 2.4, our system has three different ways to eliminate redundant bounding boxes in the output. NMS is a widely used strategy for image object detection, but it may not be suitable for polyphonic sound event detection tasks. To solve this problem, we propose two strategies, namely the bounding box mutual exclusion and the bounding box union strategy. According to the results of Table IV, we can see that the bounding box mutual exclusion strategy has superior results. The bounding boxes with higher scores tend to provide more quality predictions for classification and localization. Therefore, consistently selecting bounding boxes with the highest score can result in better coverage of target events. In comparison, the bounding box union strategy suffers from bounding boxes with low scores, which can easily overestimate the event duration. As a result, the prediction is likely to be false positive. Last, NMS discards redundant bounding boxes only based on the IoU without taking into account their class. Therefore, true positive predictions may be erroneously removed when overlapping events reach the NMS threshold and belong to different classes.

V. CONCLUSION

We propose regression-based approaches to sound event detection in this paper. This is motivated by the fact that in contrast to the mainstream classification-based approaches, regression-based approaches detects the entirety of sound events directly. The regression methodology improves the continuity of the duration prediction and alleviates the fragmentation problem, and it increases collar-based and intersection-based F1 scores. Furthermore, since the performance of the regression-based system is highly dependent on the selection of the bounding boxes, we propose two bounding-box selection methods that provide an effective strategy for selecting appropriate bounding boxes. For the proposed regression-based approach, we implemented SED systems using CRNN and VGGSK neural network models. Experiment results show that the proposed approach achieves state-of-the-art performance levels on the open and public DESED dataset.

***Abstract*—It is known that the Proportionate Normalized Least-Mean-Squares (PNLMS) algorithm is an efficient solution applicable to both Adaptive Echo Cancellation (AEC) and Adaptive Feedback Cancellation (AFC) systems. It enhances the performance by individually assigning step sizes to each filter coefficient, resulting in superior initial convergence and tracking rates compared to the NLMS. The Improved PNLMS (IPNLMS) surpasses the PNLMS by incorporating a novel rule that optimally leverages the predicted feedback channel's characteristics to compute tap-specific step sizes.**

In this paper, we introduce an enhancement strategy aimed at improving the performance of the IPNLMS algorithm on the prediction error method (PEM) in the context of Adaptive Feedback Cancellation for hearing aids. This enhancement involves the implementation of variable step-size control. We introduce the Improved Practical Variable Step-Size (IPVSS) built upon the Practical Variable Step-Size (PVSS) approach that incorporates upper and lower fixed step sizes to define a bounded range for step-size adjustments. We evaluate the proposed approach using incoming signals containing both speech and music. We also employ real-world feedback channel measurements. Our simulation outcomes clearly indicate that our method delivers an important enhancement in performance when compared to the PEM-IPNLMS approach, irrespective of whether we utilize the upper or lower step-size bounds. Furthermore, our method outperforms the PEM approach when employing the NLMS and IPVSS while preserving a good signal quality.

I. Introduction

An inherent issue in closed-loop systems like public address (PA) and open-fit hearing aid (HA) is acoustic feedback. It is produced by acoustic signal from the loudspeaker returning to the microphone, accordingly the received signal at microphone comprises of both the incoming signal and the feedback signal. The acoustic feedback issue reduces signal quality and restricts the maximum stable gain that can be achieved. Under certain conditions, it delivers the system into instability and howling may happen. Acoustic feedback cancellation is more difficult in open-fit HA than in PA because of the shorter distance from the microphone to the loudspeaker. Multiple methods for canceling acoustic feedback have been developed over the past sixty years [1]–[5]. Among them, a well-known approach is adaptive feedback cancellation (AFC), in which we employ an adaptive filter to predict the feedback channel. Then we compute the predicted feedback signal and subtract it from the microphone signal. If the prediction is perfect, the error signal $e\,(n)$ retains only the incoming signal. In practice, this prediction often produces a bias because the incoming signal is highly correlated with the loudspeaker signal.

This bias can be reduced by several algorithms proposed in the literature such as a delay insertion [4], [6], phase modulation and frequency shifting [7]–[10], probe noise insertion [11], [12], variable step-size [13]–[18], fast converging adaptive filters [19]–[22], pre-filters [23]–[25], sub-band filters [26]–[28], multiple microphones [29]–[32], etc.

Recently, PNLMS and IPNLMS algorithms have attracted audience attention for both adaptive echo cancellation (AEC) [33]–[35] and adaptive feedback cancellation (AFC) [36]–[38] applications. These algorithms leverage the sparsity of the echo/feedback channels to compute tap-specific step sizes. Due to exploiting an advanced update rule, the convergence as well as tracking rates of the PEM-IPNLMS have been improved compared to PEM-PNLMS while preserving a lower steady-state misalignment for both incoming signals as speech and music [37].

In this work, we extend the PEM-IPNLMS by integrating the improved practical variable step-size control. This provides a new algorithm that maintains the benefits of both previously published approaches. We call this new algorithm PEM-IPNLMS-IPVSS. The simulation outcomes indicate that our proposed system surpasses the system employing only the upper or the lower fixed step-size. Moreover, it also converges faster than the PEM integrating NLMS and IPVSS (called PEM-NLMS-IPVSS) while preserving a high signal quality.

II. Proposed approach

Fig. 1 illustrates a structure of the proposed PEM-IPNLMS-IPVSS approach. In this approach, pre-filters have been used to lower inherent correlation between the incoming signal and the loudspeaker signal, while the IPNLMS improved convergence and tracking abilities. Performance of PEM-IPNLMS is further enhanced by integrating the IPVSS. This variable step-size algorithm allows fast convergence and tracking rates while the framework is (or near) unstable by assigning a high step-size.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

It also produces a small step-size to obtain a low steady-state misalignment while the framework is converged.

In the PEM-IPNLMS-IPVSS approach, the microphone signal is defined as

$$x(n) = u(n) + z(n), \tag{1}$$

where $x(n), u(n)$ and $z(n) = H(q)\,y(n) = \mathbf{h}^T\mathbf{y}(n)$ denote the microphone signal, incoming signal and feedback signal, respectively. $H(q)$ represents the polynomial transfer function of the real feedback path in q, $H(q) = \mathbf{h}^T\mathbf{q}$, where L_h-length impulse response (IR) of the real feedback channel is represented as $\mathbf{h} = [h_0, h_1, \ldots, h_{L_h-1}]^T$ with $\mathbf{q} = \left[1, q^{-1}, \ldots, q^{-L_h+1}\right]^T$ and q^{-1} the discrete-time delay operator. The microphone signal is delayed and then amplified while passing a signal processing path (so-called the forward path) before going back to the loudspeaker. This generates a closed-loop system. We compute the signal received at loudspeaker as $y(n) = G(q)\,e(n)$. The loudspeaker and microphone signals are pre-whitened by using a pre-filter, i.e.,

$$y_p(n) = \hat{A}(q)\,y(n), \tag{2}$$

$$x_p(n) = \hat{A}(q)\,x(n), \tag{3}$$

where $y_p(n)$ and $x_p(n)$ denote signals at loudspeaker and microphone after pre-whitening, respectively; and $\hat{A}(q)$ denotes an estimate of $A(q)$. We assume that the incoming signal is modeled by passing white Gaussian noise, $w(n)$, through an all-pole filter, $A^{-1}(q)$, i.e.,

$$u(n) = A^{-1}(q)\,w(n). \tag{4}$$

Note that this filter must be stable and inverse. Thus, the pre-whitened error signal can be computed as follows

$$e_p(n) = x_p(n) - \hat{\mathbf{h}}^T\mathbf{y}_p(n), \tag{5}$$

with $\mathbf{y}_p(n) = \left[y_p(n), y_p(n-1), \ldots, y_p\left(n - L_{\hat{h}} + 1\right)\right]^T$ a $L_{\hat{h}}$-dimensional signal. To predict the IR of the real feedback channel we minimize the mean square prediction error, $E\left\{e_p^2(n)\right\}$, i.e.,

$$\min_{\hat{\mathbf{h}}} E\left\{e_p^2(n)\right\} = \min_{\hat{\mathbf{h}}} E\left\{\left|x_p(n) - \hat{\mathbf{h}}^T\mathbf{y}_p(n)\right|^2\right\}. \tag{6}$$

The optimal solution for (6) can be recursively approximated using IPNLMS algorithm as

$$\hat{\mathbf{h}}(n) = \hat{\mathbf{h}}(n-1) + \frac{\mu_{IPVSS}(n)\,\mathbf{B}(n-1)\,\mathbf{y}_p(n)\,e_p(n)}{\mathbf{y}_p^T(n)\mathbf{B}(n-1)\,\mathbf{y}_p(n) + \alpha_{IPNLMS}}, \tag{7}$$

where $\mathbf{B}(n-1) = diag\left\{b_0(n-1), \ldots, b_{L_{\hat{h}}-1}(n-1)\right\}$ is a diagonal matrix and its elements are calculated as

$$b_l(n) = \frac{1-\beta}{2L_{\hat{h}}} + (1+\beta)\frac{\left|\hat{h}_l(n)\right|}{2\left\|\hat{\mathbf{h}}(n)\right\|_{l_1} + \xi}, \tag{8}$$

with $\left\|\hat{\mathbf{h}}(n)\right\|_{l_1} = \sum_{l=0}^{L_{\hat{h}}-1}\left|\hat{h}_l(n)\right|$, ξ is a small positive constant and $-1 \le \beta < 1$. The regularization parameter of the proposed PEM-IPNLMS-IPVSS is defined as $\alpha_{IPNLMS} = \frac{1-\beta}{2L_{\hat{h}}}\alpha_{NLMS}$.

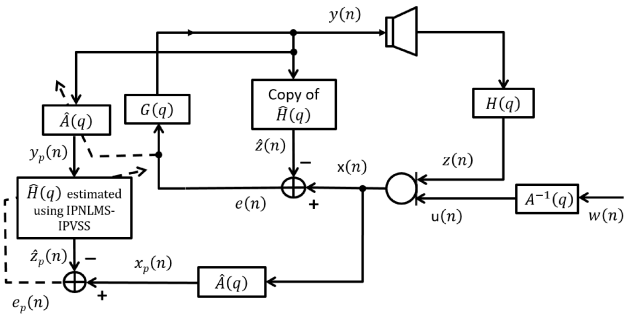

Fig. 1. Proposed PEM-IPNLMS-IPVSS model.

In addition, we implement the improved practical variable step-size algorithm for the PEM-IPNLMS to obtain further performance enhancement in both tracking and convergence. In particular, the improved practical variable step-size called $\mu_{IPVSS}(n)$ in (7) is denoted as

$$\mu_{IPVSS}(n) = \begin{cases} \mu_a & if\ \ \mu_c(n) > \mu_a \\ \mu_b & if\ \ \mu_c(n) < \mu_b \\ \mu_c(n) & otherwise \end{cases}, \tag{9}$$

with μ_a, μ_b the fixed upper and lower step-sizes respectively, and $\mu_a > \mu_b$. We have

$$\mu_c(n) = \mu_a.\left|1 - \frac{\sqrt{\hat{\sigma}_{x_p}^2(n) - \hat{\sigma}_{\hat{z}_p}^2(n)}}{\hat{\sigma}_{e_p}(n) + \epsilon}\right|, \tag{10}$$

with ϵ a small positive constant. In practice, the error signal power $\hat{\sigma}_{e_p}^2(n)$, the microphone signal power $\hat{\sigma}_{x_p}^2(n)$, the estimated feedback signal power $\hat{\sigma}_{\hat{z}_p}^2(n)$ are recursively estimated, i.e.,

$$\hat{\sigma}_{e_p}^2(n) = \lambda\hat{\sigma}_{e_p}^2(n-1) + (1-\lambda)\,e_p^2(n), \tag{11}$$

$$\hat{\sigma}_{x_p}^2(n) = \lambda\hat{\sigma}_{x_p}^2(n-1) + (1-\lambda)\,x_p^2(n), \tag{12}$$

$$\hat{\sigma}_{\hat{z}_p}^2(n) = \lambda\hat{\sigma}_{\hat{z}_p}^2(n-1) + (1-\lambda)\,\hat{z}_p^2(n), \tag{13}$$

where the weighting parameter λ is chosen close to 1.

III. Simulations

A. Simulation Setup

We select the acoustic feedback channels measured using a two-microphone hearing aid placed behind the ear [39] for the simulations. Fig. 2 demonstrates the measured feedback channels with regard to amplitude response and phase, where $H_1(f)$ represents the 1^{st} feedback channel measured in free-field and $H_2(f)$ is the 2^{nd} feedback channel measured with a telephone putting near the ear.

We utilize the recorded incoming signals, where the speech was produced based on concatenating speech segments of male and female speakers from NOIZEUS database [40]; and the music incoming signal was extracted from the John Lennon's song, Imagine. For all simulations, we chose the following

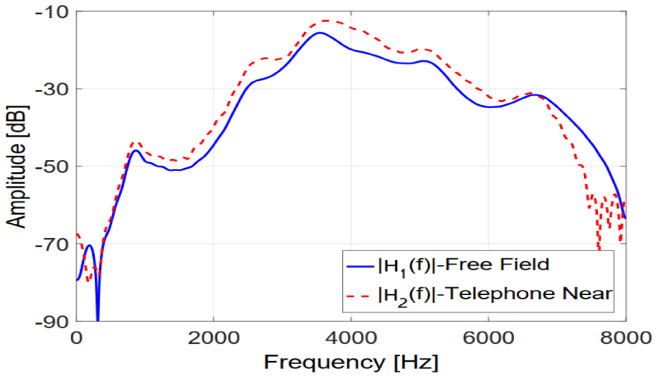
parameters. For instance, lengths of the measured and the predicted feedback channels were $L_h = 100$ and $L_{\hat{h}} = 64$, respectively. Forward path has a gain $|G| = 30$ dB and a delay $d_g = 96$ samples, while feedback canceller path has a delay $d_{fb} = 1$ sample. We chose 16 kHz for sampling frequency. The upper limit of the step-size was $\mu_a = 0.01$ and the lower limit $\mu_b = 0.001$. We set $\lambda = 0.9999$ and $\epsilon = 10^{-6}$. For PEM using NLMS we selected $\alpha_{NLMS} = 10^{-10}$. Coefficients of the pre-filter $\hat{A}(q)$ with order of 20 were estimated every 10 ms using the Levinson-Durbin algorithm.

Two metrics such as added stable gain, ASG, and normalized misalignment, MIS, [5] were chosen to evaluate the considered AFC approaches, i.e.,

$$\text{MIS} = 10\log_{10}\left(\frac{\int_0^{\pi}\left|H(\omega) - e^{-j\omega d_{fb}}\hat{H}(\omega)\right|^2 \mathrm{d}\omega}{\int_0^{\pi}|H(\omega)|^2\,\mathrm{d}\omega}\right), \quad (14)$$

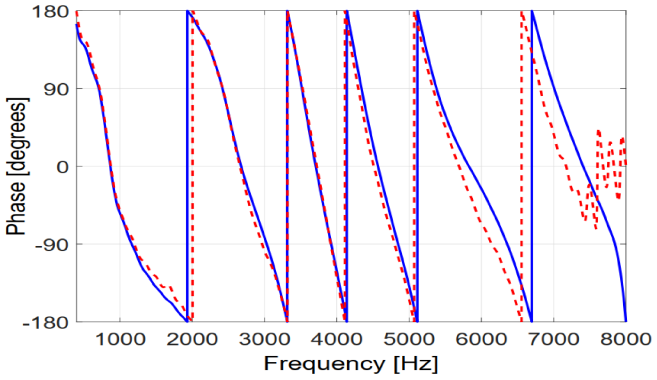
$$\begin{aligned}\text{ASG} &= 10\log_{10}\frac{1}{\max_\omega |H(\omega) - \hat{H}(\omega)|^2} \\ &- 10\log_{10}\frac{1}{\max_\omega |H(\omega)|^2}, \end{aligned} \quad (15)$$

with $H(\omega)$, $\hat{H}(\omega)$ corresponding to frequency responses of the measured and predicted feedback channels, respectively and ω the normalized frequency. The better AFC system will have a lower MIS and a higher ASG. Moreover, PESQ, the perceptual evaluation of speech quality [40], was also used to assess the quality of speech signals. The PESQ is bounded in range [-0.5, 4.5], in which -0.5 means poor whereas 4.5 means excellent quality.



All simulations were run during 80 s, and the feedback channel suddenly changed from $H_1(f)$ to $H_2(f)$ after 40 s.

B. Simulation Results



Scenario 1: recorded speech is the incoming signal.

Fig. 3 shows the comparison in terms of MIS and ASG among the proposed PEM-IPNLMS-IPVSS and some baselines such as PEM-IPNLMS with the upper step-size and the lower step-size, PEM-NLMS-IPVSS with bounded step-sizes μ_a and μ_b. We notice the proposed approach outperforms the PEM-IPNLMS with μ_b. It also obtains higher speed of convergence and tracking than PEM-NLMS-IPVSS, while achieving lower steady-state errors. Although the proposed approach converges slower than the PEM-IPNLMS with μ_a at the beginning, it achieves a similar tracking speed when the feedback channel suddenly changes and outperforms in terms of steady-state errors.

Table I demonstrates the average misalignment $(\overline{\text{MIS}_i})$, the average added stable gain $(\overline{\text{ASG}_i})$, and PESQ_i, where subscript i corresponds to the i*th* feedback channel. We compute the PESQ_i after the system has converged. Specifically, PESQ_1 is computed during the period from 20 s to 40 s; PESQ_2 is computed during the period from 59 s to 80 s. We observe the proposed system achieves the lowest average misalignment and the highest average added stable gain compared to other baselines for both measured feedback paths. Furthermore, the PEM-IPNLMS-IPVSS obtains comparable PESQ compared to the PEM-IPNLMS with μ_b and the PEM-NLMS-IPVSS while outperforms the PEM-IPNLMS with μ_a. Those results match well with the observation from Fig. 3.

(a)

(b)

Fig. 2. Amplitude and Phase responses of measured feedback channels.

Scenario 2: recorded music is the incoming signal.

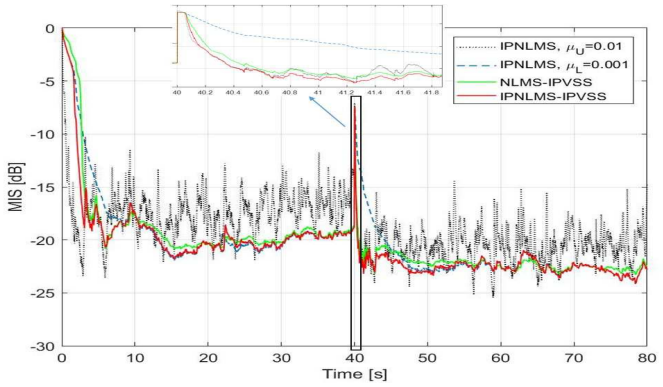


Fig. 4 compares MIS and ASG of mentioned approaches for the case of music as incoming signal. We observe the proposed approach converges quicker than PEM-IPNLMS with μ_b and PEM-NLMS-IPVSS. Although our proposed approach converges slower than PEM-IPNLMS with μ_a, it outperforms PEM-IPNLMS with μ_a in terms of steady-state errors. When we abruptly change the feedback channel from $H_1(f)$ to $H_2(f)$ after 40 s, three approaches including PEM-IPNLMS with μ_a, PEM-NLMS-IPVSS and our proposed PEM-IPNLMS-IVPSS obtain a similar tracking speed, while surpass PEM-IPNLMS with μ_b.

Table II shows that the proposed approach achieves the highest average misalignment for both feedback channels and the highest average ASG for the 1^{st} feedback channel $(\overline{\text{ASG}_1})$. For the 2^{st} feedback channel, it obtains a sightly lower average ASG $(\overline{\text{ASG}_2})$, but still higher than the PEM-IPNLMS using μ_a or μ_b.

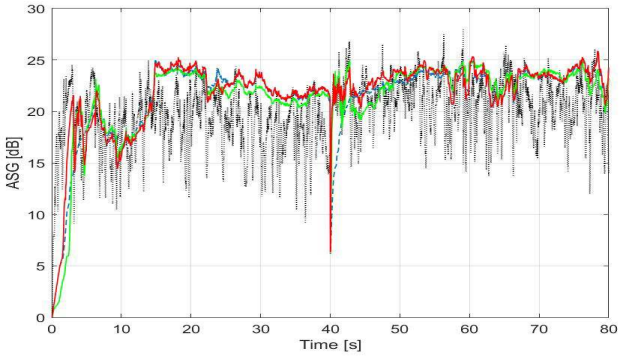

Fig. 5 illustrates the application of variable step-size to the proposed framework for the incoming signals as speech and

Fig. 4. Compare MIS (a) and ASG (b) of the proposed framework with PEM-IPNLMS (μ_a), PEM-IPNLMS (μ_b) and PEM-NLMS-IPNLMS; music as input, an abrupt change of feedback channel from H_1 to H_2.

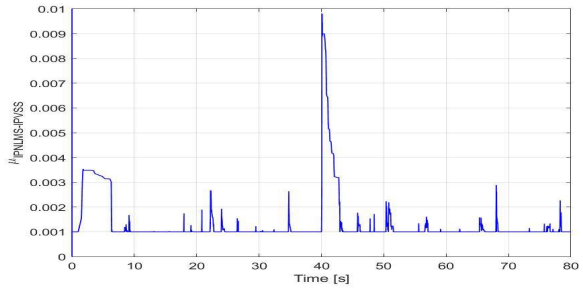

TABLE II
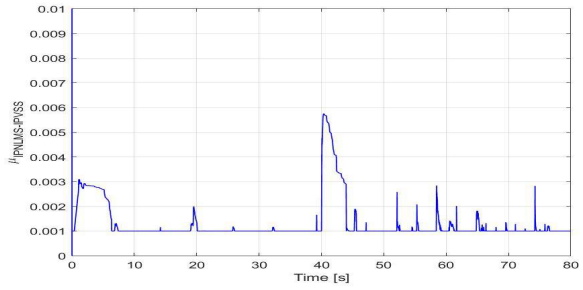
COMPARISON AMONG MENTIONED AFC APPROACHES IN AVERAGE MIS, AVERAGE ASG AND PESQ FOR MUSIC INCOMING SIGNAL. WE HIGHLIGHTED THE BEST RESULTS IN BOLD.

AFC approach	$\overline{\text{MIS}}_1$	$\overline{\text{MIS}}_2$	$\overline{\text{ASG}}_1$	$\overline{\text{ASG}}_2$
IPNLMS, μ_a	-12.56	-16.62	14.51	17.86
IPNLMS, μ_b	-12.73	-17.36	14.93	18.81
NLMS-IPVSS	-12.67	-17.82	14.68	**19.05**
IPNLMS-IPVSS	$\mathbf{-13.05}$	$\mathbf{-17.90}$	**15.39**	18.94



music. As we can see, the proposed approach takes a large step-size (strong peaks) at initialization and at a sudden change of the feedback channel (in these situations, the system is unstable). It also takes a low step-size during the time the system has converged. These outcomes coordinate well with the theory analysis of IPNLMS-IPVSS.

IV. CONCLUSIONS

A novel AFC approach that integrates the improved practical variable step-size on top of PEM-IPNLMS is proposed. This approach allows PEM-IPNLMS to obtain a high step-size while the framework is unstable or near unstable conditions, and a small step-size while the framework has converged. In overall, our proposed approach accomplishes an enhancement for the tracking and convergence abilities, normalized misalignment and added stable gain compared to other mentioned AFC approaches. It also provides a very good signal quality

***Abstract*—There have been some advances in deep learning based stereo-AEC (SAEC) systems in recent years. However, most of the studies focused on solving the non-uniqueness problem and did not explore the impact of spatial cues on SAEC. In this paper, we propose a composite SAEC system that combines conventional adaptive filters and Wiener filters with a NN-based residual echo suppression (RES) module. We adopt generalized cross correlation (GCC) as an additional input to allow the RES module to better analyze the embedded spatial cues. Experimental results show that the addition of GCC stably improves system performance with a little computational overhead. In addition, the proposed system achieves better results with much less computation than compared NN-based SAEC systems in all test conditions.**

I. Introduction

Teleconferencing, online meetings, and work-from-home (WFH) become popular during the COVID pandemic/endemic. High-quality voice communication through internet is in high demand. Acoustic echo cancellation (AEC), which removes unwanted loop-back sounds from the received signals at microphones, is a very critical module in the communication system. In modern systems, AEC is commonly accompanied by background noise suppression and speech de-reverberation. In hands-free communication applications, where multiple microphones and speakers are often used, the widely used single-channel AEC cannot perform well, thus facilitating the development of stereo-AEC (SAEC).

SAEC is for the communication scenario that uses at least two microphones and speakers. The main difference between SAEC and the single-channel AEC is the non-uniqueness problem, which leads to performance degradation of adaptive filters [1]. Due to the high coherence between signals of the stereo loudspeakers, adaptive methods would have difficulties in approximating multiple echo paths, which leads to a reduced convergence rate and even frequently re-converging. Many studies have attempted to mitigate this problem, such as modifying the far-end signal to de-correlate the stereophonic channels without largely impacting human listening experiences [2]. Another approach is to orthogonally transform the reference signal of the adaptive method and predict the echo paths of the transformed signal [3].

Neural networks have been successfully used to boost the performance of echo cancellation systems. An intuitive approach is to place the neural network behind the conventional AEC to replace the residual echo suppression (RES) module by suppressing both noise and residual echo [4][5][6]. Some studies integrate the tasks of AEC and RES, and consider echo cancellation as a task of supervised speech separation [7]. Most of the past studies proposed in several AEC Challenges are limited to single-channel AEC tasks [8][9]. Recently, fully neural network systems were proposed for SAEC to explicitly avoid the non-uniqueness problem [10][11]. Although these systems are capable of handling SAEC tasks, they only perform AEC on different microphone channels separately without using any spatial cues embedded in stereo microphone channels. In [12], a multiple-input-multiple-output (MIMO) convolutional recurrent network (CRN) architecture was proposed to handle information between multiple microphones. However, to preserve spatial information in the convolution process, the stride in convolution layers was set to one, resulting in heavy computational load.

In this paper, we propose a composite SAEC system consisting of adaptive filters, Wiener filters, and a spatial-aware neural RES module, without inducing heavy computational load as in [12]. The adaptive filters are implemented with robust short-time Fourier transform domain adaptive filters [13] to suppress echoes and to solve the double-talk problem, and with the de-correlation method in [2] to reduce the coherence between channels. The Wiener filters are then applied to suppress stationary noise. To make the neural RES module spatial-aware, we explicitly add the generalized cross correlation (GCC)[14] cues to the input of the neural RES module. Simulation results show explicitly adding GCC cues to the RES module is beneficial to performance of the SAEC system.

The rest of the paper is organized as follows. Section 2 describes the signal model of the SAEC problem. Section 3 describes the proposed system architecture. Section 4 presents the experimental settings and results. Section 5 concludes the paper.

II. Signal Model

In this paper, we focus on a two-loudspeaker, two-microphone scenario. The speech signal of the far-end user is picked up by the two microphones in the transmission room (far-end), transmitted through the communication system, and then broadcast by the two loudspeakers in the receiving room (near-end). Since we do not want the sound emitted from the loudspeakers to be captured by the microphones and sent back to the transmission room, we need to use an AEC system to

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

suppress the echo in the microphone signal. As shown in Fig. 1, the two channels of the far-end signal are labeled as x_1, and x_2, which are obtained by convolving a source signal in the transmission room with two room impulse responses (RIRs) for two microphones.

Without loss of generality, we assume the far-end signals contain only voices of the users in the transmission room, i.e., the echo signals in the transmission room are ideally eliminated. In the receiving room, the two loudspeakers play the far-end signals, generating echoes through the RIRs, h_{11}, h_{12}, h_{21}, and h_{22}, of the respective coupling paths between the loudspeakers and the microphones. These echoes, together with the near-end user voice and ambient background noise in the receiving room, constitute the signal received by the microphones y_1 and y_2, which can be expressed in the short-term Fourier transform (STFT) domain as:

$$\begin{aligned} Y_i(t,f) = X_1(t,f)H_{1i}(f) + X_2(t,f)H_{2i}(f) \\ +V(t,f) + R(t,f) + W(t,f), i = 1,2 \end{aligned} \tag{1}$$

where i is the microphone index; Y and X are the STFT of y and x. H is the transfer function of the corresponding echo path. V represents the STFT of the direct and early reflections (within 50 ms) of the near-end speech; R and W are the STFT of late-reverberations and the background noise in the receiving room, respectively. The goal of the proposed SAEC system includes not only echo cancellation and noise suppression, but also speech de-reverberation. Hence, V is used as the training target of the RES module.

III. Proposed System

Fig. 1 shows the architecture of the proposed system. The system consists of three components, the adaptive filters, the Wiener filters, and the spatial-aware RES module with a GCC encoder. First, the signals received by the microphones are transformed to the time-frequency (T-F) domain using STFT and then passed through the adaptive filters and the Wiener filters to respectively suppress linear echoes and the stationary part of the background noise. Afterward, the filtered signals, signals received by microphones, and far-end signals are fed into the RES module.

Although signals of two channels are fed into the RES module altogether, we cannot be sure the network extracts spatial information effectively. Therefore, we explicitly compute the GCC-PHAT from the microphone signals y_1 and y_2, and embed the spatial cues through the GCC encoder. The output of the GCC encoder is then added to the recurrent module of the RES module. In the following subsections, we present the system components separately.

A. Adaptive Filter

We use the robust STFT domain adaptive filter proposed in [13] for directly suppressing linear echo in the T-F domain. For each adaptive filter, the learning rate is set to 5e-2, the number of taps is set to 5, and the internal parameter γ, which adjusts the learning rate during double-talk, is set to 1e-2. The function of the adaptive filter is to estimate RIRs by minimizing the output, which can be expressed as follows:

$$\begin{aligned} E_i^{AEC}(t,f) = Y_i(t,f) - X_1(t,f)\hat{H}_{1i}(f) \\ -X_2(t,f)\hat{H}_{2i}(f), i = 1,2 \end{aligned} \tag{2}$$

where E^{AEC} is the output of the adaptive filter, and $\hat{H}$ is the transfer function of the estimated RIR. Note, to tackle the non-uniqueness problem, we first decorrelate the far-end signals using parameters given in [2] before engaging the adaptive filtering processes.

B. Wiener Filter

To enhance the robustness of the system to unseen noise, we use a Wiener filter to suppress the stationary noise after each adaptive filter. The Wiener filter proposed in [15] with the behavior controlling parameter β set to 0.99 is used in the system. This version of Wiener filter is based on time-frame energy estimation and two-stage noise suppression (TSNR).

$$E_i^{WF}(t,f) = E_i^{AEC}(t,f)\hat{M}_i^{WF}(t,f), i = 1,2 \tag{3}$$

where E^{WF} is the output of the Wiener filter and $\hat{M}^{WF}$ is the Wiener gain.

C. Residual Echo Suppression

The basic architecture of the proposed RES module is CRN, which consists of an encoder, a recurrent module, and a decoder as shown in Fig. 2. We set its hyperparameters by network pruning of the convolution layers [16]. The concatenation of Y_1, Y_2, X_1, X_2, and E_1^{WF}, E_2^{WF} is used as the input to the RES. The encoder consists of 5 causal 2D convolution layers followed by BN [17], and ELU [18]. Each convolution layer contains [16, 26, 38, 54, 54] kernels with kernel size = [3, 1], stride = [2, 1]. The recurrent module consists of two layers of unidirectional GRU with 128 units and fully connected layers with 216 units. The decoder is symmetric to the encoder except that each layer contains a transposed convolution layer.

In a typical CRN, the output of the encoder is skip connected to the input of the parallel decoder to compensate the information loss through the recurrent module. To further reduce computation, we adopt the method in [19] to first apply one-by-one convolution to organize output channels of the encoder and then to change the skip connection to summation. The activation function of the final layer in the decoder is Softplus, which does not restrict the range of output values to $[0, 1]$ to allow compensation for possible over-suppression by the preceding Wiener filter. The outputs of the RES are two magnitude masks, which can be expressed as:

$$\hat{M}_{1,2}^{RES} = G_{RES}(Y_1, Y_2, X_1, X_2, E_1^{WF}, E_2^{WF} \mid \phi) \tag{4}$$

where ϕ indicates the set of hyperparameters. Note that the time and frequency indices (t, f) of variables $\hat{M}_{1,2}^{RES}$, Y_1, Y_2, X_1, X_2, E_1^{WF} and E_2^{WF} are purposely omitted for a short expression. The final predicted magnitude spectrograms

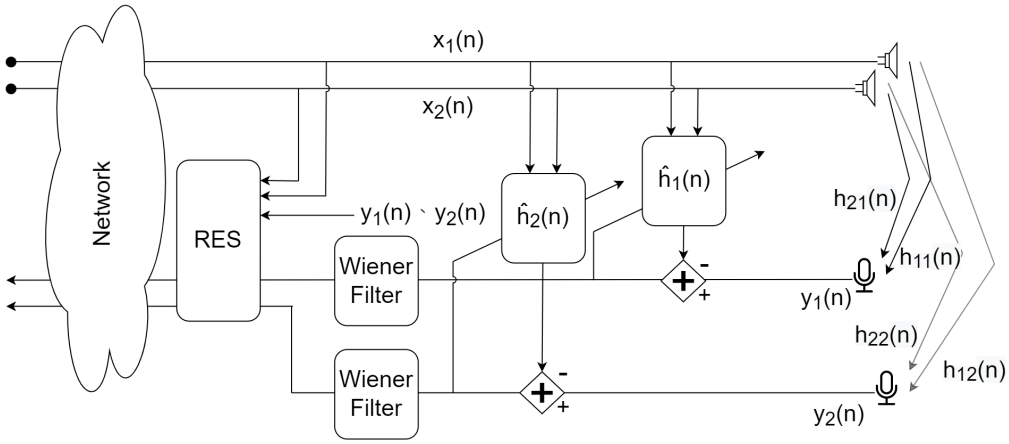

Fig. 1. Architecture of the proposed SAEC system.

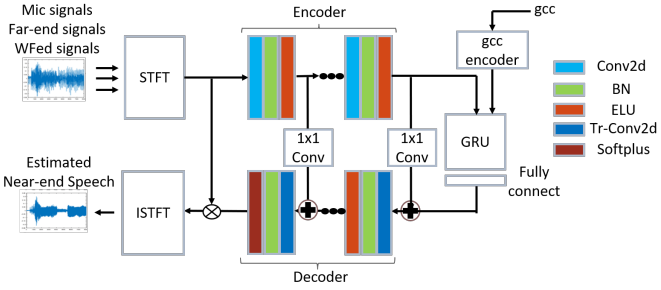

Fig. 2. Architecture of the RES module.

of speech signals are obtained by multiplying the Wiener filter outputs and the RES outputs as follows:

$$\hat{V}_i(t,\ f) = E_i^{WF}(t,\ f)\hat{M}_i^{RES}(t,\ f), i = 1, 2 \tag{5}$$

D. GCC Encoder

To explicitly provide spatial cues to the RES module, we calculate the GCC-PHAT from microphone signals as follows [14][20]:

$$\begin{aligned} GCC_{PHAT}(\psi,\ t,\ f) &= Real\{\frac{Y_1(t,\ f)Y_2^H(t,\ f)}{|Y_1(t,\ f)||Y_2^H(t,\ f)|}e^{-j2\pi\frac{f}{N}f_s\psi}\} \\ &= cos(\angle Y_1(t,\ f) - \angle Y_2(t,\ f) - 2\pi\frac{f}{N}f_s\psi) \end{aligned} \tag{6}$$

where f_s is the sampling rate, N is the number of point of FFT, and ψ are 37 possible time differences of arrival.

As shown in Fig. 2, we use the GCC-encoder, which consists of four layers of one-dimensional depth-separable convolution [21], to embed GCC-PHAT. Numbers of filters of the four layers are [64, 32, 16, 8], and the kernel size and the stride are set to 4 and 1. The encoder uses f and ψ as the channel axis and the feature axis, and performs feature extraction on each time frame. The final output features are reshaped to form the spatial embedding with the size of $(T, 37 * 8)$, where T is the total number of frames, and then concatenated to the input of GRU of the RES module.

IV. EXPERIMENTAL RESULTS

A. Dataset Preparation

For system evaluations, we used 4620 and 1680 sentences from the TRAIN and TEST categories of the TIMIT corpus [22] to build our training, validation, and test sets. TIMIT contains 630 American English speakers from different dialect regions of the United States. In this study, we included all speakers and selected different speakers to build training and test tests. For generating various diffuse noise, 10 and 15 types of noise were selected from NOISEX-92 [23] and Freesound [24] corpora as the noise sources. 13 types of diffuse noise were included in the training set. The validation and test sets contained the remaining 12 unseen types of diffuse noise. For directional noise, sound samples of PNL 100 Nonspeech Sounds [25] were selected for training, and the remaining non-stationary types of noise of NOISEX-92 were used for validation and test.

The simulation scenario is a group teleconferencing using TV in a large room. The settings of the training and test rooms are shown in Table I. The two-channel microphone array is placed in the center of the room's long side, with a distance from the back wall of at least 50 cm. The distance between two microphones is 7 cm. To mimic TV settings,

the two loudspeakers are set to line up with the microphone array, and each of which is placed 50 cm apart from the center of the array on each side. Once the room size and locations of the microphones and loudspeakers are determined, the four RIRs, h_{11}, h_{12}, h_{21}, and h_{22}, of the respective coupling paths between the loudspeakers and the microphones are simulated using the image method [26][27]. The near-end talker is randomly placed at 37 possible angles (between 0 and 180 degrees on the front semicircle with a step of 5 degrees) paired with the distance shown in Table I. To generate diffuse noise, the noise source is placed at 37 angles on the largest semicircle from the microphone array with random phase shifts. For simulating directional noise, one noise source is randomly placed on the wall to imitate leaking noise from a window.

Based on these settings, we generated $10,000$ 10-sec training sentences for a total of about 28 hours. Each of the validation and test sets contained $1,000$ 10-sec sentences. In these sentences, near-end speech appeared randomly after the initial 0.5 sec to 1.5 sec, with a length between 5 sec and 7 sec. Echoes and noise were present throughout the entire 10 sec with a 10% chance of noise-free. To better reflect the real-world situations, echo-free, slight non-linear echo, and severe non-linear echo were considered. We used the slight scaled error function in [28] and severe non-linearity functions in [4] to produce corresponding echo signals. Eventually, in training samples, there was a 20% chance of echo-free, a 20% chance with slight non-linear echo, a 20% chance with severe non-linear echo, and a 40% chance with normal linear echo.

B. Training Settings and Experimental Results

The audio signals were converted into the T-F domain by the short-time Fourier transform using a 512-point Hann window and a 256-point hop size. For training, we used the AdamW optimizer with a learning rate of 1e-3 and a weight decaying rate of 1e-2. The training batch size was 32. All of the network weights were initialized by the method described in [29], the default initialization method of Pytorch [30]. The loss function was mean absolute error (MAE). If the model did not achieve better results in the validation set for 30 consecutive epochs during training, the learning rate was cut in half. At the third time of halving, the training was terminated and the best-performing checkpoint in the validation set was selected for test.

For evaluations, we compare the proposed SAEC system with other recently proposed SAEC systems using our generated datasets. There are five compared systems, Baseline 1, Baseline 2, Proposed-M, Proposed-B and Proposed-GCC. Baseline 1 is the NN based SAEC system proposed in [11]. Baseline 2 is the NN-based MIMO SAEC system proposed in [12]. Proposed-M is our proposed system, but the RES are operated separately on two channels without incorporating GCC information. In other words, it is a bi-lateral system rather than a binaural system. Proposed-B is our proposed model without the GCC-encoder, where the spatial information is implicitly provided by the received signal y_1 and y_2. Proposed-GCC is our proposed model with the GCC-encoder which explicitly provides the spatial cue of GCC-PHAT.

We used objective measures of wide-band PESQ (PESQ-WB) [31] and echo return loss enhancement (ERLE) to assess sound quality of near-end speech and the effectiveness of echo cancellation, respectively. The test results of all compared systems in different conditions are shown in Table II. The PESQ-WB scores of Proposed-GCC outperforms other systems in all conditions. The averaged PESQ-WB scores show the performance of Proposed-B is slightly better than the performance of Proposed-M and is comparable to the performance of Baseline 2. The superior performance of the binaural system Proposed-GCC to the binaural system Proposed-B and the bilateral system Proposed-M confirms that explicitly providing spatial information encoded in GCC-PHAT to the system is beneficial to its performance. The lower performance of Proposed-B clearly demonstrates the RES module cannot effectively decode spatial information from raw data received by two microphones. Moreover, as shown in the 'MACs' column, the computation of Proposed-GCC is much less than that of Baseline 1 and Baseline 2.

Regarding the ERLE measure, Proposed-M performs the best and Proposal-GCC comes fourth. However, ERLE was originally used to assess adaptive filter's capability in reducing linear echo without considering noise suppression. In literature, NN-based methods can easily achieve an ERLE higher than 30 dB due to their noise suppression capability. The correlation between ERLE scores and subjective listening tests is unclear

at such high levels. Even with such a large gap in ERLE between Baseline 1 and Baseline 2, we did not detect any significant difference between them in our informal listening tests.

C. Limitation of the Study

In this study, all RIRs were simulated using the image method. No real-world RIRs were measured and included during training. Hence, the performance of the proposed model will deteriorate in real-world environments. The model needs to be fine-tuned using a small amount of real-world data.

V. Conclusion

In this paper, we propose a composite system to tackle the SAEC problem for the condition involving a single dominant near-end speaker. The system contains conventional de-echo, speech enhancement, and the NN-based RES modules. By explicitly incorporating spatial information from GCC-PHAT into the RES module, the performance of the binaural system is stably improved. Experimental results show that the proposed system can produce higher PESQ-WB scores with much less computation than other compared NN-based SAEC systems in all test conditions. In the future, we will replace the conventional adaptive filters and Wiener filters with NNs to have a complete NN-based SAEC system, and investigate the condition of multiple dominant speakers.

Abstract — **The window width of the short-time Fourier transform (STFT) has a critical effect on the resolution of the time-frequency distribution. Until now, due to the limitation of the fast Fourier transform (FFT) algorithm, traditional adaptive methods, such as the adaptive STFT and the adaptive synchrosqueezing transform (ST), either only considerer the time-domain width or only considerer the frequency-domain width. However, a more general adaptive method usually has a higher computation complexity due to the search for optimal parameters. In this paper, we propose the reliable region of the window widths for both time and frequency axes. We also simplify the searching process for optimal parameters. Moreover, based on the reliable region of the window widths, we propose a method called the multitaper adaptive time-frequency windowed Fourier transform (MATFWFT) that has time-variant and frequency-variant window size. It can simultaneously estimate the optimal window size for both the time axis and the frequency axis and achieve a time-frequency analysis result with high energy concentration.**

I. Introduction

Time-frequency analysis (TFA) is a critical tool for biomedicine, seismology, communications, and mechanical vibration engineering. Some of the typical methods of TFA, include short-time Fourier transform (STFT), Wigner-Ville distribution (WVD), wavelet transform (WT), and S-transform (ST). However, traditional TFA methods is their restricted resolution caused by the uncertainty principle. They are unable to achieve high resolution in the time and frequency axes simultaneously. This means that it is hard to get a sharp distribution of TFAs. Therefore, to address this problem, reassignment method (RM) [1]−[5] was developed in recent years as a method to concentrate energy to the center of gravity. For frequency-varying signals only, the RM has been improved to the SST [4]. In order to tackle the issue of fast frequency-varying signals, additional techniques were proposed, including the second order SST (SST2) [6] and high order SST [7]. Furthermore, there are also multi-step recursive methods, such as the multisynchrosqueezing transform (MSST) [8]. In addition to being based on STFT, SST can be derived using different transformations. These include the WT-based synchrosqueezing transform [9] and the ST-based synchrosqueezing transform [10, 11].

However, regardless of the traditional TFAs, i.e., STFT, WT, ST, or the post-processing methods, i.e. the RM, the SST, the SET or others, the window width is still the most important and the most critical to the clarity of the time frequency distribution. Therefore, numerous adaptive methods were proposed to automatically search for the optimal window width, i.e. adaptive STFT (ASTFT) [12], adaptive ST (AST) [13, 14], adaptive SST (ASST) [15−17], adaptive SEST (ASEST) [14], multitaper ASTFT (MASTFT) [18], etc. Among them, the adaptive methods are mainly classified into two categories, one is based on maximizing the concentration measure, such as the Rényi entropy [15] and the other is based on the chirp rate (CR) to obtain the optimal variance of window widths, for example [12, 14, 16−18].

On the other hand, the multitaper, also known as Multi resolution, is a spectral density estimation technique. It is a method of superposition of multiple scales of the spectrum. Initially, multitaper was proposed to be applied in spectrum for reducing sidelobe and noise, e.g. [19]. Then, in order to increase the TF distribution clarity and robustness to noise, it was gradually applied to TFA, e.g. [20] also known as superlets [21]. Then, it was also applied to the RM method, e.g., [22]. As well as in SET, e.g. [18]. Incidentally, multitaper is also can divided into two main categories, such as the arithmetic

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

averaging [19]−[22] or the geometric averaging [18, 20].

Although many ASTFT, AST and adaptive postprocessing methods of TFA have been proposed. However, all of these methods are only adaptive for one of the axes, either the time axis or the frequency axis. This limitation is clearly due to the constraint imposed by the FFT.

Therefore, in this paper, we propose the MATFWFT, which is an adaptive method that utilizes the MT technique to overcome the limitation of FFT. It can obtain the optimal window width in both time and frequency axes simultaneously. In other words, we combine the time varying window widths and frequency varying window widths to achieve the time-frequency varying window widths under the constrain of the FFT. On the other hand, the range of the window width is the most important issue of the adaptive method. We analyze the possible minimum and maximum limits of window widths in the time domain and the frequency domain, and derive the reliable region of the window width under the constraints of the FFT, and adopt the different sampling intervals for the time and frequency axes to achieve a small number of window widths. It deals with the circumstances of many different types of input signal and reduce the complexity significantly.

II. Previous Work

The short-time Fourier transform (STFT) is a time-frequency analysis method. Its definition is

$$V(t,f)=\int_{-\infty}^{\infty}x(\tau)w(\tau-t)e^{-i2\pi f(\tau-t)}d\tau =\int_{-\infty}^{\infty}x(t+\tau)w(\tau)e^{-i2\pi f\tau}d\tau \qquad (1)$$

where $x(t)$ is the input signal and $w(t)$ is the window (mask) function. It can be chosen as a scaled Gaussian function, i.e.,

$$w(t)=e^{-\pi t^2/\sigma^2} \qquad (2)$$

where the parameter σ control the window width which affect the clarity of the STFT and then the STFT is also called the Gabor transform.

The general ST works with many different window functions in the frequency domain [13]. It can be viewed as the STFT in the frequency domain and is defined as

$$ST(t,f)=\int_{-\infty}^{\infty}x(\tau)w(t-\tau)e^{-i2\pi f\tau}d\tau =\int_{-\infty}^{\infty}X(f+\alpha)W(\alpha)e^{i2\pi\alpha t}d\alpha . \qquad (3)$$

where $X(f)$, $W(f)$ are the Fourier transform of the $x(t)$, $w(t)$ respectively. In the ST, we also adopt $W(f)$ as the scaled Gaussian function (but it is in the frequency domain), i.e.,

$$W(f)=e^{-\pi f^2/\sigma^2} . \qquad (4)$$

III. Proposed Method

A. Adaptive STFT and Adaptive S-Transform

For considering time varying and frequency vary window, we redefine the Gaussian window function with time-varying variance and in the STFT (1) as

$$w(t)=e^{-\pi t^2/\sigma^2(t)} \qquad (5)$$

and the frequency-varying variance as the window function in the ST (3) as

$$w(f)=e^{-\pi f^2/\sigma^2(f)} \qquad (6)$$

B. Rényi Entropy

The Rényi entropy [25] is a method commonly to measure energy concentration of the time-frequency representation (TFR). We adopt it to measure the distribution of TFR. The local time Rényi entropy is defined as

$$E(t)=\frac{1}{1-\alpha}\log_2\frac{\int_{t-\tau}^{t+\tau}\int_0^{\infty}\left|V(b,f,\sigma)\right|^{2\alpha}dfdb}{\left(\int_{t-\tau}^{t+\tau}\int_0^{\infty}\left|V(b,f,\sigma)\right|^{2}dfdb\right)^{\alpha}} \qquad (7)$$

where $\alpha > 2$ is recommended for TFR measures, V denotes any TFR, and τ is denote the size of the neighborhood.

Similarly, the local frequency Rényi entropy is defined as

$$E(f)=\frac{1}{1-\alpha}\log_2\frac{\int_{f-\tau}^{f+\tau}\int_{-\infty}^{\infty}\left|V(t,b,\sigma)\right|^{2\alpha}dtdb}{\left(\int_{f-\tau}^{f+\tau}\int_{-\infty}^{\infty}\left|V(t,b,\sigma)\right|^{2}dtdb\right)^{\alpha}} . \qquad (8)$$

C. Reliable Region of the Window Width

The window width is limited by the Heisenberg uncertainty principle. In other words, if the window width in the time domain is chosen to be wider, the frequency width is narrower, and conversely, if width in the time domain is chosen to be narrower, the frequency width is wider. In order to find the reasonable range of the window width, we observe the relationship between its width and Δt, Δf are the sampling time interval and sampling frequency interval respectively.

First, we temporarily change the window width of time and frequency $\sigma(t)$, $\sigma(f)$ to fixed value σ_t and σ_f, respectively.

1) Reliable Region of the Window Width by the Closed Form of the STFT and the ST. Recalling the case of an input

signal being an impulse function in the time and frequency domains respectively, the STFT and ST can be expressed as:

$$\left|V\left(t,f\right)\right| = e^{-\pi(t_0-t)^2/\sigma_t^2} = \left|V\left(t\right)\right|, \tag{9}$$

$$\left|ST\left(t,f\right)\right| = e^{-\pi(f_0-f)^2/\sigma_f^2} = \left|ST\left(f\right)\right|. \tag{10}$$

Since the variance needs to be larger than the inherent physical constraints, we have

$$\left\{\sigma_t,\sigma_f\right\} \geq C\left\{\sqrt{2\pi}\Delta_t,\sqrt{2\pi}\Delta_f\right\} \tag{11}$$

where the constant $C \geq 1$. By the same way, recalling the case of an input signal being an exponential function in the time and frequency domains, the STFT and the ST can be expressed as:

$$\left|V\left(t,f\right)\right| = e^{-\sigma_t^2\pi\left[\phi'(t)-f\right]^2} = \left|V\left(f\right)\right|, \tag{12}$$

$$\left|ST\left(t,f\right)\right| = e^{-\sigma_f^2\pi\left[t-\varphi'(f)\right]^2} = \left|ST\left(t\right)\right|. \tag{13}$$

Note that we only care about the exponential term. Since the variance need to be larger than the inherent physical constraints, we have

$$\left\{\sigma_t,\sigma_f\right\} \leq \left\{\frac{1}{C\sqrt{2\pi}\Delta_f},\frac{1}{C\sqrt{2\pi}\Delta_t}\right\}. \tag{14}$$

where the constant $C \geq 1$. We can observe that the absolute values of the STFT and the ST can be interpreted as the exponential function in the frequency and time domains, respectively. Moreover, because the STFT (1) and the ST (3) can exchanged by the FT, the window function widths of each can be related to each other, i.e.,

$$w\left(t\right) = e^{-\pi t^2/\sigma_t^2},\ W\left(f\right) = \mathrm{F}\left\{w\left(t\right)\right\} = \sigma_t e^{-\pi\sigma_t^2 t^2}, \tag{15}$$

and the window function in the ST (3) is

$$W\left(f\right) = e^{-\pi f^2/\sigma_f^2}. \tag{16}$$

For the clarity of the time frequency resolution, we only pay attention to the influence of the window width, which is the exponential term of the scaled Gaussian function. Hence, by comparing the exponential term of the scaled Gaussian function $W(f)$ in (15) and (16), we know that σ_t and σ_f are reciprocally related, i.e.,

$$\sigma_t = 1/\sigma_f. \tag{17}$$

By observing (11), (14) with (17), we know that (11) and (14) are inherently equal, which is also highly logical.

2) Reliable Region of the Window Width by Standard Deviation of the Window

On the other hand, another common way to explore the window width is the standard deviation (SD) in [22]. The width, SD of the window function or called the temporal and spectral spreads. Consider in the time domain, its definition is

$$SD_t^2 = \frac{\int_{-\infty}^{\infty} t^2\left|w\left(t\right)\right|^2 dt}{\int_{-\infty}^{\infty}\left|w\left(t\right)\right|^2 dt} = \frac{\sigma_t^2}{4\pi},\ SD_t = \sqrt{\frac{\sigma_t^2}{4\pi}} \tag{18}$$

where $w(t)$ is defined in (2). In the frequency domain, SD is defined as

$$SD_f^2 = \frac{\int_{-\infty}^{\infty} f^2\left|W\left(f\right)\right|^2 df}{\int_{-\infty}^{\infty}\left|W\left(f\right)\right|^2 df} = \frac{\sigma_f^2}{4\pi},\ SD_f = \sqrt{\frac{\sigma_f^2}{4\pi}} \tag{19}$$

where $W(f)$ is defined in (4). Note that the SDs definition omit the mean term since the mean value of the window functions of the time and frequency domain are both zero. Obviously, in practice, since the SDs need to be larger than the inherent physical constraints, we have

$$\left\{\sigma_t,\sigma_f\right\} \geq C\left\{\sqrt{4\pi}\Delta_t,\sqrt{4\pi}\Delta_f\right\} \tag{20}$$

where the constant $C \geq 1$.

