In this study, no additional benefit monitoring responses to the GAD-7 or WSAS (vs. PHQ-9 alone) was found. However, other questionnaires may prove more useful in outcome prediction. For example, the PHQ-9 has been found to inaccurately capture the presence and intensity of suicidal ideation and self-harm [22]. Another common criticism is, by asking only the frequency of symptoms in the last two weeks, the PHQ-9 is unable to determine accurately the intensity of any symptoms experienced.

Similarly, it may also be a useful research question to develop an 'optimally short' questionnaire that can accurately monitor whether therapy is on track. The fact that monitoring individual symptoms gives no benefit over total PHQ-9 score suggests there may be redundancy in the PHQ-9 for the purposes of therapy monitoring. The PHQ-2 may be a good candidate, as features derived from the questions it contains, Q1 and Q2, both had relatively strong effect sizes. A shorter questionnaire has two main benefits - reducing time spent filling in questionnaires for patient and therapist, and subsequently reducing the frequency of missing values, which could in turn increase prediction accuracies.

Synthesising results from studies of depression treatment outcome using varied predictors (such as biomarkers, demographic information, symptom profile, patient preference) for different treatment methods (such as therapies and medication) could greatly improve initial treatment selection. In a review on treatment efficacy for depression, Khan et al. highlight the need for better understanding of how different patient profiles may respond to different treatment methods, and how the heterogeneity of depression needs to be untangled to determine which treatment will work for whom [23].

Once treatment has commenced, we have demonstrated the value of treatment monitoring to determine whether it would be in the patient's interest to transition to an alternate treatment, perhaps with closer monitoring of those considered to be of high risk of not responding to therapy as suggested by Delgadillo et al. [24]. Given the devastating personal, societal, and financial costs of depression, an improvement in treatment assignment and outcome prediction would have enormous impact and should be considered a priority.

D. Conclusion

Tracking early symptom change during CBT is a promising method of predicting future treatment outcome, with each additional session of therapy included in analysis improving prediction accuracy by around 2%, achieving accuracies of 69.67%±0.61 (OR = 5.20) by session 4. The most parsimonious models within 1 SE were trained on either (1) PHQ-9 total score and demographic information (69.18%±0.71) or (2) PHQ-9 and WSAS individual scores (69.05%±0.77). Including the GAD-7 questionnaire gave negligible improvement on prediction accuracy, despite significant effect sizes of the individual features. Including demographic information had the strongest benefit to prediction accuracy before 2 sessions of therapy have been completed, and thereafter small. Outcome prediction could be used in the future to aid clinicians and patients in making the decision to personalise and alter treatment plans, increasing patient quality of life and reducing strain on mental health services.

Learning Adapters for Code-Switching Speech