Furthermore, we recall the previously derived window width restriction (20) and reciprocal relation (17), which becomes the following restriction

$$C\sqrt{4\pi}\Delta_t \leq \sigma_t \leq \frac{1}{C\sqrt{4\pi}\Delta_f},\ C\sqrt{4\pi}\Delta_f \leq \sigma_f \leq \frac{1}{C\sqrt{4\pi}\Delta_t}. \tag{21}$$

For applying the FFT algorithm, we can set

$$\Delta_t\Delta_f = 1/N. \tag{22}$$

In this case, substitute (22) into (21) and rewrite (21) as

$$C\sqrt{4\pi}\Delta_t \leq \sigma_t \leq \frac{N}{C\sqrt{4\pi}}\Delta_t,\ C\sqrt{4\pi}\Delta_f \leq \sigma_f \leq \frac{N}{C\sqrt{4\pi}}\Delta_f. \tag{23}$$

We can observe that the reliable region of the window width determined by the SD method has stricter conditions compared to the region determined by the closed form of the STFT and the ST method. Therefore, the SD width perspective, we not only provide a reasonable lower bound for the window width, but also exploit the relationship between the window function in the STFT and ST to obtain a reasonable upper bound. In our

following work, we adopt (21) or (23), which provide suitable and reliable ranges of the window width.

D. Choosing the Time-Frequency Varying Window Width

Due to the restriction of the FFT algorithm, the window width is usually selected only for the time axis or the frequency axis. However, to overcome this issue, we propose a new approach to incorporate the selection based on both the time and frequency axes within the restriction of the FFT algorithm.

Firstly, consider the case of time-varying signal. We adopt the approach of optimizing the Rényi entropy (7) for the selection of the window width and limit its range to (21). At a fixed time t, we can use (7) to find the optimal $\sigma(t)$

$$\sigma(t) = \min_{\sigma} E(t). \tag{24}$$

Note that the local time Rényi entropy E(t) in (24) can be applied to any TFR. Specifically, apply the STFT to the local time Rényi entropy E(t) in the (7), we can get the corresponding optimal window width

$$\sigma_{STFT}(t) = \min_{\sigma} E_{STFT}(t). \tag{25}$$

where E_{STFT} denotes the local Rényi entropy of the STFT.

Secondly, similar to the time-varying method, we also consider the case of frequency varying signal. We adopt the approach of optimizing the local frequency Rényi entropy (8). At a fixed frequency f, we can use (8) to find the optimal σ(f) with the most concentrated TFR

$$\sigma(f) = \min_{\sigma} E(f). \tag{26}$$

We apply the ST to the local frequency Rényi entropy $E(f)$ in the (8) and obtain the optimal window width

$$\sigma_{ST}(f) = \min_{\sigma} E_{ST}(f). \tag{27}$$

where E_{ST} denotes the local frequency Rényi entropy of TFSEST and $\sigma_{TFSEST}(f)$ denotes its optimal window width.

E. Multitaper Adaptive Time Frequency Windowed FT

After the process of optimization of the local time and frequency Rényi entropy of the STFT and the ST, $E(t)$, and $E(f)$, we can get the corresponding optimal window width, (25) and (27), respectively. Substitute the (25) and (27) into STFT, ST respectively. Refer to them as the adaptive STFT and the adaptive ST based on the Rényi entropy.

Finally, we utilize the multitaper technique to merge the adaptive STFT and the adaptive ST to define the MATFWFT:

$$MATFWFT(t,f) = \left(\left| ASTFT(t,f) \right|^2 + \left| AST(t,f) \right|^2 \right) / 2. \tag{28}$$

The ASTFT and the AST are denoted the adaptive STFT and the adaptive ST based on the Rényi entropy respectively. It addresses the long-standing issue that adaptive the window width only depends on a single axis. The optimal window width is obtained for each time-frequency point, not only for the time axis or frequency axis.

IV. Digital Implementation

In this section, we introduce the digital implementation method of the ATFWSET. For the STFT, we can set

$$t = n\Delta_t, \quad \tau = k\Delta_\tau, \quad f = m\Delta_f, \quad \Delta_\tau \Delta_f = \frac{1}{N}. \tag{29}$$

In specifically $\Delta_t = \Delta_\tau$, then the discrete STFT becomes

$$V[n,m] = \sum_k x[n+k] w[k] e^{-i2\pi \frac{km}{N}} \tag{30}$$

For the ST, we also can set

$$t = n\Delta_t, \quad \alpha = p\Delta_\alpha, \quad f = m\Delta_f, \quad \Delta_t \Delta_\alpha = \frac{1}{N}. \tag{31}$$

Specifically, $\Delta_f = \Delta_\alpha$, then the discrete general ST becomes

$$ST[n,m] = \sum_p X[p+m] W[p] e^{i2\pi \frac{pn}{N}}. \tag{32}$$

For practical implementation, recall the reliable window widths (23) proposed in Section III. It is recommended to adopt equally spaced intervals based on multiples of the sampling time interval and sampling frequency interval respectively, i.e., the range of (50) is rewritten as follows

$$\begin{aligned} \sigma_t &= \Delta_t \cdot round\left(\left[\sqrt{4\pi}C \quad 2k\sqrt{4\pi}C \quad \cdots \quad N/\sqrt{4\pi}C \right] \right) \\ \sigma_f &= \Delta_f \cdot round\left(\left[\sqrt{4\pi}C \quad 2k\sqrt{4\pi}C \quad \cdots \quad N/\sqrt{4\pi}C \right] \right) \end{aligned} \tag{33}$$

where k is denoted multiple of sampling interval and round(.) is denoted as the operator that rounds the value.

In the first step, for each window width in the reliable region of the window width range in the time domain and frequency domain respectively. Then, the ASTFT and AST are obtained by estimating the optimal window width. Note that for each window width is limited in the reliable region of the window width.

Finally, by using the mutitaper technique for ASTFT and AST, we can obtain MATFWFT.

IV. Experiments

In this section, we demonstrate the experiments to illustrate the efficiency and robustness about the proposed method. We add the comparison of the highest resolution in the time domain and frequency domain, i.e., $STFT_{SD}$, ST_{SD} which are denoted the STFT with the window width SD_t, and the ST with the window width SD_f respectively. We also compare with several currently existing adaptive time frequency methods, including the adaptive STFT (ASTFT), adaptive ST (AST) and our proposed ATFWFT, all based on the local Rényi entropy in (7) or (8) respectively, i.e., ASTFT with the window width $\sigma_{STFT}(t) = \min E_{STFT}(t)$, AST with the window width $\sigma_{ST}(f) = \min E_{ST}(f)$. In addition to the above adaptive method, Finally, with the multitaper technique, there are $MSTFT_{SD} = (|STFT_{SD}|^2 + |ST_{SD}|^2) / 2$, MATFWFT = $(|ASTFT|^2 + |AST|^2) / 2$.

In the experiment, we set $N = 200$, $\Delta_t = 1/200$, $\Delta_f = 1$, and the local Rényi entropy size of the neighborhood $\tau = 4$ in (7), (8), and the constant $C = 2$, multiple of sampling interval $k = 1$ in (33). The reliable region of the window width is rewritten as $\sigma_t = [7\ 8 \cdots 28] \cdot \Delta_t$, $\sigma_f = [7\ 8 \cdots 28] \cdot \Delta_f$. Note that because the upper and lower bounds are restricted by reliable region of the window width, the number of them in our setting is only 22. However, it is also allowed to sample with wider intervals depending on the number of samples you need. It is efficient in reducing the complexity.

In order to show that there are various signals at the same time or frequency, first we consider the three-component exponential signals

$$x(t) = e^{-0.1t+i2\pi\left[\left(10t^2+10t\right)+\left(7.5t^3+35t\right)+\left(7.5t^4+60t\right)\right]}. \tag{34}$$

Then, we also consider the three-component impulse signals

$$x(t) = \mathcal{F}\left\{e^{-0.1t+i2\pi\left[\left(7.5t^2-80t\right)+\left(7.5t^3-20t\right)+\left(7.5t^4+30t\right)\right]}\right\}. \tag{35}$$

Then, we consider a complicated test signals that contain multi-component exponential signals and impulse signals as:

$$\begin{aligned}
x(t) &= x_1(t) + x_2(t) + x_3(t) + x_4(t) + x_5(t) \\
&\quad + x_6(t) + x_7(t), \\
x_1(t) &= 0.2\exp\left(i2\pi\left(7.5t^2+10t\right)\right),\ t \in [0, 0.4), \\
x_2(t) &= 0.2\exp\left(i2\pi\left(7.5t^2+80t\right)\right),\ t \in [0.4, 0.6), \\
x_3(t) &= 0.2\exp\left(i2\pi\left(7.5t^2+10t\right)\right),\ t \in [0.6, 1], \\
x_4(t) &= \exp\left(-10000\left(t-0.25\right)^2 + i2\pi\left(80t\right)\right), \\
x_5(t) &= 1.2\exp\left(-10000\left(t-0.5\right)^2 + i2\pi\left(10t\right)\right), \\
x_6(t) &= \exp\left(-10000\left(t-0.25\right)^2 + i2\pi\left(80t\right)\right), \\
x_7(t) &= 0.35\exp\left(i2\pi \cdot \begin{pmatrix} 0.8\sin\left(4\pi t\right) \\ +7.5t^2+10t \end{pmatrix}\right).
\end{aligned} \tag{36}$$

Figs. 1-3 provide the TF plots of signal (34)-(36), respectively, obtained by (a) the ASTFT, (b) the AST, (c) the MATFWFT, (d) the STFT with the window width SDt, (e) ST with the window width SDf, and (f) the MSTFTSD. For this multi-component signal, we observe the results as following.

Firstly, we observe the STFT and the ST using the smallest window width, SD_t and SD_f, i.e., the highest resolution in the time and frequency domain, respectively. However, some components of the signal disappear because of the limitation of the uncertainty principle where high resolution implies low resolution in the corresponding frequency and time domain.

Further, we utilize the multitaper technique to improve the concentration of the energy by combining and MSTFTSD. With the multitaper effect of MATFWFT, it obviously contours the accurate time frequency distribution. That combine the advantages of both characteristic, which contain the optimal window width of the time and frequency domain respectively.

Finally, we compare the performance of our proposed method with other different methods. We measure the energy concentration through global Rényi entropy, probability energy distribution (PED).

The PED is defended

$$PED = \frac{\sum_n \sum_k \left|V(n,k)\right|^4}{\left(\sum_n \sum_k \left|V(n,k)\right|^2\right)^2}. \tag{37}$$

It is a model of the probability to measure the sharpness of the time frequency distribution. Note that smaller the PED value represents the less concentrated the energy distribution, and vice versa.

In Table I, we show the result comparing many different adaptive methods.

VI. Conclusion

In this paper, we proposed the reliable window width region which has the advantage of reducing the complexity by narrowing the range of the window width. Based on the reliable window width region and the local Rényi entropy, we also proposed the MATFWFT, which is an adaptive method that incorporates optimal time-varying and frequency-varying

window widths simultaneously. It solves the traditional issue of the dependence of the window width on a single axis only. It has the advantage of working effectively at any time-frequency points, for both exponential and impulse signals. In total, it contributes to a time frequency analysis method with low complexity and capable of estimating the time-varying and frequency-varying window sizes in a concurrent manner.

***Abstract* — Retinal optical coherence tomography (OCT) imaging has become a valuable tool in diagnosing and monitoring retinal diseases. Recent advancements in vision transformers have demonstrated impressive performance in image classification tasks. This research article presents a novel approach, named Dual Scale Twin Vision Transformer (DST-ViT), for retinal disease classification using OCT images.**

DST-ViT combines the advantages of dual-scale representation learning and the Twin transformer architecture to improve disease classification accuracy. By leveraging dual-scale input OCT images, DST-ViT effectively captures fine-grained details and global contextual information simultaneously, enhancing classification performance. With an outstanding average accuracy of 99.92%, DST-ViT surpasses existing state-of-the-art methods.

This research contributes to the growing understanding of ViT and their application in retinal disease classification. The promising results achieved by DST-ViT open possibilities for improved diagnosis and treatment planning in the field of ophthalmology.

I. INTRODUCTION

Optical Coherence Tomography (OCT) is a powerful imaging technique used to generate cross-sectional representations of various tissues and detect pathological structures within them [1]. In the context of retinal diseases, OCT enables the study of oedemas, which are fluid accumulation and leakages caused by the erosion of retinal blood vessels. These oedemas, particularly Diabetic Macular Oedemas (DME), are the leading causes of impaired vision in advanced countries. Timely and accurate diagnosis of DME is crucial to prevent permanent damage to retina [2].

Computer-aided analysis systems have emerged to decrease the bias associated with expert interpretation and enhance the monitoring and treatment of retinal pathologies. However, many of these methodologies remain opaque, obscuring their internal logic and making it challenging for experts to comprehend their predictions' underlying rationale [3]. This lack of interpretability is particularly concerning in ophthalmology, as misguiding information from black-box systems can significantly impact patient quality of life. Consequently, researchers have published methods to elucidate the internal methods of these black-box models. For instance, Vidal et al. [4][5] proposed an intensive voting approach to create a map of recognised pathological regions. Wang et al. [6] explored through gradient-based class-activation maps, and Reza et al. [7] utilised the LIME structure.

However, existing explainable methodologies primarily focus on representing what is already present in the image without establishing connections to past learning. To refer this space, Philipps et al.[8] introduced an architecture inspired by the ViT. This study introduces a transformer-based automatic retinal lesion segmentation method in SD-OCT images. It combines the advantages of ViT and CNNs, providing efficient long-range feature extraction and aggregation capabilities with data-efficient training. While a competitor achieves a higher Dice score, the proposed method stands out for its lower computational cost. This approach has been effectively transformed to other medical imaging domains, such as chest X-Ray [9] and the diagnosis of COVID-19 [10]. In natural language processing (NLP), transformers have shown great potential for sequence-to-sequence modelling [11]. As a result, the computer vision community is now interested in

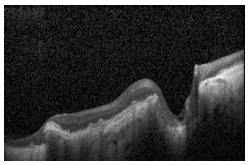
979-8-3503-0067-3/23/$31.00 ©2023 IEEE

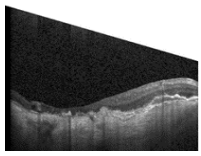
discovering whether transformers can compete with CNN-based designs like ResNet [12] and EfficientNet [13]. Previous research on ViT was primarily focused on combining CNNs with self-attention, resulting in hybrid approaches [14], [15]. While these hybrid models achieve promising performance, they are computationally less efficient than attention-based transformers. ViT [16] introduced a convolution-free approach that utilises a sequence of embedded image patches as input to a standard transformer, achieving comparable performance to CNN models. However, ViT requires large-scale datasets like ImageNet21K[17] and JFT300M [18] for training. Subsequent research, such as DeiT [19], demonstrated that high-performance ViT models could be trained with less data with appropriate data augmentation and model regularisation. ViTs have gained significant research interest as an alternative to convolutional neural networks (CNNs) in visual perception tasks. ViTs offer several advantages, including the ability to model long-range dependencies, handle multi-modal data, and introduce less inductive bias. These characteristics make ViTs a promising candidate to replace CNNs as the foundational component in future visual perception systems.

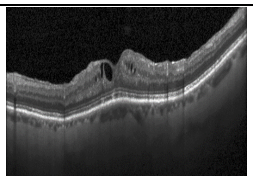
The computational complexity of the spatial self-attention operation, however, presents a barrier when applying transformers to vision tasks. The number of pixels in the input image causes its complexity to increase in a quadratic fashion. Utilising locally grouped self-attention or self-attention in non-overlapping windows, as shown in the Swin Transformer, is a solution to this problem [20]. This strategy lessens computing complexity, but it restricts connectivity between various windows, leading to a constrained receptive field. For dense prediction tasks like picture segmentation and object detection, a broader receptive field is important. The Swin Transformer introduces a moving window procedure to address this limitation, gradually moving the boundaries of local windows as the network progresses. But the uneven sizes of these shifted windows can pose challenges when deploying models with specific frameworks like ONNX or TensorRT, which prefer equal-sized windows[21]. However, applying this methodology to Diabetic Macular Oedema classification in OCT images proved challenging due to the resemblance between diagnostic shapes and other regular patterns found in normal retinal layers.

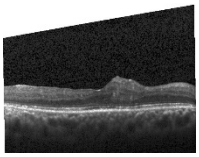
In this research article, we proposed a novel approach, the Dual Scale Twin Vision Transformer (DST-ViT), for retinal disease classification using OCT image data. The DST-ViT model combines two powerful techniques, the dual scale[22] and the twin ViT framework[22], to improve the accuracy and interpretability of retinal disease diagnosis. By using these advanced methodologies, DST-ViT can better understand and classify retinal diseases. The dual-scale approach allows the model to capture fine details and overall context from the OCT images, resulting in more accurate predictions. Additionally, the twin ViT framework enhances the interpretability of the model's decisions, providing insights into how it makes its diagnoses. We demonstrated the effectiveness of our approach in addressing the challenges posed by DME classification and provided comprehensive evaluations and comparisons with existing methods. By leveraging these advancements, DST-ViT offers a more reliable and understandable method for diagnosing retinal diseases, contributing to improved patient care and treatment planning.

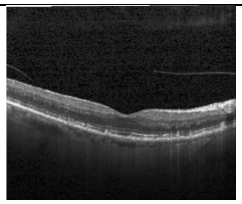
Rest of the paper is structured as follows: Section II discuss about dataset, methodology and experiment performed. Section III discuss about the results we obtained and comparison of our proposed model with the state-of-art. It also discusses about limitation and future scope of our proposed model.

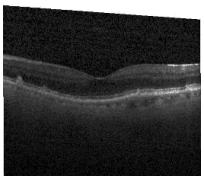


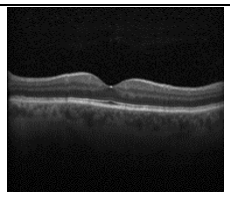


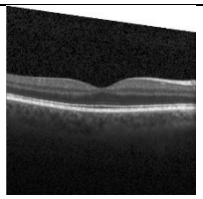












II. Materials and Methods

A. Datasets

We used a dataset of optical coherence tomography (OCT) image data for this research [23]. This publicly accessible dataset was gathered between 2013 and 2017 from five institutions. There are 1,000 test images and 108,309 total

training images in it. The collection includes four classes: normal OCT, diabetic macular oedema, and choroidal neovascularization (8,616 pictures from Drusen). The sample images of good quality and skewed image from each class is presented in Table 1. For this research, we initially combined the existing training and testing data into a single dataset. Subsequently, we followed a rigorous approach to ensure robust model evaluation by dividing each class into three distinct subsets: one for training, one for testing, and one for validation. This division was carried out in an 80:10:10 ratio, where 80% of the data from each class was allocated to training, 10% for testing, and an additional 10% for validation. This strategy allowed us to maintain a balanced and representative distribution of data across all classes while facilitating effective model training, evaluation, and hyperparameter tuning

Table 1 Sample Images from OCT-2017 Dataset

Retina Condition	Good Quality image	Skewed Image
CNV		
DME		
Drusen		
Normal		

In the case of CNV, abnormal vessel growth occurs from the choroidal vasculature to the neurosensory retina through Bruch's membrane. This results in variations below or above the RPE layer and within the intra-retinal area. These variations can manifest as macular fluid regions (depicted in black), a bumpy RPE layer, and poorly defined boundaries. For DME, intraretinal fluids are present between the Inner Limiting Membrane (ILM) and Retinal Pigment Epithelium (RPE) layers. These fluids appear as dark regions in the image. In the case of Drusen, the RPE layer exhibits a bumpy shape instead of a flat shape. Identification of Drusen can help to diagnose age-related macular degeneration[2].

Overall, this dataset provides a diverse range of OCT images showcasing different retinal conditions, enabling the development and evaluation of algorithms for retinal disease classification.

Within the dataset, the images display variations in both size and quality, accompanied by the presence of black-and-white noise, as depicted in Table 2. The figure consists of four rows, each corresponding to a specific class: CNV, DME, Drusen, and Normal.

In the first column, all the images share a square shape. However, the second column contains images with non-square shapes and a white background. Additionally, the images within the dataset possess different zoom rates. The images in the second column have lower zoom ratios than those in the first.

B. Methodology

This research article proposes a novel approach to enhance image features by combining image patches at different scales, also known as tokens in a transformer. After being linearly embedded, these tokens are input into a Twin transformer architecture that incorporates local and global self-attention mechanisms. Unlike the shifted window approach used in the original Swin transformer[20], this modified version leverages a combination of local and global self-attention to achieve more effective feature extraction. In the early ViT, single-scale non-overlapping patches were given as the input sequence to the transformer, which lacks the feature information and relation with the neighbours. To circumvent this, a swin transformer was proposed, which contains shifted window self-attention module which acts like a convolution of the image but with less computational cost. Later, a more efficient network was proposed by [21], containing local self-attention and global self-attention cascaded over each other with residual

connection. In this paper, we have modified the Twin model proposed by[21]. with a dual scale input. The detailed block diagram of the proposed model in given Fig. 1.

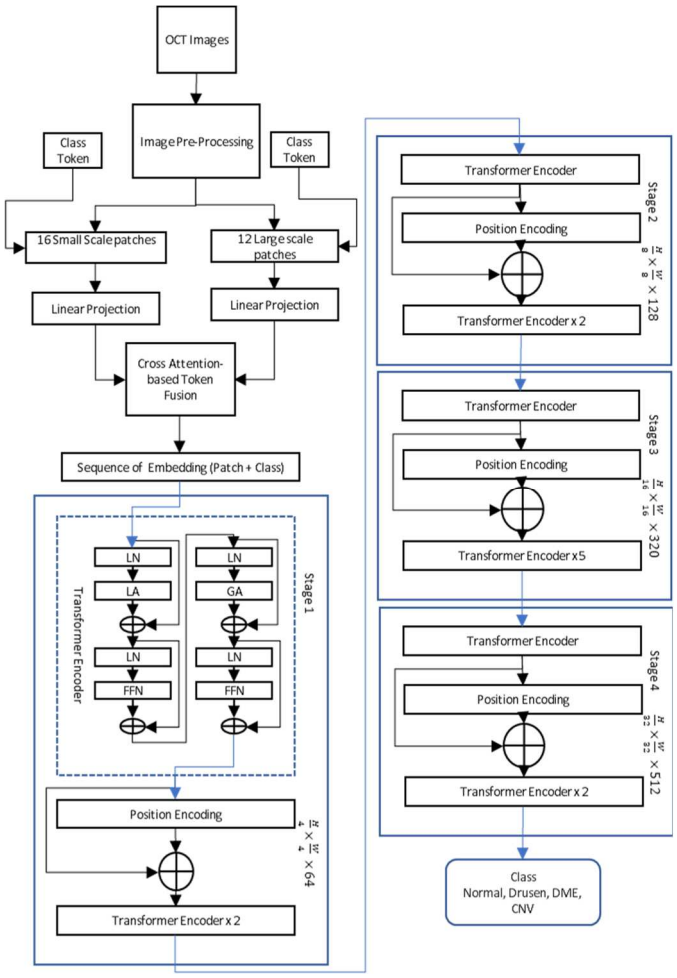


Fig. 1 Detailed Block Diagram of Proposed Dual Scale Twin Vision Transformer (DST-ViT). LN: Layer Norm, LA: Local Self-Attention, GA: Global Self-Attention, FFN: Feed Forward Network

The proposed model can be explained into two separate models, i.e., dual scale input and Local & Global self-attention-based ViT. We have seen in Table 2 that the OCT image data which we have used for this experiment contain some skewed images. These images contain some white backgrounds, which are not our subject of interest and may cause bias in the model. Also, the number of images in each dataset class is not even, which causes an imbalance in the training process. We have used some pre-processing techniques adapted from [21] to address this issue. The pre-processing involves several steps, including noise removal, rotated retina layer adjustment, and final retina layer cropping. A histogram is computed by projecting the image onto the vertical axis to ensure accurate alignment and proper orientation of the retina layer. This histogram provides information to adjust the rotated retina layer, improving the alignment and consistency of the estimated features. The final step involves cropping only the retina layer from the image, discarding irrelevant information and isolating the region of interest. The cropped retina layer serves as the input for the subsequent Transformer block.

The idea of dual-scale input for transformer block is taken from [22], which shows the importance of multi-scale input in ViT. For the sake of computational efficiency, we have used dual-scale input. As per the experiment conducted by Chun-Fu [22], images partitioned in (12, 16) patches exhibit better accuracy and have less computation burden than (8, 16). Similar to the original BERT model [24], we have added an additional class token to each small and large-scale patch. This information of position and class for both scales is fused using cross-attention-based toke fusion proposed by[22]. This approach employs the CLS token, which learns abstract information within its branch, as an agent for knowledge exchange. By interacting with patch tokens from other branches, the CLS token facilitates information integration at different scales, complementing the representation of individual patch tokens.

The Swin Transformer [25] enhances communication among patches and receptive fields by alternating local window-based attention with shifted window partitions in successive layers. However, this method lacks optimization for mobile devices and relies on memory-intensive cyclic shift operations unsupported by popular inference frameworks. In contrast, Twins models excel by eliminating the need for such operations and relying solely on optimized matrix multiplications in modern deep learning frameworks. In our proposed model, we evaluated self-attention and global

attention features on the embedded token to extract class-wise details of OCT images. Details on Local self-attention (LA) and Global self-attention (GA) and its implementation in ViT can be found in [21]

C. Experiment

The experiment was conducted on a Windows 10 core i7 processor and 32 Gb memory. We used Python 3.10 and PyTorch 1.11.0 to build the model. The models were trained on an NVIDIA Quadro P620 GPU with 512 CUDA cores. The weights were initialised using Xavier initialisation [26]. The hyperparameters β1 and β2 of the Adam optimiser represent the initial decay rates used to estimate the first and second moments of the gradient. These decay rates are multiplied by themselves exponentially at the end of each training step (batch). Reducing β1 and β2 values can slow down the learning process. Therefore, if the training progress is excessively fast, adjusting these hyperparameters can be beneficial in controlling the learning rate. In this experiment, the Adam optimiser with a β1 value of 0.900 was utilised for optimisation during training. The initial learning rate was set to 0.0002 and decayed to 0.00001 towards the end. All OCT images were resized and cropped to 224 × 224, and a batch size of 32 was used. Sixteen tokens were generated for the small-scale image patch and 12 tokens for the large-scale patch. The model was trained for 200 epochs, and the performance was evaluated using the model at the final epoch.

D. Evaluation of Model

We utilise the softmax method to evaluate the classification performance to convert logits into class probabilities. The predicted category is determined by selecting the class with the highest probability. Accuracy, precision, recall, and F1-score are employed as evaluation metrics. The formulas for these evaluation metrics are as follows:

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

$$Precison = \frac{TP}{TP+FP} \quad (2)$$

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

$$F1\ Score = \frac{2(Precision \times Recall)}{Precision+Recall} \quad (4)$$

Here, TP refers to true positive, TN refers to true negative, FP refers to false positive, and FN refers to false negative. These metrics provide comprehensive insights into the performance of the classification model. Apart from this, we have also used Score-CAM[27] to visualise the prediction and decision-making capability of the model in the form of a heatmap of the OCT image.

III. Results and Discussion

The result of this experiment is represented in two forms: one with performance metrics and another with heat map generation of the OCT image. In Table 2, we have calculated evaluation parameters (Accuracy, Precision, Recall and F1 Score) to measure the robustness of our proposed model. The average combined class accuracy is 99.92% whereas individual class accuracy ranges between 99.75-100%. Out of all classes, DST-ViT has been shown to have 100% accuracy for diabetic macula oedema (DME) and normal image. This also implies that there is less chance of misdiagnosing patients with no retinal pathology.

Table 2 Evaluation metrics of the proposed Model on the OCT 2017 dataset.

Class	Accuracy	Precision	Recall	F1-Score
Normal	1.0000	0.9990	1.0000	0.9994
CNV	0.9996	0.9960	1.0000	0.9979
DME	1.0000	0.9990	0.9980	0.9984
Drusen	0.9975	0.9985	0.9975	0.9979
Average	**0.9992**	**0.9981**	**0.9988**	**0.9984**

No model can be evaluated unless it is not compared with the state-of-art. We have compared our proposed model with the literature using transformer model to classify OCT image and with other machine learning model. The comparison is shown Table 3. The highlighted values are the average output

of each class. The result illustrated in Table 3 shows that our algorithm has not only outperformed the performance of another transformer model with fair margin but with other machine learning model with greater margin.

Table 3: Comparison of the proposed model with various *ViT*s and machine learning models.

		Accuracy	Precision	Recall	F1-Score
Transformer Models	ViT[16]	99.00	99.07	99.07	99.07
	Swin Transformer[20]	99.07	99.07	99.07	99.07
	S-Poly-transformer[21]	99.80	99.70	99.80	99.80
	DST-ViT (Proposed)	**99.92**	**99.81**	**99.88**	**99.84**
Other Machine Learning	Kim et.al.[28]	98.90	98.90	98.90	98.90
	Saleh et.al.[29]	98.50	98.50	98.50	98.50
	Inception V3[30]	96.60	97.40	97.80	97.60
	Kermany et.al.[23]	96.10	96.12	96.10	96.10
	MDFF[31]	99.60	99.60	99.60	99.60

As discussed in the evaluation model section, we have visualised some of the test images using a heat map. This heat map was generated using a model proposed by [27] to visualise how the proposed model focuses on the region of greater attention with higher probabilities. A few examples of test image with corresponding heat maps are given in Fig. 2.

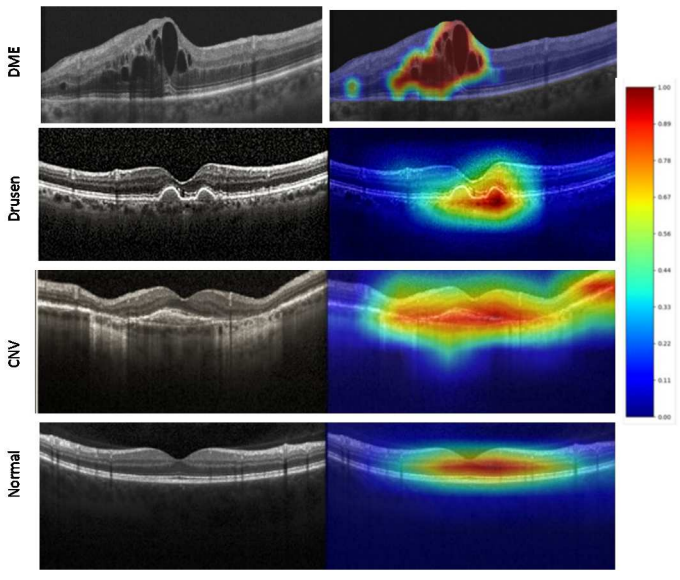

Fig. 2 Heat map of OCT image from each class.

Heatmaps provide visual evidence of the regions within an OCT image that influenced the algorithm's decision. Clinicians can visually confirm whether the algorithm focused on the correct features associated with drusen and CNV, enhancing their confidence in the diagnosis. In this research article, we proposed a novel approach, Dual Scale Twin Vision Transformer (DST-ViT), for retinal disease classification using OCT image data. Our method combines the advantages of dual-scale representation learning and the transformer architecture to enhance the accuracy of disease classification. The experimental results demonstrate the effectiveness of DST-ViT in accurately identifying various retinal diseases. Furthermore, the comparison with existing state-of-the-art methods showcases the superiority of DST-ViT in terms of classification. The incorporation of dual-scale representation allows DST-ViT to capture fine-grained details and global contextual information simultaneously, leading to improved classification accuracy. Overall, our study highlights the potential of DST-ViT as a promising tool for retinal disease classification, with implications for early diagnosis and treatment.

IV. Conclusion

In conclusion, our research article presents the Dual Scale Twin Vision Transformer (DST-ViT) as a highly effective approach for retinal disease classification using OCT image data. By leveraging dual-scale representation learning and the local and global self-attention-based transformer architecture, DST-ViT demonstrates superior accuracy in identifying various retinal diseases. The experimental results strongly support the superiority of DST-ViT over existing state-of-the-art methods based on comprehensive performance evaluation metrics.

However, it is essential to acknowledge certain limitations in our study. The performance of DST-ViT may be influenced by factors such as dataset size and class imbalance, which warrant further investigation. Additionally, exploring the interpretability of the model's decisions can provide valuable insights into the classification process and foster trust in the system.

For future work, we suggest addressing these limitations and investigating the generalizability of DST-ViT to different OCT image datasets. Efforts can be directed toward exploring

transfer learning and domain adaptation techniques to enhance the model's performance in scenarios with limited annotated data. Furthermore, integrating clinical data and longitudinal OCT scans holds promise for providing valuable information for disease prognosis and treatment planning. These avenues of research offer exciting prospects for advancing retinal disease classification using the DST-ViT framework.

The novel approach presented in this paper, DST-ViT, showcases the potential of ViT in the field of retinal disease classification. Its success highlights the importance of leveraging advanced machine-learning techniques to improve medical diagnosis and patient care in ophthalmology.

***Abstract*—Infant sleep is critical to brain and behavioral development. Prior studies on infant sleep/wake classification have been largely limited to reliance on expensive and burdensome polysomnography (PSG) tests in the laboratory or wearable devices that collect single-modality data. To facilitate data collection and accuracy of detection, we aimed to advance this field of study by using a multi-modal wearable device, LittleBeats (LB), to collect audio, electrocardiogram (ECG), and inertial measurement unit (IMU) data among a cohort of 28 infants. We employed a 3-branch (audio/ECG/IMU) large scale transformer-based neural network (NN) to demonstrate the potential of such multi-modal data. We pretrained each branch independently with its respective modality, then finetuned the model by fusing the transformer layers with cross-attention. We show that multi-modal data significantly improves sleep/wake classification (accuracy = 0.880), compared with use of a single modality (accuracy = 0.732). Our approach to multi-modal mid-level fusion may be adaptable to a diverse range of architectures and tasks, expanding future directions of infant behavioral research.**

I. Introduction

Sleep is a physiological and behavioral process central to brain development during infancy [1]–[4]. During the first six months of life, infants spend more time sleeping than awake [5]. Further, indices of infant sleep quality and quantity are associated with subsequent cognitive and language development [6]–[11], attention regulation [12]–[14], social-emotional functioning [10], [12], and physical health [15], [16]. Given the importance of infant sleep to development, automated and unobtrusive monitoring of sleep is critical. Thus, we focus on the task of sleep/wake classification in this study.

Laboratory-based polysomnography (PSG) is the gold-standard sleep assessment for adults and infants alike [18], [19]. However, given the high level of burden and expense of laboratory PSG, researchers have used wearable devices for sleep monitoring [20]. Notably, past studies of sleep/wake classification using wearable devices typically extract sleep features from single-modality data. For example, with actigraphy data, [21] carried out extensive studies on adult sleep/wake classification using traditional signal processing methods, classic machine learning methods, and several deep learning methods. Electrocardiogram (ECG) signals are also often used because stable QRS complex and longer R peak period can indicate sleep stages [22]. Studies such as [23] used ECG data to classify adult sleep/wake with a 5-layer convolutional neural network (CNN) concatenated with 2 fully connected (FC) layers. A signal-processing-based approach was suggested by [24], where audio recordings of adults' respiratory sounds were used to estimate sleep/wake likelihood from signal level features such as autocorrelation. All published studies of automatic sleep/wake classification use different datasets, therefore their accuracies are not strictly comparable, but the accuracies reported in all four of these studies are between 81%

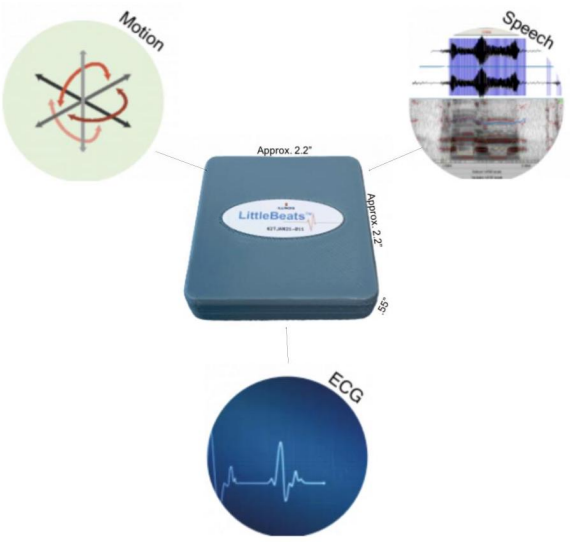

Fig. 1. LittleBeats (center) is capable of collecting audio, ECG, and IMU data. Reproduced with permission from [17]

and 84% (see Table I for details). A few studies have used bimodal data to further improve classification performance. Ref. [25] concatenated the frequency bins from respiratory signals and ECG to feed into a FC based network, achieving classification accuracy of 85.3%. Ref. [26] uses random forest to classify sleep/wake from acceleration and heart rate data collected by Apple Watch, achieving 87.3% accuracy. Recent work tend to focus on a more involved sleep classification with 5 stages. Ref. [27] extracted infant vocalizations from audio recordings and physical motions from video recordings, and classified sleep stages using a random forest, resulting in an average accuracy near 85%. Supratak et al.'s DeepSleepNet [28] and their subsequent stage of the art (SOTA) TinySleepNet [29] used only electroencephalogram (EEG) to reach 87.5% in accuracy.

To achieve further improvements in accuracy, we leveraged trimodal data collected by an infant wearable device, LittleBeats (LB), as shown in Fig. 1. LB can synchronously record infant sounds (via microphone [audio]), physiology (via 3-lead ECG), and motion (via inertial measurement unit [IMU]) for extended periods of time (8-10 hours) in the home context.

To perform sleep/wake classification using LB multi-modal data, we developed an ensemble of three large scale transformer networks pretrained on unimodal audio, ECG, and IMU datasets, and fine-tuned using trimodal data. This system has the potential to combine all important feature extraction done by the research mentioned above, including the extraction of vocalization and breathing patterns from audio recording, QRS complex features from ECG, and position and motion from IMU. To the best of our knowledge, our study is the first to access these three modalities jointly on sleep/wake classification. We show superior classification performance using all three modalities compared with any single modality or pairs of modalities combined.

In contributing to neural network (NN) architectures, we explore the benefits of pretraining large scale transformer networks on unlabeled audio, ECG, and IMU data, then finetuning a cross-attention based fusion architecture on a small LB labeled dataset. Unsupervised pretraining involves training a NN on a large, diverse dataset, which enables it to learn generic latent features that can be applied to a wide range of tasks. There is a wide range of pretraining schemes for audio, ECG, and IMU data. Specifically, wav2vec 2.0 (W2V2) [30] showed the benefits of pretraining audio using contrastive loss, achieving state of the art performance in tasks such as automatic speech recognition. Ref. [31] combined W2V2 and contrastive multi-segment coding to pretrain on ECG signals, achieving outstanding performance on cardiac arrhythmia classification and patient identification. LIMU-BERT [32] is derived from bidirectional encoder representations from transformers (BERT) [33], and is used to pretrain transformers with unlabeled IMU data. Inspired by the above architectures, we pretrained three branches of large scale transformer networks, one for each modality, and were able to extract latent features useful for sleep/wake classification.

To utilize features from all three modalities, we implemented a fusion strategy that relies on cross-attention among transformer layers. Multimodal fusion is often done by early fusion, where the input from each modality is concatenated and fed into the network as a single input, or late fusion, where each modality is processed separately and the outputs are combined at the final stage. We define early fusion as fusing right after feature extraction and not fusion of raw data. Much work has been done on these 2 fusion techniques. Ref. [34] employed early fusion by cascading learned features from ECG and IMU directly, and passed them through a dense network. Ref. [35] described a simple late fusion of different branches by summing or averaging the logit outputs. Recently, intermediate fusion has become more common. This type of feature fusion happens in the middle of the NN, and uses a variety of architectures depending on the tasks. Ref. [36] extensively used so-called "cross-stitch" modules for soft parameter fusion, taking multiple linear weighted sums of each feature extraction layer as input for the next layer. Cross-attention based fusion techniques were explored in recent papers such as [37] [38], where the attention layers take concatenated features from different modalities as input, and [39], where a single cross-attention layer is used to share information between branches. Our approach is innovative, in that we fuse the three transformer networks by alternating self and cross-attention at different layers, which both preserves each branch's transformer features and incorporates attention from other modalities.

In sum, in addition to being the first study to combine audio, ECG, and IMU for classification of infant sleep/wake states, we develop an innovative cross-attention based fusion for large scale pretrained transformer networks to combine three modalities. We not only reiterate the well known benefit of pretraining, but also demonstrate the ability of transformers to be trained using cross-attention-based multi-modal fusion to improve accuracy. We believe our work lays the groundwork for improved accuracy in a wide variety of signal processing tasks by the use of multimodal wearable devices such as LB.

II. Method

Our architecture is an ensemble of three similarly structured transformer networks, with each branch targeting audio, ECG, or IMU data respectively, as shown in Fig. 2.

For the audio branch, we utilize a standard 12-layer W2V2 [30] network because W2V2 repeatedly shows superb performance in various speech-related tasks such as automatic speech recognition and phoneme recognition. A recent study [40] showed an oracle W2V2 pretrained on 4300 hours of unlabeled infant-family audio data collected by LB or the Language ENvironment Analysis (LENA) system [41] increased performance of speech diarization and vocalization type classifications. As infant vocalization features may well include cues of sleep, we adopt pretrained weights from [40] for the audio W2V2 branch.

As for ECG data, we were inspired by the similarity between speech and ECG. As early as 1940, researchers [42] were

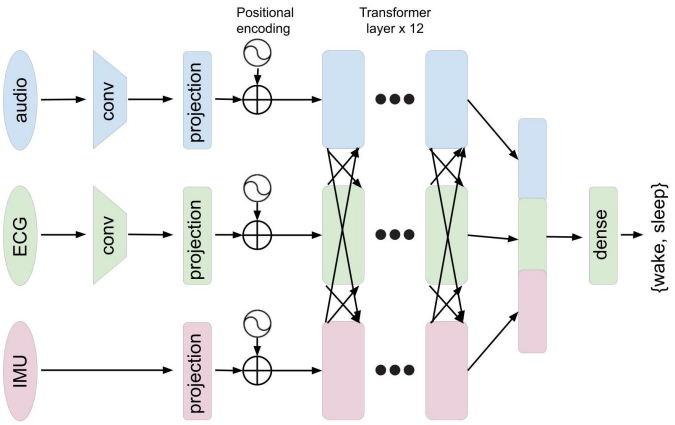

Fig. 2. The LittleBeats Model Architecture. Each of the audio (top), ECG (center), and IMU (bottom) branches consists of feature extraction (convolutional and/or feedforward projection), positional encoding, and 12 transformer layers. Each branch is pretrained individually on unlabeled data. During labeled finetuning, the three branches are combined via cross-attention at the feature level. Their outputs are then concatenated and fed into dense layers to output logits.

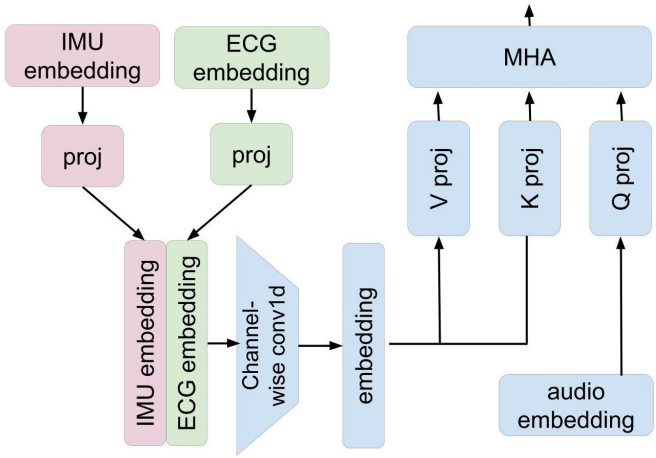

Fig. 3. Cross-attention for the audio branch. Multiheaded attention layer (MHA) takes the audio embedding as query. IMU and ECG outputs from the other two branches first get linearly projected and concatenated into a 2-channel embedding. The embedding is reduced to 1-channel by a 1-d convolution layer and passed into MHA as key and value.

actively using impulse trains to imitate glottal excitation for speech generation. R-peaks in ECG data have a similar time domain structure, so a speech-centric NN should be able to learn ECG features. Speech and ECG differ in one respect: speech contains periodicity at many frequencies (pitch and formants), while ECG is dominated by the inter-beat interval, therefore ECG features may be learnable using less pretraining than speech. We pretrain a standard 12-layer W2V2 using 574 hours of unlabeled ECG data to utilize our observations above and to match the structure of the audio branch.

IMU data does not share similar structure as audio or ECG: an IMU signal is composed of parallel 3-axis accelerometer and 3-axis gyroscope signals, whose correlations are important for signal interpretation. To take full advantage of the information contained in our IMU data, we used a pretraining paradigm based on LIMU-BERT [32]. In place of W2V2's CNN feature extraction layers, LIMU-BERT begins with a single fully-connected feature projection layer per input sample, followed by several layers of transformers. This network is pretrained with Masked Language Model objectives and a Span Masking mechanism. We pretrained 574 hours of IMU data collected from LB, on a modified LIMU-BERT architecture where we lifted the restriction that all transformers share weights, extended the number of layers to 12, and matched the transformer implementation to the one found in W2V2.

To maximize the model's ability to learn across modalities, or to extend the transformer attention beyond a single modality, we utilized linear transformation and cross-attention every 4 transformer layers, as inspired by [43] and their work using cross-attention across audio channels. An example of the cross-attention mechanism for the audio branch is shown in Fig. 3. A cross-attention layer for the audio branch consists of multiple cross-attention heads, each of which takes its query from the previous layer's audio embedding, and its values and keys from a fusion of the previous layer's ECG and IMU branches. ECG and IMU embeddings are first each passed through a linear projection layer, producing outputs with the same embedding dimension as audio, then concatenated to create a 2 channel embedding. A channel-wise 1d convolutional layer is then used to create the vector that serves as key and value of the audio cross-attention layer. The multiple audio cross-attention heads are then concatenated, added to a residual connection (from the previous audio layer), normalized, and passed through a feedforward layer. The ECG and IMU cross-attention layers have the same architecture, with each modality receiving query inputs from its own previous layer, while each modality's key and value inputs come from the other two modalities.

Mathematically, we can denote each hidden input embedding to the transformer layer as $\mathbf{H}_k \in \mathbb{R}^{N \times L_e}$, where the indices (k, l, m) are any permutation of $\{\text{audio}, \text{ECG}, \text{IMU}\}$, N is the number of samples in the input, and L_e is the architecture embedding size. Let's define the query, key, and value projection of each branch to be $\mathbf{W}^{\{Q,K,V\}} \in \mathbb{R}^{L_e \times L_e}$. Let's constrain the discussion of attention regarding one head of one branch where $k = \text{audio}$. The attention layers can be self attention or cross-attention depending on the layer index i. We found using cross-attention at layers 1, 5, and 9 (i.e. $i\%4 = 1$ for layers $0 \leq i \leq 11$) gives the best performance.

$$\text{SelfAttn}_{i,k} = \text{softmax}\left(\frac{\mathbf{H}_k\mathbf{W}_i^Q\left(\mathbf{H}_k\mathbf{W}_i^K\right)^T}{\sqrt{L_e}}\right)\mathbf{H}_k\mathbf{W}_i^V$$

$$\text{CrossAttn}_{i,k} = \text{softmax}\left(\frac{\mathbf{H}_k\mathbf{W}_i^Q\left(\mathbf{H}_{\text{cross}}\mathbf{W}_i^K\right)^T}{\sqrt{L_e}}\right)\mathbf{H}_{\text{cross}}\mathbf{W}_i^V$$

$$\mathbf{H}_{\text{cross}} = \mathbf{A}\begin{bmatrix}\text{proj}(\mathbf{H}_l^T)\\ \text{proj}(\mathbf{H}_m^T)\end{bmatrix}$$

where $\mathbf{A} \in \mathbb{R}^{L_e \times 2}$ is a trainable mixing weight. This discussion is applicable to the other heads and other branches.

The three branches' outputs are concatenated and passed through three dense layers with ReLU activations to produce binary logits for sleep and wake. With the pretrained weights loaded onto each branch and the ensemble in place, we use frame-wise cross entropy loss to finetune the network.

III. Experiment

A. Dataset

Participants were recruited via study flyers distributed to local community organizations as well as online listservs serving families of young children. In the context of larger studies of child behavioral development, study coordinators provided participating families with a LB or LENA kit, along with instructions for conducting associated recordings in the home. Families were asked to complete 2 to 3 daylong (8+ hours) recordings over a 2-week period. All study procedures were approved by the Institutional Review Board at the University of Illinois Urbana-Champaign.

Unlabeled data included (a) 4300hr of audio home recordings (1000hr collected by LB and 3200hr by LENA) from 245 families with children under 5 years of age (see [40] for further details), as well as (b) 574hr of ECG data and (c) 574hr of IMU data collected by LB from 28 families with children (54% female) under 5 years of age (Mean = 26 months, Range: 3-65 months). For the labeled data, we gathered 68.5hr of synchronized audio, ECG, and IMU data from the same 28 families. Four human annotators labeled infant sleep and wake states from 1.5hr segments of LB audio files. Annotation of sleep states was facilitated by referring to (a) parental reports of their child's activities while wearing the LB device in the home, (b) visual inspection of the wav form of the audio file, and (c) listening to audio recordings for indicators of infant sleep (e.g., slowed steady breathing, no vocalizations or movement). Human annotators were trained by the third author and achieved high inter-observer reliability on set of training tapes ($>$ 80 percent agreement). Annotators took detailed notes about any files where they had low confidence in identifying sleep versus wake states. All low-confidence files were reviewed by the team and third author; in these cases, the final labels were made by consensus, thus increasing confidence regarding reliability of the labels. Although PSG and EEG are the gold-standard for sleep detection, we did not collect these measurements in the current study. We are currently extending the work reported here, however, using PSG labels obtained during a laboratory sleep study among adult patients.

We randomly divide the labeled data into training set (50hr, 25 families), validation set (4.5hr, 1 family), and testing set (14hr, 2 families). Data from families/infants in the training, validation, and testing datasets did not overlap.

B. Data Preprocessing

As a first step, we synchronized data across modalities. LB records each modality in slightly different time segments. For each segment, LB records the timestamps in absolute UTC start time and end time, and the associated start and end sample index. Formally, let's define

$$\mathbf{T}_k^{\text{start}}, \mathbf{T}_k^{\text{end}}, \mathbf{S}_k^{\text{start}}, \mathbf{S}_k^{\text{end}} \in \mathbb{R}^{L_k}$$

where for each modality, each element in $\mathbf{T}$ is the absolute UTC start or end time, each element in $\mathbf{S}$ is starting or ending data sample index, L is the number of data chunks.

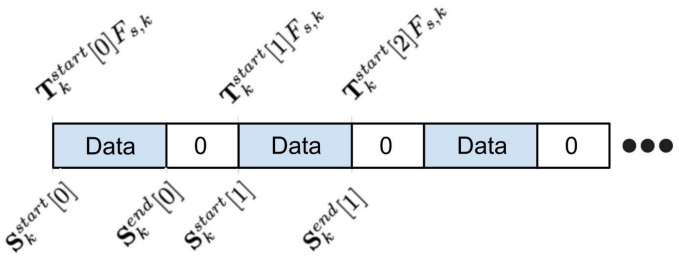

Fig. 4. Zeroing data according to timestamp. For each data segment, the recorded UTC time multiplied by sampling frequency ($F_{s,k} * (\mathbf{T}_k^{\text{end}}[i] - \mathbf{T}_k^{\text{start}}[i])$) is longer than the recorded number of samples ($\mathbf{S}_k^{\text{end}}[i] - \mathbf{S}_k^{\text{start}}[i]$). The missing data are simply filled with zeros.

LB is designed to function continuously despite variability in the number of nonzero IMU samples, therefore it sometimes fails to record all samples in a given audio or ECG segment. Such missed samples can be detected by comparing the known ground truth duration of a segment, $F_{s,k} * (\mathbf{T}_k^{\text{end}}[i] - \mathbf{T}_k^{\text{start}}[i])$, to the number of samples it contains, $(\mathbf{S}_k^{\text{end}}[i] - \mathbf{S}_k^{\text{start}}[i])$, where $F_{s,k}$ is the sampling frequency for modality k. When an incomplete segment is detected, we fill in the missing data with zeros. We obtain $\hat{\mathbf{Z}}_k$ where each of the vectors has length $F_{s,k} * (\mathbf{T}_k^{\text{end}}[i] - \mathbf{T}_k^{\text{start}}[i])$. This is shown in Fig. 4.

Timestamps of different modalities are approximately but not precisely aligned, because the writing to SD card on LB is asynchronous. In order to make multimodal processing possible, we simply discard the data that did not overlap according to the timestamp and truncate $\hat{\mathbf{Z}}_k$ to $\mathbf{Z}_k \in \mathbb{R}^L$ where L is the same across all modalities. $\mathbf{Z}_k$ is then segmented into 30s segments $\mathbf{X}_k$.

Human annotators mark the beginning and ending of each period of sleep. These times are used to assign, to each 30s segment $\mathbf{X}_k$, a binary label $\mathbf{Y}_k \in \{0, 1\}$ where 0 is wake and 1 is sleep. If both sleep and wake labels are present in segment k, $\mathbf{Y}_k$ is set equal to the label with longer duration.

C. Metric

Because this is a binary classification task, we evaluated standard accuracy, precision, recall, F1-score, and Cohen's kappa κ.

D. Implementation Details

Audio sample rate is downsampled from 24000Hz to 16000Hz and ECG sample rate is upsampled from 2381Hz to 16000Hz, to match the default sampling rate of W2V2. IMU data are kept at a sampling rate of 150Hz because upsampling to 16000Hz might introduce too many artifacts. We did not

experiment with data interpolation to fill out the zeros during time synchronization nor with data augmentation to diversify the data.

For audio and ECG W2V2 branch, we used almost the same baseline structure as described in [30], with 12 transformer layers, hidden size 768, intermediete size 3072 and 16 attention heads. Convolution feature extraction structure remain the same with hidden size 512, kernel size [10,3,3,3,3,2,2] and strides [5,2,2,2,2,2,2]. For IMU branch, the feature extraction is done by a linear layer, a normalization layer, and adding a position embedding. The decoding part has 12 transformer layers, hidden size 72, intermediate size 144 and 4 attention heads. Outputs of the three branches are concatenated into a vector of size 1608, passed through a dense structure as follows: a linear layer from size 1608 to size 1608, ReLU, linear layer from size 1608 to 804, dropout of rate 0.1, linear layer from 804 to 2.

We found empirically that training becomes unstable when the attention layers are loaded with pretrained weights, so during finetuning, our code only loads the pretrained weights from the feature extractor up to positional encoder. The attention layers are initialized by default with HuggingFace.

Each experiment was run for 2 epochs with batch size 16, with the standard Adam optimizer. This was done on a single RTX A6000 GPU. Training code was based on Huggingface Transformers and the code is available for inspection and further development. [1]

E. Baseline Implementation

The majority of sleep/wake classification baselines did not release code, so we implemented some of their algorithms with modification based on their description in the paper. Specifically, for [25] we replaced the respiratory input with LB audio data, and trained with gradient descent instead of Levenberg–Marquardt back-propagation algorithm. For [23], we used increasing strides ([1, 2, 3, 4, 5, 6]) for the CNN layers instead of using [2, 2, 2, 2, 2, 2] because each LB ECG segments has more samples than theirs. We also modified the dropout value to 0.1 based on empirical testing. [26] used 3-axis acceleration and heart rate data collected on Apple Watch as their dataset. We calculated heart rate at each recorded segment from LB ECG data, using the python package HeartPy. We then input our timestamp, acceleration data, and calculated heart rate to their released code. Finally, state of the art sleep stage classifier [29] released their code online. We used ECG as input to the model instead of EEG in the original paper.

IV. RESULTS

A. Benefits of Three Modalities

The first section in Table I shows how using all modalities together compares to using each of the modalities alone for the purpose of sleep/wake classification. The single modality architecture takes each branch in Fig. 2, with pretrained weights, and adds the final three FC layers for classification. The proposed architecture is the entire model pretrained on unlabeled data and finetuned with proposed cross-attention at every 4 layers. We see that, by quite a large margin, using all three modalities together as proposed, the network is able to learn more about infants' sleep patterns and achieve better performance across the board than using just a single modality. Note that while recall for the ECG branch outperforms the proposed network by 5%, its precision is lower by 20%, suggesting that the unimodal ECG network is a worse classifier since it too frequently classifies segments as "sleep."

The second section in Table I presents results of key baseline implementation on the LB dataset, as described in Section III-E. Because [25] and [23] have not released their code and [26] and [29] are not designed to work strictly on ECG data, results need to be interpreted with caution. However, we can still observe that our proposed model using all three modalities

TABLE II
RESULTS WHEN PRETRAINING DIFFERENT BRANCHES OF THE ARCHITECTURE. FIRST COLUMN INDICATES THE BRANCH LOADED WITH PRETRAINED WEIGHTS.

Pretrained	↑ Accuracy	↑ Precision	↑ Recall	↑ F1	↑ Kappa
-	0.797	0.829	0.850	0.839	0.565
IMU	0.837	0.874	0.863	0.868	0.655
Audio+IMU	0.871	0.858	**0.949**	0.901	0.715
ECG+IMU	0.875	0.866	0.944	0.904	0.726
All	**0.880**	**0.881**	0.934	**0.907**	**0.741**

TABLE III
RESULTS OF EARLY, LATE, AND THE PROPOSED FUSION TECHNIQUE

Fusion	↑ Accuracy	↑ Precision	↑ Recall	↑ F1	↑ Kappa
Early	0.779	0.857	0.773	0.813	0.544
Late	0.798	0.781	**0.947**	0.856	0.530
Proposed	**0.880**	**0.881**	0.934	**0.907**	**0.741**

outperforms all key baselines, which only use one or two modalities.

Numbers in the last section in Table I are results reported in other papers, using other datasets, and are therefore not strictly comparable to the numbers in the first two sections. The classifiers summarized by these results are sleep/wake classifiers using audio only [24], ECG only [23], ECG and respiratory signals [25], motion [21], and ECG and IMU [26]. While all datasets are different and comparison of the accuracies is therefore not theoretically justifiable, such a comparison nevertheless supports the conclusion displayed in the top half of the table, viz., that sleep/wake classification performed using three modalities is more accurate than sleep/wake classification performed using only one or two modalities.

B. Benefits of Pretraining

Table II shows how pretraining affects the performance of the proposed architecture. Here we configured the model to use the proposed architecture with three branches and cross attention, but only load pretrained weights onto specific branches. Cross-attention is applied at every 4^{th} layer for the 12 layers of transformers. Every time we load pretrained weights for one more branch, we have a performance increase across all metrics. For example, the accuracy is 0.797 when we don't pretrain any of the branches. This increases to 0.837 when we use pretrain weights for the IMU branch. Accuracy further improves when we load pretrain weights of audio and ECG branch. This reinforces our understanding of pretrained networks. By pretraining each branch using the unlabeled data, then fine-tuning the entire system together against a small number of labeled data, we are able to get better performance.

C. Fusion Techniques

Our discussion is incomplete without comparison to early and late fusion techniques discussed in the literature [35]. Table III presents performance of 2 fusion methods against the proposed cross-attention-based intermediate fusion technique.

TABLE IV
RESULT WITH CROSS-ATTENTION APPLIED AT VARIOUS LAYERS. THE EQUATION IN THE FIRST COLUMN SPECIFIES THE LAYERS IN WHICH CROSS-MODAL ATTENTION IS APPLIED, E.G., $i\%4 = 1$ MEANS THAT CROSS-MODAL ATTENTION WAS PERFORMED IN LAYERS 1, 5, AND 9, WHERE LAYERS ARE NUMBERED $0 \leq i \leq 11$.

Cross	↑ Accuracy	↑ Precision	↑ Recall	↑ $F1$	↑ Kappa
None	0.765	0.788	0.851	0.818	0.487
i%2=1	-	-	-	-	-
i%4=1	**0.880**	**0.881**	**0.934**	**0.907**	**0.741**
i%6=1	0.836	0.870	0.865	0.868	0.652
$0 \leq i < 4$	0.755	0.811	0.791	0.801	0.484
$4 \leq i < 8$	-	-	-	-	-
$8 \leq i < 12$	-	-	-	-	-

Early fusion is inspired by [34], where convolutional features extracted from ECG and IMU data are concatenated with anthropometric data as input to a downstream neural network. In our variation, we concatenate the three outputs from the feature extractor for each branch as shown in Fig. 2, skipping the transformer layers, and pass through the dense network for fine-tuning. As for late fusion, we leave in the transformer layers, triplicate the FC layers to generate logits for each modality, and average the three logits for evaluation. The proposed cross-attention fusion achieved better performance in almost every metric except that it has a lower recall than late fusion. Similar to the trend found in Table I, this high recall for late fusion results from a disproportional confusion matrix, as shown by late fusion's low precision score. Therefore, the proposed fusion architecture is still favorable in general.

D. Ablation Study

Table IV shows the effect of using cross-attention at different layers. All models were fine-tuned on labeled multimodal data after loading pretrained weights for all three modalities separately. "-" means the architecture did not converge. We empirically found that cross-modal attention once every 4 layers ($i\%4 = 1$) gives the best performance across the board. Many models with cross-modal attention fail to converge: convergence failure occurs with cross-modal attention every second layer, and with cross-modal attention in the middle four layers ($4 \leq i < 8$) or the last four layers ($8 \leq i < 12$). Cross-modal attention in the first four layers ($0 \leq i < 4$) converged to a system with accuracy lower than that of the system with no cross-modal attention. The sensitivity of cross-modal attention to architectural configuration was an unexpected result. We defer this to future studies.

V. CONCLUSION

With the development of multi-modal wearable devices, we are able to gather synchronized audio, ECG, and IMU data for the task of infant sleep/wake classification. We demonstrated the best classification performance when using all three modalities compared with our own single modality network or single/double modality network found in the literature. In addition, we developed an ensemble of large scale pretrained

transformer neural network, by fusing the transformer layers with cross-attention at every 4 layers. This fusion method is not limited to the task of wake/sleep classification, but seems likely to generalize successfully to any multi-modal network in which all modalities have the same number of transformer layers. Our work presents exciting directions for multi-modal studies of infant and child development.

ACKNOWLEDGMENT

We would like to thank the families who participated in this research, as well as Jordan Bodway and Jenny Baldwin for their assistance with data collection and processing. This work was supported by funding from the National Institute of Mental Health (R21MH112578), National Institute of Drug Abuse (R34DA050256), the National Institute of Food and Agriculture (ILLU-793-368), and the Personalized Nutrition Initiative and Center for Social and Behavioral Science at the University of Illinois at Urbana-Champaign through the Seed Grant program.

***Abstract*—To further reduce the number of traffic accidents, it has been necessary in recent years to develop advanced driver assistance systems with functions that provide optimal assistance based on driving performance. Recent studies have used electroencephalogram (EEG) to comprehensively evaluate the complex neural process of visual, perceptual, attentional, and motor functions. Microstate analysis, which reflects the interactions of global neural networks by measuring the temporal transition of brain activity, is widely used to capture complex cognitive processes. In this context, we hypothesized that microstate analysis is a suitable method for capturing driving-experience-dependent performance using EEG. To prove our hypothesis, we evaluated the EEG data of novice and expert drivers while they viewed driving scenes using microstate analysis to detect driving-experience-dependent performance using EEG. The results showed that the dynamic characteristic of EEG concerning driving-experience-dependent performance reflected efficient cognitive control and suppressed redundant bottom-up attention. This finding may be widely utilized for estimating the driving-experience-dependent performance of advanced driver assistant systems.**

I. Introduction

Recent advancements in supporting technologies for intelligent transportation systems, such as forward collision warnings, advanced emergency braking systems, and driver monitoring, have aided in reducing traffic accidents [1]–[6]. Developing driver assistance systems with functions optimized for driving performance-dependent assistance is needed to further reduce the number of traffic accidents [7], [8].

Pupillometry and visual attention are the most prominent approaches for evaluating driving performance using eye-tracking sensors. According to studies using pupillometry, pupil diameter variations can detect driver fatigue [9], [10]. In addition to pupillometry studies, visual attention studies have shown that driving performance can be determined by the duration and number of fixations on objects such as main road areas, cars, and pedestrians [11], [12]. However, these methods have revealed that accurately estimating driving performance is problematic owing to factors such as vehicle vibration, backlights, and traffic signals [13]–[16]. Moreover, recent studies have shown that driving performance is not solely determined by visual information processing, but also by higher cognitive functions, such as decision-making and memory [17]–[19]. Previous studies have shown a strong correlation between driving performance and the neural activity detected by electroencephalography (EEG), magnetoencephalography, and functional magnetic resonance imaging (fMRI) of the brain [20]–[24]. Due to its portability, non-invasiveness, and high temporal resolution, EEG is widely used to capture brain activity during driving [25]–[27]. Therefore, EEG, which can detect neural activity directly from the brain, may provide a comprehensive assessment of complex neural processes involving vision, perception, attention, and motor functions.

Functional connectivity, which reflects the integration of information processing between brain regions as a pair-to-pair interaction of neural activities, is a method for evaluating driving performance using EEG. [26], [28], [29]. Specifically, methods focusing on functional connectivity have revealed the network characteristics of neural activity related to driving performance that are affected by fatigue, drowsiness, and driving skill level [26], [28], [29]. Using the phase lag index (PLI), which achieves high spatial resolution by avoiding volume conduction, a previous study showed that the driving experience enhances neural pathways in a gamma-band functional network supporting visual perceptual functions [26]. However, it has been pointed out that this assessment method, based on long-term temporal averages in the PLI, is inadequate for capturing dynamic network activity during driving, which is strongly associated with cognitive processes. [26], [30].

Microstate analysis, which focuses on the quasi-stable spatial patterns of EEG, effectively captures dynamic brain activity during driving [31], [32]. This method, which simultaneously considers signals from all electrodes, can capture the interactions of global neural networks by measuring temporal transitions [32]–[34]. Specifically, these microstate transitions have been shown to reflect lethargy- and fatigue-related neural network characteristics that affect driving performance [30], [35]. In this context, we hypothesized that microstate analysis,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

which allows for the comprehensive detection of the interactions of global neural networks, is a suitable method for detecting moment-to-moment dynamics of brain activity related to driving performance, depending on driving experience as related to skill level using EEG. To prove this hypothesis, we evaluated the EEG data of novice and expert drivers while they viewed driving scenes using microstate analysis to detect driving experience-dependent EEG performance.

II. Methods

A. Participants

The EEG data were measured at the Department of Robotics Science and Technology, Chubu University, Japan. Among the 15 participants, all were healthy individuals aged 20 to 23 (comprising 1 female and 14 males). They either had natural clear vision or had it corrected to the standard using glasses or contact lenses, and each held a valid driving license. Based on their driving performance, participants were classified as novice or expert drivers. Driving frequency was used to evaluate driving performance. Participants who drove less frequently than once every two weeks were classified as the novice group, while those who drove more frequently than once every two weeks were classified as the expert group. The groups of novices and experts consisted of eight and seven members, respectively. In this study, participants were guided to view the traffic situations as though they were on their regular commute, to gauge an authentic understanding of the driving surroundings. All procedures were conducted in accordance with the principles of the Declaration of Helsinki. The study protocol was approved by tthe Ethics Committee of Chubu University. All the study participants provided informed consent. The EEG data used in this study were evaluated using the PLI and power analyses [26], [27].

B. EEG Recording and Data Preprocessing

EEG data were measured using a 21-channel system (EPOC+ produced by Emotive) at 14 electrodes (AF3, AF4, F3, F4, F7, F8, FC5, FC6, P8, P7, T7, T8, O1, and O2) in accordance with the international 10-20 system, with the two ear lobes jointly forming the reference [36]. The participants were measured for 2–3 min while sitting 60 cm away from a monitor (1920 $\times$ 1080 pixels) and watching a driving scene filmed with a video camera. The video was filmed on a highway. The scenes involve other vehicles in the same or side lanes (passing lane), signals (red, yellow, and green), road signs, pedestrians, intersections, crosswalks, highway ramps, and cars stopping at the red signal. The video only captures the forward perspective from the car's camera, excluding views from the side and rear mirrors. In a previous study, we revealed that a difference in the EEG power spectrum and PLI between expert and novice drivers can be detected through the length of the video stimulus [26], [27]. Therefore, we consider that 2 to 3 min is an appropriate movie length to evaluate the microstate considering the dynamic characteristics of EEG that are attributable to driving performance. The sampling frequency was 128 Hz. Throughout the experiment, the saline solution sustained the electrode impedance within the necessary $10\,\mathrm{k}\Omega$ to $20\,\mathrm{k}\Omega$ range, as required by the recording software. EEG data underwent artifact subspace reconstruction (ASR) to eliminate disturbances from headset movement, eye blinking, eye motion, and activity from neck and scalp muscles. Open-source MATLAB scripts to execute ASR can be found as plug-in functions for clean_rawdata in EEGLAB [37]. In this study, we used the cutoff parameter, defined as the rejection thresholds with standard deviations of $SD20\%$ to identify artifacts.

C. Microstate Analysis based on Amplitude Distribution

In this study, we employed the dynamic attributes of instantaneous amplitudes within EEG signals to categorize different brain activity states. The process for estimating instantaneous amplitude dynamics is indicated in Fig.1 (a). First, the EEG data was applied by bandpass filtering within the amplitude spectrum of 2-20 Hz [38], [39]. Next, we applied the Hilbert transform to determine the instantaneous amplitude $\theta(t)(-\pi \leq \theta \leq \pi)$ of the EEG signals. And this amplitude was converted from the mean across all electrodes to the deviation $dIA_i(t)$, where i represents the electrode position. To identify a microstate characterized by a specific spatial power distribution, we computed the global field power (GFP) based on the spatial variance among the electrodes. The spatial power distribution, corresponding to the GFP's local peak, was extracted from the $dIA_i(t)$ time series [40], [41]. As shown in Fig.1 (b), the $dIA_i(t)$ set at the GFP's local peak for both novice and expert drivers was grouped into k clusters via the k-medoid technique. Because of the small number of electrodes, this study used a cluster size of $k = 2$. By employing this approach, we hypothesized that dynamic state transitions reflected the evolving neural connections across the entire brain network [42], [43]. Furthermore, we valuated the probability of state transitions between the applied microstates using the k-medoids method.

D. Statistical Analysis

We performed a paired t-test to assess the differences in state transition probabilities between novice and expert drivers. The t-scores applied correction using the Benjamini-Hochberg false discovery rate method for multiple comparisons (involving four p-values). We defined the significance threshold at q <0.05.

III. Results

We estimated the characteristics of state transitions from the distribution of instantaneous amplitudes in EEG recordings taken from novice and expert drivers as they observed a highway driving scene. Figure 2 shows the average time for the $dIA_i(t)$ duration of each state classified by k-medoids for novice and expert drivers. For both groups, the frontal-specific activated state was identified in state #1 and the occipital-specific activated state in state #2. These microstates reflect the bottom-up and top-down neural activities involving visual attention, respectively [44], [45]. In addition, to evaluate the state transitions among the activated states in Fig.2 from

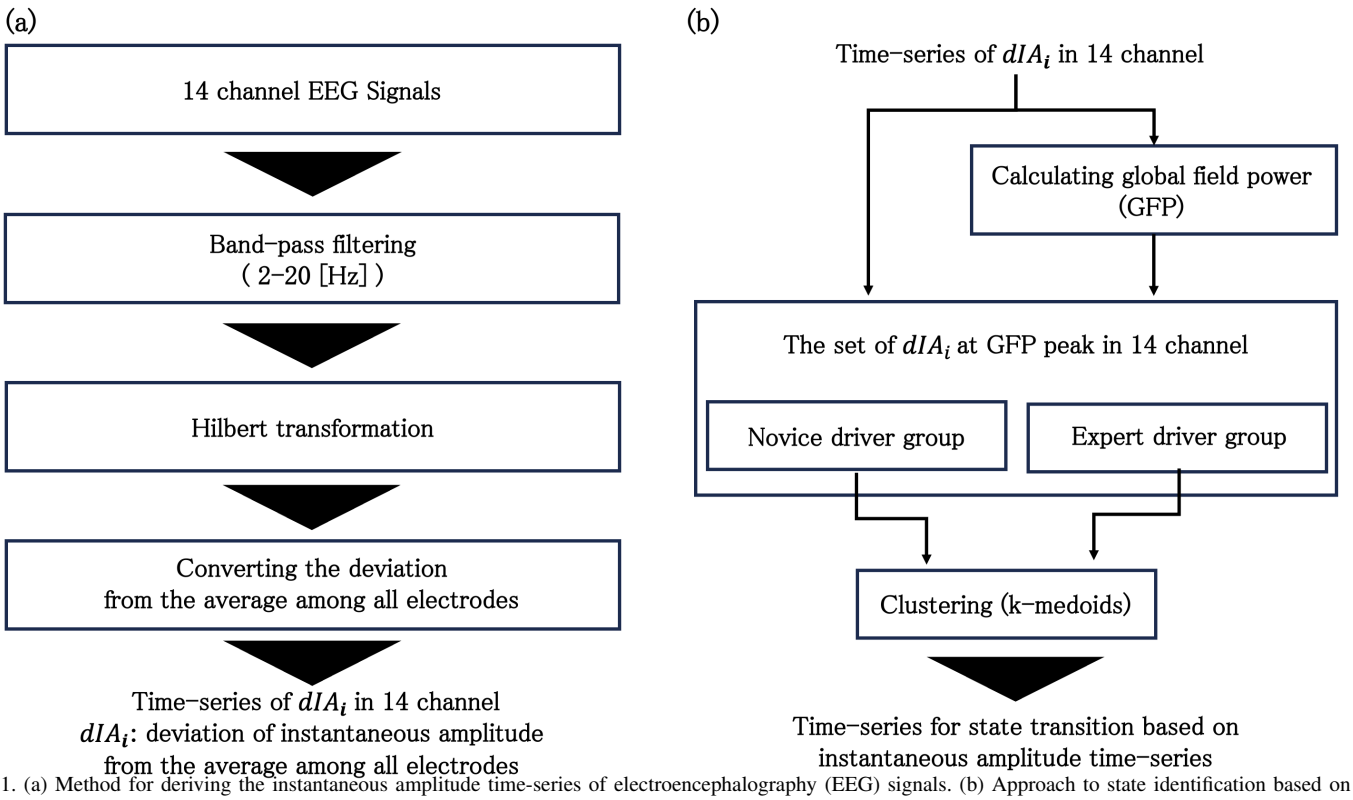

Fig. 1. (a) Method for deriving the instantaneous amplitude time-series of electroencephalography (EEG) signals. (b) Approach to state identification based on the instantaneous amplitude time-series of EEG signals, as revealed in our preceding publication

source to destination, Figure 3 (a) and (b) show the average of these state transition probabilities for novice and expert drivers. Figure 3 (c) shows the t-values of the state transition probabilities between novice and expert drivers. For the expert driver, the state transition from states #2 to #1 ($t = -3.569$ (p = 0.006 ($q < 0.05$))) was significantly lower, whereas the state transition from states #1 to #1 ($t = 3.569$ (p = 0.006 ($q < 0.05$))) was significantly higher.

IV. Discussion

In this study, we evaluated the EEG data of novice and expert drivers while watching driving scenes, using microstate analysis to detect driving performance, including driving experience. Resultantly, for both groups, the frontal-specific and occipital-specific-activated states were identified in states #1 and #2, respectively. For the expert driver, the state transition probability from #2 to #1 is significantly lower, whereas the state transition probability from #1 to #1 is significantly higher.

First, we considered why expert drivers are more active in the frontal cortex than novice drivers. Recent studies have shown that neural activity in the frontal cortex is strongly related to cognitive control during driving, including visual attention movements, decision-making, and action planning for driving behavior [46], [47]. In particular, a previous study using fMRI showed that expert drivers had more significant activation in the frontal lobe during driving than novice drivers [48]. These activated neural activities are considered when expert drivers perform cognitive control, such as visual attention movements and decision making, more efficiently than novice drivers based on their driving experience [49]–[51]. Therefore, the results of this study (Figs.3(c)) may reflect the neural activity of efficient cognitive control in expert drivers.

Second, we considered why expert drivers suppressed occipital-to-frontal transitions more than novice drivers. In previous studies, expert drivers were considered to suppress bottom-up attention because of the control of attentional functions by the frontal lobe [48], [52]. Panos *et al.* revealed that expert drivers perform efficient visual searches to anticipate danger, whereas novice drivers perform inefficient visual searches such as missing important objects or fixating on unimportant objects [50]. These differences in visual characteristics suggest that expert drivers can prioritize the visual area where hazards are most likely to occur based on past driving experience [53], [54]. Therefore, the results of this study (Fig.3(c)) may reflect the neural activity of suppressed redundant bottom-up attention of expert drivers.

Third, this study had some limitations. Although this study revealed the characteristics of microstates related to driving experience, the number of participants was small. Therefore, further studies with larger sample sizes are required. Additionally, previous studies using EEG power analysis evaluated the driving performance while viewing three different types of driving scenes (traffic jams, urban areas, and highways) [27]. However, in this study, the evaluations were conducted only while viewing highway driving scenes. It is important to address these element in the future to provide an in-depth

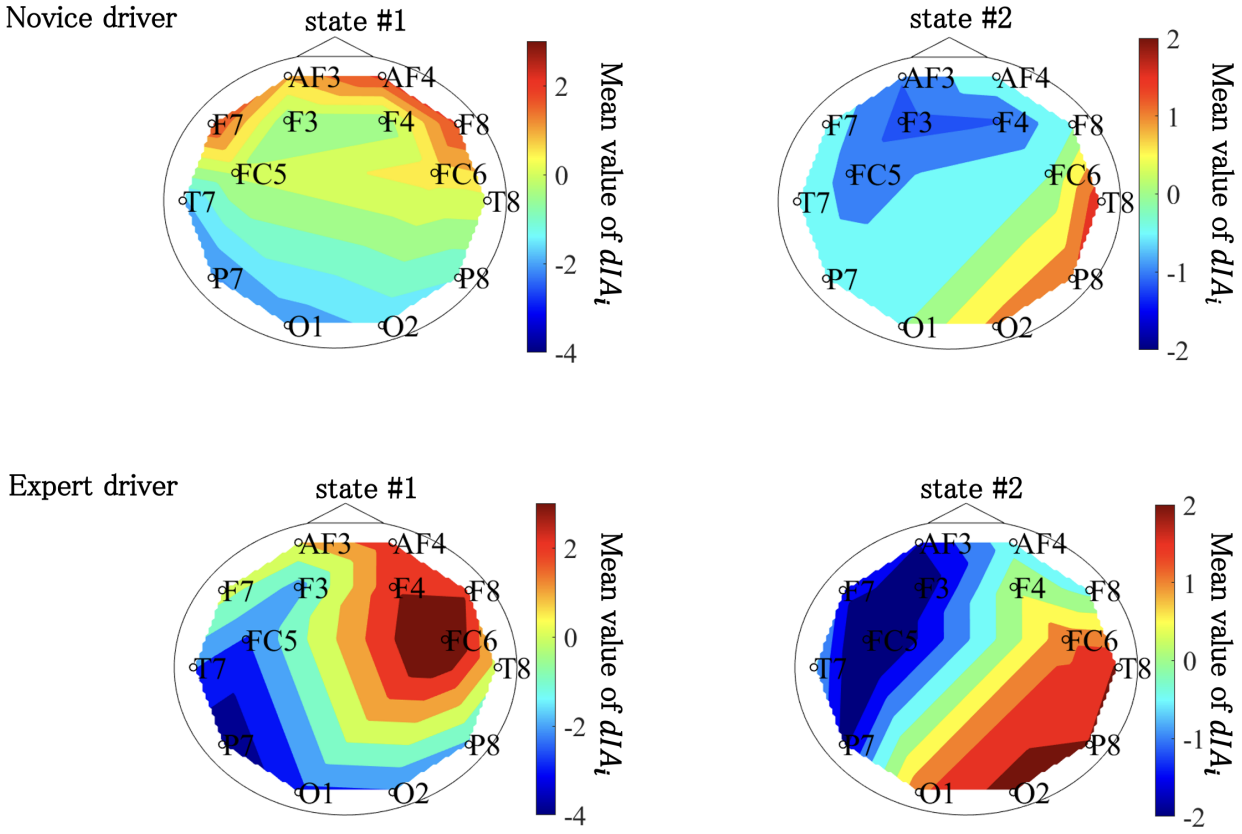

Fig. 2. Time average of $dIA_i(t)$ among all electrode durations of each state classified by k-medoids for novice and expert drivers while watching a driving scene of a highway

understanding of driving-experience-dependent performance with high accuracy in divergent situations. Additionally, this study was based on the hypothesis that driving performance, depending on driving experience related to skill level, may be reflected by the interactions of the global neural network. The EEG of the 14-electrode system used in this study is sufficient to reflect global neural network interactions, but insufficient to focus on local neural network interactions [42], [55]. Therefore, it is necessary to increase the number of electrodes and focus on local dynamics to more accurately reflect the driving experience-dependent performance from brain activity. In addition, because of the small number of electrodes used in this study, we defined two activation states to evaluate the state transitions. However, this is fewer than the number of state definitions in a general microstate analysis [32], [38]. Therefore, in this study, the results of the state definitions were not stable between expert and novice users. In the future, we intend to increase the number of electrodes and evaluate the state transitions by defining four activation states as a representative classification for microstate analysis.

In conclusion, this study identified the dynamic characteristics of EEG concerning driving experience-dependent performance, reflecting efficient cognitive control and suppressing redundant bottom-up attention. Despite the limitations of this study, this finding may be utilized to estimate driving experience-dependent performance in advanced driver assistance systems.

Quefrency Domain Features with Residual Networks for Spoof Speech Detection

Madhu R. Kamble
Samsung Research and Development Institute, Bangalore (SRI-B), India.
E-mail: madhu.r@samsung.com

***Abstract*—Despite of having such high-end solutions for spoof speech detection task, generalization approach to the unseen and convolutive complex signals still remains a challenge? The solution should handle the complexity of signals for both replay and synthetic speech signals. The objective of this paper is to extract robust quefrency-domain features along with residual networks for SSD. In particular, we focus on the replay signal that carries the characteristics of the intermediate recording and playback device and hence, the end result is the summation of the complex signal. This makes the signal very challenging and thus, the features must be capabale enough to discriminate the differences. With the recent Neural network-based approach the synthetic signal generation are very much similar to the genuine signal which make the SSD task more complicated. We investigate the short-time cepstrum features for the SSD task on ASVspoof 2019 Challenge database. The cepstrogram results on the PA task, indicates that it achieves better performance for the replay detection. For geniune speech signal, the periodic pattern are easilt observed in the cepstrogram that are missing for the replay as well as for SS and VC signals. This observation is also reflected in the performance evaluation resulting in EER of 2.08 % and t-DCF of 0.04 on evaluation set of LA task obtained with LFCC features and Resnet architecture. Whereas, for PA task with cepstrogram features the least EER we achieved is 1.07 % with 0.056 t-DCF, respectively.**

***Index Terms*—Automatic Speaker Verification, Spoof, Quefrency, Cepstrogram.**

I. Introduction

The Automatic Speaker Verification (ASV) system is a biometric speaker authentication to verify a claimed speaker's identity with the help of machines. The biometric traits that have been successfully used in practical application includes voice, face, iris, fingerprint, palmprint, palm/finger vein, etc [1]–[3]. With the recent increasing technological developments, it is possible to generate spoofed data that resembles very close to their natural counterparts. There are several kinds of spoofing attacks for ASV system, such as replay, impersonation, speech synthesis (SS), voice conversion (VC), and twins [4]. Spoofing is used by hackers to achieve numerous goals, such as getting sensitive information from their targets, or gaining access to restricted area. Hence, when it comes to the real world scenario, a generalized solution is needed to prevent from such hackers [5].

Over the past few years, a series of ASVspoof challenges focusing on different types of attacks were developed after every two consecutive years [6]–[8]. The organizers also developed the database as per the recent trends approaching towards the neural netowrk-based algorithm along with high quality gadgets used for the recording and playing back [8].

Researchers are currently focusing on the development of Spoof Speech Detection (SSD) system that are based on neaural network , graph attention, end-to-end system [9]. Recent end-to-end models have shifted fromhand-crafted features such as LFCC [10] and CQCC [11] to rawwaveforms, achieving state-of-the-art performance [12], [13]. Othereffors have focused on training strategies, such as data augmenta-tion [14] and multi-task learning [15]. A simple attention module was proposed in [16] that infers 3-dimensional attention weights for the feature map in a convolutional layer, which then optimizes an energy function to determine each neuron's importance. An attack Agnostic Dataset was introduced as a combination of two audio DeepFakes and one anti-spoofing dataset [17]. To reduce the variance of genuine embedding space, an architecture was designed called as residual variability block, which can be flexibly integrated into usual convolutional neural networks [18]. The multi-path GMM-MobileNet model was proposed in [19], which includes the GMMs trained on genuine and spoofed speech generated using various attack algorithms or codecs.

Despite of having such high-end solutions, generalization approach to the unseen and convolutive complex replay signals along with rapid development of spoof speech synthesis techniques still remains a challenge. Hence, the solution should take care of the complexity of the signals using the neural network back-end but at the same time it should not be the complex architecture that makes it challenging while developing for the applications. With complex architecture the latency period required to provide the results is more also with big models size it will make the application to work very slow. Instend of just running behind to get the good performance on a closed set database one should also think will is the next problem that we will be facing?

In this work, we are focusing on the simple front-end feature extraction approach using a short-time cepstrum (cepstrogram) features in the quefrency domain for the spoof speech detection (SSD) task. In particular, we analyze the quefrency domain representation for the logical as well as for physical access scenarios. We observed that for the replay detection task the short-time cepstrum obtained in the quefrency domain detects the spoof signals better from the genuine data. For the synthetic signal detection the cepstrogram features did not perfrom that

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

well, however for replay signal with Resnet-18 architecture along with softmax, amsoftmax and ocsoftmax loss function thats yeilds better performance for the SSD task. We performed the experiments on the ASVSpoof 2019 challenge database that focuses on the Logical Access (LA) and Physical Access (PA) tasks, respectively.

II. Details of Cepstrogram

Before proceeding in the Quefrency domain, let us operate the signal on the frequency side. Let $x(t)$ be a signal with a simple echo and it can be represented as [20]:

$$x(t) = s(t) + \alpha s(t - \tau). \tag{1}$$

The Fourier spectral density (spectrum) of signal is given by:

$$|X(f)|^2 = |S(f)|^2[1 + \alpha^2 + 2\alpha\cos(2\pi f\tau)]. \tag{2}$$

The spectral density of a signal with an echo has the form of an envelope (the spectrum of the original signal) that modulates a periodic function of frequency [21]. By taking the logarithm of the spectrum, this product is converted to the sum of two components.

$$\begin{aligned} C(f) &= \log|X(f)|^2 \\ &= \log|S(f)|^2 + \log[1 + \alpha^2 \\ &\quad + 2\alpha\cos(2\pi f\tau)]. \end{aligned} \tag{3}$$

Thus, $C(f)$ viewed as a waveform has an additive periodic component. This new *"spectral"* representation domain was not present in the frequency domain, nor in the time domain. Hence, Bogert *'et al.'* choose to refer to it as the *quefrency domain*, and they termed the spectrum of the log of the spectrum of a time waveform the *cepstrum* [20]. We believe that the periodic patterns can be easily observed in the cepstrogram, and therefore argue that cepstrogram can be a powerful feature for the detection task [22].

The power spectral energy density along with spectrogram as well as cepstrogram representation is shown in Figure 1 for genuine and replay spoof speech signal, respectively. A signal with echoes exhibits rahmonic peaks in the quefrency domain, which reflects its pitch in the cepstrum analysis [22]. We cannot observe much of the difference in the spectral energy density between genuine and the spoofed speech. However, when we analyse the cepstrogram for the genuine and replay speech, we can observe that the replay signal have strong and more dominant peaks. From this investigation we can say that when the genuine speech is re-recorded or simulated with reverberation, additional rahmonic peaks are observed in the quefrency domain.

The replay speech signal r(t) can be modeled as the convolution of the genuine speech signal, x(t), and the room impulse response of the propagating environment, and is given by [23]:

$$r(t) = x(t) * h_r(t), \tag{4}$$

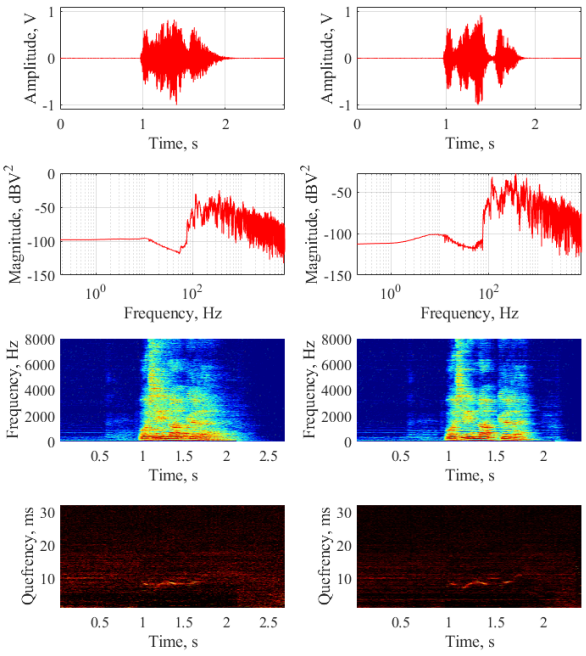

Fig. 1. (a) Time-domain speech signal of natural and replay signal corresponding representation of (b) spectral energy, (c) spectrogram, and (d) cepstrogram.

where the $h_r(t)$ is the convolution of the room impulse response obtained from the recorded room, $h_1(t)$, with room impulse response of the playback room, $h_2(t)$, i.e.,

$$h_r(t) = h_1(t) * h_2(t). \tag{3}$$

First, signals which are combined convolutionally in the time-domain have complex cepstra which are combined additively. As a result, deconvolution is reduced to subtraction in the cepstrum. Second, the complex cepstrum is a measure of the "frequency" of variation (known as quefrency) in the log spectrum, and so signals which vary slowly in the log spectrum may be separated from quickly varying signals by windowing the complex cepstrum [24].

III. Experimental Setup

In this paper, ASVspoof 2019 challenge database is used, which is mainly focused on the Logical and Physical Access (LA and PA) [8]. All the utterances in the database have a sampling rate of 16 kHz, and the resolution of 16-bits per sample. The organizers of the ASVspoof 2019 Challenge provided a baseline system that utilizes two feature sets, namely, CQCC and LFCC with 512 mixtures for modeling genuine and corresponding spoof models in Gaussian Mixture Model (GMM) [10], [11]. The ASVspoof 2019 Challenge uses the minimum Tandem-Detection Cost Function (t-DCF) as the evaluation metric along with EER [25].

We compared five different type of features, namely, Linear Frequency Cepstral Coefficients (LFCC), Constant Q Cepstral Coefficients (CQCC), Teager Energy Cepstral Coefficients (TECC), Gabor Filterbank Cepstral Coefficients (GTFB), and Cepstrogram (CPST). The feature extraction parameters for the same are mentioned below.

LFCC: The LFCC feature set is extracted using 40 linearly-spaced triangular filterbank with F_{min} = 10 Hz, and F_{max} = 8000 Hz with 40 static coefficients, resulting in total 120-D feature vector (including 40- Δ and 40 $\Delta\Delta$) [10]

CQCC: The CQCC features are extracted with a maximum frequency of $F_{max} = F_{NYQ}$, where F_{NYQ} is the Nyquist frequency of 44.1kHz. The minimum frequency is set to $F_{min} = F_{max}/2^9 \simeq 43$Hz (9 being the number of octaves). The number of bins per octave B is set to 96. Only 20 static coefficients (with log-energy) were considered, resulting in total 60-dimensional (D) feature vector (including *20*-Δ and *20*-$\Delta\Delta$) [26].

TECC: The TECC feature set was extracted using 40 Mel-spaced Gabor filterbank with f_{min}=10 Hz, and f_{max}=fs/2 Hz. For each subband filtered signals, we obtain 40-D static features appended along with their Δ and $\Delta\Delta$ coefficients resulting in 120-D feature vector [23], [27].

GTFB: The Gabor filterbank feature set were extracted using 40-dimensional linearly spaced with a maximum frequency of $F_{max} = Fs/2$ and a minimum frequency of $F_{min} = 10Hz$, with Δ and $\Delta\Delta$ resulting in total 120-D feature vector [28].

Here, we explored the two types of back-end classifier along with the above mentioned feature sets to have the better SSD system.

A. Gaussian Mixture Model

Gaussian Mixture Model (GMM) is a more popular and well known classification technique widely used in signal processing and pattern recognition literature. GMM is a generative model, which represent each class as a weighted sum of *M* multivariate Gaussian and is given by

$$p(x|\lambda) = \sum_{k=1}^{M} w_k p_k(x), \tag{5}$$

where w_k is the k^{th} mixture weight and $p_k(x)$ is a *D*-variate Gaussian density function with mean vector, μ_i and covariance matrix, Σ_i. The model parameter is defined by λ. The decision of whether the test speech being genuine or spoofed depends on the scores of Log Likelihood Ratio (LLR),

$$LLR = log\frac{P(X|H_0)}{P(X|H_1)}, \tag{6}$$

where $P(X|H_0)$ and $P(X|H_1)$ are the likelihood scores of genuine and replay speech, respectively.

B. Deep Residual Network

In this section, we explored binary classification loss functions, followed with one-class learning loss function for voice spoofing detection. The network architecture is adapted from [29] The architecture takes the extracted features as input and outputs the confidence score to indicate the classification result. We use the intermediate output before the last fully connected layer as the embedding for the speech utterances, where 256 is the embedding dimension [30].

The Softmax loss for binary classification is given as:

$$\begin{aligned}\mathcal{L}_S &= -\frac{1}{N}\sum_{i=1}^{N}\log\frac{e^{\boldsymbol{w}_{y_i}^T\boldsymbol{x}_i}}{e^{\boldsymbol{w}_{y_i}^T\boldsymbol{x}_i}+e^{\boldsymbol{w}_{1-y_i}^T\boldsymbol{x}_i}} \\ &= \frac{1}{N}\sum_{i=1}^{N}\log\left(1+e^{(\boldsymbol{w}_{1-y_i}-\boldsymbol{w}_{y_i})^T\boldsymbol{x}_i}\right),\end{aligned} \tag{1}$$

AM-Softmax improves upon this by introducing an angular margin and is given as:

$$\begin{aligned}\mathcal{L}_{AMS} &= -\frac{1}{N}\sum_{i=1}^{N}\log\frac{e^{\alpha(\hat{\boldsymbol{w}}_{y_i}^T\hat{\boldsymbol{x}}_i-m)}}{e^{\alpha(\hat{\boldsymbol{w}}_{y_i}^T\hat{\boldsymbol{x}}_i-m)}+e^{\alpha\hat{\boldsymbol{w}}_{1-y_i}^T\hat{\boldsymbol{x}}_i}} \\ &= \frac{1}{N}\sum_{i=1}^{N}\log\left(1+e^{\alpha\left(m-(\hat{\boldsymbol{w}}_{y_i}-\hat{\boldsymbol{w}}_{1-y_i})^T\hat{\boldsymbol{x}}_i\right)}\right),\end{aligned} \tag{2}$$

Another countermeasure we used to perform our experiments is based on one class classification technique. The One-class Softmax (OC-Softmax) is denoted as:

$$\mathcal{L}_{OCS} = \frac{1}{N}\sum_{i=1}^{N}\log\left(1+e^{\alpha(m_{y_i}-\hat{\boldsymbol{w}}_0\hat{\boldsymbol{x}}_i)(-1)^{y_i}}\right), \tag{3}$$

where $\boldsymbol{x}_i \epsilon \mathbb{R}^D$ and $y_i \epsilon 0, 1$ are the embedding vector and label of the i-th sample respectively, $\boldsymbol{w}_0 \epsilon \mathbb{R}^D$ are the weight vectors of the two classes, and N is the number of samples in a mini-batch, α is a scale factor, m is the margin for cosine similarity, and $\hat{\boldsymbol{w}}$, $\hat{\boldsymbol{x}}$ are normalized $\boldsymbol{w}$ and $\boldsymbol{x}$ respectively. For systems trained with OC-Softmax, the CM score is the cosine similarity of $\boldsymbol{x}_i$ and $\boldsymbol{w}_0$.

C. Evaluation Metric

The ASV system uses a standard evaluation metric, i.e., Equal Error Rate (EER), which is indicated on the Detection Error Trade-off (DET) curve. When the operating point in the DET curve of the False Acceptance Rate (FAR) and the False Rejection Rate (FRR) or miss probability is *equal*, then it is referred to as EER.

IV. Experimental Result

The experiments are performed on the standard ASVSpoof 2019 Challenge database on both LA and PA task.

A. Results on LA Task

The results in terms of EER and t-DCF with Resnet architecture along with different loss functions for LA task is reported in Table I. We compared OC-Softmax with the conventional binary classification loss functions, under the setting of the same input features and models. In additon, we also compared the results with other feature sets instead of only focusing on the LFCC features. The three losses perform similarly for CQCC, LFCC, TECC, and GTFB on the development set, showing that they have good discrimination ability to detect known attacks. We can observe that on development set TECC feature gave a lower EER of 0.022 %, however with the unknown attacks in the evaluation set, it failed to achieve the better performance. With the quefrency-domain features (CPST) failed to achive the good performance in development as well as in evaluation set. This proves that because of the loss of the natural harmonic periodic patterns the CPST features do not perform good for the synthetic signals and voice converted signals. With LFCC feature set along with OCsoftmax loss function the SSD system achieved a low EER of 2.08 % and t-DCF of 0.04, respectively.

We also compare the performance on individual unseen attacks in the evaluation set reported in Table II. As for individual attacks, LFCC with OC-Softmax achieves good performance over all the other features. However, for A17 attack, it shows the efficacy of one-class learning to detect unknown attacks. Though it is the case for all the features too. As reported in [8], A17 is the most difficult attack in the evaluation set, but still LFCC with oc softmax shows a significant improvement resulting in 9.50 % EER.

B. Results on PA Task

This sections discusses the results on PA task as reported in Table III. The CPST feature set gave better performance with binary classification specifically with softmax loss function resulting in an EER of 0.66 % and 1.70 % on developemnt and evaluation set, respectively. The corresponding min t-DCF for CPST is 0.056. Here, we can observe from the results that the complex cepstra developed which are combined convolutionally in the time-domain generated during the replay recording phase shows its significance discrimination patterns. That yeilds to obtain a good performance for CPST features when compared with other features sets.

We also compare the performance on individual unseen attacks in the evaluation set reported inTable IV. With softmax and one class loss function, CPST features gave least EER for the individual unseen attacks compared to other feature sets. With OCsoftmax loss function, we can observe that for AC, BC, and CC unseen attacks it yeilds lower EER compared to the binary loss function for CPST features. This shows that the replay configurations used during the recording of the signals do matter for the performance degradation and improvements. The attacks with AC, BC, and CC have used low quality device for recording the speech data. Also the distance from talker to the device is more hence, the speech recorded at the final stage is the convoluted with other complexity here. This

all parameters helps to discriminate the speech signal in the quefrency domain as discussed above.

V. SUMMARY AND CONCLUSIONS

This paper focuses on the short-time cepstrum features for the spoof speech detection (SSD) task. We analysed the cepstrogram for the genuine and replayed signal and compared it with the traditional spectrogram. We observed that because of the reverberation and simulated replay signal additional dominant peaks are obtained. The periodic pattern are clearly visible in the cepstrogram for the genuine signal which is missing for the spoofed signal. This difference helps us to detect the replay signal from its natural part. Which eventually reflected it terms of the results for the PA task of ASVspoof 2019 challenge database. On the other side, for LA task, the signals are very much similar to the genuine speech because of the way they are generated using neural networks techniques that makes it to not perform so well with cepstrogram features. In future, we will focus more on the reverberation concept to have better clarity of the replay signal.

E-mail: {jkyung, hyungseob.lim, miseul4345@dsp.yonsei.ac.kr}, hgkang@yonsei.ac.kr

***Abstract*—In this paper, we propose a method to significantly improve the performance of the intra-gender comparison task in a neural speaker verification (SV) system. Recent state-of-the-art neural SV models have a substantial performance decline in the same gender comparison trials, but few studies have comprehensively investigated this problem. To this end, we develop a light-weight pitch-adaptive dynamic filter network (PDF-NET) that generates the convolutional filters conditioned on the input pitch information, from the observation that intra-gender speakers share a similar pitch range. By doing so, speaker embeddings from the same speakers are well clustered with each other even within the same gender class. Experimental results show that our proposed method outperforms the baseline for various SV datasets. In particular, female SV trials on LibriSpeech performed herein achieve a relative improvement of 11.4% in terms of equal error rate with only 1.6k additional parameters.**

Index Terms: Intra-gender speaker verification, dynamic filter network, pitch-adaptive filter, light-weight system

I. Introduction

Voice biometrics or speaker verification (SV) is a technology that uses voice to authenticate a claimed person. SV has received considerable attention in recent years because of its ease of use, a variety of potential applications [1]–[3], and advances in neural network architectures.

Most recently developed deep learning-based SV models have similar frameworks, wherein the input raw waveform is first converted into hand-crafted acoustic features such as mel-spectrograms or mel-frequency cepstral coefficients (MFCCs). Then, those acoustic features are fed into a trunk network such as ResNet [4], [5] or TDNN-based models [6], [7] to generate frame-level speaker embeddings. In the end, the frame-level embeddings are aggregated into a fixed-dimensional utterance-level embedding through various pooling methods [8], [9]. Nowadays, the dominant research on SV focuses on finding a reliable trunk network architecture to improve the representation capacity of the models. Stacking a large number of layers, enlarging feature dimensions to the axis of depth and width are typical examples of the approaches [6], [10], [11].

Despite the development of well-established trunk networks, most SV systems still exhibit low discriminative performance on intra-gender verification tasks where the fundamental frequencies of speakers tend to be within a similar range [12]–[14]. The low discriminative performance can be attributed to two limitations of existing SV models. First, the frequency resolution of input mel-scale features is not sufficiently high for capturing speaker-specific features such as fundamental frequencies. Second, most of the SV networks use input-invariant static convolutional filters [6], [15] to extract an embedding vector from the mel features, hence it is very difficult to reflect dynamic local characteristics of input features.

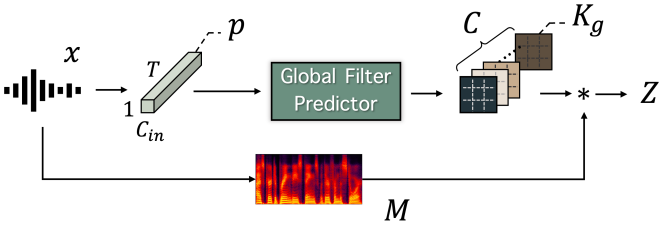

Figure 1. Illustration of the global filter predictor (GFP). Global filter K_g is obtained from an utterance-level condition $\boldsymbol{p}$. The output embedding Z is combined with the embedding obtained from static filters to be used as an input of the trunk network.

To overcome the aforementioned limitations, it was proposed to utilize high-dimensional acoustic features [16]–[20] rather than only utilizing the mel-scale features. For example, some early studies incorporate fundamental frequency (f0) or delta-f0 into the existing SV models [16]–[19], and succeed in improving the SV performance. However, we found that directly utilizing f0 features as input to the system could not contribute to the intra-gender tasks (see Section V-A for more details). On the other hand, there exists some predominant methods that stack a large number of layers or increase the channel size [6], [7], [11] thereby improving the modeling performance. However, those methods exhibit high computational complexity and require a large memory size, which can not satisfy the increasing demand for light-weight SV systems [21]–[23].

In this paper, we propose a light-weight SV model named pitch-adaptive dynamic filter network (PDF-NET) to improve the SV performance on the intra-gender comparison tasks. Our PDF-NET consists of dynamic convolutional filters that are adaptive to the pitch[1] information of the input signal. More specifically, we design two filter prediction modules named global filter predictor (GFP) and local filter predictor (LFP). The former generates global pitch-adaptive filters in the utterance-level, while the latter generates local pitch-adaptive filters in the frame-level. Experimental results show that our proposed model's equal error rate (EER) on the female comparison task on LibriSpeech is decreased by 11.4% from the baseline model, with a marginal increase in the number of

[1]In this work, we use the term "pitch" as a synonym of "fundamental frequency" for brevity, although their precise meanings are different.

model parameters.

Our contributions in this paper are summarized as follows:

- To the best of our knowledge, our approach is the first attempt to demonstrate the efficacy of pitch-adaptive dynamic convolutional filters on intra-gender SV tasks.
- Based on the famous Fast ResNet architecture, we develop a light-weight SV model which shows better performance than the baseline model while maintaining the number of parameters in the system.

II. Related Work

A. Pitch-conditioned SV

In the early exploration stage of speaker verification research, several efforts had been made to utilize pitch information to improve the performance. Yegnanarayana et al. [17] highlights the importance of the suprasegmental information and incorporates these features into a baseline SV system that only uses the spectral information. In [18], Dehak et al. additionally utilize various prosodic features (e.g., pitch, energy, and duration) using joint factor analysis to improve the SV performance. Gong et al. [19] introduce a pitch synchronous feature extraction method which utilizes pitch information to determine the size of the short-time Fourier Transform (STFT) window, demonstrating the effectiveness of the proposed method.

However, these studies only focus on the selection or extraction of the input features, and an effective way to exploit the information (especially upon the deep neural network architectures) has not been thoroughly explored. Based on the analysis of the neural SV architectures, we develop a sophisticated method to efficiently provide pitch information to a neural SV model.

B. Adaptive Convolutional Neural Network for SV

Several methods have been proposed to generate input-adaptive convolutional neural network (CNN) filters. For example, Kim and Park [24] utilizes input-dependent filters during the feature extraction stage to accurately model the dynamic nature of phonetic variations in each analysis frame. Furthermore, a temporal dynamic convolutional neural network (TDY-CNN) [25] has been proposed to apply an adaptive filter for each time sequence. Here, the adaptive filters are obtained from the weighted sum of basic filters with a softmax constraint on attention weights.

Although the aforementioned approaches can achieve high performance in various SV tasks, they have a few limitations: 1) They require a large number of parameters and involve complex computations, which make it difficult to build a light-weight real-time SV system. 2) The adaptive filter estimation process only relies on input mel-scale features with low frequency resolution. In this study, we generate filters based on more elaborate speaker-related features (i.e., pitch) to effectively estimate speaker-discriminative embeddings with a small increment of model size compared to the baseline model. In other words, our proposed SV network is designed to be more pitch-aware and distinctive to identify the differences between intra-gender speakers having similar pitch ranges.

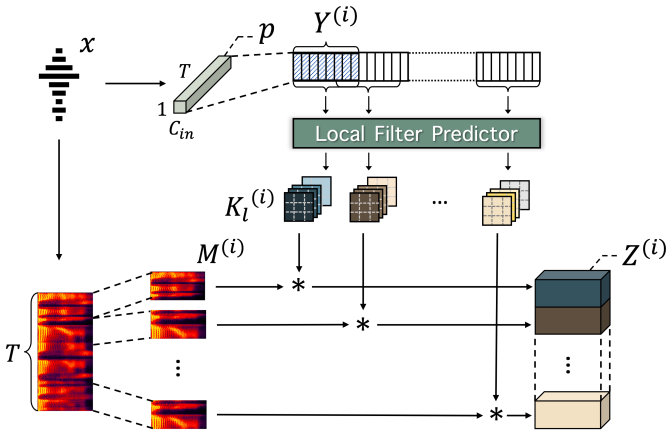

Figure 2. Illustration of the local filter predictor (LFP). Predicted filter $K_l^{(i)}$ is obtained from $Y^{(i)}$, then is convolved with $M^{(i)}$ to generate $Z^{(i)}$. Finally, the concatenated output Z is combined with features obtained from static kernel to feed into the trunk network.

III. Proposed Model

As shown in Table III, existing neural SV models exhibit relatively poor performance on the intra-gender comparison tasks[2], for the reason that those speakers have similar pitch ranges. In order to solve this problem in an efficient way, we propose PDF-NET which adaptively generates dynamic convolutional filters conditioned on the pitch information of the input signal.

We propose two different filter prediction modules—global filter predictor (GFP) and local filter predictor (LFP). Although both of them generate pitch-adaptive dynamic filters from the input fundamental frequencies, the scopes of the filters are different. The GFP generates global utterance-level pitch-adaptive filters by summarizing all the information extracted from its input pitch contour. By contrast, the LFP generates different local pitch-adaptive filters for different time frames. The latent vectors obtained from the dynamic filters are combined with the ones obtained from static convolutional filters to form a new speaker representation. The following sections describe the structures of the two pitch-adaptive filter predictors in more detail.

A. Global filter predictor (GFP)

Figure 1 illustrates the operation of GFP, which can be summarized as follows:

$$K_g = \text{Reshape}(\text{FC}(\text{Conv1D}(\boldsymbol{p}))). \quad (1)$$

First, the pitch contour $\boldsymbol{p} \in \mathbb{R}^{1\times T}$ is extracted from an input raw waveform, $\boldsymbol{x}$, where T denotes the total number of frames. Then, the pitch contour passes through 1-D CNN layers after log-compression to enlarge the channel dimension into C. A fully-connected (FC) layer is applied along the time dimension to summarize the temporal variation of the pitch contour into a single vector of length k^2C, where k denotes the filter size. The vector is reshaped into a tensor $K_g \in \mathbb{R}^{C\times 1\times k\times k}$, which is convolved with the mel-spectrogram, M, extracted from

[2]Similar observation has been found when we conducted the verification task using other SV models and intra-gender datasets.

the same input waveform, $\boldsymbol{x}$. Note that the dynamic filters are applied only to the input mel-spectrogram and not used in the intermediate layers of the trunk network.

B. Local filter predictor (LFP)

Figure 2 depicts the process of generating and applying dynamic local filters. Unlike the GFP, the LFP generates different filters for different time steps. To obtain local frame-level filters that account for temporal-dynamic speaker characteristics, 1-D CNN with filter size k and stride s is applied to the log-compressed pitch contour, $\boldsymbol{p}$. The obtained latent vectors, Y, and the mel-spectrogram, M, are aligned and segmented so that each segment includes the n number of vectors. Thereafter, local filters for the i-th segment, $K_l^{(i)}$, is generated from $Y^{(i)}$. A segment of the mel-spectrogram, $M^{(i)}$, is convolved with the filters to generate a speaker representation $Z^{(i)}$. The same process is repeated for all the segments. In summary, the process of local filter prediction is given by:

$$K_l^{(i)} = \mathrm{Reshape}(\mathrm{FC}(Y^{(i)})), \tag{2}$$

where $Y^{(i)}$ is the i-th segment of the output of the convolutional layer with stride s. The optimal number of filters, k, and the stride, s of the 1-D convolutional layer were experimentally determined to obtain localized pitch-adaptive dynamic filters.

IV. Experiment setup

A. Dataset

We use two popular datasets, named VoxCeleb [26], [27] and LibriSpeech [28], for the experiments. For training, we use the development subset of VoxCeleb2 [27] without any augmentation methods. For the performance evaluation, we use the benchmark VoxCeleb1-O test dataset. Because there is no available public dataset designed for intra-gender verification task, we construct two additional intra-gender test datasets to evaluate the performance on the task. As illustrated in table I, the newly-developed datasets are named – Vox1-F, Vox1-M, Libri-F and Libri-M. Vox1-F and Vox1-M, which consists of samples in the VoxCeleb1 development subset. Vox1-F contains the data of 561 female speakers, and 100 pairs are made for each speaker; Vox1-M contains data from 100×690 trials with male speakers. Similarly, we also sampled trials from the LibriSpeech [28] train-clean-100 set to construct LibriSpeech intra-gender dataset, named Libri-F and Libri-M, which contain 12,500 and 12,600 random pairs from 125 female and 126 male speakers, respectively.

B. Implementation details

For the input acoustic features, we use 40-dimensional mel-spectrogram and 1-dimensional pitch. We convert the time domain raw waveform into frequency domain acoustic features with a frame length of 25 ms and a hop length of 10 ms. We estimate the frame-level pitch values using the pyin algorithm [29] and then convert the pitch values into a log scale for a better performance.

Table I
Details of intra-gender datasets. Vox1 and Libri are the abbreviations of VoxCeleb1 and LibriSpeech datasets, respectively. F and M indicates the gender of intra-gender trials.

	# of speakers	Trial/speaker	Total # of trials
Vox1-F	561	100	56,100
Vox1-M	690	100	69,000
Libri-F	125	100	12,500
Libri-M	126	100	12,600

Table II
Overall performance of the proposed model compared with the baseline on Vox1-O dataset in terms of equal error rate (EER) and minimum detection cost function (MinDCF), along with the number of model parameters.

Model	Params. (M)	EER (%)	MinDCF
Baseline	1.438	2.797	0.197
GFP	1.448	2.691	0.191
LFP (s=8, k =3)	1.444	2.781	0.186
LFP (s=8, k =5)	1.449	**2.617**	**0.176**
LFP (s=10, k =3)	1.445	2.622	0.180
LFP (s=10, k =5)	1.450	2.792	0.187

Regarding the choice of the trunk network, we adopt the Fast ResNet-34 model [15] because of its light-weight architecture (about 1.4M parameters) and small number of channels. After extracting frame-level embeddings from the trunk network, self attentive pooling (SAP) [9] is used to summarize frame-level features into a 512-dimensional utterance-level speaker embedding. Then, additive margin softmax (AM-Softmax) loss [30] is applied to the embedding for speaker verification task.

During the training stage, we use a 2-second segment for a stable training, which is randomly cropped from each utterance. And we train all the baseline and proposed models for 150 epochs equally. For the inference stage, we adopt the testing scheme of [15], where ten 2-second temporal crops are generated at regular intervals. The Adam optimizer [31] with an initial learning rate of 0.001 and StepLR scheduler with a learning decay of 0.95 are used for training.

C. Evaluation metric

For the evaluation metric, we use the equal error rate (EER) and the minimum of the detection cost function (MinDCF) to compare the performance of the proposed and baseline models. EER indicates the point where both false acceptance (FA) and false rejection (FR) rates are equal. MinDCF is a weighted sum of FA and FR probabilities with given parameters $P_{\mathrm{Target}} = 0.05, C_{\mathrm{Miss}} = C_{\mathrm{FalseAlarm}} = 1$.

Table III
PERFORMANCE OF THE PROPOSED MODEL COMPARED WITH THE BASELINE ON VARIOUS INTRA-GENDER DATASETS.

Model	Vox1-F		Vox1-M		Libri-F		Libri-M	
	EER (%)	MinDCF	EER (%)	MinDCF	EER (%)	MinDCF	EER (%)	MinDCF
Baseline	4.659	**0.269**	4.135	0.242	1.824	0.108	1.222	**0.055**
Baseline (Mel+f0)	4.784	0.288	4.195	0.249	1.776	0.115	1.397	0.067
GFP	4.601	0.295	**3.901**	0.238	**1.616**	0.100	**1.206**	0.060

V. EXPERIMENTAL RESULTS

A. Performance Evaluation

Results on the Voxceleb-O dataset. Table II summarizes the performances and corresponding model size of the proposed method and baseline models evaluated on the benchmark Voxceleb1-O test dataset. All trials of the proposed GFP and LFP modules outperform the baseline Fast ResNet-34 models by a large margin, even with a small increments (0.01M $\sim$ 0.04M) on the number of parameters. For GFP, it outperforms the baseline system with 3.8% and 3.0% relative improvements in terms of EER and MinDCF, respectively. Moreover, the LFP module exhibits superior performance compared with the GFP. The optimal setting of the LFP with stride 8 and filter size 5, improves the SV performance by 6.4% EER and 10.7% MinDCF relatively.

Results on the intra-gender datasets. To evaluate the performance of the proposed models more accurately, we further investigate the models in some more challenging intra-gender SV trials. As discussed in section IV-A, we generate four additional datasets: Vox1-F, Vox1-M, Libri-F and Libri-M. As shown in Table III, directly incorporating f0 into the system as an additional input does not contribute to the intra-gender verification task. Instead, our proposed model and its variants show an improvement on the intra-gender SV performance in various scenarios. Especially, the model using the GFP module exhibits good performance on the intra-gender verification task; it improves the relative EER score by 6.3% and 3.5% in the intra-female and intra-male comparison tasks, respectively. Furthermore, a significant improvement has been found in the LibriSpeech female comparison where our proposed GFP module outperforms the baseline by 11.4 % EER relatively. However, there is lack of a single configuration that works best in all domain, presumably due to the distinct characteristics of the two datasets we used. Still, our proposed models show superior performance in most cases.

B. Visualization of the pitch-adaptive dynamic filters

To investigate the role of the dynamic filter predictors, we visualize the local pitch-adaptive dynamic filters together with the static ones obtained from two female speakers as illustrated in Figure 3. We plot 4 different local filters extracted from 4 different time sequences for each speaker, and all the local pitch-adaptive and static filters are extracted from the same utterance and channel. Because the local pitch-adaptive filter predictor generates dynamic filters for each speaker in a time-dependent manner, all of the filters obtained from different speakers and time sequences are not the same. Especially, even for those speakers who are in the same gender category, our proposed local filter predictor is able to generate totally different filter patterns so that it enables better discrimination between different speakers. In contrast, the static filters are invariant for various speakers (for brevity, we only plot one filter for each speaker). Hence it could not adaptively filter the input vectors in a speaker-dependent way.

C. t-SNE plot of the speaker embedding

In order to analyze the different characteristics of the output speaker embedding extracted from static filters and proposed

pitch-adaptive dynamic filters, we visualize the embeddings using t-SNE plots, as displayed in Figure 4. The female speakers are annotated with labels 0 to 3 and depicted in light (orange, yellow, hot pink, light pink) colors, while male speakers are annotated with labels 4 to 7 and depicted in deep (blue, mint, grey, navy) colors. Comparison of the two different types of filters with respect to the density of the clusters reveal that the embeddings obtained from the static filters are well clustered within the same speaker. However, the intra-class variance is still large. On the contrary, speaker embeddings extracted from pitch-adaptive filters have smaller intra-class variance compared to that of the static filters, which demonstrate the efficiency of our pitch-adaptive dynamic filters on discriminating intra-gender speakers.

VI. Conclusion

In this study, we proposed a pitch-adaptive dynamic filter network (PDF-NET) model to improve the speaker verification performance on intra-gender trials. PDF-NET consists of two pitch-adaptive filter predictors; one generates global utterance-level dynamic filters and the other generates local frame-level dynamic filters. Since our proposed model adaptively generates filters depending on the different pitch characteristics of input speakers, it is easy to discriminate intra-gender speakers who have similar pitch ranges. Our proposed model shows better performance than the baseline model in various SV datasets only with marginal increment on the number of parameters. Specifically, our model outperforms the baseline model by 11.4 % relative EER improvement in the LibriSpeech female comparison task, indicating the efficiency of the proposed method.

***Abstract*—Herein, we investigated the subjective impression of a mid-air sound source whose position was directly manipulated by hand tracking. The mid-air sound source was generated as a focused sound source based on wave field synthesis with a 32-channel linear loudspeaker array. The hand position was tracked using motion capture equipment (Leap Motion). If the focused sound source is not moved within the frame depending on the motion capture acquisition period, the focused sound source cannot be moved smoothly. To achieve smoother and more natural movement of the focused sound source, we moved the focused sound source sample-by-sample in the frame using an all-pass filter. Subjective tests indicated that sound localization and enjoyment increased when the focused sound source followed the hand movements of a listener. Moreover, when the focused sound source was pinched and moved, the sense of movement was enhanced by changing the sound volume according to the moving speed of the focused sound source. The proposed system can contribute to the development of innovative 3D audio applications.**

I. Introduction

Recently, the demand for 3D audio technology has increased owing to the development of 3D video technology. For example, movies use audio technologies, e.g., the 5.1 surround sound system. However, such 3D sound is designed by professional sound creators, and the audience can only hear it. However, the importance of sound in a 3D space has attracted attention owing to recent developments in XR [1]. Spatial sound considerably influences immersion in a 3D virtual space [2]. For example, soundscapes and footsteps that match walking in a virtual space can enhance the sense of immersion in the virtual space [3]. In addition, research is being conducted to make the body feel lighter and support the learning of sports and rehabilitation by playing sounds along with movements [4], [5]. However, these studies focused on the listener's body instead of changing the perception of the sound. Some systems use motion capture to mix sound in 3D space and reproduce moving sound sources acquired by motion capture in real time in a remote room [6], [7]. However, these systems do not allow listeners, who can manipulate sound through movements, to feel sound in real time. Another system allows the listener to adjust the spatial equalizer and move the virtual sound source at the listening position [8]. However, this system uses knobs to make adjustments, which is not intuitive. In the field of virtual reality as well, research on the application of sound and research on the relationship between images and localization accuracy are being conducted, but they can still be examined [9], [10]. Therefore, in this study, we investigated how listeners perceive sounds when they actively change the sound source position. We used a hand-manipulation-focused sound source generation system that can directly change the position of the focused sound source.

We generated focused sound sources using the wave field synthesis (WFS) method [11], [12]. In conventional WFS, filters for obtaining loudspeaker driving signals are analyzed in the frequency domain. In this method, if the focused sound source position changes for each sample, the filter must be regenerated at every sample time, resulting in an enormous amount of computation. However, when the loudspeaker drive signal is calculated for each frame, it is necessary to overlap and add frames by windowing. In this case, the phases of the loudspeaker output signals between the two frames do not match, and the sound may not be natural.

Herein, we use a time-domain-focused sound source formulation instead of a frequency-domain formulation [12]. This approach helps segregate focused sound source generation filters into three parts. The first part is a filter specific to the system that can be pre-convoluted into a source signal. The other two parts are delays and scalar gains, which depend on the loudspeaker and focused sound source positions. Although the delays are fractional, they can be considered as all-pass filters to move the focused sound source sample-by-sample within a frame based on a small amount of computation.

We used Leap Motion, a hand-tracking device, to capture hand positions [13]. When a focused sound source is generated at the position of the hand acquired using Leap Motion, the listener can feel as if he/she is moving the focused sound source manually. Moreover, BoomRoom [14] uses a circular loudspeaker array; however, we use a linear loudspeaker array and simple motion capture.

Using the aforementioned system, we investigated the ex-

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

perience of people when a focused sound source moves as they manipulate it. In the experiment, we first investigated the localization accuracy of the focused sound source generated using the proposed system without hand tracking. Next, we investigated sound localization and listener enjoyment when the sound image was generated at the position of the listener's hand. Finally, we investigated whether there was a sense of moving the sound image, which was weightless and irrelevant, when the position and sound volume of the focused sound source were adjusted by simulating the movement of the focused sound source by pinching it with a hand.

The remainder of this study is organized as follows: Section II describes a hand-manipulation focused sound source generation system that can move the focused sound source position via hand tracking. Section III presents the listening experiments conducted using the aforementioned system. Section IV presents the conclusions and prospects of generating interactively focused sound sources.

II. Proposed Method

The proposed system uses a 32-channel linear loudspeaker array, motion capture technology, personal computer for signal generation, and Digital-to-Analog Converter (D/A converter). Fig. 1 shows the overview of the system. This system generates a focused sound source that moves according to hand movements, which listeners hear.

A. Smoothly moving focused sound source generation method

Using (1), a focused sound source can be generated using a linear loudspeaker array [12]. $D_{2.5\mathrm{D}}(\mathbf{r}_s, \omega)$ is a frequency domain formula that derives the loudspeaker output signal at $\mathbf{r}_s$. This equation was derived from the Rayleigh integral, and the Hankel function was replaced with an approximate exponential function.

$$D_{2.5\mathrm{D}}(\mathbf{r}_s, \omega) \approx -g_s \sqrt{\frac{\frac{\omega}{c}}{2\pi j}} \frac{y_s - y_F(n)}{|\mathbf{r}_s - \mathbf{r}_F(n)|} \frac{e^{j\frac{\omega}{c}|\mathbf{r}_s - \mathbf{r}_F(n)|}}{\sqrt{|\mathbf{r}_s - \mathbf{r}_F(n)|}} \quad (1)$$

Here, $\mathbf{r}_s = [x_s, y_s]$ denotes the loudspeaker position, s denotes the number of loudspeakers, and $s = 1 \sim S$ when the number of loudspeakers is S. ω denotes the angular frequency, c denotes the sound speed, and j denotes an imaginary unit. $\mathbf{r}_F(n) = [x_F(n), y_F(n)]$ denote the position of the focused sound source at time n. g_s is defined as $g_s = \sqrt{2\pi\,|\mathbf{r}_{\mathrm{ref}} - \mathbf{r}_s|}$, and $\mathbf{r}_{\mathrm{ref}}$ are the coordinates for approximately correcting the sound attenuation characteristics in 2.5 dimensions.

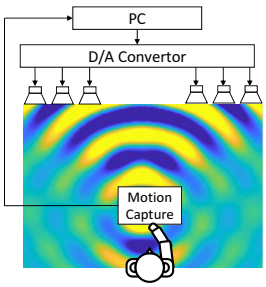

Fig. 1. Overview of proposed system.

The time-domain filter $d(\mathbf{r}_s, n)$ is obtained using the inverse Fourier transform of (1).

$$d(\mathbf{r}_s, n) = G_s(n) Q(t) \delta(n - \tau_s(n)) \quad (2)$$

$G_s(n)$ denotes the scalar gain that differs for each loudspeaker.

$$G_s(n) = -g_s \sqrt{\frac{1}{2\pi}} \frac{y_s - y_F(n)}{|\mathbf{r}_s - \mathbf{r}_F(n)|} \frac{1}{\sqrt{|\mathbf{r}_s - \mathbf{r}_F(n)|}} \quad (3)$$

$Q(t)$ denotes the Finite Impulse Respomse (FIR) filter obtained in advance using (4) and is a fixed filter that does not depend on the position of the loudspeaker or focused sound source.

$$Q(t) = \mathrm{IFFT}\left(\sqrt{\frac{\omega}{jc}}\right) \quad (4)$$

As this filter does not depend on the loudspeaker position, it can be pre-convolved with the source signal.

$\delta(n - \tau_s(n))$ is realized with a delay. However, the delay of each loudspeaker $\tau_s(n) = \frac{|\mathbf{r}_s - \mathbf{r}_F(n)|}{c}$ is fractional. Fractional delays should be implemented precisely by using a sinc function [15]. However, as this function requires a large amount of computation, we replace it with a first-order time-varying all-pass filter [16]. First, we divide $\tau_s(n)$ into integers and fractional parts $\alpha(n)$. Then, we express the fractional delay using a first-order time-varying all-pass filter, as expressed in (5).

$$H_n(z) = \frac{z^{-1} + (1 - \alpha(n))}{1 + (1 - \alpha(n)) z^{-1}} \quad (5)$$

Using the aforementioned method, the position of the focused sound source was smoothly changed for each sample.

B. Directly manipulate the focused sound source using motion capture

By generating a focused sound source at the position obtained through hand tracking, it is possible to generate a mid-air sound image following the hand position. The proposed system uses motion capture hand-tracking technology known as Leap Motion [13]. Leap Motion Controller is an optical hand tracking module that can measure hand movements in detail by holding the hand over. Leap Motion measures hand movements at a maximum of 200 fps [13]. This value is below the sound-sampling frequency of 48000 Hz. Therefore, frame processing is introduced. This system acquires the hand position once per frame and interpolates it within the frame using a uniform linear motion. To interpolate the hand position in the frame from the previous hand position, the focused sound source position was delayed by one frame from the actual hand position. Let N be the frame size and $\mathbf{h}(n)$ be the hand position obtained at time n. The focused sound source

positions at nth time and $n+N$th time are expressed in (6) and (7), respectively.

$$\mathbf{r}_F(n) = \mathbf{h}(n-N) \tag{6}$$

$$\mathbf{r}_F(n+N) = \mathbf{h}(n) \tag{7}$$

The focused sound source position $\mathbf{r}_F(n+i)$ $(i = 0, 1, 2, ..., N-1)$ is expressed in (8).

$$\mathbf{r}_F(n+i) = \frac{(\mathbf{r}_F(n+N) - \mathbf{r}_F(n))}{N} i + \mathbf{r}_F(n) \tag{8}$$

III. Experiments

We conducted subjective evaluations using the system described in Section II. First, we conducted a basic experiment to investigate the localization accuracy of the focused sound source, including the source distance from the listeners. Next, we investigated sound localization and sense of enjoyment while directly manipulating the focused sound source manually. Furthermore, the sensation obtained by pinching and moving an insubstantially focused sound source was subjectively evaluated.

A. Experiment A: basic localization without hand motion

First, we conducted a sound-localization experiment using a 32-channel linear loudspeaker array. The listening experiment did not involve hand tracking.

1) Implementation: Fig. 2 shows the positional relationship between the equipment and listener. The number of loudspeakers was 32, and the loudspeaker spacing was 10 cm. The movement range of the focused sound source is indicated by the colored area in Fig. 2 considering the possible generation area of the focused sound source. The sampling frequency was 48 kHz, signal bandwidth was 120 Hz $\sim$ 8 kHz, and frame length was 4800 samples. The sound source signal was white noise with a duration of 8 s.

2) Procedure: The experiment included 10 people aged 22–29 years. Localization experiments were first conducted with a stationary focused sound source and then with a moving focused sound source without hand tracking. Fig. 3 shows the position and movement direction of the focused sound source. Position 9 was at a distance of 0.3 m from the participant's position in the direction of the linear loudspeaker array. Positions 1–8 are eight points set at 45-degree intervals on a circle with a radius of 0.3 m centered at position 9. The participants were asked to face forward and keep their heads still while listening. In addition, the participants did not move their hands in this experiment A.

In the experiments with a stationary focused sound source, the focused sound source was reproduced at any position from 1 to 9. The focused sound source was presented twice at each position in a random order, i.e., it was presented 18 times in total. The participants listened to the sounds and answered with a number from 1 to 9 as to which position they felt was the most appropriate for the image sound position.

In the experiments, the focused sound source moved among positions 1–8, which existed in a straight line passing through position 9. The focused sound source remained stationary at the starting point for 2 s, moved at a constant speed for 4 s, and remained stationary for 2 s after reaching the end position. The focused sound source was presented twice at each position in a random order, i.e., it was presented 16 times in total. Participants listened to the presented sound and answered with a number ranging from 1 to 8 that they felt was the most appropriate arrival position for the focused sound source. For example, the participants responded with 6 when they felt that the focused sound source was at position 2, passed position 9, and arrived at position 6. The participants practiced before starting the experiment.

3) Results: Figs. 4 and 5 show the experimental results. The horizontal and vertical axes represent the reproduced

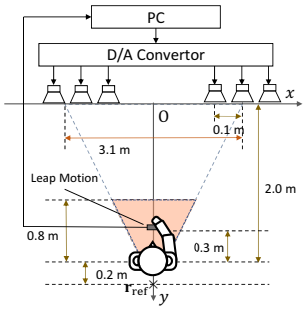

Fig. 2. Layouts of experiments A (basic localization w/o hand motion) and B (manipulating focused sound source with hand). The colored range indicates moving range of the focused sound source.

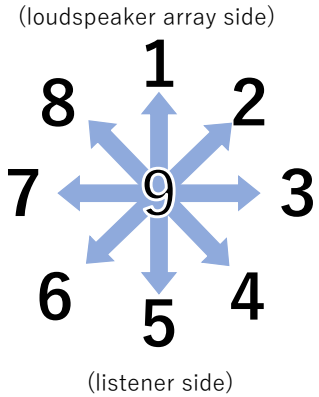

Fig. 3. Numbers indicating the positions and directions of the movement of the focused sound source for experiment A (basic localization w/o hand motion).

position of the focused sound source and listener's response, respectively. The size of each circle represents the number of responses.

According to the experimental results, we found that a moving focused sound source exhibited better sound localization than a static sound image. In addition, the participants could perceive the left and right directions for stationary focused sound sources and the front, back, left, and right directions for moving focused sound sources. Based on these results, we conclude that our system is suitable for generating focused sound sources.

B. Experiment B: directly manipulating focused sound source with hand

Next, we conducted an experiment to investigate whether the direct manipulation of the focused sound source by hand enhances sound localization and whether it is enjoyable.

1) Implementation: Fig. 2 shows the positional relationship between the experimental system and participant. In this system, there is a total delay of approximately 200 ms, which is approximately 100 ms for frame processing and approximately 100 ms for others, until the focused sound source is generated at the hand position acquired using Leap Motion. Other conditions are the same as considered in the previous experiments.

2) Procedure: The participants in the experiment were 10 people aged 22–29 years. They answered the following two questionnaires for each trial:

1) Is the sound image localized in a clear position?
2) Have you enjoyed?

Participants responded to these questions on a five-point Likert scale. Choices were as follows: 5 is "agree," 4 is "somewhat agree," 3 is "cannot say either way," 2 is "somewhat disagree," and 1 is "disagree."

Table I lists the control methods for sound images. A, B, C, and D denote the control methods for investigating whether sound localization can be improved by manually manipulating the focused sound source position. E and F are the control methods for investigating whether sound localization can be improved even if the sound volume changes with stereo playback instead of a focused sound source. Fig. 6 shows a subject conducting the experiment with 32-channel linear loudspeaker array.

In the case of the sound image that moved automatically, the participants listened only, and in other cases, the participants could move the sound image following hand movements using motion capture. There are four trajectories for moving the sound image: closer or farther from the face, left and right, clockwise, and counterclockwise. We used a display to instruct the participants whether the trial was automatic, closer or farther, left–right, clockwise, or counterclockwise for each

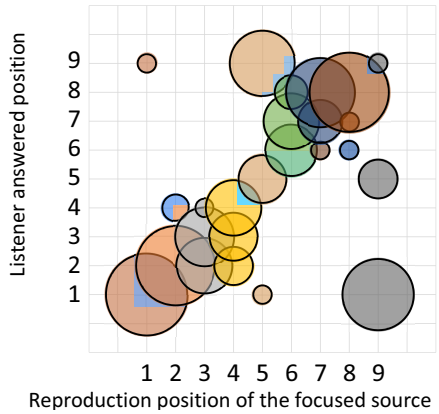

Fig. 4. Relation between the reproduced position and response of the stationary focused sound source for experiment A (basic localization w/o hand motion).

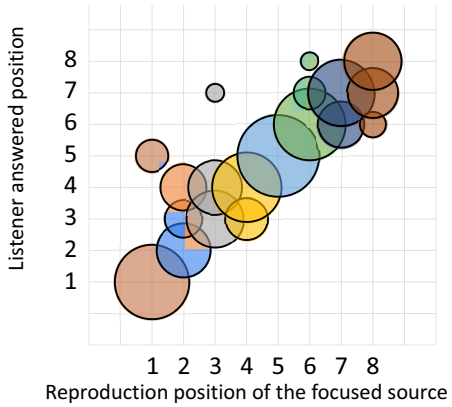

Fig. 5. Relation between the reproduced position and response of the moving focused sound source for experiment A (basic localization w/o hand motion).

TABLE I
SOUND IMAGE CONTROL METHOD FOR EXPERIMENT B.

A	Auto-moving focused sound source
B	Focused sound source following hand position
C	Focused sound source following hand position with a delay of 0.7 s
D	Randomly moving focused sound source
E	Auto-moving stereo sound source
F	Stereo sound source following hand position

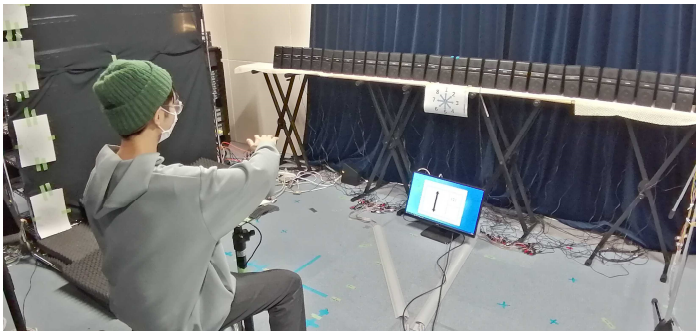

Fig. 6. Subject conducting the experiment with 32-channel linear loudspeaker array.

trial. The sound image moved slowly within a radius of 30 cm and was centered on the motion capture. For the auto-moving focused sound source (control method A), the focused sound source trajectory was fixed. The participants practiced in advance so that the operation would be similar to an automatic operation.

The participants listened to 48 sound sources consisting of 24 combinations of six types of sound-image control methods and four types of trajectories. The order in which participants listened to the sound sources was randomized. Participants were given 10 s to answer each time they listened to one stimulus and allowed to take a 1-min break after completing 24 trials.

The stereo reproduction output signal was generated by multiplying the output obtained based on the sine law by six times the gain obtained using (3). This output signal was reproduced using two left and two right loudspeakers near an equilateral triangle, including the listening position.

3) Results: Figs. 7 and 8 show the answers to questionnaires 1 and 2 of the sound image control methods, respectively. The bar graph represents the mean of the responses, and the error bar represents the standard deviation.

Fig. 7 shows that among the six control methods, B, in which the focused sound source follows the position of the hand, exhibits the highest average evaluation value, with a small number of low evaluation responses. By comparing B and F, A and E, respectively, we found that the focused sound source was evaluated to be higher than the stereo sound source. By comparing B, C, and D, we found that the evaluation decreased slightly when the focused sound source was followed and decreased significantly when the focused sound source moved randomly. Furthermore, by comparing C and F, we found that the localization of the focused sound source with a relatively long delay was better than that of the stereo sound source following the hand.

As shown in Figs. 7 and 8, the relationship between the sound image control method and enjoyment exhibited the same tendency as the relationship between the sound image control method and sound localization.

Based on the aforementioned results, we found that the focused sound source that follows the hand possessed the most localized experience and was enjoyable among all the sound image control methods. Moreover, the focused sound source was as enjoyable as the stereo sound source if there was a delay. Therefore, it is important to process minimal delays to ensure enjoyment.

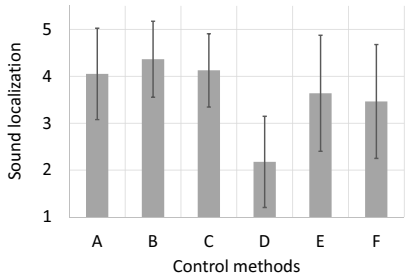

Fig. 7. Relationship between the sound image control method and sound localization for experiment B.

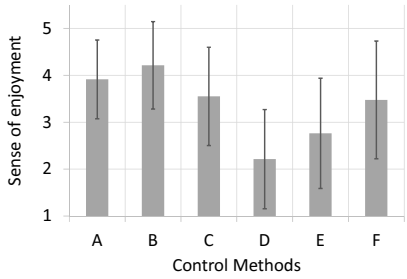

Fig. 8. Relationship between the sound image control method and enjoyment for experiment B.

C. Experiment C: pinching and moving focused sound source

The results of experiment B (directly manipulating focused sound source with hand) indicated that moving the focused sound source improved sound localization and enjoyment. Finally, we used a system that generates a focused sound source that can be moved by pinching the hand and conducted an experiment to investigate whether there was any experience of moving the focused sound source.

1) Implements: Fig. 9 represents the positional relationship between the system and participants. The previous experimental conditions were considered, and the focused sound source generation area was placed closer to the linear loudspeaker array.

In this experiment C, the focused sound source follows the hand only when the thumb and index fingers are pinched. Leap Motion can detect the shape of the user's hand in detail. Therefore, we determined whether the fingers were pinched by measuring the distance between the tip of the thumb and

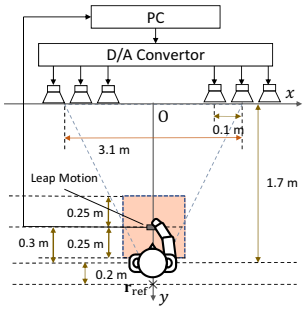

Fig. 9. Positional relationship between the system and participants of experiment (pinching and moving focused sound source). The colored range is the moving range of the sound image.

index finger.

2) Procedure: Seven people aged 22-26 years participated in the experiment. We instructed the participants to sit in the listening position, pinch, and move the focused sound source after reproducing white noise. We instructed the participants to move the focused sound source closer to them, farther from them, left, and right and move the focused sound source away from them at least once during the movement. The moving speed of the focused sound source was not specified. The participants answered the following questionnaire after each trial:

1) Did you feel like you were moving something?

Participants responded to these questions on a five-point Likert scale. Choices were as follows: 5 is "agree," 4 is "somewhat agree," 3 is "cannot say either way," 2 is "somewhat disagree," and 1 is "disagree." In addition, the participants freely wrote their impressions of the experiment after all trials finished.

Table II lists the focused sound source control methods, which control the source movement velocity and sound volume to simulate the weight. β was introduced to control the movement of the focused sound source in terms of moving ahead or delaying the position of the hand. If β is larger than 1.0, the focused sound source position moves more than the actual hand movement; if it is smaller than 1, the focused sound source position moves less than the actual hand movement. This processing was implemented by applying pseudo-haptics to the sound, in which a pseudo-tactile sense of resistance was felt by slowing the movement of the cursor [17]. Figs. 10 and 11 show the changes in the positions of the focused sound source.

For example, the focused sound source moved, as shown in Fig. 10 when $\beta = 2.0$. In this case, the sound image was localized in front of the hand position; therefore, it moved faster than the hand movement. Meanwhile, the focused sound source also moved, as shown in Fig. 11 when $\beta = 0.5$. In this case, the sound image is localized behind the position of the hand; therefore, it moves slower than the movement of the hand.

Sound volume change processing enhances and reduces the sound volume as the hand moves faster and slower, respectively. The upper and lower limits were set for the sound volume, and the maximum change was approximately 6 dB. The results of the previous study relate to loud sound with rough textures, and soft sound with smooth textures [18]. Therefore, we assume that loudness while moving an object is related to the weight of the object. Moreover, in the real world, fricative sounds tend to become louder as the moving speed increases. Therefore, to this experimental system, we add a process that changes the sound volume according to the moving speed of the focused sound source.

TABLE II
FOCUSED SOUND SOURCE CONTROL METHOD FOR EXPERIMENT C

Sound volume change	Position of focused sound source			
	ahead ($\beta = 2.0$)	follow ($\beta = 1.0$)	delay ($\beta = 0.5$)	stationary
Yes	A	C	E	G
No	B	D	F	H

3) Results: Fig. 12 shows the answers to questionnaire 1 for each focused sound source control method. The bar graph represents the mean of the responses and the error bar represents the standard deviation. As shown in Fig. 12, it is possible to present the sense of movement by moving the focused sound source according to the hand motion. In addition, we compared

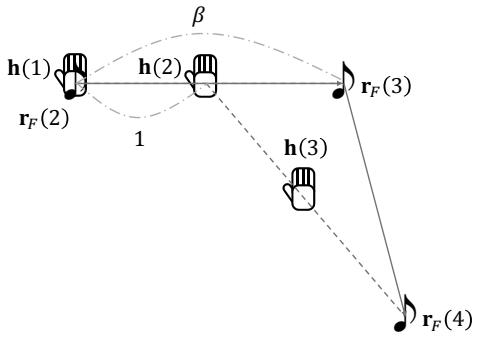

Fig. 10. Focused sound source moves ahead of the hand for experiment C ($\beta = 2.0$).

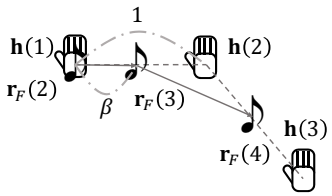

Fig. 11. Focused sound source delays the hand for experiment C ($\beta = 0.5$).

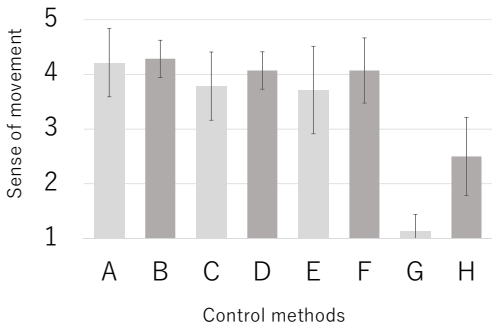

Fig. 12. The relationship between the control method of the focused sound source and the sense of movement for experiment C.

A and B, C and D, E and F, and G and H, which possessed the same moving speed but different sound volumes (changes in sound volumes). In all the combinations, when the sound volume of the focused sound source was changed according to the hand movement, the sense of movement was higher than when it was not changed. Therefore, it implies that changing the sound volume of the focused sound source according to the hand movement tends to increase the sense of movement.

There were opinions on the impression of the free description after the experiment. "The movement that followed the hand was interesting, and I got the impression that an object was there," "It felt like I was remotely controlling it rather than moving it with the hand." Based on these opinions, it may be possible to present sensations other than auditory by manipulating the focused sound source, although there are individual differences in perception.

IV. Conclusion

Herein, we investigated the experience of listeners when they interactively change their mid-air sound source position. We created a system that generates a focused sound source whose position can be manually manipulated and improved it so that the focused sound source can be pinched by the hand. The experimental results indicated that sound localization and the sense of enjoyment can be improved by moving the focused sound source as desired. Moreover, we found that by changing the sound volume of the focused sound source according to the movement speed, the sense of movement tended to increase. In the future, we plan to study methods for generating interactively focused sound sources.

***Abstract*—To protect the integrity and privacy of cloud storage images, this paper proposed a self-embedding fragile watermarking scheme in encrypted images. An original image is divided into the seven least significant bit-planes (7LSBs) and the most significant bit-plane (MSB). 7LSBs plane is encrypted using pixel XOR and block scrambling. MSB plane is predicted and compressed for encoding to vacate space for reversible embedding of watermark. A time sensitive hash (TSH) method is designed to resist the collage attack. The TSH enables the hash function to generate a unique hash value under the same input, which greatly reduces the probability of missed detection under collage attack. The adaptive image recovery (AIR) method is also proposed to improve the quality of image recovery. The effectiveness of AIR is achieved by adaptively selecting the recovery method based on the estimated tamper attack type. Experimental results show that the proposed scheme effectively protects the confidentiality of image content and exhibits a strong recovery effect against various tamper attacks, even achieving lossless recovery without tamper. Compared with the existing schemes, the proposed scheme has certain effectiveness and superiority.**

I. Introduction

With the rapid development and increasing popularity of cloud storage, more and more people are inclined to store digital images in the cloud due to its advantages such as high storage efficiency, low cost, and intelligent management. However, cloud storage also entails a series of security issues, such as data tampering [1], data loss, and data leakage [2]. These security issues may arise from cloud storage service providers, hacker attacks, internal personnel and other factors. According to a survey conducted by the data security company Varonis, the number of data leakage incidents in 2020 reached 3,950, an increase of 41% compared to 2019 [3]. Therefore, ensuring the integrity and privacy protection of digital images during the process of using cloud storage services has significant social implications and broad application prospects.

Self-embedding fragile watermark is one of the effective methods for protecting the integrity of images. In [4], Zhang et al. proposed a reference sharing mechanism (RSM) to achieve perfect restoration of watermarked images within a certain tamper range. In order to obtain the best recovery performance at different tamper rates, Qin et al. [5] proposed an embedding mode adaptive selection scheme based on Zhang's work. Compared with [4], it has better flexibility and higher quality restored images. However, these schemes [4], [5] cannot resist collage attacks. [6], [7] introduced the discrete cosine transform (DCT) and integer wavelet transform (IWT) into fragile watermark, but the recovery quality of these schemes is relatively low. In addition, [8]–[12] proposed fragile watermarking schemes based on block truncation coding (BTC) and absolute moment block truncation coding (AMBTC). These methods generated the recovery watermark by compressing the image information in a lossy manner. Compared to methods that use block mean value as recovery watermark, the recovery quality for images with high texture complexity is better.

However, the above fragile watermark scheme can only guarantee the integrity of the image, but not the privacy of the image. In addition, in order to ensure the imperceptibility of the watermark, researchers usually replace the LSB of the original image with the watermark, so that the process of generating the watermarked image is irreversible. This has great limitations in military and medical applications. Therefore, fragile watermarking schemes for encrypted images have emerged. Jiang et al. [13] proposed a high-capacity fragile watermark scheme with probabilistic encryption. Although this scheme can achieve pixel-level tamper detection and localization, it has a high time complexity and cannot recover tampered images. Huang et al. [14] proposed a multi-level authentication scheme for cloud storage, which embeds watermark in the redundant space after image POB compression. Although this scheme can still recover images despite large-scale tamper, due to the introduction of POB compression method, the time complexity of this scheme is relatively high. In addition, for each image uploaded to the cloud, users need to save the number of binary digits '1' before compressing each pixel, which requires additional storage space. We call this phenomenon data expansion.

The above mentioned issues are summarized: 1) Fragile watermarking schemes in plaintext images cannot protect the privacy of the image and the process of watermark embedding is irreversible 2) Some fragile watermarking schemes cannot resist collage attack. 3) The existing fragile watermarking schemes in the encrypted images have high time complexity and data expansion.

In this paper, based on the idea of RDH-EI [15]–[17], we propose a self-embedding fragile watermarking scheme in the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

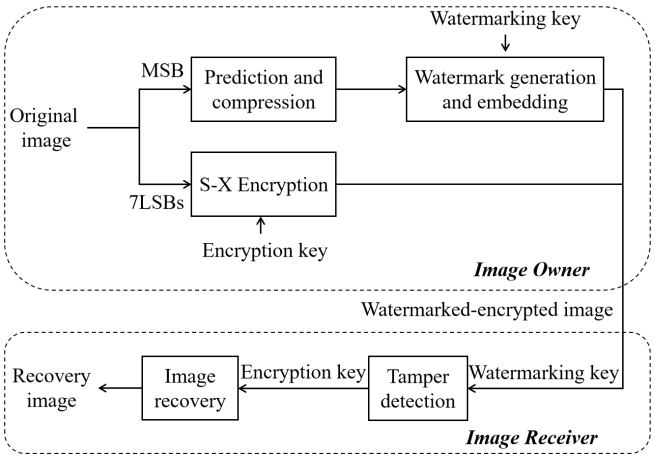

Fig. 1. Framework of the proposed scheme.

encrypted images to achieves high tamper detection performance and good recovery image quality at a low time cost. The contributions of this paper are summarized as follows.

1) A self-embedding fragile watermarking scheme in encrypted images is proposed to simultaneously solve the integrity and privacy of the images. This scheme has low time complexity and no data expansion.

2) Design a time sensitive hash (TSH) method to resist collage attack. This is achieved by combining the timestamp with the image block index as the unique hash key of the hash function. Experimental results show that the average is reduced by more than 0.9 compared with [4] under the collage attack.

3) Design an adaptive image recovery (AIR) method to improve recovery image quality. This is achieved by adaptively selecting the image recovery method according to the estimated tamper attack type. It greatly improves the quality of the recovery image under random noise attack.

The rest of this paper is organized as follows. The proposed scheme is described in detail in the section II. The section III carries on the experimental analysis and comparison. See section IV for conclusion.

II. Proposed scheme

As shown in Fig 1, the proposed self-embedding fragile watermarking scheme in encrypted images includes two participants: image owner and image receiver. The image owner encrypts the 7LSBs through the encryption key (Key_1) and embeds encrypted watermark in the redundant space vacated after MSB prediction and compression using the watermarking key (Key_2). Finally, upload the generated watermarked-encrypted image to the cloud. The image receiver, who owns Key_1 and Key_2, can download watermarked-encrypted image from the cloud, extract watermark for tamper detection and image recovery.

A. S-X Encryption

An original image $I = \{I_k | k = 1, 2, ..., 8\}$ of size $M \times N$ contains 8 bit-planes. The higher the bit-plane of an image, the stronger the correlation between adjacent pixels, so we split it into MSB I_{msb} and 7LSBs I_{lsb}. Then, we divided it into 8×8 non-overlapping image blocks $B = \{B_n | n = 1, 2, \ldots, N_B\}$, where $N_B = (M/8) \times (N/8)$. According to the Key_1, we pseudo-randomly permute all blocks in the 7LSBs and then perform a bitwise XOR operation on each pixel within the block.

B. Prediction and compression

In order to make more images can vacate enough space to embed the watermark, we designed a MAP prediction method. The MAP optimizes compression encoding performance by changing the number of '1' in the prediction bit-plane. The MAP consists of two prediction methods: MSB median prediction (MMP) and MSB flip prediction (MIP),

$$P = \begin{cases} MMP(I_{msb}), & if \quad L_{MMP} \leq Th \\ MIP(I), & if \quad L_{MMP} > Th \end{cases} \tag{1}$$

among them

$$Th = 22 \times N_B - 10 \tag{2}$$

where P represents the predicted bit-plane, L_{MMP} is the length of the prediction compression code C after using MMP, Th is a threshold value, it represents the maximum length of the original data when using RSM. MMP is an prediction method based on median prediction, which takes the bit-plane as the object. MIP is a non-iterative flip prediction method that designed based on iterative MSB-inversion prediction [16].

All images prioritize using MMP prediction because when the image is tampered, only MSB using RSM can be restored losslessly, while MIP needs to use eight planes of the image to restore the prediction, resulting in image distortion. However, after using MMP in the MSB of complex textured images, the number of '1' in the predicted bit-plane is still too large, making it difficult for compression encoding to vacate enough space to embed watermark. At this time, MIP should be utilized. Finally, adaptive compression coding [15] is used to obtain the C.

C. Watermark generation and embedding

The watermark mainly consists of three parts: recovery bit, anti-collage bit, and authentication bit. For each image block , we allocate 33 bits recovery bit, 1 bit anti-collage bit, and 30 bits authentication bit.

1) Recovery bit: In order to lossless recovery of the prediction compression code, we use the RSM to generate the recovery bit. Two reference sharing parameters α, β are chosen, where $\alpha = 256$ and $\beta = 128$. The generation process of the recovery bit is shown in Fig 2. Firstly, we divide original data into $S = \lceil (L + 10)/\alpha \rceil$ subjects $C_1, C_2, \ldots, C_S$, each group contains α bits. L is the code length of C. The x th subset C_x are denoted by $c_{x,1}, c_{x,2}, \ldots c_{x,\alpha}$, $x = 1, 2, \ldots S$. In particular, the first 10 bits of the subset C_1 are used to store S, and if the length of the subset C_S is not equal to α, the rest space will be filled with '0'. Then, equation (3) is used

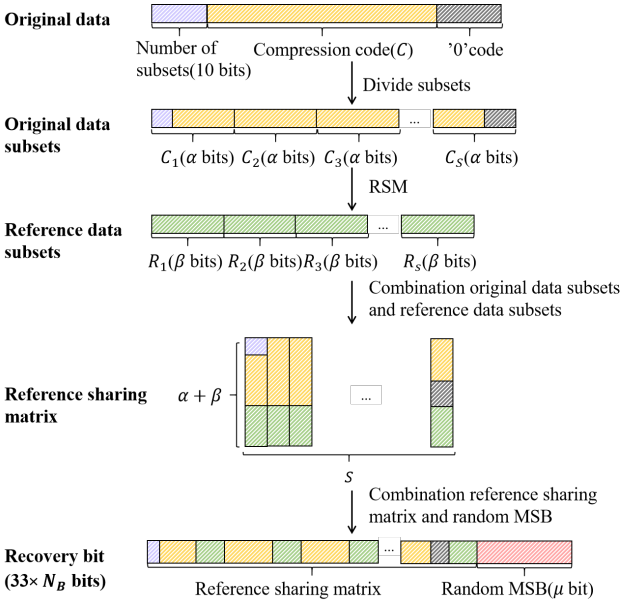

Fig. 2. Recovery bit generation.

to convert the α bits original data of subset C_x into the β bits reference data of subset R_x, $_{x,1}, r_{x,2}, \ldots r_{x,\beta}$,

$$\begin{bmatrix} r_{x,1} \\ r_{x,2} \\ \vdots \\ r_{x,\beta} \end{bmatrix} = A_x \begin{bmatrix} c_{x,1} \\ c_{x,2} \\ \vdots \\ c_{x,\alpha} \end{bmatrix} \tag{3}$$

where A_x is a pseudo-random binary matrix of size $\beta \times \alpha$ generated by the key. Then, the original data and reference data of each subset are concatenated by column. Finally, for the μ bits space remaining after using the RSM, we filling it by R_P randomly selected from the MSB to obtain the recovery bitstream C_R. C_R is scramble and XOR encryption based on Key_2 and divided into N_B groups, distribution of each image block 33 bits.

2) Anti-collage bit: To resist the collage attack, we develop the TSH method, which uses the timestamp as the random number seed to generate the anti-collage key $Ckey$. $Ckey$ is converted into a 50 bits binary sequence and concatenated repeatedly. Then, N_B bits are intercepted from sequence to generate the anti-collage bitstream C_C. C_C is scramble and XOR encrypted by Key_2 and divided into N_B groups, distribution of each image block 1 bit.

3) Authentication bit: For each image block B_n, 33 bits of recovery bit and 1 bit of anti-collage bit are concatenated, and the rest of 30 bits are filled with '0' to obtain the watermark sequence. The watermark sequence is combined with the corresponding encrypted 7LSBs block as the input of the hash function. The hash key $Hkey$ is formed by combining the $Ckey$ with the block index. We use the first 30 bits of the hash function output as authentication bit W_A, W_A is scramble and XOR encryption according to the Key_2.

$$Hkey = Ckey + n \tag{4}$$

Finally, The authentication bit replaces the 30 bits '0' of the watermark sequence in order to generate the watermarked MSB. The watermarked-encrypted image I_w is obtained by combining the watermarked MSB with the encrypted 7LSBs.

D. Tamper detection

After downloading image I_a from the cloud, the image receiver performs tamper detection on it through authentication bit, and estimates the type of tamper attack through anti-collage bit.

Firstly, the image I_a is divided into 8×8 non-overlapping image blocks. The anti-collage bits are extracted from the 34th bit of each image block in MSB. We splice it in sequence and decrypt it with Key_2 to obtain the anti-collage bitstream $C_C{}'$. Since C_C is formed by repeated splicing of $Ckey$, the sequences of each group (except the last group) grouped by $C_C{}'$ should be equal. If not, the image is tampered. In this process, we can extract the correct $Ckey$ and calculate the error proportion of the $C_C{}'$ according to equation (5),

$$ep^{C_C} = \sigma^{C_C}/N_B \tag{5}$$

Where ep^{C_C} represents the proportion of the error bit in $C_C{}'$ and σ^{C_C} represents the number of the error bit in $C_C{}'$.

Subsequently, when $Hkey$ is obtained by combining $Ckey$ and block index, the authentication bits $W_A{}'$ are regenerated by the same steps. The 35th to 64th bit of B_n in the MSB are extracted to obtain the authentication bits $W_A{}''$. If $W_A{}' = W_A{}''$, the block is a complete block, otherwise the block is a tampered block. In this way, the tamper localization $flag_1$ of the encrypted image can be obtained. After using Key_1 to recover the scrambled $flag_1$, we can also obtain the tamper localization $flag_2$ of the plaintext image.

Finally, the type of tamper attack can be estimated by using the proportion of tampered pixels ep^{flag} in $flag_1$ or $flag_2$ and ep^{C_C} through equation (6),

$$\theta = ep^{flag} - 100 \times ep^{C_C} \tag{6}$$

If $\theta > 0$, the type of tamper attack is random noise attack, otherwise, it is regional attack. We will perform the secondary tamper localization of the image to reduce the number of misjudged pixels under random noise attack. The decrypted 7LSBs plane is divided into 2×2 blocks, and the principle of correlation between pixels is used to get tamper localization $flag_3$ of random noise attack.

E. Image recovery

Image recovery can be divided into two situations: image not tampered and image tampered. If I_a is not tampered, the image receiver decrypts the 7LSBs using Key_1, then decrypts the $C_R{}'$ using Key_2 and restores the compression and prediction of the C' to obtain the MSB. The recovery image I_r is obtained by recombining the MSB and 7LSBs.

If I_a is tampered, determine whether S is tampered according to $C_R{}'$. If S is tampered, the first subset $C_1{}'$ is extracted, and the complete reference data is used to recover the tampered original data to obtain the correct S. Then, We use the same steps to recover tampered original data in all subsets. Finally, the prediction compression code C' is obtained by concatenating all the original data in sequence. The recovery equation is shown in (7),

$$\begin{bmatrix} r_{x,1} \\ r_{x,2} \\ \vdots \\ r_{x,\beta'} \end{bmatrix} - A_x^{(E,R)} \cdot C^{(R)} = A_x^{(E,T)} \cdot C^{(T)} \tag{7}$$

where $C^{(R)}$ and $C^{(T)}$ denote the complete original data and the tampered original data, respectively. $A_x^{(E,R)}$ and $A_x^{(E,T)}$ are the corresponding columns of $C^{(R)}$ and $C^{(T)}$ in $A_x^{(E)}$, $A_x^{(E)}$ is a matrix that extracts the rows corresponding to the complete reference data from A_x. We use Gaussian elimination method to solve. If there is a unique solution, we can recover the tampered original data in the subset. If the solution is not unique or there is no solution, the recovery fails.

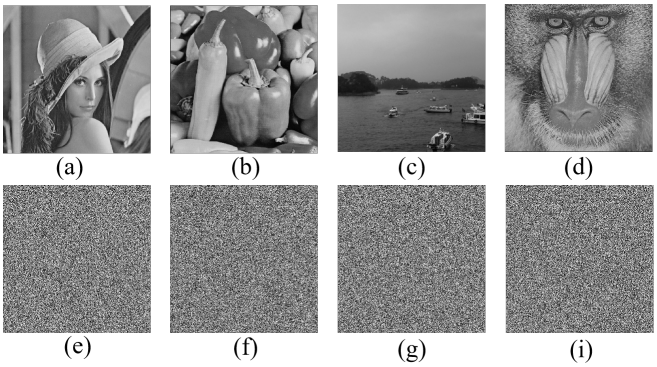

Fig. 3. The selected test images. (a) Lena, (b) Pepper, (c) Lake, (d) Baboon, (e)-(i) are the watermarked-encrypted image for (a)-(d), respectively.

Finally, the AIR method is selected adaptively according to the prediction method, the estimated tamper attack type and the recovery situation of C', so as to achieve the best recovery quality. The details are shown in Algorithm 1.

III. Experimental results

This section mainly evaluates the proposed scheme from four aspects: watermarked-encrypted image security, tamper detection, image recovery and time cost. Fig.3 (a)-(d) show four standard test images of size 512×512 as original images, Lena, Pepper, Lake, Baboon. After embedding the watermark, their corresponding watermarked-encrypted images are shown in (e)-(i). From the visual effect, the human eye cannot recognize the original image content.

A. Security analysis

1) Key space: It is known that the security of a cryptosystem depends solely on the key. In this scheme, we use Key_1 and Key_2 to encrypt the 7LSBs and C, respectively. Then the probability that an attacker correctly gets MSB for all pixel without knowing the key is $1/((1/L!) \times (1/2)^L)$. For 7LSBs, if the brute force method is applied, the probability to correctly obtain 7LSBs is $1/((1/N_B!) \times (1/2)^{7\times M\times N})$. Therefore, for an image of size $M \times N$, the probability of the attacker successfully recovering to the original image is $1/((1/L!) \times (1/2)^L \times (1/N_B!) \times (1/2)^{7\times M\times N})$.

2) Pixel adjacent correlation: A good image encryption algorithm should be able to reduce the correlation of adjacent pixels, as far as possible to achieve zero correlation. We randomly selected 1000 pixels from the original image and the watermarked-encrypted image from the horizontal, vertical and diagonal directions for correlation analysis. table I shows the average value of 100 results. It can be seen from table I that the original image has a large correlation in three directions, while the adjacent correlation of the watermarked-encrypted image is almost zero, indicating that the watermarked-encrypted image effectively hides the correlation between adjacent pixels.

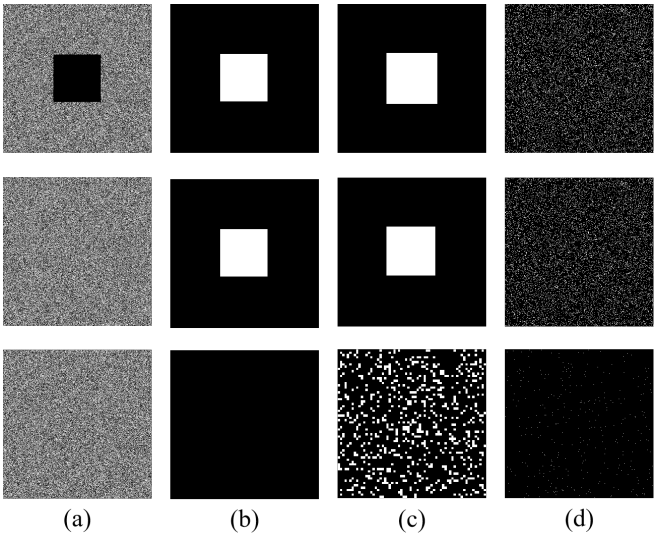

Fig. 4. Tamper detection of Lena under different types of attacks. (a) $\gamma = 10\%$ cropping attack, $\gamma = 10\%$ college attack and $\rho = 1000$ random noise attack from top to bottom, (b) true tamper location, (c) tamper detection localization of encrypted images, (d) tamper detection localization of plaintext images.

B. Tamper detection analysis

For tamper detection, we use the probability of false rejection (PFR), probability of false acceptance (PFA), and probability of false decision (PFD) to evaluate the detection performance of the watermark,

$$PFR = \frac{FT}{M \times N} \tag{8}$$

$$PFA = \frac{TF}{M \times N - \sigma^{flag}} \tag{9}$$

$$PFD = \frac{\sigma^{flag}}{M \times N} \times PFA + (1 - \frac{\sigma^{flag}}{M \times N}) \times PFR \tag{10}$$

Where TF represents the number of complete pixels judged as tampered pixels, FT represents the number of tampered pixels judged as complete pixels, σ^{flag} represents the number of the tampered pixel in $flag_1$ or $flag_2$.

As shown in Fig 4, taking the Lena image as an example. Column (a) shows the tampered image under the cropping attack with $\gamma = 10\%$ in the center region, the collage attack with $\gamma = 10\%$ in the center region and the random noise attack with $\rho = 1000$ from top to bottom, respectively. Column (b) is the true tamper location in encrypted images. Column (c) shows the tamper detection localization results of encrypted images. Column (d) shows the tamper detection localization results of plaintext images. γ represents the tampered range, rho represents the number of tampered pixels. The detailed detection results of the four images are shown in table II. As can be seen from table II, the average PFD is all less than 2% under the cropping attack and collage attack. Under the collage attack, the average PFA is 0.001, this means that the probability of missed detection is very low. However, the accuracy under random noise attack is relatively low.

TABLE I
CORRELATION OF IMAGES

Direction	Image type	Lena	Pepper	Lake	Baboon
Horizontal	Original	0.9697	0.9730	0.9907	0.8649
	Watermarked	0.0047	-0.0022	-0.0022	-0.0013
Vertical	Original	0.9843	0.9762	0.9780	0.7533
	Watermarked	-0.0004	-0.0008	-0.0078	0.0019
Diagonal	Original	0.9562	0.9575	0.9719	0.7197
	Watermarked	-0.0030	-0.0064	-0.0003	0.0007

Fig. 5. Recovery image of Lena under different types of attacks. (a) $\gamma = 10\%$ cropping attack, (b) $\gamma = 10\%$ college attack, (c) $\rho = 1000$ random noise attack.

Table III shows the results of PFR, PFA and PFD under collage attack with different γ for proposed scheme, [4] and [14]. The proposed scheme and [14] are both able to resist collage attack. Compared with the [4], which also uses hash function to generate authentication watermark, the average PFA of the proposed scheme is less than 1%. Although under a large-scale collage attack, the proposed scheme can still accurately detect the tampered area, but [4] have a high error detection rate. Therefore, TSH method performs well.

C. Image recovery analysis

In this subsection, we mainly adopt Peak Signal-to-Noise Ratio (PSNR) and Structural similarity (SSIM) to measure the recovery image quality. The recovery images corresponding to Fig 4 (a) are shown in Fig 5 (a)-(c). Table IV shows the PSNR and SSIM of the four original images and the recovery images corresponding to the above attacks. It can be seen from table IV, the recovery quality of baboon image is lower than other images. The texture complexity of Baboon image is too high, so MIP prediction is used. However, the peoposed scheme only uses compression codes on the MSB as the original data

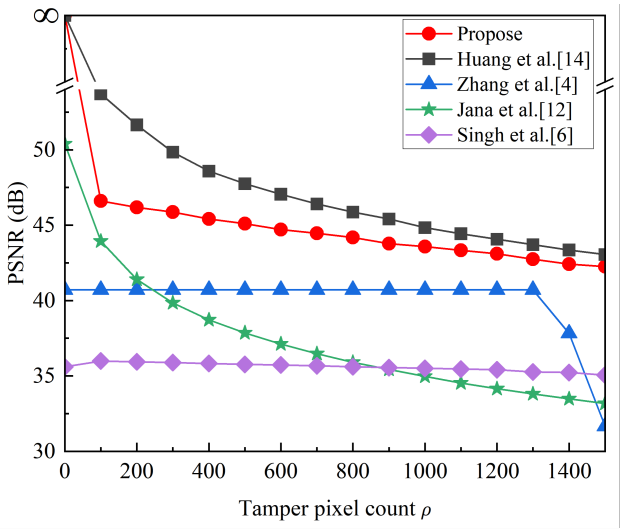

Fig. 7. PSNR of image recovery under random noise attack.

to generate recovery watermark, and 7LSBs is restored using domain complete pixels. This leads to failure of MIP prediction recovery when the image is tampered. However, the average PSNR of the remaining three images under cropping attack and collage attack reaches 41.18dB and 41.02dB, and the average SSIM is above 0.96, which indicates that the recovery effect is good. Especially for random noise attack, the average PSNR reaches 45.99dB and the average SSIM is above 0.99. Fig. 6 and Fig. 7 compare the average PSNR of the recovery image and the original image of 50 randomly selected UCID images [18] under cropping attack and random noise attack. When the image is not tampered, except the proposed scheme and [14], other schemes cannot achieve lossless recovery. This is because both schemes utilize the redundant space after compression to embed the watermark, rather than directly replacing the LSB of the image. Under the cropping attack, the proposed scheme outperforms all schemes when $\gamma < 8\%$. While , the PSNR of [4] is superior to the proposed scheme when $\gamma > 8\%$, this is because [4] uses the RSM to losslessly restore the 5MSBs of the image. Under the random noise attack, the PSNR of the proposed scheme is greater than 40dB, and the average PSNR is 44.25dB. This is better than the same 8×8 block size [4] and slightly lower than the 2×2 block size [14]. The results show that the AIR method is effective.

TABLE IV
PSNR, SSIM FOR TEST IMAGES AGAINST VARIOUS TAMPER ATTACKS

Direction		Lena	Pepper	Lake	Baboon
Cropping($\gamma = 10\%$)	PSNR	41.05	40.75	41.73	14.38
	SSIM	0.9653	0.9626	0.9589	0.5063

	SSIM	0.9942	0.9923	0.9933	0.92427

D. Time analysis

We count the time required by the image owner and the image receiver in proposed scheme, respectively.It can be seen

TABLE V
COMPARISON OF RUNNING TIME BETWEEN PROPOSED SCHEMES AND RELATED WORKS

Tamper rate	Participant	Time(/s)			
		[14]	[4]	[12]	Propose
$\gamma = 5\%$	Image owner	114.89	18.54	16.29	2.63
	Image receiver	38.53	150.49	18.62	3.37
$\gamma = 10\%$	Image owner	115.89	18.07	16.26	2.62
	Image receiver	38.98	222.05	18.66	3.9
$\gamma = 15\%$	Image owner	115.63	18.86	16.33	2.65
	Image receiver	38.37	283.78	19.03	4.45
$\gamma = 20\%$	Image owner	115.24	18.75	16.21	2.64
	Image receiver	38.09	351.93	18.97	4.79
$\gamma = 25\%$	Image owner	115.24	18.06	16.22	2.65
	Image receiver	38.17	391.91	19.15	4.78

from table V that the average running time of the proposed scheme is the shortest. Compared with the [4], which also adopt the RSM, our scheme greatly reduces the time required by the image receiver. This is because [4] uses all bits of the 5MSBs as original data, while the proposed scheme only uses the MSB plane prediction compression code as original data, which greatly reduces the number of solutions to equation (7). Compared with scheme [14], which is also a fragile watermarking scheme in encrypted images, the time required for two participants is about 20 times slower than the proposed scheme. This is because the time complexity of the POB compression is high.

IV. Conclusion

To simultaneously protect the integrity and privacy of cloud storage images, we propose a self-embedding fragile watermarking scheme in encrypted images. In this scheme, the TSH method is designed to resist collage attacks by using timestamp to make the hash function generate unique output. Another contribution is the AIR method, which adaptively selects the best image recovery method for different types of tamper attacks. Furthermore, experimental results confirm that the proposed scheme achieves high tamper detection performance and good recovery image quality at a lower time cost. Future work will focus on increasing the tolerable tamper range of image using advanced image processing methods.

***Abstract*—Stress, as the perceptual prominence within sentences, plays a key role in expressive text-to-speech (TTS). It can be either the semantic focus in text or the acoustic prominence in speech. However, stress labels are always annotated by listening to the speech, lacking semantic information in the corresponding text, which may degrade the accuracy of stress prediction and the expressivity of TTS. This paper proposes a multi-granularity stress prediction method for expressive TTS. Specifically, we first build Chinese Mandarin datasets with both coarse-grained semantic stress and fine-grained acoustic stress. Then, the proposed model progressively predicts semantic stress and acoustic stress. Finally, a TTS model is adopted to synthesize speech with the predicted stress. Experimental results on the proposed model and synthesized speech show that our proposed model achieves good accuracy in stress prediction and improves the expressiveness and naturalness of the synthesized speech.**

I. Introduction

In recent years, text-to-speech (TTS) systems have made remarkable progress in terms of speech quality and generation speed [1]–[8]. The TTS system is even capable of producing almost human-like speech. However, the expressiveness and naturalness of the synthesized speech can still be improved [9]–[11]. Prosody, which is crucial and essential for expressive speech synthesis, is mainly composed of rhythm, stress and intonation [12]–[16]. Stress, as a perceptual prominence within words or utterances, is a critical factor in prosody [17]. Therefore, accurately modeling stress is beneficial to improve the expressiveness and naturalness of TTS.

Constructing a Mandarin dataset with stress annotations is more challenging compared to constructing one in English. English is a stress-timed language, so it is relatively easy to label the prominence using a well-established English ToBI annotation system [18]. While, Mandarin is a syllable-timed language, which is characterized by syllables with the corresponding tone and pitch contour [19]. The interaction between tone, intonation, and stress makes the stress annotation of Mandarin difficult. Chinese Mandarin stress can be categorized into sentential stress and lexical stress [20], [21]. Sentential stress always reflects on certain syllables or words in need of logical semantics or emotional expressiveness. While, lexical stress, as a part of the word phonetic structure, can be used to distinguish the word sense and part of speech (POS), which is affected by acoustic features, such as pitch, duration and energy.

Generally, there are two typical approaches to acquiring stress labels from text. One is a manual approach by listening to the speech and perceiving the prominence. Li *et al*. released ASCCD, an open-source Mandarin corpus with stress annotations that are labeled by human perception [22]. The other is an automatic approach via Continuous Wavelet Transform (CWT) analysis of the speech [23]. Talman *et al.* [24] utilized the CWT to automatically extract word-level acoustic prominence of LibriSpeech [25]. Both methods are performed based on acoustic information in speech without the consideration of semantic information in the text transcription of the speech, which may result in less accuracy for stress detection and less expressivity for speech synthesis.

Based on the dataset either with manual stress annotations or automatic stress annotations, stress can be predicted from the acoustic features extracted from the speech [26], [27], such as minimum pitch, maximum pitch, duration and so on, linguistic features [19] analyzed from the text, such as tone, POS, positions of the words, or the combination of acoustic and linguistic features [20], [26]. As for TTS, it is more practical to predict stress from only text because no speech is accessible when generating speech from text. Accordingly, word embedding extracted from the text is introduced into the model of stress prediction [17], [28]. Furthermore, with the significant improvement of pre-trained language models, such as BERT [29], the learned contextualized word representation is involved in rich semantic and syntactic cues of the text, which could be beneficial to the stress prediction and the downstream TTS task. Talman *et al.* [24] employed the contextualized word representation extracted from BERT to predict stress, outperforming other models using word embedding or linguistic features. However, although it achieved an excellent result in stress prediction, the performance of TTS with the predicted stress is unknown.

In this paper, we propose a multi-granularity stress prediction model for TTS, in which stress is predicted from the contextualized word representation extracted from text via BERT and the TTS framework of VITS [8] is adopted to generate speech with stressed words. Considering the two-level nature of Mandarin stress in terms of semantic information of text and acoustic information of speech, we first build two Chinese Mandarin datasets with multi-grained stress

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

annotations. One is labeled with coarse-grained stress which attends to the phrase based on the semantic information of the text. The other is labeled with fine-grained stress that mainly focuses on specific words according to the prominence perception of the speech. Then, we design a multi-granularity stress prediction model to progressively predict stress from coarse-grained level to fine-grained level. Finally, we feed the predicted stress into a TTS model to synthesize speech with stressed words. We objectively and subjectively evaluate the performance of the stress prediction and the corresponding synthesized speech. Experimental results demonstrate that the proposed multi-granularity stress prediction model achieves more accurate performance and the generated speech based on the predicted stress is more expressive and natural.

II. Dataset Construction

For the standard stress corpus collection, the voice actor is often required to read well-designed utterances fluently and accurately, and then professional labelers or people from crowdsourcing projects annotate the stress according to the perceived prominence from the recordings, as shown in the left part of Figure 1. The stress expression obtained by this approach depends on the voice actor's performance and is limited by the recording environment, pre-designed script, etc. It may not suitable for real-world scenarios and is unaffordable as well. We propose a new multi-grained stress annotation method as shown in the right part of Figure 1, which is comprised of coarse-grained stress with semantic information and fine-grained stress with acoustic information. It is noted that we mainly focus on stressed and unstressed behavior instead of different stress levels [17], so we explicitly annotate the stressed words and then the remaining words are classified into unstressed words. Additionally, before labeling the stress, crowdsourcing people are trained on a subset corpus multiple times in advance, aiming to ensure intra- and inter-rater annotation consistency and reliability. The consistencies of those two-stage stress labeling after training are 76% and 85% in all annotators.

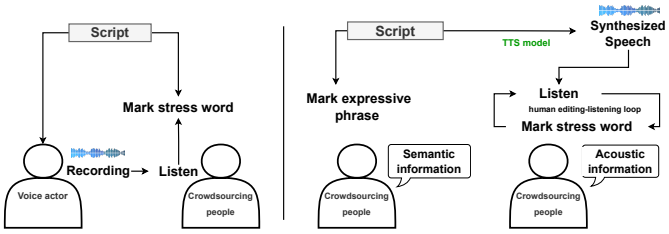

Fig. 1. The difference of stress data construction

A. Coarse-grained Semantic Stress

We first construct a coarse-grained stress corpus that centralizes semantic phrases within a sentence. To this end, people from the crowdsourcing label phrases which are potential stress according to the semantic information delivered in the text. To ensure the accuracy and consistency of the stress label, we establish semi-open annotation criteria. The specification of stress annotation are as follows:

- Mainly focus on emphasized entities, descriptive phrases, and tone conjunctions in the text. For example, the stress phrase of the sentence "年轻的母亲暴跳如雷，竟然打翻了桌子" (The young mother gets into a rage, unexpectedly knocking over the table) is "暴跳如雷" (gets into a rage) and "竟然" (unexpectedly), both of which clearly express the emotion, i.e., angry and surprise.
- To maintain the annotation consistency, we recommend annotating 1 to 3 phrases per sentence by extending or reducing the annotations based on the first rule.
- Based on our statistical results of subword length for stress character, all annotated phrases should keep a full sub-phrase length within the range of 2 to 6 characters.

B. Fine-grained Acoustic Stresss

年 轻 的 母 亲 暴 跳 如 雷， 竟 然 打 翻 了 桌 子!
年 轻 的 母 亲 暴 跳 如 雷， 竟 然 打 翻 了 桌 子!
The young mother gets into a rage, unexpectedly knocking over the table!

Fig. 2. An example of the dataset with multi-grained stress. The character in blue is semantic stress and the character in red is acoustic stress

As mentioned before, standard stress labels are annotated by listening to the recordings, in which stressed words are fixed. Consequently, such stress datasets may lack flexibility and diversity for stress prediction and speech synthesis. To solve this problem, we propose a new fine-grained stress labeling method based on acoustic information. Specifically, we first utilize a high-quality stress-controllable **TTS model** as described in Section III-C to let users set the desired stressed words in the given text to generate speech with stress. Please kindly take note that the TTS model can synthesize speech with stressed words by feeding stress tags, but it cannot predict stress. Then, we use the generated speech for fine-grained stress labeling. Additionally, we introduce a human listening-editing loop to modify the stress position and repeatedly. The human listening-editing loop consists of two circular steps: (1) Listening, where people listen to the synthesized audio generated from the above TTS model. (2) Editing, where people listen to the synthesized speech and then mark the stress word in the current transcript to make the speech perceived more natural. For example, even though "暴跳如雷" (gets into a rage) can be a semantic stress, the speech with all these 4 continuous stress characters does not natural, so finally, we're going to set the stress position at "暴". Similarly, to ensure the reliability of stress labeling, specifications of acoustic stress annotation are as follows:

- Only the locations with high stress intensity are annotated to ensure the accuracy of stress annotation.
- We recommend annotating 1 to 3 positions per sentence, and each position should be in the range of 1 to 2 characters, which maintains the annotation consistency
- To mitigate potential confusion arising from repeated listening, annotators are allowed to engage in the human

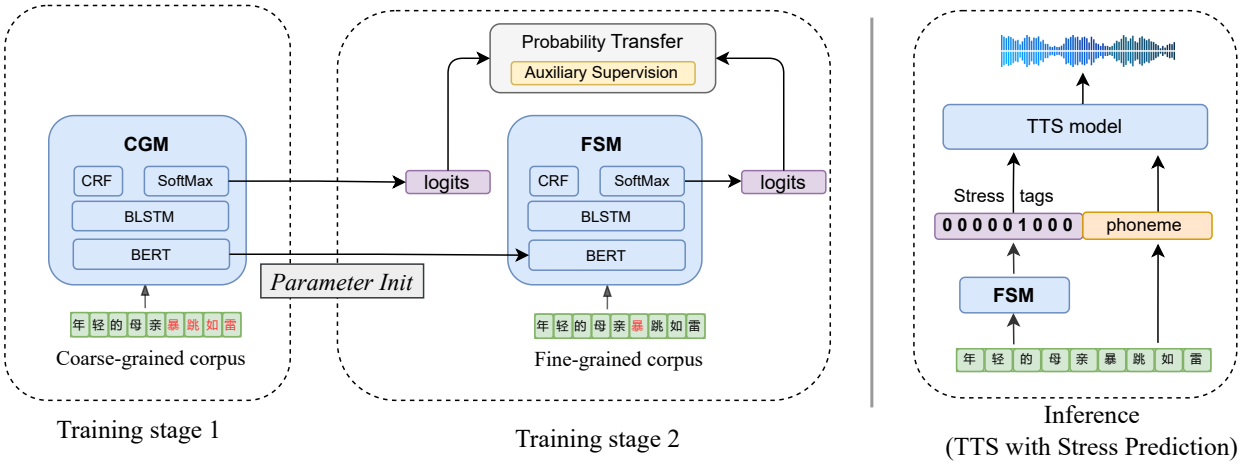

Fig. 3. The overall architecture of our proposed model, where the character in red is ground-truth stressed words. The illustration for the calculation of auxiliary supervised loss in training stage 2

listening-editing loop for each transcript a maximum of 3 times.

Figure 2 shows an example of our dataset with multi-grained stress, where the character in blue is labeled as semantic stress and the character in red is labeled as acoustic stress.

III. Multi-granularity Stress Prediction

The overall architecture of our proposed multi-granularity stress prediction model is presented in Figure 3. The coarse-grained stress and fine-grained stress provide different aspects of information within a sentence, i.e., semantic and acoustic information, respectively. To take full advantage of these two types of stress, the stress prediction model we proposed is a two-stage training model. In the first stage, we trained a coarse-grained stress model (CGM) using a coarse-grained stress corpus. In the second stage, we trained a fine-grained stress model (FSM) using a fine-grained stress corpus. We connected these two stages using two strategies: (1) initializing FSM's BERT parameter with the parameters learned from CGM, and (2) designing a coarse-grained supervision loss to maintain CGM's supervision effect and meanwhile ensure the diversity of FSM. The final stress is predicted from FSM, which is learned by transferring knowledge from CGM. Compared with the model trained on the dataset with acoustic stress only, our model incorporates stress from both semantic and acoustic information, improving the diversity of stress and also benefiting expressive speech synthesis.

A. Stage 1:Coarse-grained Semantic Stress Prediction

As shown in Figure 3, in the first stage, the coarse-grained stress model (CGM) is trained on the coarse-grained corpus as described in Section II-A to identify the salient entities within a sentence. The input of the model is Chinese Mandarin characters, which is consumed by a pre-trained Chinese BERT [30] with 12 transformer layers and 768 hidden states, followed by a Bidirectional Long Short-Term Memory (BLSTM) [31], [32] layer with 768 hidden units. In the BLSTM layer, dropout with the probability of 0.1 is adopted to prevent overfitting.

The loss function of CGM L_{CGM} includes a sequence loss of CRF [33] L_{crf} and a cross-entropy loss L_{ce}, i.e., $L_{CGM} = L_{crf} + L_{ce}$, which could better perform classification task (0 is unstressed and 1 is stressed) and meanwhile keep the contextual connection of the input character sequences. Specifically, the L_{crf} is:

$$\begin{aligned} L_{crf} &= -logP(y|x) \\ &= -(score(y) - log(\Sigma_{\hat{y}} score(\hat{y}))) \end{aligned} \tag{1}$$

where y is the predicted sequence label, x is the current input sentence, $score(y)$ is the score of the current CRF predicted path y, and $score(\hat{y})$ denotes all possible sequences of labels. Besides, L_{ce} is:

$$L_{ce} = -\sum_{i=1}^{seq_len} \sum_{k=1}^{n_class} y_{ik} log G1(\hat{y}_{ik}|x) \tag{2}$$

where seq_len is the length of the input sequence, n_class is the number of label classes, y_{ik} refers to the true label, $\hat{y}_{ik}$ is the k-th value of the predicted label and $G1$ refers to the output probability of the softmax layer in CGM.

B. Stage 2:Fine-grained Acoustic Stress Prediction

After acquiring the coarse-grained semantic stress in the stage 1, we further extract fine-grained acoustic stress.

In the stage 2, a fine-grained stress model (FSM) is utilized to predict stress from Chinese Mandarin characters using the fine-grained stress corpus as described in Section II-B. The structure of FSM is similar to that of CGM, but the BERT is initialized by the parameters learned from CGM. The dropout is also applied to the BLSTM layer with a probability of 0.3.

The loss function of FSM L_{FSM} is $L_{FSM} = L_{crf} + L_{cgce}$, where L_{crf} is CRF loss same as that of CGM and L_{cgce} is the auxiliary supervised loss which is designed based on the focal loss [34] . We use L_{cgce} to preserve the semantic information learned from the CGM so as to better connect the two training stages and predict stress as well. L_{cgce} is formulated as:

$$L_{cgce} = -\sum_{i=1}^{seq_len}\sum_{k=1}^{n_class} y_{ik} log(F2) \quad (3)$$

$$F2 = Min(\beta G2_i, 1) F1(\hat{y}_{ik}|x) \quad (4)$$

where $F1$ refers to the output probability of softmax layer in the FSM, $G2_i$ is the probability transferred from $G1_i$ for the i-th character, which is calculated by the following equation:

$$G2_i = \begin{cases} \frac{1}{\beta} & , if\ gt_i = 1 \\ G1_i & , otherwise \end{cases} \quad (5)$$

where gt_i is the ground-truth of fine-grained stress label and $G1_i$ is the predicted probability from CGM. β is the reciprocal of $1/\beta$. $1/\beta$ is the probability threshold for CGM to be 1 (if $G1_i >= 1/\beta$, then the i-th character is stressed). We use β as a regularization parameter to constrain the impact of coarse-grained supervision on the FSM.

We empirically suggest that β smaller than 10 is more effective. Moreover, the Min truncated normalization is employed to transfer the probability, preventing gradient explosion.

The process of $F2$ calculation is illustrated in Figure 4, in which $G2_i$ is transferred from $G1_i$ according to gt_i and then multiplies β and $F1$, generating $F2$. So, $F2$ is adjusted by gt_i:

- When the gt_i is 1 (stressed), the $F2_i$ will not be affected.
- When the gt_i is 0 (unstressed), the direction of $F2_i$ change is consistent with $G1_i$.

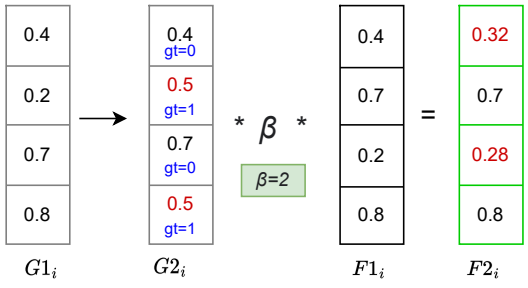

Fig. 4. Probability transfer, where **gt** means the ground-truth of fine-grained stress label and $1/\beta$ is the probability threshold for CGM to be 1.

In other words, we strengthen the L_{cgce} only when the CGM's predicted probability is larger than $1/\beta$, and vice versa, maintaining the CGM supervision effect and ensuring the diversity of the FSM itself.

C. TTS with Predicted Stress

The TTS model adopts the framework of VITS, which is able to synthesize speech with stressed words by feeding the stress tags. As shown in the right part of Figure 3, FSM takes the text as input and outputs the stress tag for each character in the text. And then, the TTS model takes the phoneme sequence extracted from the text and the predicted stress tags as input and generates speech with the corresponding stress. The TTS model is used to verify the effectiveness of the proposed model by feeding the predicted stress as the stress tag. Besides, it is also used to build the dataset with fine-grained acoustic stress (Section II-B) due to its high performance of speech generation.

IV. Experiments

A. Experimental Setups

The detailed information of the datasets, which have varying numbers of sentences, is listed in Table I. As the description of the dataset collection process in Section 2, we collected the coarse-grained stress dataset and fine-grained stress dataset separately. The coarse-grained stress dataset contains 6,817 sentences and the fine-grained stress data includes 13,615 sentences. The stress distribution of the datasets listed in the last column shows that the percentage of fine-grained stress is smaller than that of coarse-grained stress, which is consistent with our annotation specifications as described in Section II, indicating that the annotation results are valid. To train the stress prediction model, we divide each dataset into three subsets with a ratio of 8:1:1, including the training set, validation set and testing set. Moreover, the TTS model is trained on the voice actor's recordings with pre-defined stressed words. Only in this way, we can obtain a relatively reliable TTS system that can generate speech with stressed words.

TABLE I
STATISTICAL RESULTS OF THE STRESS DATASET.

Data Type	#Sentence	Stress Distribution		
		#Character	#Stress	Percentage(%)
Coarse-grained	6,817	125,645	37,063	29.50
Fine-grained	13,615	205,132	22,714	11.07

In the two stages of model training, the batch size is set as 4 for two GPUs and the learning rates of BERT and CRF are 1e-3 and 5e-5, respectively. β in the auxiliary supervised loss L_{cgce} is set to 2.

B. Experimental Results

Objective Evaluations We objectively evaluate the performance of CGM and FSM, comparing with different stress predictor models investigated in Talman *et al.* [24] using our fine-grained acoustic stress corpus. The objective evaluation results, including precision (micro), recall (micro) and F1 (micro) score, are listed in Table II. As we can see, the results show that the performance of our proposed model, i.e., FSM, is better than BERT-base, 3-layer BLSTM and CRF. We suggest that pre-trained language models, such as BERT, are more suitable for our small dataset to capture contextual semantic information. Moreover, FSM and FSM (*one-stage) has a lower F1 score than CGM, while it tends to generate more natural speech (as shown in Table III and Figure 5). The results demonstrate the challenge of directly modeling fine-grained stress, indicating the effectiveness of our proposed multi-granularity stress prediction approach.

Subjective Evaluations We carry out 5-point MOS [35] subjectively listening tests in terms of naturalness (NMOS)

TABLE II
OBJECTIVE EVALUATION RESULTS.

Model	Precision	Recall	F1
CGM	0.8471	0.9061	0.8756
FSM	0.7593	0.6762	0.7153
FSM (*one-stage)	0.6218	0.6284	0.6251
BERT-base	0.6050	0.5737	0.5890
3-layer BLSTM	0.0100	0.8471	0.0197
CRF	0.5278	0.0252	0.0482

and expressiveness (EMOS). Twenty listeners participate in the listening test, rating on 20 samples randomly selected from the testing set [1]. The subjective results are shown in Table III. Except for the first-stage stress prediction model CGM and our final stress prediction model FSM, there are other three types of generated speech for comparison: (a) **Original** represents the synthesized speech without stress; (b) **ManualSet** stands for the synthesized speech with manual annotated acoustic stress; (c) **CGM**$_{random}$ is the generated speech with a random selection of stress positions based on the results of the CGM.

TABLE III
SUBJECTIVE EVALUATION RESULTS.

Type	Original	ManualSet	CGM	CGM$_{random}$	FSM
NMOS	3.86	3.98	3.75	3.83	**3.95**
EMOS	3.9	4.08	3.83	3.88	**4.07**

From the subjective results, we can see that CGM performs poorly, resulting in unnatural and abnormal speech. This can be attributed to the fact that CGM solely focuses on semantic stress (sentential level) annotated from the text without considering of acoustic features of the speech. The final stress should be at the fine-grained level (lexical level) based on acoustic information, which is why CGM$_{random}$ outperforms CGM. The result of our proposed model FSM is close to that of the ground-truth result from ManualSet. We speculate that FSM improves the naturalness and expressiveness of TTS by leveraging both semantic and acoustic information.

C. Ablation Studies

In this section, we conduct ablation studies on the auxiliary supervised loss L_{cgce} and two-stage training strategy. Specifically, we replace L_{cgce} with L_{ce}, i.e., w/o L_{cgce}, and further use the parameters of pre-trained Chinese BERT instead of CGM to initialize FSM, i.e., w/o CGM. Please kindly take note that 'w/o CGM' denotes the utilization of a one-stage training approach solely with the fine-grained stress corpus (acoustic stress information).

The ablation results of objective evaluations are shown in Table IV. It can be seen that the initialization of CGM can enhance the effect of the FSM a little bit. However, the auxiliary supervision loss of CGM significantly improves the performance of the FSM, achieving the highest F1 score of 71.53% with 7% to 8% improvement. We guess that while BERT can provide abundant semantic information, the CGM model still offers remarkable stress-related information in the sentence, thereby facilitating the FSM in detecting fine-grained stress keywords. The subjective preference test results, as depicted in Figure 5, demonstrate that the speech produced by FSM trained on a two-stage approach with coarse-grained information exhibits greater naturalness and expressiveness. Overall, the results demonstrate that the incorporation of coarse-grained information supervision is an effective approach to preventing stress weight dispersion during training.

TABLE IV
ABLATION RESULTS OF OBJECTIVE EVALUATION

Model	Loss	Model$_{\text{init}}$	Precision	Recall	F1
FSM	L_{cgce}	CGM	0.7593	0.6762	0.7153
FSM	w/o L_{cgce}	CGM	0.6981	0.5780	0.6335
FSM (*one-stage)	w/o L_{cgce}	w/o CGM	0.6218	0.6284	0.6251

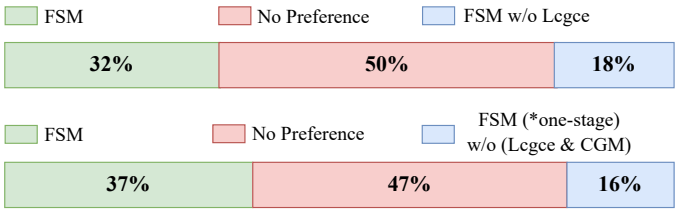

Fig. 5. Preference test results for ablation studies.

V. CONCLUSIONS

In this work, we propose a multi-granularity stress prediction model to improve the naturalness and expressiveness of TTS. In consideration of the nature of multi-grained stress, we construct the dataset with coarse-grained semantic stress and fine-grained acoustic stress to incorporate both the semantic knowledge in the text and the acoustic information in the speech. Then, the two-stage stress prediction model progressively predicts the coarse-grained stress and fine-grained stress from text, where the pre-trained language model is adopted to extract contextualized word representation from the text. Experimental results objectively and subjectively show that our proposed stress prediction model gets a higher F1 score and achieves more natural and expressive synthetic speech. In the future, we will further improve the multi-stage stress prediction model to close the performance gap between human speech and synthetic speech.

***Abstract*—The goal of speech enhancement (SE) is to eliminate the background interference from the noisy speech signal. Generative models such as diffusion models (DM) have been applied to the task of SE because of better generalization in unseen noisy scenes. Technical routes for the DM-based SE methods can be summarized into three types: task-adapted diffusion process formulation, generator-plus-conditioner (GPC) structures and the multi-stage frameworks. We focus on the first two approaches, which are constructed under the GPC architecture and use the task-adapted diffusion process to better deal with the real noise. However, the performance of these SE models is limited by the following issues: (a) Non-Gaussian noise estimation in the task-adapted diffusion process. (b) Conditional domain bias caused by the weak conditioner design in the GPC structure. (c) Large amount of residual noise caused by unreasonable interpolation operations during inference. To solve the above problems, we propose a noise-aware diffusion-based SE model (NADiffuSE) to boost the SE performance, where the noise representation is extracted from the noisy speech signal and introduced as a global conditional information for estimating the non-Gaussian components. Furthermore, the anchor-based inference algorithm is employed to achieve a compromise between the speech distortion and noise residual. In order to mitigate the performance degradation caused by the conditional domain bias in the GPC framework, we investigate three model variants, all of which can be viewed as multi-stage SE based on the preprocessing networks for Mel spectrograms. Experimental results show that NADiffuSE outperforms other DM-based SE models under the GPC infrastructure. Audio samples are available at: https://square-of-w.github.io/NADiffuSE-demo/.**

I. Introduction

In the last decade, deep learning (DL) methods [1], [2] have become the mainstream for speech enhancement (SE), which can be divided into two categories: the discriminative and generative ones [3]. The discriminative methods learn non-linear mappings[4] or estimate time-frequency masks [5]–[7] through annotated speech data pairs, but suffer from non-linear artifacts and poor generalizations [8]. The generative approaches [9]–[11] employ different infrastructures such as Generative Adversarial Networks (GANs) [12], Variational Autoencoders (VAEs) [13] and flow-based models [14] to learn the distribution of clean speech signals, which can be more robust to complex and varying noise scenarios [15].

Diffusion Denoising Probabilistic Models (DDPM) [16] is a new kind of generative model inspired by the nonequilibrium thermodynamics [17]. DDPM corrupts the data to the pre-defined Gaussian distribution by gradually adding noise at the forward process, and the random noise is progressively denoised and finally restored to the original data at the reverse stage. Many works [18]–[20] have employed the DDPM to generate natural and high-quality human voice from the given text or Mel spectrogram. Recently, DDPM-based SE methods [21]–[29] have also been explored for the promising result in speech generation.

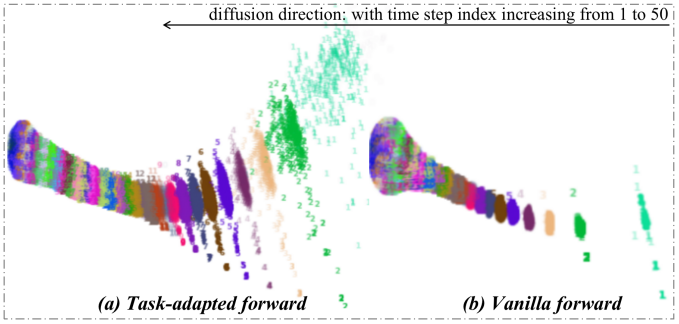

Fig. 1. To demonstrate the effect of non-Gaussian noise in diffusion-based SE, we visualize the vanilla and task-adapted diffusion process: we randomly selected 2000 utterances, which are first converted into Mel spectrograms, then cropped to 62 frames (same as the training settings), and finally visualized in two dimensions using the t-SNE algorithm. We use different colors and indexes to label the data at different time steps.

Current diffusion-based SE models can be categorized into three types. The first [21]–[23] is to change the mathematical form of the diffusion process to adapt to the task of SE, in which the mean of clean speech signals is gradually pulled towards the noisy ones by interpolating the asymptotically increasing noisy signal, so that the reverse stage is directly the speech enhancement process. The second [23]–[26] is to train a conditional network based on a well-trained pure speech generation network (Generator-plus-Conditioner, GPC). Under this setting, the enhanced speech signal is generated with the acoustic feature produced by the conditioner, which can be expressed as ***output = generator(conditioner(noisy input))***. The last is to develop a multi-stage SE where the diffusion model aims to learn the fine-grained or residual speech signal based on the coarsely enhanced one [27]–[29]. This study focuses on the first two lines, and leverages a task-adapted diffusion process under the GPC architecture to deal with the real noise.

However, there exists three problems in the existing works: (1) **Non-Gaussian Estimation**. As shown in Fig. 1, incorporating the noisy signal into the forward process makes the data

*Corresponding author.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

no longer satisfies the tight Gaussian distribution at each step, which we attribute to the effect of background noise. Noise interference varies in realistic scenarios, hence it is challenging for SE models to understand the patterns of various noise and to adaptively learn the ability of denoising in real situations [30]–[33]. Moreover, the estimation target changes from the added Gaussian noise to a combination of Gaussian noise and non-Gaussian background noise, which makes training the model harder [21]. (2) **Conditional domain bias**. In the GPC framework, the generator and conditioner determine the upper and lower bounds for the SE performance: If a conditioner can ideally map the noisy features completely to the pure ones, the best performance of SE is then obtained (upper bound). Otherwise, if the conditioner does not work at all, the worst performance is obtained (lower bound). Table I records the SE performance bounds of [23]. We observe that current conditioner is not sufficient to compensate for the gap between lower and upper bounds. We define it as conditional domain bias, which results from the change in the dimension, type and purity of the acoustic features (usually Mel spectrogram). (3) **Under-explained interpolation**. In the original inference algorithm (*cf.* Line 11, Alg. 1), the linear interpolation operation [21], [23], [26] is commonly used in the last step with a certain percentage ($r = 0.2$), which serves as an implicit post-processing method to supplement the lost speech details. Although the interpolation does improve the objective evaluation metrics (*cf.* Table III row 4 and 5), its validity is limited due to the introduced large amount of additional noise. We give a comparison between with and without the interpolation in Fig. 4 as an example of evidence: the white dashed box in (f) indicates the presence of the significant noise components.

To address the above issues, our improvements are refined into a noise-aware diffusion-based SE model (NADiffuSE). The main contributions of this work are summarized as follows:

1. To more accurately estimate the non-Gaussian noise component in the task-adapted diffusion process, we propose to use noise encodings to guide the diffusion model for adaptive noise reduction in real noisy situations.
2. To further reduce the conditional domain bias under the GPC architecture, we design three network variants based on the additional pre-processor network to improve the quality of regenerated speech signals.
3. To reduce the additional noise introduced by the interpolation operation, we construct a relatively accurate data anchor point from noisy speech signals at specified time steps, based on which we use iterative interpolation operations to refine the speech details.

II. Related Work

A. Diffusion Model

The diffusion model [16], [34], [35] contains a forward and a backward process. In the mathematical form of DDPM [16], each process is represented by a first-order Markov chain with fixed time steps. In the forward process, a series of corrupted data $x_{1:T} = x_1, x_2, ..., x_T$ can be obtained from the original clean data x_0 through the transfer distribution $q(x_t|x_0) = \sqrt{\bar{a}_t}x_0 + \sqrt{1-\bar{a}_t}\epsilon$, where $\bar{a}_t = \prod_{i=1}^{T} a_i$, $a_t = 1-\beta_t$, $\epsilon \sim \mathcal{N}(0, I)$ and β_t is a constant defined in advance. In the reverse process, the original data x_0 can be recovered from the latent distribution x_T by iteratively performing the backward transfer step $p_\theta(x_{t-1}|x_t) = \mu_\theta(x_t) + \widetilde{\beta}_t I$, where $\widetilde{\beta}_t$ is a constant and $\mu_\theta(x_t) = \frac{1}{\sqrt{a_t}}(x_t - (\beta_t/\sqrt{1-\bar{a}_t})\epsilon_\theta(x_t))$.

B. Diffusion-based SE Methods

The current technical routes of diffusion-based SE mothods can be divided into three categories: Task-adapted diffusion formula, GPC structures and multi-stage frameworks.

Task-adapted diffusion formula [21]–[23] adapt the task of SE by incorporating the noisy sigal y into the diffusion process: the mean of x_t is progressively pulled from the x_0 to y. The data degradation in [23] is formulated as Eq. 1, where $m_t = \sqrt{(1-\bar{\alpha}_t)/\sqrt{\bar{\alpha}_t}}$ denotes the asymptotic coefficient and $\bar{\delta}_t = 1-(1+m_t^2)\bar{\alpha}_t$ is the variance for added Gaussian noise.

$$x_t = \sqrt{\bar{a}_t}((1-m_t)x_0 + m_t \cdot y) + \sqrt{\bar{\delta}_t}\epsilon \tag{1}$$

While [21], [22] have the closed-form solution for the mean value as $\mu(x_0, y, t) = e^{-\gamma t}x_0 + (1-e^{-\gamma t})y$.

GPC structures consist of a generator which can generate the clean speech signal based on the clean conditions and a conditioner, i.e. network designs or training methods. One kind of conditioner [23], [26] works through two-stage training: the first stage uses the 80-dim pure Mel spectrogram as a condition (pre-training), and the second one adjusts the weights using the 513-dim noisy amplitude spectrogram (fine-tuning). The other [25] is replacing the submodule in the generator

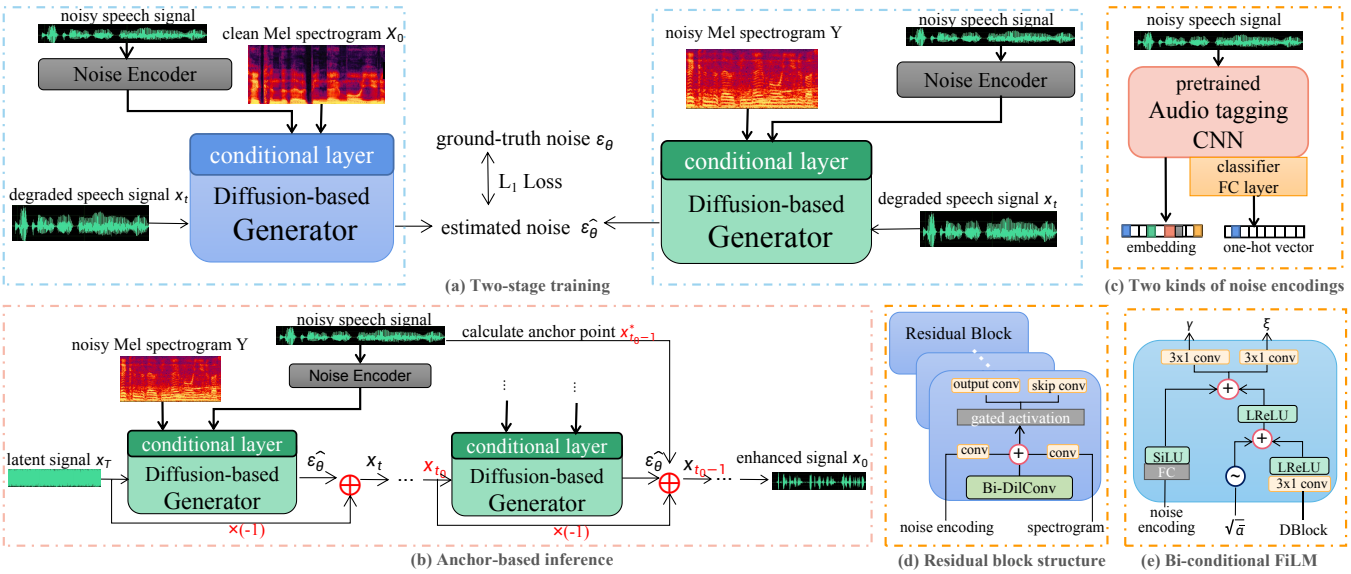

Fig. 2. An overview of the proposed NADiffuSE: (a) pre-training (left) and fine-tuning (right), both of which are conditioned on Mel spectrograms and noise encodings; (b) improved inference process where the iterative interpolation operates in the last t_0 steps based on the anchor point; (c) latent embedding (left) and category classifier (right) of noise encoding in proposed noise-aware training; (d) bi-conditional Residual blocks.

with a newly trained one to alter the degraded conditions to match the original ones.

Multi-stage frameworks take full advantage of the nature that the diffusion model is more suitable for detail refinement. The coarsely enhanced result is obtained through a discriminative model or also a diffusion-based mothod. And then conditioned on the coarsely enhanced signal, the diffusion model is used to generate the fine-grained enhanced signal [28], [29] or the residual signal [27] against the clean one.

III. Proposed Method

We make improvements to address the above issues and give an overview diagram in Fig. 2. The training process in (a) follows the same two-stage paradigm as [23], where both noise encodings and spectrograms are used as conditional information. The inference process in (b) is iterative and improved using noisy speech signals y in the last steps.

A. Noise encodings

We propose to additionally use noise coding as global conditional information in an aim to mine the priori information of the acoustic noise to guide the diffusion model for accurate combine noise estimation. We explore two different types of noise encodings as drawn in (c).

1) Category classifier: We first use the categorical properties of the background noise, in which the noise type labels are fed into the learnable embedding layer in the form of one-hot vectors. In order to get the ground truth noise label during training, we only consider a fixed number of closed sets of noise scenes. At the inference stage, a noise classifier is required to predict the noise type of the noisy speech signal. The background noise is usually labeled using the the keywords of the acoustic scene where the noise is collected, like living room, street, bathroom and etc. The concept of noise semantics is difficult to define and we propose to describe the background noise with acoustic events. We observe a one-to-many relationship between noise scenes and sound events, for example, keyboard tapping, TV background and babble noise may exist simultaneously in a living scene. Therefore, we perform transfer learning based on a large-scale pre-trained network structure [37] for the audio tagging task. We load the pre-trained weights as initialization and add a linear classification into the original structure. As described above, we build a noise classifier whose input is the noisy speech signal and output is a value belonging to a predefined set of noisy scene labels $\{0, 1, ..., N-1\}$, with N being the total number of noise categories.

2) Latent embedding: In order to extend the noise encodings to the open domain, we further explore to characterize the noise properties in a latent embedding mechanism. We directly use the output of the classifier's (described above) last hidden layer as a noise feature. The 2048-dimensional embedding is extracted from the noisy speech signal and aligned with the hidden dimension of the residual block through MLP structure. It is worth noting that we still fine-tune the convolutional feature extractor using the classification task in order to make it more relevant to the background noise characterization.

B. Anchor-based inference algorithm

The ideal case of inference is that the reverse data distribution fits the forward one exactly. We use the same conditional diffusion process as in Eq. 1, where the mean value is determined partly by x_0 and partly by y. Thus we can use the noisy signal y (known during inference) to construct a relatively accurate anchor point for the reverse process in Eq

Algorithm 1 Anchor-based Inference algorithm

Sample $x_T \sim p_{latent}$
for $t = T-1, T-2, ..., 0$ **do**
  Compute $\mu_\theta(x_{t+1}, y)$ and $\bar{\delta}_t$ as in Eq. (3)
  Sample $x_t = \mu_\theta(x_{t+1}, y) + \bar{\delta}_t I$ from $p_\theta(x_t|x_{t+1}, y)$
  if select Improved Sampling and $t < t_0$: **then**
    Calculate the anchor point x_t^* using Eq. (2)
    Do interpolation $x_t = r_t \cdot x_t^* + (1 - r_t) \cdot x_t$
  end if
end for
if select Original Sampling: **then**
  $x_0 = r \cdot x_0 + (1 - r) \cdot y$
end if
return x_0

2, where $\bar{\alpha}_t$ and $\bar{\delta}_t$ follow the previous definition.

$$x_t^* = m_t\sqrt{\bar{\alpha}_t}y + \sqrt{\bar{\delta}_t}\epsilon \tag{2}$$

Anchors contain both useful clean speech details and degraded background noise. We have described in Section I the pros and cons of the current interpolation operation used in the inference process. Rather than directly interpolating the result using noisy speech at the final step, We use anchors for the interpolation to decrease the extra noise. We use the anchor-based interpolation repeatedly in and only in the last few steps, because the data will be more sensitive to the slight inaccuracies as inference finishes. Therefore, we have used iterative interpolation operations to remove some of the noise residules contained in the anchor points by stepwise refinement. To further weaken the effect of noise, we linearly anneal the interpolation coefficients at the rate of $1/t_0$ (other annealing options are worth exploring). Our improved anchor-based inference algorithm is given in Alg. 1: we follow Eq. (3) at each step to sample x_{t-1} from the reverse probability distribution, and in the last t_0 steps perform an interpolation with the anchor point. The mean is a linear combination of x_t, y and the estimated noise term ϵ, where c_{xt},c_{yt} and $c_{\epsilon t}$ are constants and the detailed derivation follows [23].

$$\begin{aligned}\mu_\theta(x_{t+1}, y) =& c_{xt}x_t + x_{yt}y_t + c_{\epsilon t}\epsilon_\theta \\ \bar{\delta}_t =& \delta_{t-1} - \frac{1 - m_t}{1 - m_{t-1}}^2 \alpha_t \frac{\delta_{t-1}^2}{\delta_t}\end{aligned} \tag{3}$$

C. Model variants in the conditioner design

In the section I we give a definition of the conditional domain bias, a problem that exists under the generator-plus-conditioner (GPC) structure. Following the similar conditioner design in [23], we first consider using the 80-dimensional Mel spectrogram as conditional information in both training stages to reduce the difficulty of aligning the conditional domain in the fine-tuning phase. Given that the current conditional mapping layer contains only a simple up-sampling layer and a shallow MLP structure, we are inspired by [38] to additionally train a preprocessing network (preprocessor) for enhancing the Mel spectrogram. Thus we can get the pre-enhanced Mel

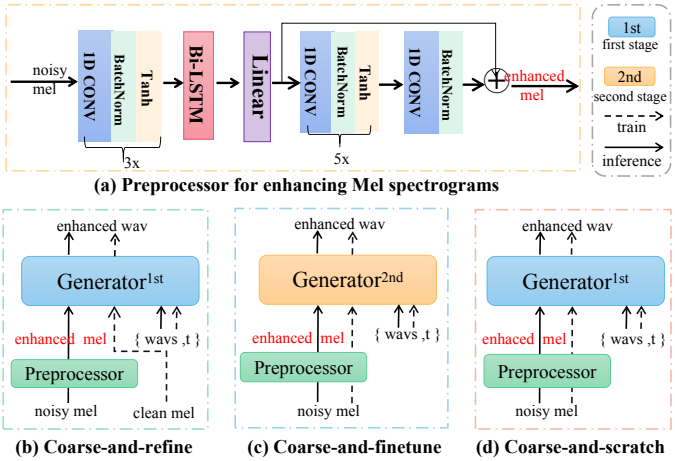

Fig. 3. Training (dashed line) and inference (solid line) pipelines of three conditioners based on the preprocessor: (a) preprocessor used for enhancing the noisy Mel spectrograms (known as *coarse*) (b) *coarse-and-refine* only needs one training stage in which the generator is trained with clean Mel spectrograms and inferenced with enhanced ones (c) *coarse-and-finetune* stills goes through the second training stage where the generator is finetuned with enhanced Mel spectrograms (d) *coarse-and-scratch* also needs only one training stage where the generator uses enhanced Mel spectrograms in both the training and inference phases.

spectrogram and name this process as *coarse*. Given the pre-enhanced Mel spectrogram: on the one hand it can be directly used as the initial result of the enhancement and then refined using the generator (coarse-and-refine). On the other, compared to the noisy speech signal's Mel spectrogram, it is less difficult to perform fine-tuning with the pre-enhanced one (coarse-and-finetune). Last, the pre-enhanced Mel spectrogram is available in both training and testing phases, which can be used to directly train a generator from scratch, without further fine-tuning. In conclusion, three feasible conditioner designs are illustrated in Fig. 3 (b), (c) and (d).

1. Coarse-and-refine: The generator which is only trained with clean Mel spectrograms can be directly used to generate the speech with the pre-enhanced Mel spectrograms.
2. Coarse-and-finetune: After training with clean Mel spectrograms, the generator is then fine-tuned with enhanced Mel spectrograms instead of the noisy ones.
3. Coarse-and-scratch: The generator is trained from scratch using the pre-enhanced Mel spectrograms.

All three network variants use the pre-enhanced Mel spectrogram as a condition for inference, and Gaussian-like speech signal sampled from latent distribution $N(x_T; \sqrt{\bar{\alpha}_T}y, \delta_T I)$ as signal input. The above proposed conditioner mechanism is applicable for all SE models under the GPC structure.

IV. Experiment

A. Experimental Setup

1) Dataset: We evaluated above all methods on the original and newly simulated VoiceBank-DEMAND [39] dataset. The new one follows the same setting which consists of 30 speakers from the VoiceBank [40] corpus and was mixed with 12

TABLE II
COMPARATIVE RESULTS OF THE PROPOSED NADIFFUSE ON AUXIALIARY INFORMATION. ALL RESULTS ADOPTED THE ORIGINAL INTERPOLATION OPERATION WHERE 20% NOISY SIGNAL IS ADDED AT THE END OF THE REVERSE PROCESS. SIGN * MEANS REPRODUCED RESULTS.

noise types* from the DEMAND [41] database. It was then divided into a training, validation and test set with 26, 2 and 2 speakers, containing 10792, 770 and 824 synthesized utterances, respectively. The signal-to-Noise (SNR) range of the training and validation set is $\{0, 5, 10, 15\}$, and the test set is $\{2.5, 7.5, 12.5, 17.5\}$. All of the utterances were resampled to 16KHz sampling rates. We use PESQ, CSIG, CBAK and COVL as evaluation metrics for enhanced speech, with higher scores indicating better performance.

2) Model infrastructure: Our proposed model follows the generator-plus-conditioner architecture mentioned in the previous section. The generator is constructed based on DiffWave [18], which is a diffusion model based vocoder and has been extended to the task of SE by [23], [25], [26]. The network in above works constructs from WaveNet [36] which has 30 layers of residual blocks with dilated convolution (conv) and gated activation. As shown in Fig. 2 (d), each residual block has two 1x1 conv layers for Mel spectrograms and noise encodings.

3) Training settings: All of experiments are based on the same training configurations as CDiffuSE-base [23] in which 50-step linear noise scheduler $\beta_t \in [1 \times 10^{-4}, 0.035]$ is used. The learning rate is 2×10^{-4} and the batch size is 16 for both training stages. The dimension for the Mel spectrogram is 80, which is transformed by STFT with the window size of 1024 and the shift of 256. We uniformly train 100w iterations in the first training stage and 30w in the second stage. The full sampling scheme is used in the reverse process.

B. Evaluation results for noise encodings

To resolve the non-Gaussian estimation problem proposed in the Section I, two types of noise encodings, namely category classifier (Cls) and latent embedding (Emb) were explored in Table I. Among them, the latent embedding form cannot obtain good performance gain in upper bound probably because it contains too much redundant information about audio events in the background noise that does not need to be considered. Therefore, our following proposed model uses the noise representation in the form of one hot vectors by default. In order to get the ground-truth background noise labels, we conducted experiments on the new simulated dataset. The ablation studies are done to validate the effectiveness of noise encodings. From Table II we can observe: (1) Under the GPC archietecture, mel-spectrogram works as an important condition to improve the metric scores of restored speech signals when compared with row 3 and 4; (2) Metrics in row 5 increase a little compared to row 3, showing that the noise embeddings can improve the enhancement performance to some extent, but slightly lacks in speech detail fidelity; (3) The best performance is obtained when two conditions are both used as NADiffuSE (row 6) reach the highest scores among all combination of auxiliary information. It can be explained that the noise embedding provides the priori information about noise patterns, and thus viewed as an implicit multi-branch switch that guides the model for adaptive noise reduction. We also visualized the effects in in Fig. 4: when inference only with Mel spectrograms, more details in the input noisy speech signal are reserved, but also including residual background noise components according to the dashed box in (c); when only using noise encodings, the noise is removed more completely, owing to the explicit use of noise characteristics, but some speech details are lost as shown by the solid ellipse in (d). Another point of interest is that the difference between Table II row 2 and 4 is only in the spectral information used in the second training phase. The results show that row 4 can achieve comparable (or even a little better) results than row 2, which validates our view that there is no need to change the type and dimensionality of spectrograms before and after the two training phases, and lays the foundation for our proposal of a preprocessing network for the Mel spectrogram later on.

C. Evaluation results for the improved inference

To evaluate the anchor-based inference algorithm, we first analyze the original interpolation operation in the inference algorithm and further investigate different parameter settings for the improved inference algorithm. We can first summarize from Table III that without any interpolation operation, the performance will significantly degrade because there is a big gap between NADiffuSE- and NADiffuSE. As we have analyzed in Section III-B, we only use iterative interpolation operations in a limited number of time steps because of the increasing sensitivity to extra noise during the inference. In Fig. 5, we give an example of visualization on the inference process where the last five steps play an important role in restoring the speech signal. Therefore, we empirically choose $t = 5$ first and explore the effect of different interpolation coefficients on the final performance in the row 8, and we can find that

*TCAR, PSTATION, DLIVING, TBUS, TMETRO, OMEETING, SPSQUARE, STRAFFIC, PRESTO, OOFFICE, PCAFETER, NFIELD.

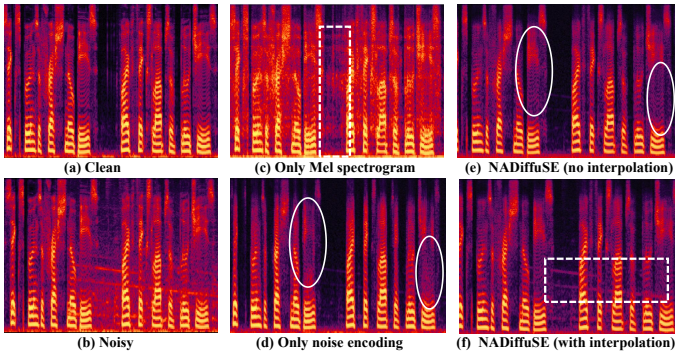

Fig. 4. Mel spectrograms of (a) clean speech, (b) noisy speech, (c) enhanced speech only using the mel-spectrogram as condition, (d) enhanced speech only using noise encodings, (e) NADiffuSE's enhanced speech without the interpolation and (f) NADiffuSE's enhanced speech with the interpolation. The dashed box indicates noise residuals and the solid ellipse indicates speech distortion.

TABLE III
COMPARATIVE RESULTS OF THE THE ANCHOR-BASED INFERENCE ALGORITHM. FOR THE SAMPLING OPTION, "$t = 0$" WITH "$r = 0.2$" MEANS THE ORIGINAL INTERPOLATION DURING INFERENCE (DENOTED BY "-"). SIGN "+" MEANS OUR IMPROVED INFERENCE ALGORITHM. ALL BASELINE ARE REPRODUCED ON THE NEW DATASET.

Row-Id	Method	Sampling		Metrics			
		Ratio (r)	Step (t)	CSIG	CBAK	COVL	PESQ
0	Unprocessed	✗	✗	3.65	3.16	2.91	2.13
1	SEGAN	✗	✗	3.71	3.12	3.04	2.35
2	SGMSE+	✗	✗	**4.18**	**3.47**	**3.58**	**3.24**
3	DiffuSE	r=0.2	t=0	3.80	3.10	3.15	2.52
4	CDiffuSE	r=0.2	t=0	3.83	3.13	3.19	2.55
5	CDiffuSE-	✗	✗	3.80	3.13	3.16	2.52
6	NADiffuSE	r=0.2	t=0	3.91	3.15	3.26	2.63
7	NADiffuSE-	✗	✗	3.84	3.09	3.18	2.55
8	NADiffuSE+	r=0.2	t=5	3.92	3.15	3.25	2.62
		r=0.5		3.81	3.11	3.09	2.37
		r=0.8		3.77	3.15	2.92	2.15
9	NADiffuSE+	r=0.1	t=5	**3.94**	**3.18**	**3.31**	**2.69**
10	NADiffuSE+	r=0.1	t=50	3.88	3.12	3.25	2.63
			t=10	3.89	3.13	3.26	2.64
			t=2	3.91	3.16	3.27	2.64

the smaller the coefficient is, the higher the performance gain can be obtained. Specially, we degrade the coefficients linearly on average with the time step, e.g. for $t = 5, r = 0.1$, we would apply coefficients of $[0.1, 0.08, 0.06, 0.04, 0.02]$ for the last five steps respectively. After we experimentally selected r = 0.1, we did a validation test in row 10 and the results showed that the final performance indeed decreases as the time step t increases. Ovarally, we have some conclusions: (1) Our proposed inference algorithm is more effective than the original one. (2) $r = 0.1, t = 5$ is the best parameter setting.

D. Evaluation results for the proposed model and its variants

1) Overal model: Through the previous experiments, our proposed model is identified as a time-domain diffusion model that uses Mel specrograms and the category classifier form of noise encodings as conditional information in both training stages. For inference, we need to train a noise classifier (detail in Section III-A1) to get the estimated noise type from the given noisy speech signal. The experimental results in Table IV show that the convergence of the noisy classifier on our newly simulated dataset is not difficult and there is no significant difference in the final SE performance between the two trained classifiers with 92% and 96% accuracy (row 1 v.s. 2). This

TABLE IV
EVALUATION RESULTS OF NADIFFUSE+ AND ITS VARIANTS. FOR THE NEEDED NOISE LABELS, WE NEED AN ACCURATE NOISE CLASSIFIER. WE DENOTE THE GROUND-TRUTH NOISE LABEL AS GT. MODELS WITH THE 92% AND 96% ACCURACY CLASSIFIER ARE ABBREVIATED AS 92%-NADIFFUSE+ AND 96%-NADIFFUSE+.

Row-Id	Method	CSIG	CBAK	COVL	PESQ

1	*92%-NADiffuSE+*	3.94	3.18	3.29	2.66
2	*96%-NADiffuSE+*	3.94	3.18	3.31	2.69
3	*Coarse-and-refine*	**4.06**	**3.22**	**3.44**	**2.84**
4	*Coarse-and-finetune*	3.93	3.20	3.24	2.54
5	*Coarse-and-scratch*	3.98	3.19	3.35	2.74

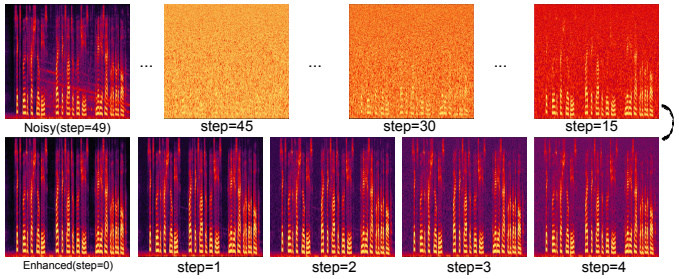

Fig. 5. Visualization of the iterative reverse stage. The spectrograms of specific time steps are given, showing the importance of the last five steps for speech restoration.

can be interpreted as redundancy in the current category labeling of background noise, which inspires us to explore more fine-grained noise encoding. Our proposed NADiffuSE and NADiffuSE+ both perform better than DiffuSE [26] and CDiffuSE [23]. But this way of diffusion-based SE models still lag behind spectral domain methods such as [22], which uses the stochastic differential equation to formulate the diffusion process. Furthermore, we also conduct out-of-domain experiments to validate NADiffuSE's generalization ability for unseen noise scenes compared with baselines. We simulated the new dataset using VoiceBank [40] and Noisex-92 with the same setting in Section IV-A1. Results in Table V show that our method achieves better scores than other time-domain models under the GPC structure.

2) Variants: We compare the performance of the three network variants described in the previous paper and all our inferences are based on the improved algorithm with the best parameter setting, $r = 0.1, t = 5$. All variants are based on 96%-NADiffuSE+. As shown in Table IV, the coarse-and-refine approach achieves the best performance. The coarse-and-scratch can get a small performance gain with only one training stage required. The coarse-and-finetune performs comparably to the originally proposed model, with no significant performance gains, which may further need a well-selected pre-trainig checkpoint and fine-tuning strategy. We can gain insight from row 3 that multi-stage iterative speech enhancement can help recover speech details better, and generative diffusion models have great potential for detail refinement in data reconstruction. All above network variants essentially rely on the training of respective sub-modules, so the quality of the pre-enhanced spectrogram feature would limit the final SE performance.

TABLE V
RESULTS OF UNSEEN NOISE SCENES FROM THE SIMULATED DATASET WITH VOICEBANK AND NOISEX-92.

Method	CSIG	CBAK	COVL	PESQ
Unprocessed	2.84	2.75	2.21	1.59
DiffuSE	2.92	2.69	2.40	1.89
CDiffuSE	2.97	2.72	2.42	1.91
NADiffuSE+	**3.04**	**2.73**	**2.46**	**1.92**

V. CONCLUSIONS

We summarize and analyze the current diffusion-based speech enhancement methods, where in the setting of generator-plus-conditional architecture (GPC), we propose a noise-aware diffusion-based SE model (NADiffuSE), which conducts denoising under the global guidance of noise encodings to help the non-Gaussian noise estimation. To reduce the additional noise introduced by the original interpolation operation, we propose the anchor-based inference algorithm to to complement speech details and reduce the residual noise. Plus, we investigate three variants of NADiffuSE which use the preprocessing network to enhance the Mel spectrogram in advance, to further bridge the gap in the performance bounds. Through experiments, we have shown that our model performs better than other diffusion-based SE models under the GPC structure.

***Abstract*—Second language learners are usually influenced by their first languages and thus produce varied and complex accents difficult for pronunciation assessment. Meanwhile, obtaining sufficient human-labeled data for accented speech is tedious and costly, which limits the robustness and accuracy of pronunciation assessment. In this paper, we propose an end-to-end (E2E) method for multi-accent pronunciation assessment. We utilize a cross-lingual pre-trained acoustic model to ensure the discriminative capability of feature representations for the assessment of different accents. Moreover, to improve the robustness of pronunciation assessment on low-resource or unannotated accented speech, we employ domain adversary training to make representations accent-invariant for assessment. Experimental results show the proposed method outperforms the baselines across multiple accents of English, including Chinese, Korean, German, and Indonesian, in the Pearson correlation coefficient (PCC). When assessing unseen English pronunciation with Japanese accents, it also shows superiority to other baselines.**

Index Terms: pronunciation assessment, multi-accent, multi-lingual pre-trained acoustic model, low-resource accented data, domain adversarial training

I. Introduction

It has been found that the first language (L1) affects the acquisition of the second language (L2) [1][2][3], which is called accent transfer or language transfer [1][4]. Previous work has pointed out that when there are differences between L1 and L2, the learner's L1 knowledge would interfere with the L2, and when the L1 and L2 are similar, the L1 could aid L2 learning [1]. One way to help L2 learners reduce the impact of L1 accent is through Computer-Assisted Pronunciation Training (CAPT). Automatic pronunciation assessment in CAPT can serve as an essential tool to guide L2 learners. Due to data scarcity, there is an increasing need for a generic automatic pronunciation assessment method for multi-accent scenarios, which should not only be based on discriminative representations for different accent transfers, e.g., phonetic transfer, but can also be generalized to novel/unseen accents.

Much effort has been put into the investigation of L2 pronunciation assessment for single L1 accent scenarios. Classical methods normally utilize traditional feature representations such as GOP, which is defined as the posterior probability of the uttered phoneme given the corresponding acoustic segment [5]. GOP was first computed using Gaussian-mixture-model-hidden-Markov-model-based (GMM-HMM) acoustic models [5], and later was optimized based on the DNN-HMM-based acoustic model to improve the performance of CALL with the development of the deep neural network (DNN) [6]. Although it has prevailed in the related studies ever since [7], [8], there are still many limitations in the current DNN-HMM-based GOP computation, and a lot of effort has been put into resolving the problems [9]. There is also works for better utilization of GOP scores. Pronunciation scoring at the word or sentence level is obtained by averaging the phone level GOP scores [6][9]. Although GOP plays an important role in automatic pronunciation assessment, it may not provide sufficient information for the pronunciation proficiency assessment [10], [11] and doesn't perform well across multiple accents of L2 learners [12].

Other than GOP-based methods, many neural network (NN)-based methods have been investigated for better representations for pronunciation assessment [13][14]. Recently, pre-training has gained popularity in different areas such as natural language processing (NLP) and speech processing [10][15]. By fine-tuning the pre-trained representations, many downstream tasks have achieved the state-of-the-art (SOTA) performance with limited amounts of labeled data. A pre-trained model called wav2vec 2.0 was proposed, and it has achieved SOTA performance in many speech applications [15]. It has also been successfully applied to mispronunciation detection and diagnosis (MDD) with connectionist temporal classification (CTC) to decode phoneme sequences [16]. Recently, a model trained on multiple languages called XLSR-53 has been proposed [17], which learns generic cross-lingual representations in an unsupervised way. In this paper, we leverage data from different languages by utilizing the cross-lingual pre-trained representations to assess different kinds of pronunciation accents.

Cross-lingual pre-training is good for generating discriminative feature representations, which can be further enhanced, with carefully-designed training criteria, for generic pronunciation assessment of different seen/unseen accents. One popular method is training the model based on mixed data of different accents. However, it is proved to be incapable of generalizing to unseen accents. Another approach is to utilize multi-task learning (MTL) training criterion, and it has been proven effective in accented speech recognition [18]. Instead of extracting shared representations across multiple accents by MTL, previous work utilizes domain adversarial training (DAT) to extract domain-invariant representations. DAT has been applied successfully to speech recognition and computer vision tasks [19][20]. Inspired by these studies, we adopt DAT to learn accent-invariant representations for multi-accent

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

automatic pronunciation assessment.

In this paper, the proposed multi-accent automatic pronunciation model is based on cross-lingual pre-trained representations for the sake of better discriminative capability of different accents. To improve the zero-shot capability of the model, we further enhance the representations such that they can be accent-invariant through DAT. Experimental results for L2 English learners with different accents, i.e., Chinese, Korean, German, and Indonesian, show the proposed method outperforms the MTL and other baselines. The proposed method shows better zero-shot capability for unseen accents compared with the baselines.

II. Proposed method

Here, we will briefly introduce the network structure for automatic pronunciation assessment, which is similar to the previous work [21]. We will also illustrate the methodologies of pronunciation assessment for multiple accents.

A. Model for pronunciation assessment

The basic structure of the proposed model comprises a phoneme and acoustic encoder shown in Figure 1. The phoneme encoder takes canonical phonemes as input and outputs phoneme representations. The acoustic encoder takes the waveform as input and outputs acoustic representations. The acoustic representations are re-trained by CTC-based phoneme recognition. The weighted acoustic representations, which are calculated based on the attention between each phoneme and the whole acoustic features, are fused with phoneme representations to obtain the final pronunciation score.

B. Multi-accent feature representations

It is well-known that L1 has impact on the acquisition of L2, resulting in different accents of English. It has been found that if there are no or few similarities between the structure of the L1 and L2, the learners will face a lot of problems in L2 acquisition [2]. For example, as there are no vowels like 'DH' (a phoneme in English) in Chinese, Chinese learners tend to substitute it with 'S' or 'Z' (phonemes in Chinese). Different from the previous work utilizing English pre-trained representations [21], to better evaluate the transferred phonetic pronunciation, we utilize cross-lingual speech representations for multi-accent pronunciation assessment, which were pre-trained based on 56 thousand hours of speech data consisting of 53 languages and have been proved very effective for learning generic cross-lingual representations in an unsupervised way [17]. In the following experimental settings, we will show its superiority to the pre-trained model trained based on monolingual data only.

C. Accent-invariant feature representations

To improve the robustness of pronunciation assessment for low-resource or unseen accents, we adopt DAT to learn accent-invariant feature representations. Traditional DAT is composed of a feature extractor, a domain classifier, and a label predictor, where the domain classifier and label predictor share representations from the feature extractor. Gradient reverse layer (GRL) is inserted between the feature extractor and domain classifier [22]. The whole network is optimized through DAT to obtain domain-invariant features. In this paper, we adopt this mechanism for automatic pronunciation assessment. The simplified schematic is shown in Figure 2, where the accent classifier is based on the weighted acoustic representations, and the scoring regressor utilizes the fused multi-modal representations combining phoneme and acoustic representations. Considering different accents mainly depend on acoustic representations, and the pronunciation assessment needs to determine whether the pronunciation comply with the canonical reading text, we share the weighted acoustic representations between the scoring regressor and the accent classifier instead of the fused multi-modal representations. The shared weighted acoustic representations are averaged based on a pooling layer followed by a fully connected layer with SoftMax activation to calculate the final accent classification results.

Specifically, the loss function is defined in Eq. (1). In the equation, $\theta_a, \theta_p, \theta_y$, and θ_d indicate parameters for acoustic representations, phoneme representations, scoring regressor, and accent classifier, respectively. L_y^i and L_d^i are the scoring regression and accent classification loss for the ith sample. β is the hyper-parameter to balance the weight between scoring regression and accent classification. The model parameters are updated by the optimizer such as Adam or stochastic gradient descent (SGD). Different values of β also indicate different training strategies. We perform experiments for multi-task learning MTL ($\beta > 0$) and direct pronunciation assessment ($\beta = 0$). We will illustrate the comparison results for different training strategies.

$$E(\theta_a, \theta_p, \theta_y, \theta_d) = \frac{1}{N} \sum_{i=1}^{N} (L_y^i(\theta_a, \theta_p, \theta_y) - \beta \times L_d^i(\theta_a, \theta_d)) \tag{1}$$

III. Experiments

A. Corpus

We collect L2 English speech from different sources to conduct experiments for multi-accent English learners including Chinese, German, Indonesian, Japanese, and Korean. Data with Chinese accent comes from speechocean762 [23]. It comprises $5,000$ English sentences spoken by 250 Chinese speakers. It is annotated by five experts and scored at three levels, including phoneme level, word level, and sentence level. The sentence-level scores include accuracy, completeness, fluency, and prosody. In this paper, we mainly focus on sentence-level accuracy. Datasets spoken by Indonesian, Japanese and Korean learners are from the International Corpus Network of Asian Learners of English (ICNALE) [24]. They are constructed by L2 English learners in ten countries and regions of Asia as well as native English speakers. There are spoken monologue, spoken dialog, written essays, and edited essays. We utilize the speech from the spoken monologue task, and select data

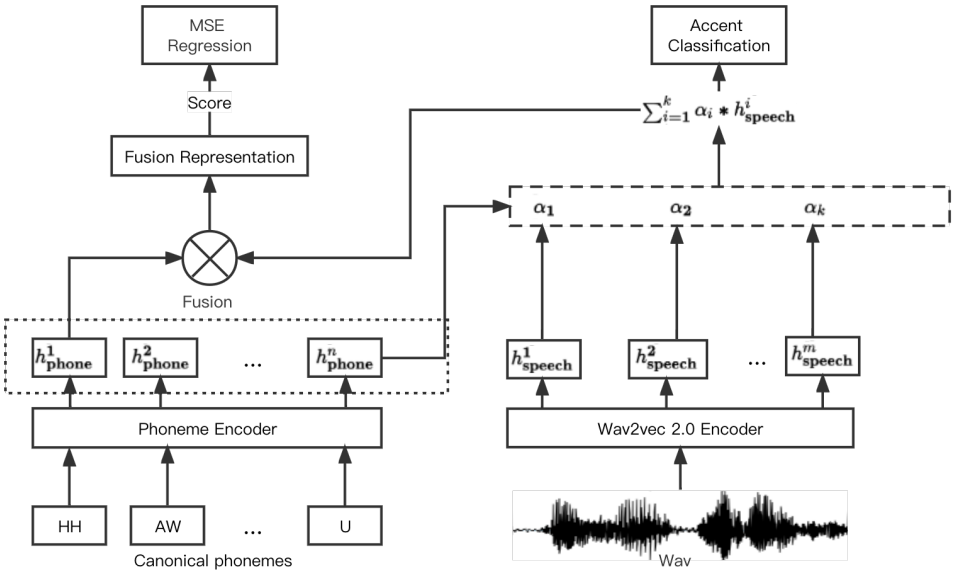

Fig. 1. Model for automatic pronunciation assessment

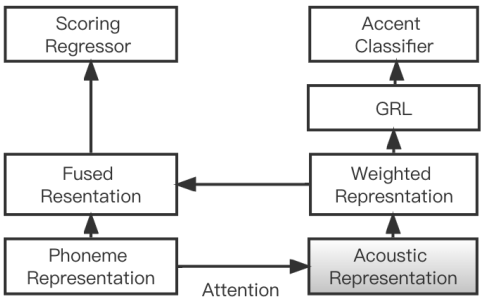

Fig. 2. DAT for automatic pronunciation assessment

of Korean, Japanese, and Indonesian accents for experiments. We cut each long speech into around 5s for the convenience of training and processing. Finally, we obtain $4,000$ utterances for each of the Korean, Japanese, and Indonesian. Data with German accent comes from Dresden Corpus [25], which was based on assessment interviews that lasted 25 minutes composed of three parts in three languages. We select the first part in English and divide it into sentences for testing. After processing, we obtain $4,000$ utterances with German accents. Except for the speechocean762 dataset, the rest datasets from L2 learners are all annotated by three experts and averaged to obtain the final pronunciation scores. The averaged inter-rater calculated by Pearson correlation coefficient (PCC) between the scores of one rater and the average scores of the other two, is 0.8. We scale all scores to the range from 0 to 1 for convenience. The processed multi-accent corpora are summarized in Table I. For Chinese, Korean, German, and Indonesian accents, we split the data into halves for training and testing. The Japanese-accented data are used for testing only to validate the zero-shot capability of the proposed method for unseen/novel accents.

TABLE I
MULTI-ACCENT CORPORA

Accent	Corpus	Train	Test
Japan	ICNALE Corpus	0	4,000
Korean	ICNALE Corpus	2,000	2,000
Indonesia	ICNALE Corpus	2,000	2,000
China	Speech Ocean	2,500	2,500
German	Dresden Corpus	2,000	2,000

B. Experimental setup

We perform experiments using the public Huggingface Transformers [26]. To demonstrate the superiority of multi-lingual representations for multi-accent pronunciation assessment, for multi-lingual representations the acoustic encoder is initialized from wav2vec2-large-xlsr-53 [*], while for mono-lingual representation we initialize it from wav2vec2-large [*]. The phoneme encoder is initialized with the dimensionality of 1024, which is the same as that of acoustic representations and based on the phoneme vocabulary of 39 according to Carnegie Mellon University (CMU) Pronouncing Dictionary [*]. The dimensionality of the fully connected layer followed the fused representations is 1024×1.

We evaluate the proposed method in the Pearson correlation coefficient (PCC), which is calculated between human labels and predicted scores.

TABLE II
COMPARISON WITH DIFFERENT BASELINES IN PCC BETWEEN LABELS AND PREDICTED SCORES

Method	Monolingual					Multi-lingual				
	CH	KO	GER	IND	JP	CH	KO	GER	IND	JP
Separate	0.67	0.53	0.52	0.48	0.56	0.68	0.51	0.55	0.5	0.57
Joint	0.67	0.52	0.54	0.50	0.48	0.69	0.54	0.53	0.49	0.50
MTL	0.69	**0.54**	0.54	0.53	0.54	0.7	0.54	0.55	0.52	0.53
DAT (the proposed)	**0.7**	**0.54**	**0.55**	**0.55**	**0.54**	**0.72**	**0.56**	**0.57**	**0.54**	**0.58**

C. Experimental results

First, we will show the comparison results of different baselines. Then, we will visualize phoneme acoustic representations for different accents before and after DAT training to demonstrate its effectiveness.

1) Comparison of baselines: We compare the baselines including separate training with each accented dataset trained separately (Separate), joint training by simply mixing all accented datasets without any additional objective (Joint), MTL training with mixed data and an additional accent classification objective (MTL), and DAT training with additional DAT mechanism as proposed (DAT). Also, as mentioned in Section III-B, we initialize the acoustic encoder with different representations, including monolingual and multi-lingual pre-trained representations. For separate training, we divide the data of each accent into halves for training and testing. For other training strategies, we mix data of different accents for training except for Japanese, which is treated as an unseen accent here. We denote Chinese, Korean, German, Indonesian, and Japanese accents as CH, KO, GER, IND, and JP. The results are shown in Table II.

From the results, we can see there is no significant difference between separate and joint training for the seen accents, while the performance deteriorates significantly for the unseen accent, i.e., Japanese. The MTL training with additional accent classification can improve the performance compared with separate training for the seen accented data, but has similar performance for the unseen accent. When trained by DAT, it obtains the best performance for both seen and unseen accents, indicating its effectiveness and generalizability. Overall, the model initialized from multi-lingual representations performs better than that from monolingual representations, indicating better discriminative capability for multi-accent situations.

2) Visualization of phoneme acoustic representations for different accents: To show effectiveness of DAT, we visualize the acoustic representations before and after the DAT using t-SNE calculated by a sklearn package [27]. Specifically, we extract the weighted acoustic representation for each phoneme based on the attention mechanism between phoneme embeddings and the acoustic representations of the whole utterance shown in Figure 1, which is also the penultimate layer before accent classification. We choose utterances with pronunciation scoring labels higher than 0.7 for each accent, which can be treated as well-pronounced utterances. Then, We randomly select four different phonemes to visualize their acoustic representations. Here, we aggregate the representations of different accents for each of the phoneme together as shown in Figure 3, where blue and green colors indicate representations for DAT and Joint training, respectively. From the figure, we can see for a particular phoneme, the acoustic representations of different accents becomes much more concentrated with DAT training compared with joint training. There are distinct groups of points for joint training, while for DAT there is only one concentrated cluster, indicating DAT makes the representations domain-invariant regardless of accents.

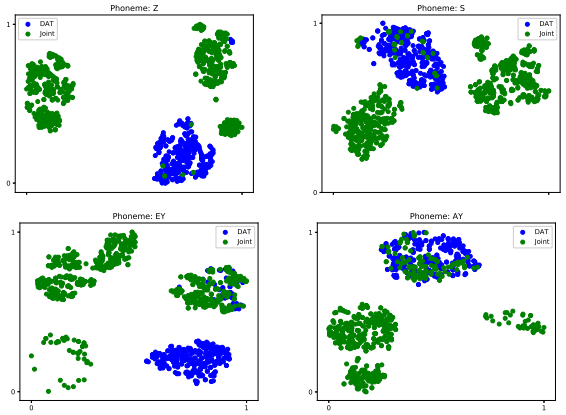

Fig. 3. Visualization of weighted phoneme acoustic representations with different accents by DAT and Joint training

IV. CONCLUSION

In this paper, we propose a multi-accent automatic pronunciation assessment approach considering its generalizability. To take the impact of L1 on the L2 English learners into account, we utilize multi-lingual pre-trained representations to make them more discriminative for assessment of different accents. To improve the zero-shot capability for low-resource or unseen accents, we adopt DAT to learn acoustic representations invariant to different accents. Experimental results based on multi-accent data demonstrate the superiority of the proposed method for seen and unseen accents in PCC.

***Abstract* — In the speech communication over the internet, due to the latency and jitter of the network, the data packets may be lost and result in a degraded user experience. Therefore, the packet loss concealment (PLC) technology plays an important role in recovering the lost information. In this paper, a PLC method only using few historical information is proposed based on generative adversarial network (GAN). In this method, the generator is composed of the improved gated attention unit (IGAU) and temporal convolution network, which can fully exploit the available time-domain information and recover the lost speech signal. Specially, a consistent mapping approach is devised to enhance the quality of the generated speech. In addition, two additional loss functions are used to assist in the training of network. The experimental results show that the proposed method has better performance in terms of both perceptual quality and speech intelligibility at different packet loss rates.**

I. INTRODUCTION

Voice over Internet Protocol (VoIP) is a technology that can package speech according to Transmission Control Protocol/Internet Protocol (TCP/IP) and send data packets to the receiver through the internet. However, due to the latency or jitter of the network, the data packets may be damaged or lost during the transmission [1], which is one of the main reasons for the degradation of speech quality in the VoIP based communication. The target of packet loss concealment (PLC) is to recover the lost speech signal for mitigating the degradation of speech quality caused by the packet loss.

The conventional PLC methods [2-4] simply used the silent speech, history speech and noise to replace the lost speech. In [5], Sanneck et al. proposed the Waveform Similarity Overlap Add (WSLOA) method to recover the lost speech by elongating a segment of speech in front of the lost frame in the time-domain. In [6], Rodbro et al. used the hidden Markov model (HMM) to predict the spectral parameters of the lost speech frame for synthesizing speech in the frequency-domain. These conventional PLC methods can be implemented in real-time because of their low computational complexity. However, it is difficult for these methods to deal with burst packet loss, especially for continuous loss (more than 40ms duration) [7].

With the development of deep learning, many PLC methods have been proposed by fully exploiting the powerful modeling ability of neural network. In [8], Lee et al. used the logarithmic power spectrum and phase spectrum of the previous speech frames as the input feature to train a deep neural network (DNN) model for recovering the lost speech frames. Besides, since the PLC algorithm based on recurrent neural network (RNN) can model the global and local dependencies of speech signal and recover the lost speech in a sequential manner, many network architectures using RNN have been proposed and applied to the task of the PLC, such as the Long Short-Term Memory (LSTM) [9], Wave-RNN [10], Wave Network Equalizer (Wave-Net-EQ) [11] and convolutional recurrent network (CRN) [12]. Meanwhile, the generative adversarial network (GAN) [13] was also widely used in the generative tasks for its parallel calculation ability, which can reduce the inference time. In [14], Shi et al. utilized the speech enhancement generative adversarial network (SEGAN) to conceal the lost speech in the time-domain. Whereas Wang et al. [15] proposed a temporal-spectral generative adversarial network (TFGAN) with a temporal discriminator and a spectral discriminator to distinguish the generated speech and ground-truth speech signal by the waveform and spectral details. Some GAN-based PLC methods [16-19] have obtained good recovery results. However, some of them still need the future information [17, 18], which is harmful for real-time processing.

In this paper, a time-domain PLC method based on GAN is proposed to recover currently lost speech frame by only using eight previous speech frames. Specifically, the generator of the proposed GAN model combines the improved gated attention unit (IGAU) and the temporal convolution network (TCN) to learn the features of the previous eight speech frames at different scales, which can better model the contextual information of lost speech frame. Besides, proposed consistent

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

mapping approach used in GAN network can improve the perceptual quality and intelligibility of the reconstructed speech. Furthermore, two additional loss terms are used to assist in the network training so that the generated speech is more closed to real one.

The remainder of this paper is organized as follows. The PLC model and the related GAN are first reviewed in Section II. Then, the network architecture and mapping approach of the proposed method is detailed in Section III. Subsequently, the experimental setup is given in Section IV and the experimental results are analyzed in Section V. Finally, the conclusions are drawn in Section VI.

II. PLC Model And Related GAN

A. PLC Model

In VoIP, speech signal is usually segmented into the frames and there is no overlap between the frames [17]. Besides, the framed speech signals are formed into the packets for efficient transmission. For simplicity, we assume that each packet contains only one speech frame, i.e.:

$$P_i = \{s_i(n), ..., s_i(n-1+M)\} \tag{1}$$

where $s_i(n)$ represents the speech signal of the i^{th} frame at the time n. P_i refers to the packet consisting of the i^{th} frame speech. M is frame length. When the current packet P_i is lost, the PLC uses the packets consisting of some previous frames to recover the current packet P_i, that is,

$$P_i = F(P_{i-1}, ..., P_{i-N}) \tag{2}$$

where $\hat{P}_i$ is the estimated result of P_i. F represents the nonlinear mapping relationship learned by the network. N denotes the number of the packets consisting of previous frames. Subscript i is the frame index.

B. TFGAN

The TFGAN [15] is a pioneering GAN model for PLC. Its block diagram is illustrated in Fig. 1, which is composed of the time-domain generator and the time-frequency discriminator. The time-domain generator takes a U-Net structure [20] with a temporal convolution network encoder (TCN-Encoder) and a temporal convolution network decoder (TCN-Decoder) [21], which is used to extract the time-domain feature of input speech. To learn the temporal dependencies and enhance the feature correlation of time-domain feature extracted by TCN, the gated linear units (GLU) [22] are used as the bottleneck layer between the encoder and decoder of the U-Net, where the dilation rates in individual GLU are different. In addition, a time-domain discriminator and a frequency-domain discriminator are employed to distinguish the speech generated by the generator from the real speech in both the time-domain and frequency-domain so that the generator could generate more realistic speech as the replacement of the lost speech.

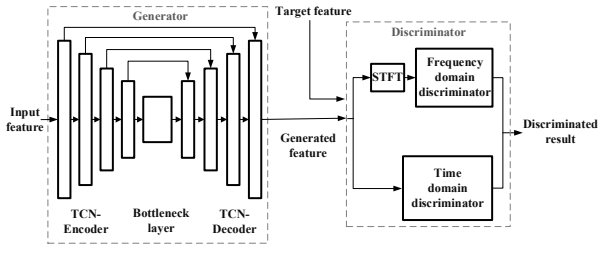

Fig. 1 Block diagram of TFGAN model.

In TFGAN, the mapping approach used during the network training is shown in Fig. 2(a). In the training phase, the input feature consists of N speech frames in front of the lost frame and one zero-padding frame, where speech samples are all set to zero. The target feature is composed of N+1 real speech frames. The TFGAN is trained to learn the mapping relationship between the input feature and the target feature. In the testing phase shown in Fig. 2(b), once the packet loss is detected, the input feature with the same structure as the training phase is fed into the network. Finally, the last frame of the output (N+1) frames is used as the recovered speech frame.

Although the TFGAN-based PLC method has achieved good performance, there is still room for the improvement. Firstly, when GLU is used as the bottleneck layer, the TFGAN could not model the global dependency effectively. Thus, the amplitude of the recovered speech frame may be inaccurate and the partial detail information may be lost. Secondly, during the training phase, the TFGAN not only aims to learn the identity mapping for the first N frames, but also trying to learn a more

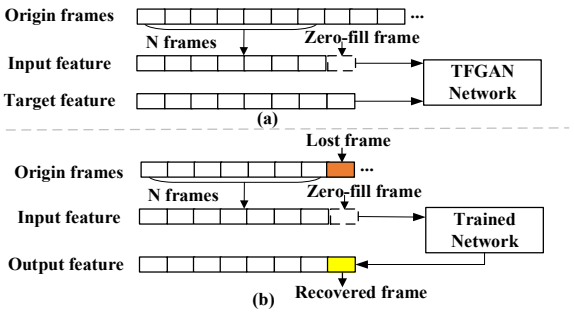

Fig. 2 Schematic diagram of mapping approach in TFGAN during the (a) training phase; (b) testing phase.

complex mapping from the zero-padding frame to the real speech frame for the last one frame. This inconsistent mapping makes the network difficult to be trained, and results in a poor quality to the generated speech waveforms. Therefore, we need to design a more appropriate network which can fully exploit the global dependencies of input speech frames. At the same time, it is necessary to propose a consistent mapping approach to improve the generated speech quality of the network for obtaining better PLC results.

III. Proposed Method

A. Generator with the Proposed IGAU

In TFGAN [15], the generator adopts the U-Net structure, which can aggregate information at different levels and alleviate the gradient vanishing problem through skip connections. However, the GLU is utilized as the bottleneck layer and it mainly consists of convolutional block. Thus, its ability of modeling the global dependency is limited. For the PLC, this may lead to a poor quality of the recovered speech. Recently, the Gate Attention Unit (GAU) [23] was proposed to better model global dependencies by utilizing an attention matrix that weights input feature based on the similarity between features at different positions. In [24], two different modules for modeling global dependency were organized in an interleaved way, which has been proven to be efficient for extracting global dependencies. Based on this idea, the IGAU is proposed in this paper to improve the GAU.

The IGAU module which consists of N_B IGAU is used as the bottleneck layer, which is designed for effectively modeling the global dependencies and obtaining better PLC results. As mentioned above, this module consists of several IGAU stacked sequentially, which is composed of a gated dilated convolution [15, 22] and a Gated Attention Unit. The gated dilated convolution primarily employs a gated mechanism to regulate the flow of information, highlighting the important parts within its input feature. In addition, GAU possesses the capability to model global dependencies by incorporating attention mechanism. Specifically, assume that the input of GAU is $F_{in} \in R^{C\times T}$ and is transformed by two multilayer perceptron (MLP). The obtained feature tensors are denoted as $U \in R^{C\times 2T}$ and $V \in R^{C\times 2T}$. The feature F_{in} is also fed into a single head attention module to obtain the query $Q \in R^{C\times E}$ and the key $K \in R^{C\times E}$, where E denotes the feature dimension of Q and K. These query and key are utilized to obtain the attention weight $A \in R^{C\times C}$, which is expressed as:

$$A = relu^2(Q \bullet K^T + B) \tag{3}$$

where B and $relu^2$ represent the relative positional embedding and squared ReLU activation function, respectively. The superscript T is the transpose operation. Combing the feature tensors U, V and the attention weight A, the output of GAU is expressed as:

$$O = F_{MLP}(U \odot AV) \tag{4}$$

where F_{MLP} denotes the transform achieved by MLP. The symbol $\odot$ represents the Hadamard product and $O \in R^{C\times T}$ denotes the output of GAU.

By stacking several IGAU sequentially, the gated dilated convolution and the GAU are combined alternately and iteratively in the IGAU module. Furthermore, the residual connection is used in proposed IGAU, as illustrated in Fig. 3. This is the first work that employs GAU for the PLC.

B. Consistent Mapping Approach of the Network

In this paper, a consistent mapping approach in the time-domain is proposed. Different from the mapping approach used in TFGAN, this consistent mapping approach effectively models the nonlinear function from each speech frame to its next speech frame, which improves the quality of the recovered speech for the task of PLC. The effectiveness of this consistent mapping approach will be demonstrated in the section V-B.

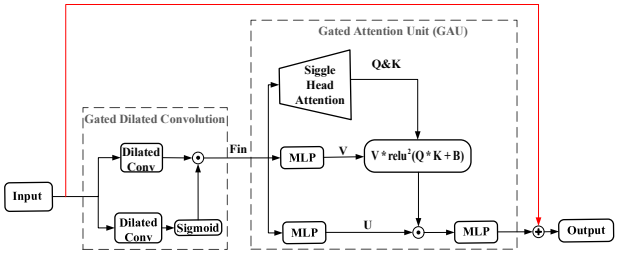

Fig. 3 Diagram of the IGAU.

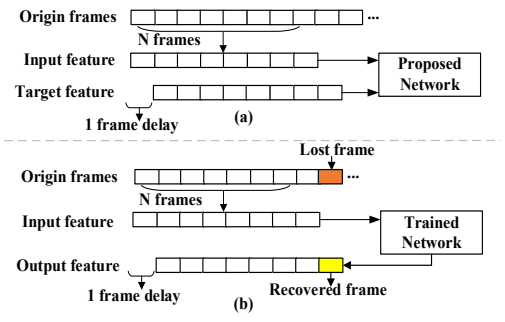

Fig. 4 Schematic diagram of the mapping approach during the (a) training phase; (b) testing phase.

In the training phase shown in Fig. 4(a), the proposed network concatenates the *N* frames in front of the lost frame as the input feature, whereas another *N*-frame set consists of (*N*–1) frames in front of the lost frame and the real value of the lost frame are used as the training target.

During the testing phase, the proposed method detects the packet loss frame-by-frame, and the relationship between the input and output features are illustrated in Fig. 4(b). That is, when a packet loss is detected, the trained network model is fed with the feature consists of *N* frames in front of the lost frame, and the trained model generates an output feature consists of *N* frames too, from which the last one frame is extracted as the recovered speech frame.

C. Loss Function

The original loss function in [13] is difficult to converge with the unbalanced generator and discriminator, resulting in a decrease of the speech quality recovered by PLC algorithm. To address this issue, the least squared loss function for GAN (LSGAN) [25] is used in proposed PLC method. The loss functions of LSGAN are shown in (5) and (6).

$$min_D L(D) = \mathrm{E}_{x\sim p_x}(D(x)-b)^2 + \mathrm{E}_{z\sim p_z}(D(G(z))-a)^2 \tag{5}$$

$$min_G L(G) = \frac{1}{2}\mathrm{E}_{x\sim p_x}(D(x)-c)^2 + \frac{1}{2}\mathrm{E}_{z\sim p_z}(D(G(z))-c)^2 \tag{6}$$

where *x* and *z* are the target feature and input feature as shown in Fig. 4. p_x and p_z are the target distribution and input distribution, respectively. *a*, *b* and c are the constants same as TFGAN.

Apart from the LSGAN, two additional loss functions are introduced to assist the training. The loss functions L_{time} computes the difference between the output feature and the target feature in the time-domain, as shown in (7):

$$L_{time} = \frac{1}{L}\|x-\tilde{x}\|_2^2 \tag{7}$$

where $\tilde{x}$ is the output feature generated by the generator. *L* and $\|\cdot\|_2$ represent the length of the input feature and L_2 norm.

According to the [26], multi-resolution STFT loss can effectively measure the spectral difference between *x* and $\tilde{x}$, as shown in (8):

$$L_{freq} = \frac{1}{R}\sum_{r=1}^{R}\left[\left(\frac{\left\|f^r(x)-f^r(\tilde{x})\right\|_F}{\left\|f^r(x)\right\|_F}\right)+\frac{1}{L}\left\|\log\frac{\left|f^r(x)\right|}{\left|f^r(\tilde{x})\right|}\right\|_1\right] \tag{8}$$

where $|\cdot|$ is modulus operation. $\|\cdot\|_1$ and $\|\cdot\|_F$ are L_1 norm and Frobenius norm, respectively. $f^r(x)$ and $f^r(\tilde{x})$ are the time-frequency representation of the *x* and $\tilde{x}$ at resolution *r*, using short-time Fourier transform (STFT). *R* is the total number of different resolutions. The same STFT configurations of [26] is used in this paper. The final loss functions used in our proposed method are expressed as:

$$L_D^{final} = L_D^{LS} \tag{9}$$

$$L_G^{final} = L_G^{LS} + C_{freq}L_{freq} + C_{time}L_{time} \tag{10}$$

where L_D^{LS} and L_G^{LS}, are the loss functions of LSGAN, as given in (5) and (6). The C_{freq} and C_{time} are the weighting coefficients determined in the experiments.

IV. Experiment Setup

A. Dataset

A total number of 11500 utterances are selected from Librispeech dataset [27] in this paper. Note that only the clean speech in this dataset is chosen to generate the training and testing data in the experiment. All speech signals are re-sampled to 16 kHz. The training set, validation set, and testing set consist of 10000, 1000, and 500 utterances, respectively. The Gilbert-Elliott packet loss model [28] is used to simulate random packet loss with the packet loss rates (PLR) varying from 10% to 40%.

B. Parameter Settings and Training Details

The frame length is set to 320 samples without overlap. The time-frequency discriminator and the parameters of TCN are same with those used in [15]. In the IGAU module, the number of IGAU N_B is set to 5. The dilated rates of 5 IGAU are set to 1, 2, 4, 8 and 16. The channel dimension *C* and time dimension *T* are 128 and 160, whereas the feature dimension *E* of the query and key is 80. The number *N* of the frames used for our proposed mapping approach is 8. The weighting coefficients C_{freq} and C_{time} are 0.5 and 100, respectively. The Adam optimizer is used for optimizing the generator and time-frequency discriminator. The initial learning rates are set to 0.0001 and 0.00005 with beta coefficients of 0.5 and 0.9. The number of the training epoch is set to 80.

V. Experiment Result

In this section, the quality of the reconstructed speech is evaluated through two objective metrics: the wide-band perceptual evaluation of speech quality (WB-PESQ) [29] and the short-term objective intelligibility (STOI) [30].

A. Ablation Study

In order to verify the effectiveness of the proposed IGAU, three different structures (GLU, GAU and IGAU) were used as the bottleneck layers. The mapping approach of ablation study has been described in Section III.B. The result of ablation study is shown in Tab. I and Tab. II.

TABLE I. WB-PESQ RESULTS OF THE ABLATION STUDY

Method	PLR			
	10%	20%	30%	40%
GLU	2.54	1.93	1.63	1.46
GAU	2.59	1.95	1.65	1.48
IGAU	**2.65**	**2.02**	**1.70**	**1.52**

TABLE II. STOI RESULTS OF THE ABLATION STUDY

Method	PLR			
	10%	20%	30%	40%
GLU	0.971	0.949	0.925	0.904
GAU	0.975	0.952	0.931	0.911
IGAU	**0.976**	**0.955**	**0.933**	**0.914**

As can be seen from Tab I and Tab II, the method IGAU, which takes IGAU as the bottleneck layer of U-Net network, could achieve better performance than those using GLU and GAU at different packet loss rates. This implies that the proposed method effectively models the global dependencies of speech signal. This is achieved through the alternation and iteration [24] of gated dilated convolution and GAU in our IGAU module.

B. Comparative Experiments

To evaluate the effectiveness of our proposed PLC method, several methods are used as the references including DNN-based method [8], CRN-based method [12], TFGAN-based method [15] and a variant of TFGAN, $\text{TFGAN}_{\text{proposed}}$, which is trained using the mapping approach described in Section III.B. The WB-PESQ and STOI results are shown in Tab. III and Tab. IV, respectively.

In Tab III, the DNN [8], CRN [12] and TFGAN [15] could recover the lost speech frames to some extent and obtain higher WB-PESQ scores than the impaired speech. Compared with the TFGAN, the variant $\text{TFGAN}_{\text{proposed}}$ achieves a WB-PESQ improvement of 0.26 at a packet loss rate 10% and of 0.1 at other loss rate, which demonstrated the effectiveness of our proposed consistent mapping approach. Compared with the $\text{TFGAN}_{\text{proposed}}$, our proposed network shows another 0.1 improvement at low packet loss rate. Thus, our proposed method achieves the highest performance and its effectiveness is validated. Similar results can be seen for STOI in Tab IV. Note that both results decrease with the increase in the packet loss rate, which is reasonable since more information is lost.

TABLE III. WB-PESQ RESULTS AT DIFFERENT PACKET LOSS RATES

Method	PLR			
	10%	20%	30%	40%
Impaired Speech	1.65	1.24	1.12	1.07
DNN	1.68	1.52	1.36	1.21
CRN	2.01	1.63	1.43	1.29
TFGAN	2.28	1.85	1.55	1.37
$\text{TFGAN}_{\text{proposed}}$	2.54	1.93	1.63	1.46
Proposed	**2.65**	**2.02**	**1.70**	**1.52**

TABLE IV. STOI RESULTS AT DIFFERENT PACKET LOSS RATES

Method	PLR			
	10%	20%	30%	40%
Impaired Speech	0.919	0.840	0.761	0.687
DNN	0.932	0.867	0.825	0.809
CRN	0.941	0.884	0.842	0.827
TFGAN	0.954	0.942	0.913	0.886
$\text{TFGAN}_{\text{proposed}}$	0.971	0.949	0.925	0.904
Proposed	**0.976**	**0.955**	**0.933**	**0.914**

The examples of the recovered voiced frame and unvoiced frame using different methods are depicted in Fig. 5 and Fig. 6, respectively. The voiced frames contain crucial speech information. Their restoration depends on the PLC algorithms. Fig. 5 (c), (d) and (e) show the recovered results of TFGAN, $\text{TFGAN}_{\text{proposed}}$ and our proposed method in the case of losing two frames (40ms), respectively. Compared with the TFGAN, the waveforms recovered by the $\text{TFGAN}_{\text{proposed}}$ and our proposed method are better aligned with the original speech signal. This demonstrates that the mapping approach proposed in Section III.B is more effective. In addition, by analyzing Fig. 5 (d) and (e), it can be observed that the proposed method better preserves the waveform details and amplitude values compared to the $\text{TFGAN}_{\text{proposed}}$, confirming that our proposed network structure can better model the dependencies contained in the speech signal and is more effective than the TFGAN.

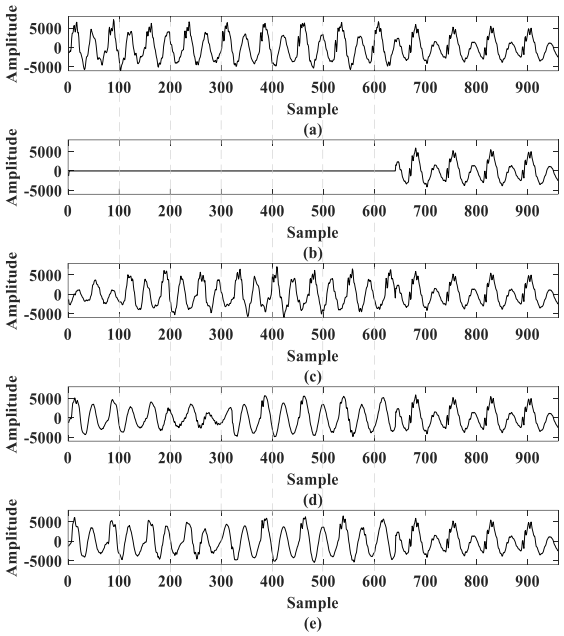

Fig. 5 Voiced speech comparison. (a) Origin speech; (b) Impaired speech; (c) Recovered speech by TFGAN; (d) Recovered speech by $\text{TFGAN}_{\text{proposed}}$; (e) Recovered speech by proposed method.

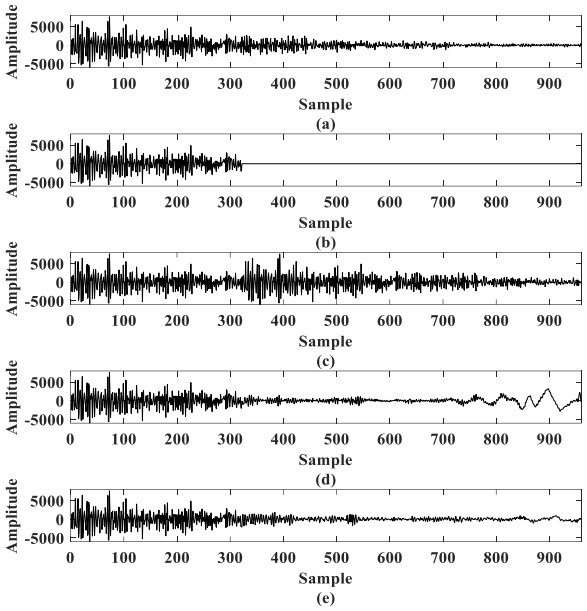

Fig. 6 Unvoiced speech comparison. (a) Origin speech; (b) Impaired speech; (c) Recovered speech by TFGAN; (d) Recovered speech by $TFGAN_{proposed}$; (e) Recovered speech by proposed method.

Unlike voiced speech, unvoiced speech is much more difficult to be recovered. As shown in Fig. 6(c), the restoration of unvoiced speech by TFGAN is poor since the recovered waveform of unvoiced frames is almost the same as the waveform in front of lost speech frames. However, our proposed method could get better restoration in amplitude.

Since our proposed method does not use of any future information, there may be discontinuities at the connection between the recovered frame and its next frame. To address this issue, we plan to design and incorporate smoothing methods without additional latency into the network training to ensure smoother transition between the frames in future work instead of a post-processing.

VI. Conclusions

In this paper, we proposed a novel approach for packet loss concealment, in which only eight historical speech frames in front of the lost frame are used. The TCN and IGAU were combined in the generator for exploiting the available time-domain information so that the amplitude and detail information of lost speech are effectively recovered. In addition, a consistent mapping approach and two additional loss terms were designed to improve speech quality. Experimental results show that the proposed PLC method has the higher performance than the reference methods at different packet loss rates.

***Abstract*—Considering that traditional multiple histogram modification (MHM)-based reversible data hiding (RDH) methods utilize fixed features to generate multiple prediction-error histograms (PEHs), we propose a novel MHM-based RDH method by adaptively selecting different features with considering the statistical properties of images, so that multiple sharper PEHs are constructed. Moreover, two predictors, namely the rhombus and gradient-based edge direction predictors, are exploited to further improve the prediction performance. The experimental results also demonstrates that the proposed method provides better embedding performance in terms of the visual quality and payload than several related works.**

I. Introduction

Data hiding refers to the process of hiding data into a carrier in an imperceptible manner to convey the presence of embedded data, or to protect the transmitted contents **HongINS2014**. Among various carriers such as images, videos, and audios, digital images are one of the most popular carriers because they are widely transmitted over the Internet. The image used for carrying data is called the cover image while the image with embedded data is called the stego image. When data are embedded into a cover image, the pixels will be changed, and thus the distortion is inevitably introduced. If the pixels are distorted permanently after data embedding, they cannot be recovered to their original states after completely extracting the embedded data. However, for some sensitive applications such as medical or military imaging, any permanent distortion caused by data embedding is unacceptable due to high requirements for legal consideration or high-precision nature. To this end, reversible data hiding (RDH) is introduced to fulfill the requirements by restoring the original image from the stego image along with the extraction of the embedded data. The embedding performance of an RDH method is evaluated using the tradeoff between the embedding capacity versus the image quality.

Early RDH methods mainly achieve data embedding by lossless compression **Fridrich2002EURASIP**, **Celik2005**. A common feature of these methods is to losslessly compress features extracted from the cover image for leaving embedding space; however, the obtained embedding capacity is limited. In 2003, Tian proposed an RDH method based on difference expansion (DE), in which the difference value between two adjacent pixels is expanded to carry 1 bit of data. By expanding difference values to embed data, Tian can achieve the maximum capacity of 0.5 bit per pixel (bpp) but introduces relatively large distortion. Ni *et al.*'s method **Ni2006** proposed to embed data using histogram shifting (HS). The primary idea of HS is to embed data into peak bins of an image histogram while shifting the other bins to leave embedding spaces for data embedding. Since pixels are modified by 1 at most, Ni *et al.*'s method can offer high visual quality. However, the embedding capacity is limited by the peak bin heights. Afterwards, Tian's method are extended from the following three aspects, namely DE **HuTSVT2009**, **TaiTSVT2009**, **LiTIP2011**, prediction error expansion (PEE) **Thodi07** and integer-to-integer transform **Alattar04**, **ColtucSPL2007**, **Weng08**, **WangSPL2010**, **PengSP2012**, **ColtucTIP2012**. PEE is the most effective RDH method owing to its efficient payload-distortion tradeoff. PEE was firstly proposed by Thodi *et al.* **Thodi07**, which performs DE and HS on the prediction errors of pixels generated by a median edge detection (MED) predictor **WeinbergerTIP2000**, rather than difference value of two adjacent pixels in **Tian03**. Subsequently, PEE-based RDH has been widely investigated in research such as two-dimensional (2D) prediction error histogram(PEH) modification **Ou.BIEEE2013**, two-layer embedding **LuoTIFS2008**, **Sachnev09**, **WengIS2016**, **KouhINS2020**. In addition, some PEE-based methods focus on generating sharply distributed prediction error histogram (PEH) by improving predictors such as MED **WeinbergerTIP2000**, gradient-adjusted predictor **FallahpourIEE2008**, rhombus predictor **Sachnev09**, **YangJSS2013**, interpolation technique **LuoTIFS2008**, asymmetric predictor **ChenJSS2013**, **KouhINS2020** and multiple predictors **MaJVCIR2015**. Among the aforementioned techniques, Chen *et al.* **ChenJSS2013** proposed to generate a asymmetric PEH using a predictor based on MED, thus reducing the embedding distortion by decreasing the number of shifted prediction errors. Kouhi *et al.* **KouhINS2020** proposed to generate two asymmetric PEHs using weibull generalized exponential distribution (WGED) **Mustafa2016arXiv**, thereby increasing the visual quality by reducing the number of invalid modifications.

Note that, most existing PEE-based RDH methods are based on one-dimensional (1D) or two-dimensional (2D) PEH. Given that the 1D or 2D PEH modifies all prediction errors uniformly without considering their local properties, Li *et al.* **LiXLTifs2015** proposed an embedding mechanism based

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

on multiple histograms modification (MHM), in which the embedding performance is optimized by adaptively determining two expansion bins (i.e., a pair of expansion bins) for each PEH according to the local properties of each PEH. The optimal expansion bin determination is formulated as a rate-distortion optimization problem. However, directly exploiting exhaustive search to solve the rate-distortion optimization would result in huge computational complexity. To reduce the computational complexity, Li *et al.* utilize exhaustive search to determine two optimal bins for each histogram after decreasing the solution space. Afterwards, MHM has received increasing attention **OuITCSVT18**, **QiTCSVT2020**, **Wang2019Multiple**, **WengIS2021**, **WangTCSVT2021**. Among them, Ou *et al.* **OuITCSVT18** proposed to expand multiple pairs in each PEH for achieving high embedding capacity, rather than expanding a single pair of each PEH like in Li *et al.*'s method **LiXLTifs2015**. Moreover, an advisable expansion bin selection strategy is used to optimize the embedding performance. Differently from the expansion bin selection strategy used in Ou *et al.*'s method **OuITCSVT18**, Qi *et al.* **QiTCSVT2020** proposed a computationally efficient algorithm to adaptively determine optimal multiple pairs for each histogram. Wang *et al.* proposed to utilize the fussy C-means (FCM) clustering with multiple features for constructing multiple sharper PEHs. Weng *et al.* **WengIS2021** proposed to employ K-means clustering with multiple features for constructing multiple sharper PEHs and utilize an improved crisscross optimizing algorithm to determine optimal expansion bins for each histogram. Wang *et al.* **WangTCSVT2021** proposed to construct an RDH general framework based on MHM, which involves several key issues, namely generating multiple PEHs based on optimized multi-features, allocating the embedding capacity among multiple histograms and solving the optimization problem using the evolutionary algorithms.

Different from traditional MHM-based RDH methods that select fixed features of pixels to construct multiple PEHs, this paper focuses on adaptively selecting different features based on the statistical properties of images to construct sharper PEHs. Moreover, two predictors, including the rhombus and gradient-based edge direction predictors, are conductive to generate higher peak points for each PEH.

The rest of this paper is organized as follows. The proposed method is presented in Section II. Section III provides the experimental results and the conclusions are given in Section IV.

II. The Proposed Method

This paper focuses on generating sharper PEHs by adapting various strategies like multiple predictors or adaptive feature selection, thereby reducing unnecessary pixel modifications while improving the embedding performance. Different from traditional MHM-based RDH methods that construct multiple PEHs using fixed features of pixels, the proposed method generates sharper PHEs by adaptively choosing features based on the statistical properties of images, thereby enhancing the embedding performance. The proposed method is mainly composed of the following two parts: two predictors and adaptive feature selection. Subsequently, we will introduce each part separately in the following subsections.

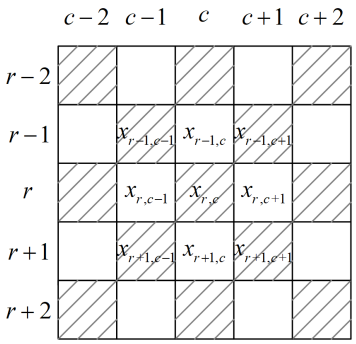

Fig. 1. Two non-overlapping sets Ψ_+ and Ψ_-.

A. Two predictors

A cover image $\mathcal{O}$ is split into two non-overlapping sets Ψ_+ and Ψ_- according to the layout of a chessboard. The pixels in Ψ_+ are used for predicting the pixels in Ψ_- and the prediction errors of the pixels in Ψ_- are embedded with data, and vice versa. Since two sets are processed in the same manner, we only discuss the case of Ψ_+.

Different from traditional RDH methods that exploit an advanced predictor to generate a symmetric PEH, the proposed method utilizes two predictors, including the rhombus predictor **Sachnev09** and gradient-based edge direction predictor (GEDP) **YangJSS2013**, to generate two asymmetric PEHs with long and short tails. Specifically, for a pixel $x_{r,c}$ in Ψ_+, suppose its four neighboring pixels constitute a set denoted by $\mathcal{S}_\mathcal{N}$, namely, $\mathcal{S}_\mathcal{N} = \{x_{r-1,c}, x_{r,c-1}, x_{r,c+1}, x_{r+1,c}\}$. Let two prediction values be $\hat{x}^1_{r,c}$ and $\hat{x}^2_{r,c}$, namely $\hat{x}^1_{r,c} = \lfloor (x_{r-1,c} + x_{r+1,c} + x_{r,c-1} + x_{r,c+1})/4 \rfloor$, and $\hat{x}^2_{r,c}$ is calculated below:

$$\hat{x}^2_{r,c} = \left\lfloor \sum_{s,t\in\Phi} w_{s,t} \times x_{s,t} \Big/ \sum_{s,t\in\Phi} w_{s,t} \right\rfloor, \tag{1}$$

where $\Phi = \{(r \pm 1, c), (r, c \pm 1)\}$, $w_{s,t}$ is the weight assigned for $x_{s,t}$, i.e., $w_{r-1,c} = 1/(1 + |\Delta v_{r,c}| + 2|\Delta v_{r-1,c}| + |\Delta v_{r-2,c}|)$, $w_{r+1,c} = 1/(1 + |\Delta v_{r,c}| + 2|\Delta v_{r+1,c}| + |\Delta v_{r+2,c}|)$, $w_{r,c-1} = 1/1 + |\Delta h_{r,c}| + 2|\Delta h_{r,c-1}| + |\Delta h_{r,c-2}|$, and $w_{r,c-1} = 1/1 + |\Delta h_{r,c}| + 2|\Delta h_{r,c-1}| + |\Delta h_{r,c-2}|$.

$\Delta h_{r,c}$ is defined below:

$$\Delta h_{r,c} = \begin{cases} \frac{3}{2} \sum\limits_{u\in\{\pm1\}} (x_{r+u,c+1} - x_{r+u,c-1}) \\ +\frac{1}{2}(x_{r,c+2} - x_{r,c-2}), \quad \text{if } x_{r,c} \in \Psi_+; \\ \frac{1}{4} \left(\sum\limits_{u\in\{\pm2\}} (x_{r+u,c+1} - x_{r+u,c-1}) \right. \\ \left. + \sum\limits_{u\in\{\pm1\}} (x_{r+u,c+2} - x_{r+u,c-2}) \right) \\ +\frac{5}{2}(x_{r,c+1} - x_{r,c-1}), \quad \text{otherwise.} \end{cases} \tag{2}$$

And, $\Delta v_{r,c}$ is calculated as follows:

$$\Delta v_{r,c}=\begin{cases} \frac{3}{2}\sum\limits_{u\in\{\pm1\}}(x_{r+1,c+u}-x_{r-1,c+u}) \\ +\frac{1}{2}\left(x_{r+2,c}-x_{r-2,c}\right), \text{ if } x_{r,c}\in\Psi_{+}; \\ \frac{1}{4}\left(\begin{array}{l}\sum\limits_{u\in\{\pm2\}}(x_{r+1,c+u}-x_{r-1,c+u}) \\ +\sum\limits_{u\in\{\pm1\}}(x_{r+2,c+u}-x_{r-2,c+u})\end{array}\right) \\ +\frac{5}{2}\left(x_{r+1,c}-x_{r-1,c}\right), \text{ otherwise.}\end{cases} \tag{3}$$

After comparing $\hat{x}^1_{r,c}$ with $\hat{x}^2_{r,c}$, the larger and smaller numbers are denoted by $\hat{x}_{\max}$ and $\hat{x}_{\min}$, respectively. The final prediction value of $x_{r,c}$, denoted by $x^*_{r,c}$, is obtained using the following rule:

$$x^*_{r,c}=\begin{cases}\hat{x}_{\min}, \text{ if } \hat{x}_{\min}==\hat{x}_{max}; \\ \hat{x}_{\min}, \text{ if } x_{r,c}\le\hat{x}_{min}; \\ \hat{x}_{\max}, \text{ if } x_{r,c}\ge\hat{x}_{max}; \\ null, \text{ otherwise.}\end{cases} \tag{4}$$

The prediction error $e_{r,c}$ is calculated as $e_{r,c}=x_{r,c}-x^*_{r,c}$ when $\hat{x}_{min}\ge x_{r,c}$ or $x_{r,c}\ge\hat{x}_{max}$.

B. Adaptive feature selection

To efficiently estimate the local smoothness, 16 features $\{f_1,f_2,\cdots,f_{16}\}$ derived from Weng *et al.*'s method **WengJVCIR2022** are generated for each pixel $x_{r,c}$. 16 features $\left\{f^k_{r,c}\right\}^{16}_{k=1}$ are extracted for $x_{r,c}$, and the k^{th} ($\omega_k\in\{1,2,\cdots,16\}$) feature ω_k is allocated to the k^{th} weight termed ω_k.

$$\ell s(x_{r,c})=\sum_{k=1}^{16}\omega_k\times f^k_{r,c}, \tag{5}$$

where $\ell s(x_{r,c})$ denotes the weighted summation of 16 features.

For the cover image $\mathcal{O}$, the correlation between the absolute value of each prediction error and the corresponding is calculated using the following formula:

$$\begin{aligned}R_{\mathbf{p_e},\mathbf{l_s}}(\mathbf{w})&=\frac{\mathrm{cov}(\mathbf{p_e},\mathbf{l_s})}{\sigma_{\mathbf{p_e}}\times\sigma_{\mathbf{l_s}}} \\ &=\frac{\sum\limits_{e_{r,c}\in\Psi_+}(e_{r,c}-\mu_e)\times(\ell s(x_{r,c})-\mu_{\ell s})}{\sqrt{\sum\limits_{e_{r,c}\in\Psi_+}(e_{r,c}-\mu_e)^2}\sqrt{\sum\limits_{x\in\Psi_+}(\ell s(x_{r,c})-\mu_{\ell s})^2}},\end{aligned} \tag{6}$$

where $\mathbf{w}=\{\omega_k\}^{16}_{k=1}$, μ_e denotes the mean value of the total prediction errors in Ψ_+, $\mu_{\ell s}$ is the mean of the total weighted features in Ψ_+. $\mathbf{p_e}$ is the vector containing all the prediction errors in Ψ_+, and $\mathbf{l_s}$ denotes the vector containing all the weighted features in Ψ_+.

The sequential quadratic programming (SQP) algorithm **Boggs1995** is used to calculate the maximum value of Eq. 6, and therefore, the corresponding 16 weights are obtained accordingly. Each of 16 weights is normalized to a real number in the range of -255 through 255. Subsequently, the absolute values of the 16 normalized weights are sorted in descending order, so that the features corresponding to the first 8 sorted weights are chosen. For some cover image, there exist $C^1_8+C^2_8+C^3_8+C^4_8+C^5_8+C^6_8+C^7_8+C^8_8=255$ combinations of 8 features. 255 combinations are sequentially visited to search for the optimal feature combination for each image, which generates the best power signal-to-noise ratio (PSNR).

After obtaining the optimal feature combination, all the pixels in Ψ_+ are sorted in ascending order of weighted summation of the selected feature combination and then split into 16 classes $\{h_1,h_2,\cdots,h_{16}\}$. The genetic algorithm (GA) is exploited to search for the optimal embedding points for each histogram. The detailed implementation details of GA are mentioned in **ZhangJVCIR2022**.

C. Data hiding

1) The additional information: For the κ^{th} histogram h_κ, the improved discrete particle swarm optimization (IDPSO) **WengJVCIR2022**, rather than the exhaustive search, is used to search for two optimal bins. Suppose that the two optimal bins of h_κ are ℓ^*_κ and γ^*_κ. For blind data extraction and image restoration, the additional information has to be embedded into the cover image. The additional information for each of two non-overlapping sets, i.e., Ψ_+ and Ψ_-, is mainly composed of the following several parts.

- The selected feature combination of 8 features;
- The parameters associated with IDPSO;
- $\{\ell^*_\kappa\}^{16}_{\kappa=1}$ and $\{\gamma^*_\kappa\}^{16}_{\kappa=1}$ for all 16 histograms;
- The compressed location map (LM) used to avoid overflow and underflow. If a pixel in Ψ_+ or Ψ_- is valued at 0 or 255, the corresponding bit in the LM is recorded by 1; otherwise, the corresponding bit is 0. Simultaneously, the pixel valued 0 or 255 is changed to be 1 or 254, respectively.

The additional information is embedded into the cover image along with the payload. The border pixels having no sufficient neighbors to predict, are simply skipped, and their least significant bits (LSBs) are used to carry the additional information. The replaced LSBs are appended to the payload. The detailed data embedding of $e_{r,c}$ in h_κ is given by

$$e'_{r,c}=\begin{cases}e_{r,c}-b, \text{ if } e_{r,c}=\ell^*_\kappa; \\ e_{r,c}-1, \text{ if } e_{r,c}<\ell^*_\kappa; \\ e_{r,c}+1, \text{ if } e_{r,c}>\gamma^*_\kappa; \\ e_{r,c}+b, \text{ if } x_{r,c}=\gamma^*_\kappa,\end{cases} \tag{7}$$

where b is one bit of data and $b\in\{0,1\}$.

D. Data extraction

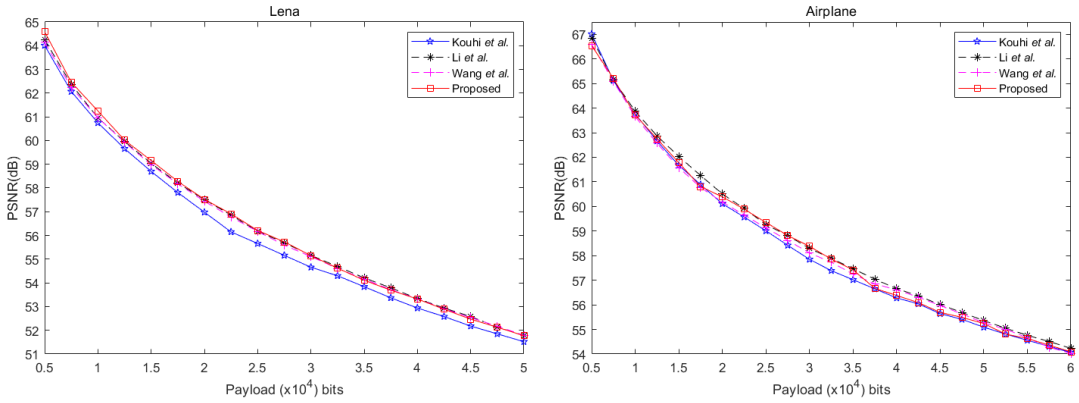
The additional information must be extracted prior to the payload from the border pixels. With the aid of the additional information, e.g., ℓ^*_κ and γ^*_κ, $e_{r,c}$ is retrieved by

$$e_{r,c}=\begin{cases}e'_{r,c}-1, \text{ if } e'_{r,c}\le\ell^*_\kappa; \\ e'_{r,c}+1, \text{ if } e'_{r,c}\ge\gamma^*_\kappa.\end{cases} \tag{8}$$

Simultaneously, the embedded bit b is extracted as

$$b=\begin{cases}0, \text{ if } e'_{r,c}=\ell^*_\kappa \text{ and } e'_{r,c}=\gamma^*_\kappa; \\ 1, \text{ if } e'_{r,c}=\ell^*_\kappa-1 \text{ and } e'_{r,c}=\gamma^*_\kappa+1.\end{cases} \tag{9}$$

III. Experimental results



In this section, several experiments are conducted to demonstrate the superiority of the proposed method. The proposed method is compared with four related works including Kouhi *et al.*'s **KouhINS2020**, Li *et al.*'s **LiXLTifs2015**, Wang *et al.*'s methods **WangTCSVT2021**. Eight images taken from USC-SIPI **USID** are utilized as test images. From Fig. 2, it can be clearly observed that the proposed method achieves higher or comparable embedding capacity than the three compared methods.

IV. Conclusion

This paper improves the embedding performing by constructing sharp PEHs from two aspects: two predictors and adaptive feature selection. Unlike fixed feature selection utilized in traditional MHM-based RDH methods, the adaptive feature selection strategy adaptively selects different features for images by considering the statistical characteristics of images. Two predictors are jointly utilized to include the smaller predictor errors into data embedding while excluding larger prediction errors from data embedding. The experimental results also demonstrate the proposed method offer higher or comparable embedding performance than several related works.

***Abstract*—With the rapid development of steganography, researches on the adaptive steganography have made steganalysis more and more difficult. In order to improve the detection accuracy, there are plenty of works introducing complex high-dimensional features to steganalysis, among which the rich model steganalysis features are particularly classical. However, there are many redundant features in high-dimensional features, which greatly increase the time and computational cost. How to eliminate redundant features while maintaining detection accuracy is still a research hotspot. In this paper, we propose a novel feature selection method based on Clonal Selection Algorithm (FS-CSA) for image steganalysis, which separates features into multiple populations according to the idea of niche technique, and proposes a feature similarity function to calculate the affinity of features in each population, and finally uses FS-CSA to select features based on the affinity in each population in turn. The experimental results show that FS-CSA can significantly reduce the feature dimensionality while maintaining the detection accuracy, where the Spatial Rich Model (SRM) features can be reduced to about 8000 dimensions, and the Gabor Filter Residual (GFR) features can be reduced to about 7000 dimensions. The crossover experiments show that the steganalysis features selected by FS-CSA are also generalizable to any steganography algorithm.**

I. Introduction

Steganography embeds secret information into redundant parts of cover images, and there is no obvious visual difference between the cover image and the stego image, thus it can achieve the purpose of covert communication. As the opponent of steganography, steganalysis aims to detect steganography signals in an image to determine whether the image contains secret information or not. Steganography has evolved from non-adaptive steganography algorithms, such as LSB (Least Significant Bit) and Jsteg, to adaptive steganography algorithms. The representative adaptive steganography algorithms for the spatial domain are WOW [1], S-UNIWARD [2], MiPOD [3], etc. The representative adaptive steganography algorithms for the JPEG domain are nsF5 [4], J-UNIWARD [2], UERD [5], etc. The development of adaptive steganography algorithms has greatly improved the security of steganography, and brought great challenges to steganalysis, making it difficult to achieve better detection performance with the simple statistic-based features.

This work was supported in part by the National Natural Science Foundation of China (NSFC) under Grants 61972269 and 62272331 and Open Foundation of Henan Key Laboratory of Cyberspace Situation Awareness under Grant HNTS2022003. (Corresponding Author: Hongxia Wang.)

Therefore, there are plenty of works introducing complex high-dimensional features to steganalysis in order to improve detection accuracy. In the spatial domain, Fridrich et al [6] proposed the Spatial Rich Model (SRM). SRM features have high detection performance and are widely used in current image steganalysis. In the JPEG domain, Kodovsky et al [7] who drew on the idea of co-occurrence matrix of SRM proposed JPEG Rich Model (JRM) features. In addition, there are high-dimensional feature steganalysis based on random projection and phase perception. The representative ones are Discrete Cosine Transform Residual (DCTR) [8] and Gabor Filter Residual (GFR) [9]. Compared with the 64 convolution kernels in DCTR, GFR can better capture steganography signals and has better detection performance for adaptive steganography algorithms.

Although high-dimensional steganalysis features have shown better performance in detecting steganography signals, they consume a lot of time and computational cost in performing feature extraction and using classifiers to train models. In addition, there are redundant features in high-dimensional features. Removing redundant features does not degrade detection accuracy, and may even improve it slightly. Therefore, feature selection which can reduce the feature dimensionality while maintaining detection accuracy is an effective method.

Recently, with the rapid development of deep learning, steganalysis methods based on deep learning have been extensively investigated, and a considerable number of deep steganalysis networks (DSNs) have been proposed. Among them, DSNs such as Xu-Net [10], SRNet [11], Zhu-Net [12], SiastegNet [13], and SESNet [14] have achieved desirable detection performance. However, most DSNs, like SRNet, Zhu-Net, focus on building deeper and more complex networks to improve detection performance, which leads to excessive model training time and huge computational cost. Moreover, DSNs also has the problem of unsatisfactory generalization, which leads to the lack of generality when facing complex and changeable images in the real world.

Meanwhile, with the continuous development of computational intelligence, the branch, Clonal Selection Algorithm (CSA), has attracted much attention, The CSA ensures fast convergence to the global optimal solution by using the memory mechanism and has excellent search capability, which has achieved excellent results in pattern recognition, character recognition, and classification problems. Therefore, in this

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

paper, we propose a novel feature selection method based on Clonal Selection Algorithm (FS-CSA) for image steganalysis. The proposed method is able to select discriminative features from the high-dimensional features while maintaining detection accuracy. The main contributions of our proposed method are as follows:

- A novel feature selection algorithm based on Clonal Selection Algorithm for image steganalysis is proposed. And the proposed algorithm achieves about 80% feature reduction for SRM and about 60% feature reduction for GFR while maintaining detection accuracy.
- Since CSA has the ability to find the global optimal solution while converging quickly, FS-CSA can quickly select the feature subset with the highest discriminative power in high-dimensional features, and the feature subset is the optimal subset in high-dimensional features. In general, the distribution of images in the same dataset is similar, so the selected feature subset should be the approximate optimal solution on that dataset. In this paper, extensive experiments also confirm that the feature subset selected by FS-CSA is generalizable to different steganography algorithms.

The rest of this paper is organized as follows. In Section II, we summarize the previous work on feature selection for image steganalysis. In Section III, the design details of our proposed algorithm will be shown. In Section IV, the results of extensive experiments are analyzed and summarized. Finally, this paper is concluded in Section V.

II. Related Work

The purpose of feature selection is to select discriminative features from high-dimensional features, which have better performance for classifying cover images and stego images. Feature selection removes irrelevant and redundant features in high-dimensional features, which are not effective or may even be counterproductive for the classifier in order to reduce feature dimensions.

In recent years, researchers have done a lot of researches on feature selection for image steganalysis. Kaur et al [15] used Mutual Information (MI) to calculate the differentiability of features, and selected features with high differentiability. In addition, adaptive inertia-weight based Particle Swarm Optimization (APSO) was used further with Area Under Curve (AUC) as a fitness function to improve feature reduction. Ma et al [16] proposed a feature selection method based on decision rough set α-positive region reduction. A quantitative method of attribute separability was proposed to evaluate the separability of features, and features were sorted according to the separability. This method could reduce the sorted features while maintaining the detection accuracy. Pathak et al [17] proposed a variant form, levy flight-based gray wolf optimization (LFGWO). The idea of the algorithm is using the collective behavior of wolves to find the optimal solution. Several experiments were conducted on two methods of extracting features using AlexNet and Subtractive Pixel Adjacency Model (SPAM) [18], and the results showed that the algorithm had a faster convergence rate while maintaining detection accuracy. Liu et al [19] proposed a nature-inspired feature selection method using the Binary Bat Algorithm (BBA) based on the idea of echolocation behavior of bats to search for discriminative features, and the selected feature subset was used to train multiple classifiers to improve detection accuracy. Gupta et al [20] proposed an improved algorithm with Fisher linear discriminant classifier, which identified the feature submodels of SRM based on binary particle swarm optimization and local best particle swarm optimization (GLBPSO) to achieve feature reduction.

The Clonal Selection Algorithm (CSA) can converge to the global optimal solution quickly by using the affinity function, clone proliferation and mutation, and memory mechanism. And there is a correspondence in CSA and feature selection. Feature selection is to select discriminative features from high-dimensional features, in order to find the subset of features with the strongest classification ability. In CSA, antibody selection is to select the combination of antibodies with the strongest recognition ability to antigens. Feature selection based on CSA can accelerate the search for the best feature subset and maintain the fast convergence property while enhancing the global search capability. Therefore, we propose a novel feature selection method based on Clonal Selection Algorithm for image steganalysis to find the best feature subset while maintaining detection accuracy.

III. Proposed Method

In this section, we will give the feature selection based on Clonal Selection Algorithm (FS-CSA) for image steganalysis in detail. Firstly, the feature values are preprocessed to facilitate the subsequent population division. Secondly, we will determine the number of iterations, i.e., the number of populations. Then, the affinity of features in each population is calculated based on the feature similarity function. Finally, we will use FS-CSA to perform feature selection and feature update on high-dimensional features. The framework of FS-CSA is shown in Fig. 1.

A. Preprocess the feature value

As we can see from Fig. 1, after finishing feature extraction on the cover $\boldsymbol{X}$ and the stego $\boldsymbol{Y}$, the feature values will be preprocessed. First, considering that there may be regional differences between different images, in order to avoid the subsequent normalization of feature values to offset such differences, the dataset of cover and stego images is randomly disrupted and then equally and non-overlappingly divided into $n\,\{n \in N^{+}\}$ parts. And then for each of them, we preprocess features values to facilitate the subsequent population division. In the experimental stage, the value of n is fixed at 100.

First, we perform a linear normalization operation on the features to avoid the adverse effects of singular samples. The normalization operation is computed by Min-Max Normalization as

$$norm_{fc} = \frac{fc - min_c}{max_c - min_c} \tag{1}$$

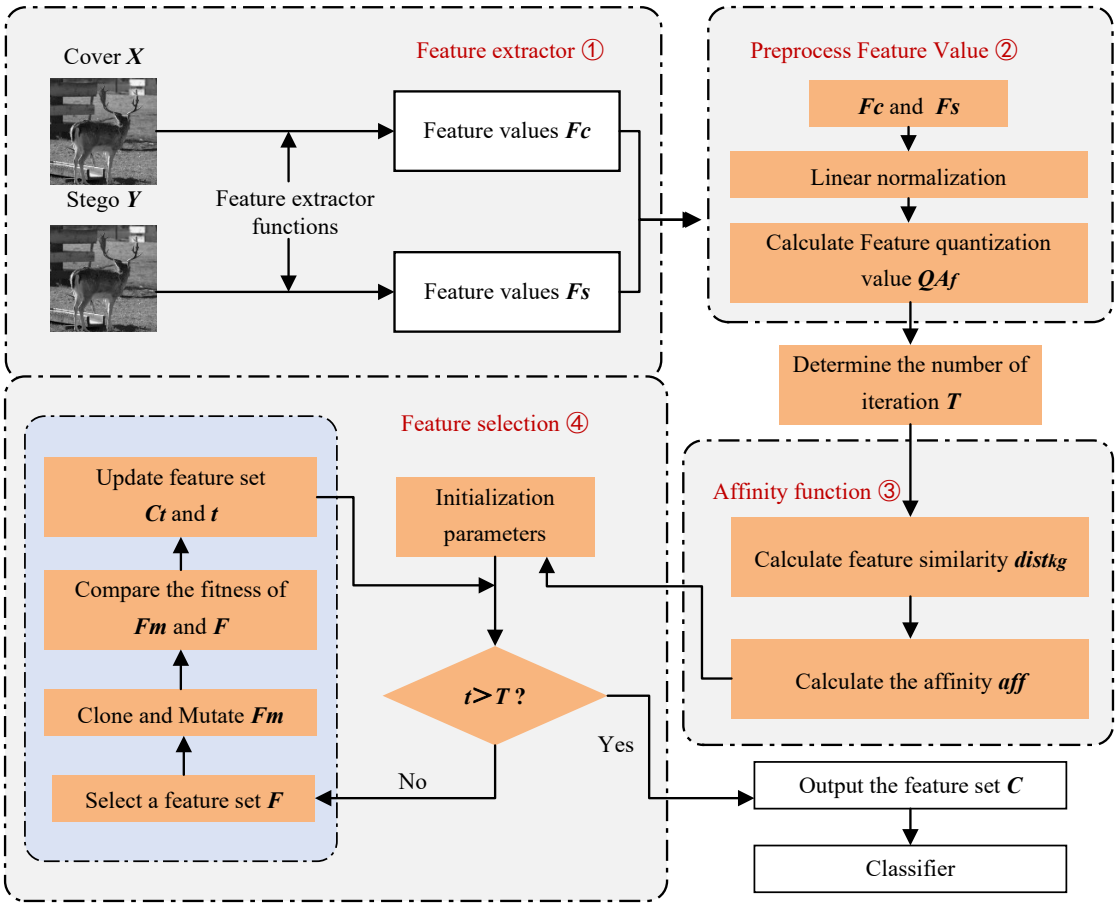

Fig. 1. The framework of FS-CSA.

where the $norm_{fc}$ is obtained by normalizing each feature of $\boldsymbol{X}$. The min_c and max_c denote the minimum value and the maximum value of all $\boldsymbol{X}$ features separately. Similarly, we can get the $norm_{fs}$ by normalizing each feature of $\boldsymbol{Y}$.

Then, according to the core idea of Fisher's Linear Discriminant and the attribute separability measurement (ASM) in [16], the $\boldsymbol{X}$ and $\boldsymbol{Y}$ features are projected onto the X-axis, and the difference value of the intra-class mean of each dimensional feature is used as the quantifier of inter-class dispersion, and the sum value of the intra-class standard deviation of each dimensional feature is used as the quantifier of intra-class aggregation. Finally, the two are divided to obtain the quantified values QA_f of each dimensional feature.

B. Determine the number of iterations

There are large differences between different feature types of feature values and feature dimensions. For example, GFR has 17000 dimensional features while SRM has 34671 dimensional features. In order to avoid a large number of features in the feature subset of different feature types obtained in each round of feature selection, which will have an impact on filtering out redundant features, the number of iterations T is determined dynamically based on the quantified values QA_f as

$$T = \lceil \frac{min(QA_b) - max(QA_l)}{niche} \rceil \tag{2}$$

where the QA_b denotes the maximum value of $n\{n \in N^+\}$ quantified values, and the QA_l denotes the minimum value of $n\{n \in N^+\}$ quantified values. Then, we take the minimum value of QA_b and the maximum value of QA_l. The purpose of this is to ensure that all features of each share can be selected in the subsequent iterations. The $niche$ refers to the iteration radius. In biology, niche refers to a role or organizational function with common characteristics in a specific environment. The niche provides the potential for species diversity and has been introduced into several optimization algorithms. In this paper, niche is used to ensure the diversity of the extracted features. Features can be divided into different groups according to the quantified values to select the excellent features in each group, which can avoid falling into the local optimal solution, and ensure that every feature can be selected. The value of $niche$ will change dynamically because the dispersion of the quantified values for different feature sets

is varied. In the experimental phase, the preset value of $niche$ is 0.008.

C. Calculate the feature affinity

After determining the number of iterations T, calculate the affinity of features which are in a specific niche. In order to filter out the redundant features, we give a feature similarity function as the affinity function to sort the importance of the features in the niche.

For the features of each iteration which are in a specific niche, the similarity between feature k and feature g is computed as

$$dist_{kg} = \sqrt{\sum_{i=1}^{n}(QA_i(k) - QA_i(g))^2}, \quad n \in N^+ \qquad (3)$$

where the similarity is calculated based on the sum of the Euclidean Distance between the quantified values of each feature k and feature g in $n\,\{n \in N^+\}$.

Then, for the calculated $dist_{kg}$, find all features that are smaller than the similarity threshold $S_t \ \ \{0 < S_t < 1\}$ and count the number of similar features for each feature. Features with a higher number of similar features are less important, because they can be replaced by other features to achieve the same effect. Therefore, we define the affinity of a feature as the reciprocal of its number of similarities, and the greater the affinity, the better the feature performs in classification.

D. Feature Selection by FS-CSA

After calculating the feature affinity, feature selection is performed on the features of each iteration which are in a specific niche. Select out the features with the highest affinity, and use its similar features as redundant features to form the similar subset until the similar subset is the same as all features which are in the niche. Then, output the subset of features $\boldsymbol{F}$

Feature update is performed on the selected feature subset $\boldsymbol{F}$ in each round of iteration. Feature update mainly includes clonal proliferation and clonal mutation. The purpose of this paper is to reduce features. Thus, this paper only performs clonal mutation on $\boldsymbol{F}$. The mutation operation refers to randomly selecting a certain number of features from the similar feature set of $\boldsymbol{F}$ and adding them to the feature subset to get the mutated feature subset $\boldsymbol{F_m}$. If the classification effect of $\boldsymbol{F_m}$ is better than $\boldsymbol{F}$, the $\boldsymbol{F_m}$ is added to the updated feature subset $\boldsymbol{C_t}$, otherwise, the $\boldsymbol{F}$ is added to the updated feature subset $\boldsymbol{C_t}$. Then, update $\boldsymbol{t}$ and perform feature selection on the features in the other niche. After the finish of the iteration, select the best feature subset $\boldsymbol{C_t}$ in each iteration as the final feature subset $\boldsymbol{C}$. Finally, use the classifier to obtain the detection accuracy of the feature subset $\boldsymbol{C}$.

IV. Experimental Results and Analysis

In order to verify the performance of the FS-CSA proposed in this paper, extensive experiments are performed on SRM and GFR.

A. Experimental setting

All experiments in this paper are performed on the dataset BOSSbase 1.01, which contains 10,000 grayscale images. The image size used in the experiments is 256×256. First, in the spatial domain, S-UNIWARD is used to construct 0.2, 0.4, 0.5, 0.8 and 1.0bpp (bits per pixel) stego images, and WOW, MiPOD are used to construct 0.4, 0.8bpp stego images. In the JPEG domain, J-UNIWARD is used to construct 0.2, 0.4, 0.5, 0.8 and 1.0bpnzAC (bits per non-zero cover AC DCT coefficient) stego images, and nsF5, UERD are used to construct 0.4, 0.8bpnzAC stego images. Specifically, UERD utilizes all DCT coefficients. The quality factor for JPEG domain methods is 95. Thus, 1 group of cover images and 18 groups of stego images are obtained. Then, SRM features (34671-D) and GFR features (17000-D) are extracted by using corresponding extraction algorithms. Finally, in this paper, we adapt the ensemble classifier to classify the images and evaluate the performance of FS-CSA using P_E (minimum total testing error under equal priors). $P_E = \min_{P_{FA}}[P_{FA} + P_{MD}(P_{FA})]/2$ and $P_A = 1 - P_E$, where P_{FA} denotes the false alarm rate and P_{MD} denotes the missed-detection rate, P_A denotes the detection accuracy. During the experiment, 10 repetitions of the experiment are conducted for each group of images, and the average of 10 P_A is taken as the final comparison result. In the experiments, 5000 pairs of images are used to train the classifier, and other 5000 pairs of images are used to test and verify the classification effect.

B. Feature Selection of SRM

SRM features are extracted from stego images which are obtained by S-UNIWARD with different payloads, then use FS-CSA to reduce SRM. Fig. 2 shows the comparison results of the average detection accuracy $\overline{P_A}$ between each iteration and the 34671-dimensional SRM features. As we can see from Fig. 2, SRM features can be efficiently reduced by FS-CSA. Under different payloads, FS-CSA can reduce SRM features to less than 7000 dimensions and to about 3000 dimensions at 0.8bpp while maintaining detection accuracy.

The average detection accuracy $\overline{P_A}$ of SRM features extracted from stego images obtained by MiPOD with different payloads before and after reduction by FS-CSA is shown in Fig. 3, and it can be seen that SRM features can be reduced to about 8,000 dimensions at 0.4bpp and 7,000 dimensions at 0.8bpp by FS-CSA.

The average detection accuracy $\overline{P_A}$ of SRM features extracted from stego images obtained by WOW with different payloads before and after reduction by FS-CSA is shown in Fig. 4, and it can be seen that SRM features can be reduced to about 9,000 dimensions at 0.4bpp and 3,000 dimensions at 0.8bpp by FS-CSA.

Extensive experiments show that FS-CSA can effectively reduce SRM features. From the experimental results, the detection accuracy of the feature subset obtained by FS-CSA can even exceed that of SRM features, which also verifies that there are indeed redundant or irrelevant features in SRM

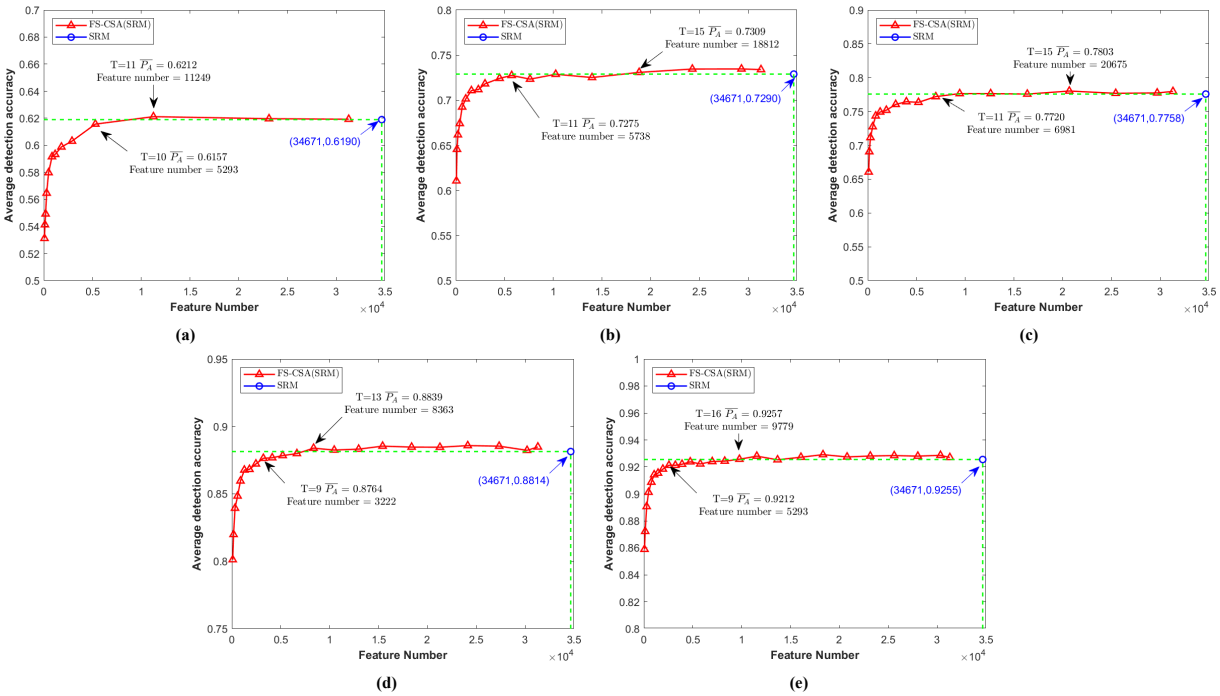

Fig. 2. Average detection accuracy $\overline{P_A}$ of SRM extracted from stego images obtained by S-UNIWARD with different payloads before and after reduction by FS-CSA (a) 0.2bpp, (b) 0.4bpp, (c) 0.5bpp, (d) 0.8bpp, (e) 1.0bpp.

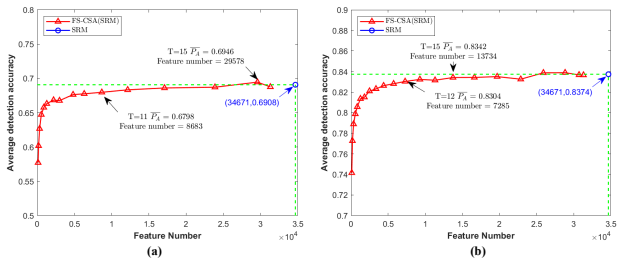

Fig. 3. Average detection accuracy $\overline{P_A}$ of SRM extracted from stego images obtained by MiPOD with different payloads before and after reduction by FS-CSA (a) 0.4bpp, (b) 0.8bpp.

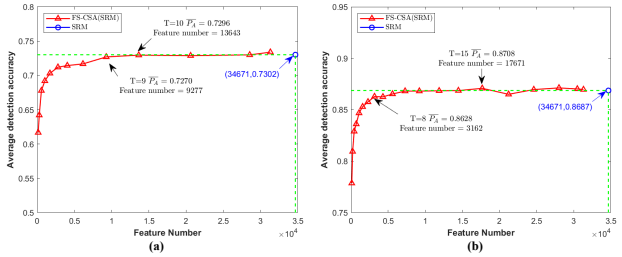

Fig. 4. Average detection accuracy $\overline{P_A}$ of SRM extracted from stego images obtained by WOW with different payloads before and after reduction by FS-CSA (a) 0.4bpp, (b) 0.8bpp.

features, and FS-CSA can effectively delete these features to achieve the purpose of reducing the feature dimension.

C. Feature Selection of GFR

The dimension number of the GFR features extracted by the GFR algorithm is 17,000, and FS-CSA proposed in this paper is used for feature selection of the GFR features. Fig. 5 shows the comparison results of the average detection accuracy $\overline{P_A}$ between each iteration and the 17000-dimensional GFR features. As we can see from Fig. 5, GFR features extracted by J-UNIWARD can be reduced to about 7000 dimensions.

The average detection accuracy $\overline{P_A}$ of GFR extracted from stego images obtained by nsF5 with different payloads before and after reduction by FS-CSA is shown in Fig. 6, and it can be seen that GFR features extracted by nsF5 can be even reduced to about 400 dimensions at 0.8bpnzAC.

The average detection accuracy $\overline{P_A}$ of GFR extracted from stego images obtained by UERD with different payloads before and after reduction by FS-CSA is shown in Fig. 7, and it can be seen that GFR features extracted by UERD can be reduced to about 10,000 dimensions.

The experimental results show that the proposed method can considerably reduce feature dimension while maintaining the detection accuracy.

D. Crossover experiments on feature selection of GFR

In this subsection, a series of crossover experiments are performed on GFR features with the same experimental setup as Section IV-C. First, crossover experiments are performed

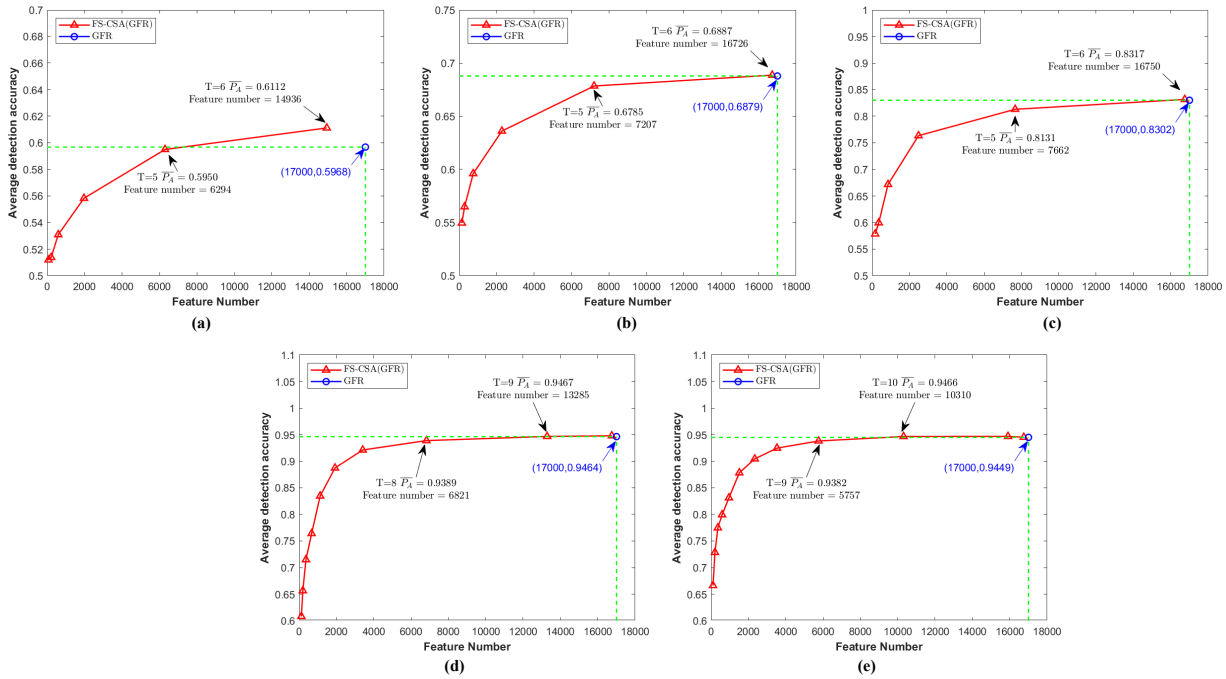

Fig. 5. Average detection accuracy $\overline{P_A}$ of GFR extracted from stego images obtained by J-UNIWARD with different payloads before and after reduction by FS-CSA (a) 0.2bpnzAC, (b) 0.4bpnzAC, (c) 0.5bpnzAC, (d) 0.8bpnzAC, (e) 1.0bpnzAC.

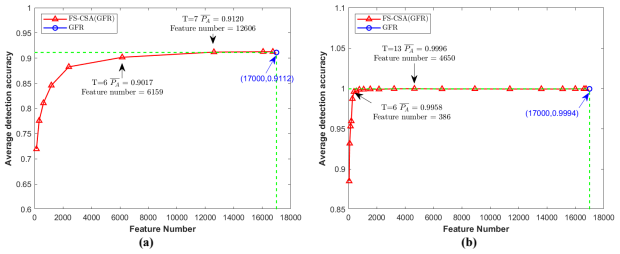

Fig. 6. Average detection accuracy $\overline{P_A}$ of GFR extracted from stego images obtained by nsF5 with different payloads before and after reduction by FS-CSA (a) 0.4bpnzAC, (b) 0.8bpnzAC.

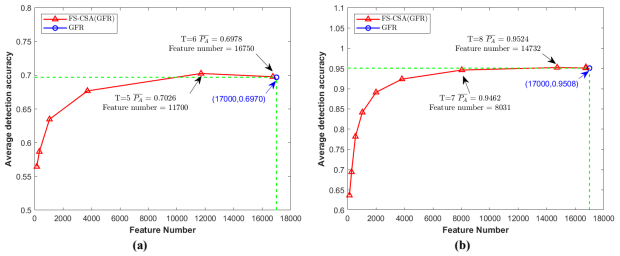

Fig. 7. Average detection accuracy $\overline{P_A}$ of GFR extracted from stego images obtained by UERD with different payloads before and after reduction by FS-CSA (a) 0.4bpnzAC, (b) 0.8bpnzAC.

on GFR features with different steganography methods and the same payload. Then, crossover experiments are performed on GFR features with the same steganography method and different payloads. Finally, crossover experiments are performed on GFR features with different steganography methods and different payloads. Table I shows the comparison results of the average detection accuracy between GFR features and the crossover features obtained by J-UNIWARD at 0.4bpnzAC. As we can see from Table I, the average detection accuracy of the crossover features is considerably close to the average detection accuracy of GFR.

The crossover experiments verify that the discriminative features in GFR features perform similarly under different steganography algorithms with different payloads. It can be proved that the feature subset obtained by J-UNIWARD (J-UNI, 0.4bpnzAC) can be directly applied to the classification detection of another steganography algorithm with different payloads, while maintaining detection accuracy.

V. Conclusion

In this paper, we propose a feature selection method based on Clonal Selection Algorithm for image steganalysis (FS-CSA). Extensive experiments show that the proposed method achieves about 80% feature reduction for SRM and about 60% feature reduction for GFR while maintaining detection accuracy. In addition, the crossover experiments show that the steganalysis features selected by FS-CSA are also generalizable to different steganography algorithm. In the future, the feature selection for steganalysis based on CSA will be further

TABLE I
THE COMPARISON RESULTS OF THE AVERAGE DETECTION ACCURACY $\overline{P_A}$ BETWEEN GFR FEATURES AND THE CROSSOVER FEATURES OBTAINED BY J-UNIWARD AT 0.4BPNZAC.

Average detection accuracy	**Steganography method (payload/bpnzAC)**					
	J-UNI(0.2)	J-UNI(0.8)	nsF5(0.4)	nsF5(0.8)	UERD(0.4)	UERD(0.8)
$\overline{P_A}$ of crossover features	**0.6005**	0.9347	0.9455	0.9993	0.7656	0.9349

***Abstract*—Processing speech at multiple temporal scales greatly improves the performance of automatic speech recognition, but its effect has not been fully exploited in speech enhancement tasks. In this study, we propose a novel Transformer-based neural network termed ScaleFormer, which analyzes speech at multiple temporal resolutions. In ScaleFormer, we utilize an encoder that employs multi-scale convolution to extract different temporal scale features. Then, an intra-scale transformer is used to extract the representation within each scale. After obtaining the output of the intra-scale transformer, an inter-scale transformer is used to model the relationship between multiple scales. All transformer block in ScaleFormer is designed with a dual-path framework to learn short and long-term dependencies. We conduct the experiments on the WSJ0 SI-84 corpus. Experimental results show that our approach outperforms previous representative systems in terms of objective metrics.**

I. Introduction

Noise degrades the speech quality and intelligibility. Additionally, it can severely degrade the performance of speech-based applications, such as automatic speech recognition, telecommunication, and hearing aids. The goal of speech enhancement is to restore clean speech from a mixture that is corrupted by noise, thereby improving speech quality and intelligibility. It is typically used as a pre-processing step in speech-related applications.

In recent years, deep neural networks (DNNs) have triggered breakthroughs in speech enhancement, primarily due to their powerful capability to learn complicated relations from supervised data. Conventional DNN-based speech enhancement methods [1]–[3] are based on the time-frequency domain and use short-time Fourier transform (STFT) to extract input features and training targets. However, most of the time-frequency domain approaches aim at enhancing only the spectral magnitude and the noisy phase is employed unaltered for time domain signal reconstruction. A recent study has demonstrated that phase plays an important role in the quality of enhanced speech, especially in low SNR conditions [4]. Consequently, researchers have started to explore methods to enhance magnitude and phase jointly.

Two types of approaches enhance magnitude and phase jointly: complex spectrogram enhancement and time domain enhancement. The complex spectrogram is decomposed into real and imaginary parts in the Cartesian coordinates and jointly enhanced. In this way, both magnitude and phase can be implicitly estimated. The training targets also can be further categorized as complex ratio masking [5], [6] and complex spectral mapping [7], [8].

On the other hand, the time domain methods [9]–[12] aim to predict the clean speech signal from noisy speech directly. In this process, the trouble of estimating phase information in the time-frequency domain is circumvented. As a typical approach in the time domain, the convolutional time-domain audio separation network (Conv-Tasnet) [13] can implicitly encode phase information of speech into a latent representation. The main idea behind Conv-Tasnet is to use convolutions to replace transformations like STFT to extract features directly from the raw speech signal. Based on Conv-Tasnet, SpEx+ [14] employs multiple parallel 1-D CNNs with different kernel sizes to encode the noisy speech into multi-scale speech embeddings. It has been proved that multi-scale encoding can improve the performance of automatic speech recognition [15].

Motivated by SpEx+[14], we propose a novel framework called ScaleFormer for speech enhancement task, mainly consisting of a multi-scale encoder, an intra-scale transformer, and an inter-scale transformer. The multi-scale encoder can extract speech features at multiple temporal scales through three parallel 1-D CNNs with different kernel sizes. The intra-scale transformer is utilized to extract the representation at each certain scale. And the inter-scale transformer can model the relationship between multiple temporal scales. For all the transformer layers of ScaleFormer, we adopt the dual-path framework introduced by DPRNN [16] that can learn both short and long dependencies.

This paper is organized as follows: We first describe the ScaleFormer in the next section. Section 3 describes the experimental details. Results and comparisons are given in Section 4. Section 5 concludes the paper.

II. The Model

The proposed speech enhancement network consists of a multi-scale encoder, a ScaleFormer block, and a decoder, as shown in Fig. 1. The multi-scale encoder is responsible for transforming the mixture waveform into a multi-scale representation. The ScaleFormer block can extract features on a certain temporal scale and model the relationships between different temporal scales. The decoder reconstructs the clean signals in the time domain using the mask predicted by the ScaleFormer block. In the following sections, we will introduce key components and loss functions used in our model.

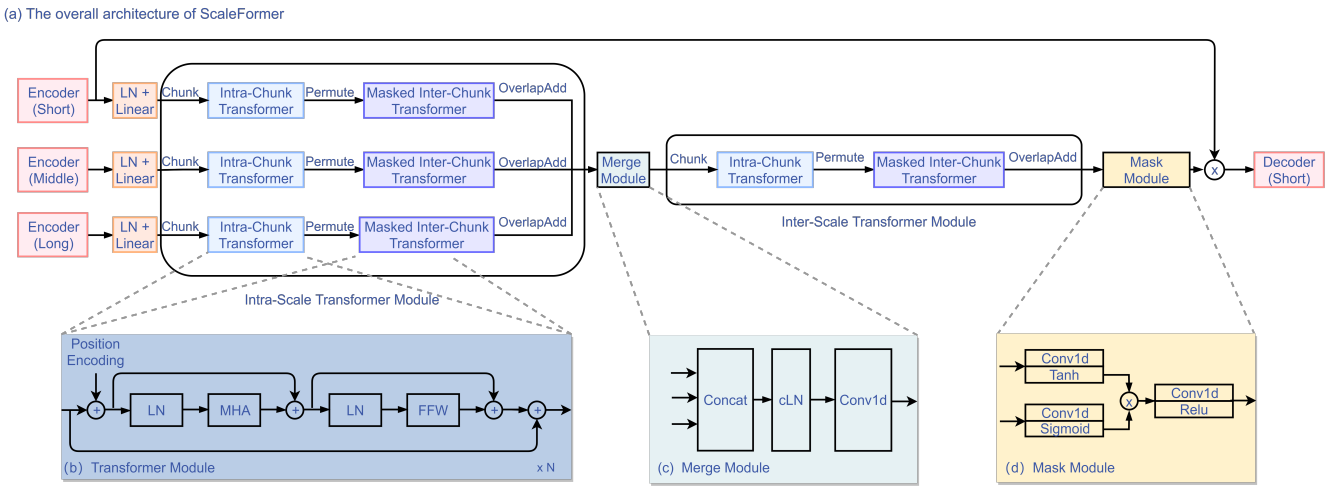

Fig. 1. The architecture of ScaleFormer.

A. multi-scale encoder

Speech contains rich feature information over multiple temporal scales such as phonemic and prosodic so the performance of speech recognition systems can be greatly improved by multiple temporal resolutions [14]. Motivated by SpEx+, we use three parallel 1-D convolutions with different kernel size, l_1 (short), l_2 (middle), l_3 (long) to extract the different temporal scale features. The multi-scale encoder can transform the speech signal $x \epsilon R^T$ directly into a higher level representation, and a rectified linear unit (ReLU) enforced a non-negative constrain, so we have

$$W_{short} = ReLU(Conv1d(x; l_1)) \quad (1)$$

$$W_{middle} = ReLU(Conv1d(x; l_2)) \quad (2)$$

$$W_{long} = ReLU(Conv1d(x; l_3)) \quad (3)$$

where W_{short},W_{middle}, and W_{long} $\epsilon R^{F \times T'}$. l_1, l_2, and l_3 are the different kernel size in the 1-D CNNs, respectively. The outputs of the multi-scale encoder are further processed by layer normalization and a linear layer.

B. ScaleFormer Block

The ScaleFormer Block consists of three modules: an intra-scale transformer module, an inter-scale transformer module, and a masking module. The intra-scale transformer module can perform feature extraction on a certain scale. Afterward, the inter-scale transformer module is utilized to model the relationship between different temporal scale features. At last, a masking module is used to predict a mask for the output of the encoder.

1) Intra-Scale and Inter-Scale Transformer: SepFormer [17] splits the input into smaller chunks and uses a dual-path transformer to process intra-chunk and inter-chunk data. The intra-chunk transformer can model the short-term dependencies by processing each chunk independently and the inter-chunk transformer can model the long-term dependencies across the chunk. The dual-path transformer framework also makes it possible to reduce the quadratic complexity of the transformer by processing smaller chunks.

In this work, both the intra-scale and inter-scale transformers are based on SepFormer, which works on different scales. The intra-scale transformer is responsible for modeling a specific scale representation. Three intra-scale transformers correspond to the outputs of three different scales of the multi-scale encoder respectively. A specific scale feature is fed into a dual-path transformer to extract representation within a certain scale by capturing short-term and long-term dependencies. Fig. 1(b) shows the architecture of the transformer employed in the intra-scale transformer. The building blocks of the transformer are layer normalization, multi-head attention block (MHA), and feed-forward block (FFW). Sinusoidal positional encoding is added to the input, which can introduce position information to the model. The procedure is computed as:

$$w_1 = w + pe \quad (4)$$

$$w_2 = MultiHeadAttention(LayerNorm(w_1)) + w_1 \quad (5)$$

$$w_3 = FeedForward(LayerNorm(w_2)) + w_2 + w \quad (6)$$

where w is the output of the multi-scale encoder and pe is the positional encoding. This producer is repeated N times. To ensure the causality of the system, masked multi-head attention is used in the inter-chunk transformer module, as shown in Fig. 2(b). The output is merged back via the overlap-add method.

Merge Module is employed to preliminarily fuse features of different scales. The architecture is shown in Fig. 1(c). The outputs of the intra-scale transformer are concatenated along the channel dimension, and then cumulative layer normalization (cLN)[13] is applied. Finally, a 1-D convolution is used to adjust the number of channels.

Due to the Merge Module just can fuse features in channel dimension, it cannot model accurately the relationship between different scales. So the outputs of the Merge Module are further fed into an inter-scale transformer to model the relationship between different scales. The inter-scale transformer module

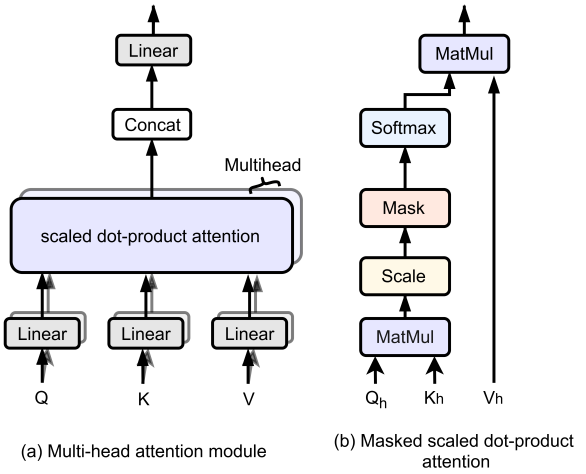

Fig. 2. The architecture of attention [18].

has the same structure as the intra-scale transformer module, but its input aggregates information from all temporal scales.

2) masking module: The structure of the masking module is shown in Fig. 1(d), which uses sigmoid and hyperbolic tangent(Tanh) branches to perform gating and restricts the mask to the [-1,1]. And a ReLu is also employed to enforce a non-negative constraint.

C. Decoder

The decoder merely uses a transposed convolution layer to reconstruct the time-domain signal whose kernel size and stride are the same as the short encoder. Note that we only use one speech decoder to recover speech as estimating a single mask can make the network more focused on synthesizing speech at a specific scale and further reduce the parameters and computational cost of the model.

$$\hat{s} = ConvTranspose1d(M \otimes W_{short}) \tag{7}$$

where $\otimes$ is an operation for element-wise multiplication. M and W_{short} are the mask predicted by the ScaleFormer block and the output of the encoder, respectively.

D. Loss Function

To train the model, we utilize the time-domain loss which is based on the mean square error (MSE) between the denoised speech and clean speech. The time-domain loss is defined as:

$$L\left(s, \hat{s}\right) = \frac{1}{N} \sum_{i=0}^{N-1} \left(s\left(i\right) - \hat{s}\left(i\right)\right)^2 \tag{8}$$

where s and $\hat{s}$ are the sample of the clean speech and the denoised speech, respectively. And N denotes the number of samples in the waveform.

III. Experiment

A. Datasets

In our experiments, we evaluate the performance of our proposed network on the WSJ0 SI-84 dataset [19] which includes 7138 utterances from 83 speakers (42 males and 41 females). Among these speakers, we use the utterances of 77 speakers for training and the rest for the test. we employ 10000 non-speech sounds from a sound effect library (available at www.sound-ideas.com)[20] and generate 320,000 and 3,000 utterances. Specifically, we mix randomly selected training utterances with a random cut from the 10000 training noises at a signal-to-noise ratio (SNR) than is randomly chosen from {-5,-4,-3,-2,-1,0}dB for training and validation, respectively. For the test set, two noises (babble and cafeteria) from Auditec CD (available at http://www.auditec.com) are used to generate 300 mixtures at each SNR of -5dB,0dB, and 5dB.

B. Experimental Setup

In order to facilitate the comparison with SpEx+, we set the kernel size of the convolution in the multi-scale encoder to be the same, l_1 = 2.5ms, l_2 = 10ms, and l_3 = 20ms for the speech of 16kHz sampling rate, respectively, and the stride is half the size of the short convolution kernel (l_1).

The chunk size is 250 with a 50 $\%$ overlap. The number of global and local repeats is R = 2 and N = 4 in ScaleFormer, respectively. We use 2 parallel attention heads and a 256-dimensional feed-forward network within each Transformer layer. The number of channels is 64 and remains unchanged.

All utterances are sampled at 16kHz. The models have trained with Adam [21] optimizer with a learning rate of 0.001. And the batch size is set to 4 at the utterance level. Note that a random segment of 7 seconds is intercepted from an utterance if it is larger than 7 seconds. The smaller utterances are zero-padded to match the size of the largest utterance in the batch. We trained all models for 15 epochs.

C. Baselines

In our experiments, we compare our proposed ScaleFormer with the other baselines, namely CRN [1], GCRN [7], DCCRN-E [6], AECNN [22], and SpEx+ [14]. We keep the best configuration in the original papers.

- CRN: The network is an encoder-decoder structure and 2 LSTM layers are used for sequence modeling. The input of CRN is a magnitude spectrum.
- GCRN: It is a gated convolutional recurrent network for complex spectral mapping. It has a similar structure to CRN except that GCRN has two decoders to model real and imaginary, respectively. The input of GCRN is a complex spectrum.
- AECNN: The network is an autoencoder-based fully convolutional neural network for speech enhancement in the time domain. The input of AECNN is a raw waveform.
- DCCRN-E: It has a similar architecture to CRN but the real-valued convolution is replaced with complex-valued convolution to simulate the complex-valued operation and LSTM layers are not changed. The input of DCCRN-E is a complex spectrum.
- SpEx+: It is a speaker extraction network that extracts multiple temporal resolutions through three parallel CNNs with different filter lengths. In order to apply it in the

ScaleFormer	**84.8**	**92.7**	**95.9**	**91.1**	**81.8**	**90.8**	**95.2**	**89.2**	**2.26**	**2.8**	**3.12**	**2.73**	**2.2**	**2.71**	**3.09**	**2.67**	3.3M

speech enhancement task, we remove the speaker encoder which is designed to extract the speaker embedding of the target speaker from the reference speech. For a fair comparison, we use the MSE loss function instead of SI-SDR in SpEx+ and ScaleFormer.

D. Evaluate Metrics

The performance is evaluated with two objective metrics: perceptual evaluation of speech quality (PESQ)[23] and short time objective intelligibility (STOI)[24]. STOI values typically range from 0 to 1, which can be roughly viewed as percent correct. PESQ values range from -0.5 to 4.5. For both of the STOI and PESQ metrics, the higher number indicates better performance.

IV. RESULT

A. Comparison with Baselines

We show the evaluation results on the WSJ0 SI-84 dataset and compare the performance of our proposed ScaleFormer with baselines. Table I presents the STOI and PESQ score on the test sets and the best result is highlighted by a boldface number. According to the table, we can observe that the ScaleFormer achieves competitive performance compared with other advanced baselines. When compared with GCRN [7], an average improvement of 2.3% and 2.2% for babble and cafeteria is achieved, respectively. For PESQ, ScaleFormer has a 0.15 improvement over GCRN in the case of babble and cafeteria, respectively. Similarly, when compared with the AECNN [22], the STOI is improved by 2.7% and 1.4% and PESQ is improved by 0.25 and 0.17 for babble and cafeteria, respectively.

Next, we compare ScaleFormer with SpEx+. Although both SpEx+ and the proposed ScaleFormer use multi-scale representation in speech enhancement, structures are totally different. SpEx+ is based on TCN. While ScaleFormer is based on the transformer in which we use intra-scale and inter-scale transformers to fully explore the information within each scale and the relationship between different temporal scales. For STOI, ScaleFormer has a 1.0% and 1.1 % improvement over SpEx+ in the case of babble and cafeteria, respectively. And for PESQ, ScaleFormer also has a 0.11 on -5dB improvement over SpEx+ in the case of babble and cafeteria, respectively. This demonstrates the effectiveness of both intra-scale and inter-scale modeling for different scales. We also compare the number of trainable parameters of our proposed network. The proposed network has much fewer parameters, and its results are better than other baselines.

B. Ablation Study

To further demonstrate the validity of our proposed model, we conducted an ablation analysis and present the results in Table II on the test sets. ScaleFormer-Inter represents the utilization of a multi-scale encoder and the exclusion of three intra-scale transformers, including only the inter-scale transformer. On the other hand, ScaleFormer-Intra utilizes multi-scale encoders and three intra-scale transformers but excludes the inter-scale transformers. To ensure a fair comparison, the number of parameters of the three models was kept essentially the same.

After comparing ScaleFormer-Inter, ScaleFormer-Intra, and ScaleFormer, it is evident that ScaleFormer outperforms the other models, demonstrating the importance of modeling both

intra-scale and inter-scale relationships. Specifically, in the case of babble and cafeteria, ScaleFormer shows a 0.4% and 0.2% improvement over ScaleFormer-Intra in terms of STOI and an average improvement of 0.05 over ScaleFormer-Intra in terms of PESQ.

V. Conclusions

In this study, we propose a novel framework for single-channel speech enhancement, which consists of a multi-scale encoder, intra-scale transformer, and inter-scale transformer. The multi-scale encoder can transform the raw speech into a multi-scale representation. The intra-scale transformer can extract the representation at each certain scale and the inter-scale transformer can model the relationship between multiple temporal scales. The results show that the proposed model outperforms other advanced models in terms of objective intelligibility and quality scores.

***Abstract*—As an efficient spoofing attack, pitch scaling can conceal speakers' identities at a low cost by raising or lowering the pitch in a linear style, making it harmful to the security of speaker identification systems. Several studies have explored the possibility of recognizing pitch-shifted voices and also tried to restore them to their original versions. However, they primarily focus on improving the recognition process, while neglecting the restoration process, resulting in poor acoustic quality in the restored voice. In this paper, we propose a unified framework (UniVR) that includes a transformer-based estimator for recognizing pitch-shifted voices and a specially designed voice restoration network for restoring them in high quality. Experiments on AISHELL-1 and AISHELL-3 datasets demonstrate that UniVR achieves state-of-the-art results compared to current anti-pitch-scaling methods, in terms of both recognition accuracy and restoration quality of pitch-shifted voices. Moreover, UniVR can protect current speaker identification systems from pitch-scaling attacks.**

I. Introduction

Speaker Identification (SI) aims to determine an anonymous speaker's identity from a set of enrolled speakers depending on the similarity between the input utterance and the utterance of enrolled speakers [1]. Due to the recent emergence of SI in high-security-required fields, such as multimedia forensics, there is growing concern about its security risks [2]–[4]. One of the main threats to SI is *pitch scaling*, which enables real-time pitch raising or pitch lowering in a linear style [5], [6]. This process can be formulated as follows:

$$p_s = 2^{\alpha/12} \cdot p_o, \tag{1}$$

where p_o and p_s represent the original pitch and scaled pitch, which are marked in Hz. α is the disguising parameter, which is marked via semitone to describe the degree of disguise. Pitch scaling can be easily implemented via numerous software programs, such as Audacity, Audition, iZotope, etc. Besides, several studies reveal that pitch information plays a crucial role in SI [7]–[9]. Consequently, attackers can exploit pitch scaling to conceal their identities and deceive the advanced SI systems at very low cost. Hence, restoration of the pitch-shifted voice is of great significance for trusted speaker identification and voiceprint forensics in digital crime.

As revealed in Equ 1, the original pitch can be uniquely determined by the disguising parameter. Therefore, restoring pitch-shifted voices typically involves two stages: estimating the disguising parameters and resolving the original voice based on the estimated parameters. However, existing studies primarily focus on developing a robust estimator, while simply performing the opposite-degree pitch scaling to restore the pitch [10]–[14], as shown in Fig. 1. This lack of exploration of the restoration process results in several issues. Firstly, due to the artifacts introduced during pitch scaling [15], [16], the acoustic quality of the speech restored by existing methods through multiple pitch shifting is generally unsatisfactory. Secondly, conventional pitch-scaling algorithms are undifferentiable, making it difficult for current methods to utilize multiple loss information in the restoration process to further supervise the estimator, thus increasing the training difficulty. Furthermore, most current methods directly train the estimator on handcrafted datasets in supervised mode to learn a mapping between the pitch-shifted speech and the disguising parameter. Unfortunately, the scale of handcrafted datasets is generally small, and the patterns of pitch-shifted speech disguised by various algorithms are also different, making it challenging for them to build generalizable estimators.

To address these issues, we propose a unified framework termed *UniVR* for pitch-shifted voice retoration. As shown in Fig. 1, UniVR is mainly composed of two components: a pre-trained estimator for adaptive estimation of disguising

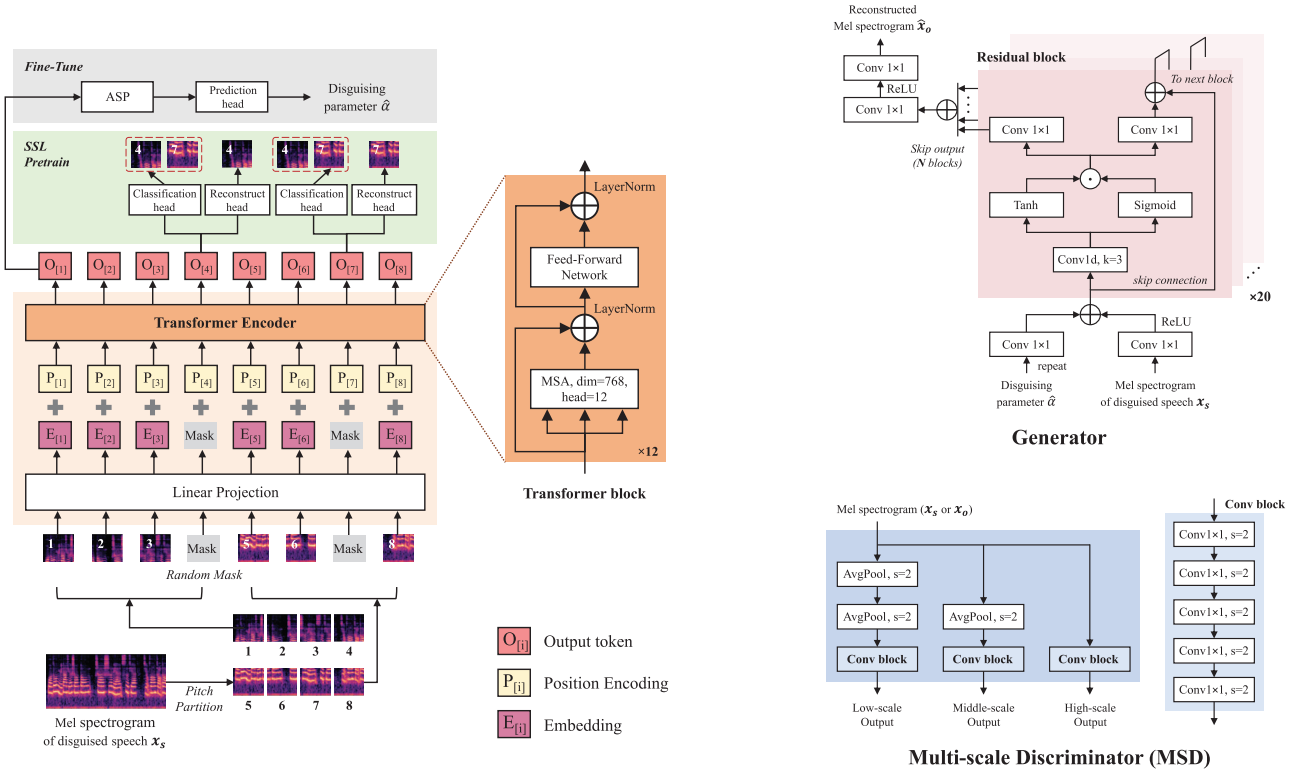
parameters and a learnable *Voice Restoration Network* (VRN) for high-quality restoration of pitch-shifted voice, which can be jointly optimized end-to-end. Experiments on AISHELL-1 and AISHELL-3 demonstrate that UniVR achieves state-of-the-art results when compared with popular baselines [12]–[14] in terms of both the estimation accuracy of the disguising parameter and the quality of the restored speech. The main contributions of our work are listed as follows:

- To our best knowledge, this study is the first to leverage transformer blocks together with self-supervised learning (SSL) pretrain to enhance the performance and generalization of the estimator trained on handcrafted datasets.
- A Voice Restoration Network (VRN) is elaborately designed to restore the pitch of disguised speech and remove the distortions introduced during pitch scaling, thus improving the acoustic quality of restoration.
- Incorporating the transformer-based estimator and VRN, we build a unified framework (UniVR) for pitch-shifted voice restoration, which can be jointly optimized end-to-end. We conduct numerous experiments on AISHELL1 and AISHELL3k, and the results demonstrate that UniVR achieves state-of-the-art anti-pitch-scaling performance.

II. Related work

Existing methods for disguising parameter estimation on pitch scaling can be divided into two categories: reference-free methods [10]–[13] and reference-based methods [14]. Specifically, [10] builds a support vector machine (SVM) to classify whether the pitch has been shifted based on several handcrafted features of the speech. [11] proposes the first convolutional neural network-based (CNN) estimator for adaptively extracting features from pitch-shifted speech and mapping them to the disguising parameters. In [12], a data augmentation strategy is proposed, which is helpful for improving the generalization ability of the estimator. Later, authors in [13] propose a multi-task learning strategy, which boosts the performance of the estimator by simultaneously identifying pitch-shifted speech and estimating the disguising parameter. On the other hand, [14] proposes a reference-based method. It produces a series of restored samples based on assumed disguising parameters, and then determines the correct disguising parameters from the assumations based on the similarity between the restorations and the original pitch reference.

III. Methodology



The overall architecture and data pipelines of UniVR are shown in Fig. 2. In general, UniVR is made up of a reference-free estimator and a voice restoration network (VRN), which are jointly optimized end-to-end. We detail these components in subsections *A* and *B*, respectively.

A. Estimator

Recently, many studies reveal the capability of transformers in learning robust speech representations [17]–[19]. Therefore, we develop a transformer-based estimator E that receives 80-dimensional Mel spectrograms of the pitch-shifted speech, i.e., $\boldsymbol{x}_s \in \mathbb{R}^{80\times T}$, as inputs and then outputs the estimation of disguising parameters $\hat{\alpha}$. It can be formulated as follows:

$$\hat{\alpha} = E(\boldsymbol{x}_s). \tag{2}$$

Specifically, the estimator mainly consists of a linear projection and a transformer encoder composed of 12 transformer blocks, as shown in Fig. 3 (a). Firstly, the input is partitioned into a series of 16×16 patches. Subsequently, these patches are flattened and fed to the linear projection layer for feature embeddings. As the standard transformer [20], cosine function is applied to preserve the position information of the embeddings. Finally, an Attentive Statistics Pooling (ASP) [21] together with the prediction head composed of two fully connected layers are applied to yield the estimated disguising parameter according to the output tokens. To ease the training difficulty, we also introduce a novel self-supervised learning (SSL) pretrain term *MSPM* [22], which randomly masks some of the input patches, and then utilizes the estimator to recognize and

Fig. 3: Detailed structure of the components in UniVR, where MSA denotes Multi-head Self-Attention, ASP denotes Attentive Statistics Pooling, and Conv1 $\times$ 1 denotes a one-dimensional (1D) convolutional operation with kernel size 1.

reconstruct the masked patches. MSPM can help the estimator learn a strong speech representation that is equally effective for the pitch-shifted samples.

B. Voice Restoration Network

VRN is built on the *Generative Adversarial Network* [23], where a generator G is employed to reconstruct the original-pitch mel spectrogram in high quality, an associated multi-scale discriminator (MSD) D_ϕ is utilized to guide the generator, and a neural vocoder V is applied to transform the reconstructed mel spectrogram into the corresponding waveform.

1) Generator: As shown in Fig. 3 (b), the generator mainly consists of 20 gated residual blocks with 256 channels. It receives the element-wise summation of the estimated disguising parameter $\hat{\alpha}$ and the disguised mel spectrogram $\boldsymbol{x_s}$ as the input and reconstructs the original-pitch mel spectrogram $\hat{\boldsymbol{x}}_o$:

$$\hat{\boldsymbol{x}}_{\boldsymbol{o}} = G(\boldsymbol{x_s}, \hat{\alpha}) \in \mathbb{R}^{80\times T}. \tag{3}$$

2) multi-scale discriminator: MSD aims to distinguish the reconstructed mel spectrogram from the real mel spectrogram. As shown in Fig. 3 (b), MSD can be viewed as a combination of three branches with different receptive fields, where each branch employs five convolutional layers to extract the features of the mel spectrograms. It can simultaneously focus on different scales of temporal information in the speech. It accepts the mel spectrogram as the input and outputs the distribution of input authenticity at different scales:

$$D^i_\phi(\boldsymbol{x}) := [D^i_{ls}(\boldsymbol{x}), D^i_{ms}(\boldsymbol{x}), D^i_{hs}(\boldsymbol{x})], i \in 1, 2, ...5, \tag{4}$$

where $D^i_\phi(\boldsymbol{x})$ is the i-th feature map in D_ϕ. $D^i_{ls}(\boldsymbol{x})$, $D^i_{ms}(\boldsymbol{x})$, and $D^i_{hs}(\boldsymbol{x})$ is the i-th feature map in the low-scale, middle-scale, and high-scale branches, respectively.

3) Neural Vocoder: We directly applied the advanced neural vocoder term HiFiGAN [24] in UniVR to produce high-quality restored speech at very low latency. It accepts the reconstructed mel spectrogram $\hat{\boldsymbol{x}}_{\boldsymbol{o}}$ as the input and outputs the corresponding waveform $\hat{\boldsymbol{\omega}}_{\boldsymbol{o}}$. Formally, this process is written as:

$$\hat{\boldsymbol{\omega}}_{\boldsymbol{o}} = V(\hat{\boldsymbol{x}}_{\boldsymbol{o}}) \in \mathbb{R}^{1\times T}. \tag{5}$$

Notably, the neural vocoder is well trained on CN-Celeb 1&2 [25], [26] and frozen during the training process of UniVR.

C. Objective function

We design a set of objective functions for training UniVR. To be specific, the pretrained estimator E is first fine-tuned with the $\mathcal{L}_{est}$ defined as the L2 loss between the estimated disguising parameter and the ground truth:

$$\mathcal{L}_{est}(E) = ||\alpha - E(\boldsymbol{x}_s)||_2. \tag{6}$$

Then, the combination of adversarial loss $\mathcal{L}_{adv}$, spectrogarm reconstruction loss $\mathcal{L}_{spec}$, and feature matching loss $\mathcal{L}_{fm}$ is

applied to simultaneously constrain the estimator, generator, and discriminator. The $\mathcal{L}_{adv}$ is defined as follows:

$$\begin{aligned}\mathcal{L}_{adv}(E,G,D) =& \mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x_o})}[D_\phi^N(\boldsymbol{x})^2]+ \\ & \mathbb{E}_{\boldsymbol{z}\sim p(\boldsymbol{x_s})}[(D_\phi^N(G(\boldsymbol{z},E(\boldsymbol{z})))-1)^2].\end{aligned} \tag{7}$$

$\mathcal{L}_{spec}$ is measured by L2 distances between the spectrogram of original speech and its reconstructed counterpart, which can be formulated as follows:

$$\mathcal{L}_{spec}(E,G) = ||\boldsymbol{x_o} - G(\boldsymbol{x_s}, E(\boldsymbol{x_s}))||_2. \tag{8}$$

$\mathcal{L}_{fm}$ is computed by summing L1 distances between every discriminator feature map of real and generated samples in D_ϕ, which is defined as follows:

$$\mathcal{L}_{fm}(E,G,D) = \sum\nolimits_{i=1}^{N} ||D_\phi^i(\boldsymbol{x_o}) - D_\phi^i(G(\boldsymbol{x_s}, E(\boldsymbol{x_s})))||_1. \tag{9}$$

To further improve the naturalness of the restored speech, we also present a vocoder loss $\mathcal{L}_{NV}$, which is measured by the L2 loss between the restored speech and the ground truth:

$$\mathcal{L}_{NV}(E,G) = ||\boldsymbol{\omega_o} - V(G(\boldsymbol{x_s}, E(\boldsymbol{x_s})))||_2. \tag{10}$$

Notably, the vocoder loss only propagates to the estimator and generator to prevent overfitting of the neural vocoder. Finally, the total loss function of UniVR is formulated as follows:

$$\begin{aligned}\mathcal{L}_{total}(E,G,D) =& \mathcal{L}_{est}(E) + \mathcal{L}_{adv}(E,G,D) + \mathcal{L}_{spec}(E,G) \\ & + \lambda_{fm}\mathcal{L}_{fm}(E,G,D) + \lambda_{NV}\mathcal{L}_{NV}(E,G),\end{aligned} \tag{11}$$

where λ_{fm}, λ_{NV} are scalars set to 0.5, 0.1. E, G aim to minimize $\mathcal{L}_{total}$, while the objective of D is opposite to others.

IV. Experimential setup

A. Datasets

Several multi-speaker Mandarin datasets: CN-Celeb 1&2 [25], [26] and AISHELL-1&3 [27], [28], are used in our experiments, where the CN-Celeb is used for the SSL pre-train of the estimator and vocoder, the development part of AISHELL-1 is employed for the training of UniVR, and the test part of AISHELL-1&3 is used for evaluation. As shown in Table I, CN-Celeb consists of about 660,000 utterances from a total of 3000 speakers, while the train set of AISHELL-1 includes about 60,000+ utterances from a total of 340 speakers. The utterances in the train set are resampled to 16 kHz, and 3 extra samples are generated for each utterance using the pitch-scaling algorithm randomly selected from *Phase Vocoder* [29], *Frequency-domain Pitch Synchronous Overlap Add* (FD-PSOLA) [30], *Time-domain Pitch Synchronous Overlap Add* (TD-PSOLA) [31], and *Waveform Similarity Overlap Add* (WSOLA) [32]. The disguising parameter α follows a uniform distribution $\mathcal{U}(-8,8)$. A small subset of the synthetic data (about 2%) is reserved for hyperparameter optimization.

To evaluate different methods on more challenging and practical scenarios, the test sets of AISHELL-1&3 are disguised by not only the Phase Vocoder, FD-PSOLA, TD-PSOLA, and WSOLA, but also three commercial software programs, i.e., Audacity, Audition, and iZotope, which generate a total of 14 evaluation sets marked as A_1D_1–A_1D_7 and A_3D_1–A_3D_7, respectively. Each evaluation set is further divided into 33 subsets, where the applied disguising parameter α is increased from -8 to 8 with a step of 0.5.

TABLE I: Speech attribute distribution

Dataset	#Spks	#Utters	#α Range	#Duration
CN-Celeb1	1000	130109	-	7.57 sec
CN-Celeb2	2000	529485	-	7.41 sec
AISHELL-1 train	340	60209	$\mathcal{U}(-8,8)$	4.82 sec
AISHELL-1 test	60	651×33	$[-8,8,0.5]$	4.41 sec
AISHELL-3 test	214	750×33	$[-8,8,0.5]$	3.16 sec

B. Baseline systems

We assess the performance of UniVR in terms of both the accuracy of estimated disguising parameters and the quality of restored speech. To establish the baselines for estimation accuracy, we consider two advanced reference-free estimators [12], [13] and a reference-based estimator [14], which are introduced in Section II. The reference-free estimators are trained on the same dataset as UniVR, while the reference-based estimator uses a TDNN [33] trained on AISHELL-1 to extract speaker features. It takes a pair of speech signals $\{x, y\}$ as input, where x is the pitch-shifted speech and y is the original-pitch reference. As for restoration quality, we use the popular sound processing library, librosa [29], as the baseline to restore the pitch-shifted speech based on the estimated disguising parameter from the UniVR estimator.

Notably, pitch scaling aims to conceal the attacker's identity and deceive the SI system, which is distinct from voice conversion. Thus, the SI system can be degenerated into a speaker verification (SV) system when investigating the impact of pitch scaling on speaker characteristics. In this work, we adopt a classical SV system that employs ECAPA-TDNN [34] as the front-end to extract speaker features and applies cosine similarity as the back-end to calculate the trial scores. Subsequently, we use adaptive score normalization [35] to normalize the trial scores. The imposter cohort is constructed by averaging the embeddings from the same speaker in AISHELL-1.

C. Training strategy

The estimator is first pre-trained by MSPM on CN-Celeb 1&2 [25], [26] with 400 epochs and then fine-tuned together with the VRN on AISHELL-1 with 150 epochs. The batch size is 512. Both of them are trained with an exponentially decreased learning rate from the initial 10^{-3} to the final 10^{-5} with the Adam optimizer [36]. Furthermore, the augmentations are also applied during the fine-tuning, which follows the Kaldi recipe [37] in combination with the publicly available MUSAN dataset (music, speech, and noise) [38] and the RIR dataset (reverb) provided in [39]. The input of UniVR is an 80-dimensional Mel spectrogram calculated by a 25 ms window with a 10 ms frame shift. The experiments are implemented with an NVIDIA A100 80GB.

V. Experimental Results

A. Accuracy of estimation

We employ the mean absolute error (MAE) measured between the estimated disguising parameter and the ground truth to evaluate the accuracy of different systems. The experimental results on the test sets of AISHELL-1 and AISHELL-3 are reported in Tables II and III, respectively. It is easy to find that UniVR achieved the highest accuracy and the best generalization ability for estimating disguising parameters in all cases compared with the existing reference-free estimators. In addition, SSL pre-training can significantly boost the performance of UniVR. Furthermore, even though the reference-free estimation is more challenging than the reference-based estimation, pretrained UniVR still obtains very competitive results compared to the reference-based baseline. Noteworthily, since the reference-based method essentially estimates the disguising parameters by solving Equ 1, its performance is almost not affected by the type of pitch-scaling algorithm. As a result, the reference-based baseline achieves better results than UniVR when facing unseen disguising methods, i.e., D_5–D_7. However, the gap between the reference-free method and the reference-based method will be narrowed in the cross-dataset evaluation, i.e., A_3D_1–A_3D_7. The reason is that the reference-free methods estimate the disguising parameters by recognizing the distortions introduced during pitch scaling, which are not actually linked to the speaker characteristics. Thus, they can be transferred well to unseen speakers. In the most complex case, i.e., cross-dataset evaluation with unseen disguising methods (A_3D_5–A_3D_7), the pretrained UniVR has achieved the best performance, giving it the most promising prospects for applications in real life.

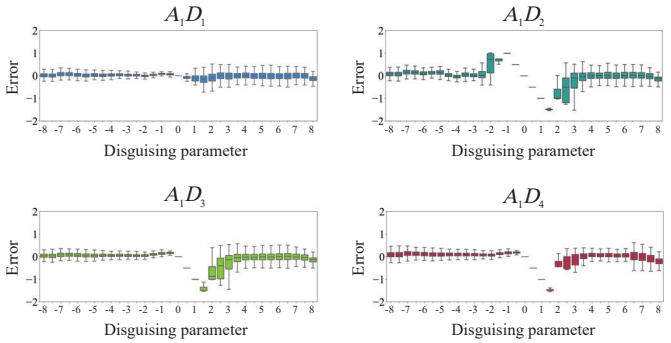

Fig. 4: Box-plot of the estimation deviation on the subsets of A_1D_1–A_1D_4 with various disguising parameters.

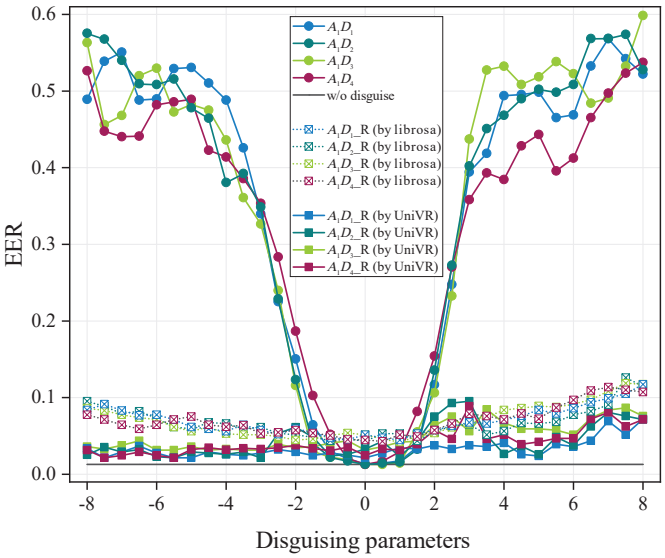

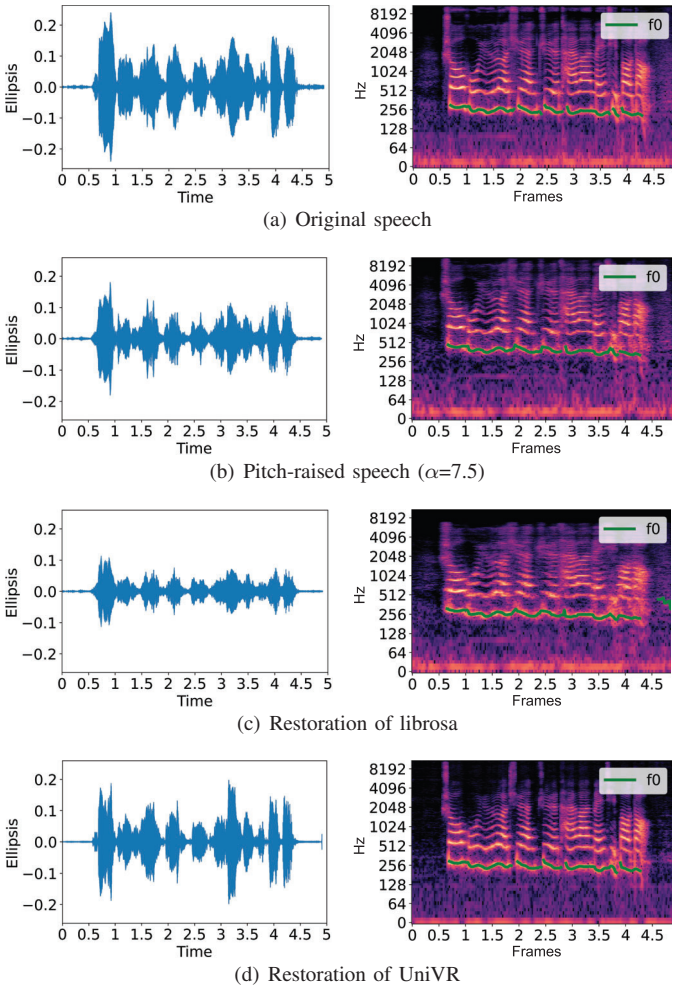

Fig. 5: EER of the SV system when faced with the pitch-shifted / restored samples from A_1D_1–A_1D_4.

We also further investigate the link between pitch-scaling degree and the performance of UniVR. Specifically, we measure the estimation deviation of UniVR on A_1D_1–A_1D_4 under different disguising parameters, which is shown in Fig. 4. The estimation of negative α is more accurate than that of positive α, which is consistent with the conclusion in previous studies [11], [12] that pitch-lowered speech is easier to distinguish than pitch-raised speech. Notably, the performance of the esitimator in UniVR shows the most serious decline when facing tiny disguising parameters within $[0, 3]$.

B. Quality of restoration

The impact of the pitch-scaling attack on the speaker verification system (SV) is shown in Fig. 5, which is measured by the Equal Error Rate (EER). Without restoration, pitch-shifted speech with the disguising parameter exceeding $[-2, 2]$ will obviously affect the performance of the SV system, making it unable to determine the speaker's identity. This problem can be effectively alleviated by restoring the pitch-shifted speech. In addition, although various pitch-shifting algorithms may cause

(a) Original speech

(b) Pitch-raised speech (α=7.5)

(c) Restoration of librosa

(d) Restoration of UniVR

Fig. 6: Waveforms and spectrograms of a pitch-shifted speech from A_1D_1 with the corresponding restorations.

different patterns of distortion, UniVR always provides higher restoration quality than the baseline, which is reflected by the lower EER of the SV system.

To demonstrate the superiority of UniVR in the acoustic quality of the restored speech, we also provide a visualization of a pitch-raised example with the corresponding restoration obtained via different methods. Notably, we only present the visualization of a pitch-raised sample from A_1D_1, as shown in Fig. 6, while the results in other cases exhibit the same trend. It is easy to find that although both librosa and UniVR can precisely restore the pitch of the speech, i.e., the f0 highlighted in green lines, librosa is unable to remove the artifacts or restore the missing high-frequency information in pitch-shifted speech and even distorts the speech more severely. In contrast, UniVR employs the specially designed VRN to remove the distortions in disguised speech by reconstructing its original mel spectrogram, yielding a more reasonable restoration. This issue can be reflected by the fact that both the mel spectrogram and the waveform of the restored speech of UniVR are closer to the ground truth than those of the librosa.

VI. Conclusions

In this study, we propose a unified framework (UniVR) for restoring pitch-shifted voice in high quality. UniVR consists of a reference-free estimator and a meticulously designed VRN that can effectively mitigate the distortion introduced during pitch scaling. Our experiments on AISHELL-1&3 demonstrate that the estimator in UniVR outperforms popular reference-free baselines, while also being extremely competitive with the reference-based baseline. Furthermore, the VRN has significantly better restoration quality than the popular method. As a result, UniVR achieves a state-of-the-art result for anti-pitch-scaling, which has significant implications for improving the security of speaker identification systems.

GLOBAL INTERNSHIP PROGRAM 2024
Research and Development Division
in Hamamatsu Japan

INTERNSHIP
Yamaha Corporation is recruiting a wide range of competitive R&D engineers for its internship programs. Interns will be working at the Innovation Center, which is Yamaha's dedicated R&D headquarters located in Hamamatsu Japan. The program will span approximately 12 weeks in 2024 summer season and will support your travel and accommodations in case of working at Yamaha. Interns will be members of teams which include other Yamaha researchers and engineers.

WHO WE ARE
With over 130 years of proud history, Yamaha Corporation is the largest and most dynamic manufacturer of acoustic and digital musical instruments and professional audio products in the world.

ABOUT RECRUITMENT
Doctoral or master's students in engineering, computer science, and/or mathematics.
Apply for our research internship
and enjoy your stay in Japan's city of music!

Please visit our website for more information on our Global Internship Program.
www.yamaha.com/en/recruitment/internship/

CyberAgent AI Lab

An R&D organization based in Japan that focuses on the utilization of a wide range of AI technologies in digital marketing

Following an R&D approach, we address a variety of challenging topics at the business level, while contributing to the academic community.

In the AI Lab, Research Scientists and Research Engineers are responsible of creating new knowledge through academic publications, and applying that knowledge to practical solutions, respectively.

Accepted
>50
papers in 2022

▼ Past accepted conferences

AAAI	ICLR
CVPR	ICML
EMNLP	IROS
HRI	NAACL
ICASSP	NeurIPS etc…

AI Implementation
>100
Projects

Our mission is contributing to academia and implementing our research results into society. We have already implemented more than 100 projects.

Audio Team

The Audio team is engaged in the research and development of speech synthesis/voice conversion methods to impersonate a specific human or to generate a variety of voices. In addition, speech recognition /enhancement methods is used for robust voice recognition regardless of the environment.

We aim to develop speech synthesis for CG models of celebrities, voices for advertisements, and other applications.
We are also engaged in research and development of speech recognition/synthesis for automatic telephone answering.

Speech synthesis for CG models

Automatic telephone answering

【Keywords】#Speech Synthesis #Lip Sync #Speech Recognition #Speech Enhancement #Source Separation #Auditory Analysis #Dialogue Systems #Voice Conversion

Recruitment Information

We are currently looking for talented Research Scientists and Research Engineers to join our team.
We will also announce internship opportunities for Ph.D. students in the upcoming winter term.

Entry

＜Experienced professionals＞

Entry

＜Internship for Ph.D. students＞

Google University Relations Programs
(research.google/outreach)

To cultivate collaborations with the academics, Google administers a variety of programs that provide resources and support to the academic and external research communities.

Opportunities for Faculty

/ Google's Research Grant
Not for open calls. Please reach out to Google contact to apply for.

/ Award for Inclusion Research
[research.google/outreach/air-program]
Supports research addressing the needs of populations historically underrepresented in the tech industry (e.g. women, people with disabilities etc.). Applications open in Summer.

/ Research Scholar Program
[research.google/outreach/research-scholar-program/]
Supports research conducted by early-career faculty globally. Applications open in Fall.

/ Google Cloud Platform (GCP)
[edu.google.com/programs/credits/research/]
Provide researchers and PhD students with computing power, storage and AI tools to develop bold ideas and make cutting-edge discoveries. Applications open any time.

/ Academic Conference Sponsorship
Sponsorship to both international and domestic academic conferences on areas relevant to Google research priorities. Not for open calls. Please reach out to Googler contact to apply for.

/ exploreCSR (CSR diversity)
[research.google/outreach/explore-csr/]
Awards that support universities to host computer science research (CSR) workshops in order to increase the number of students from groups traditionally underrepresented in CS. Applications open in Spring.

/ Visiting Researcher Program
[research.google/outreach/visiting-researcher-program/]
Academic researchers work with research and engineering teams at Google for 3-12 months.

/ Research Exchange
Research talks by people from both sides to foster research interactions and sharing.

Opportunities for Student

/ PhD Fellowship Program
[google.com/intl/en_cn/university/research/phdfellowship/]
Fellowships recognize outstanding PhD students doing exceptional and innovative research. Applications open in March.

/ Student Travel Grants
[buildyourfuture.withgoogle.com/scholarships/google-conference-scholarships]
Support outstanding research students to attend leading conferences. Applications open any time (APAC tab, East Asia form).

/ Student Researcher
[email to eastasia-ur@google.com]
Research internship to work with Google research / engineering teams at Google. Flexible internship period. BS, MS or PhD students are all eligible.

/ Visit to Google Office
Provides opportunities for students to visit Google offices and meet Googlers from different functions.

For any questions, please reach out to eastasia-ur@google.com
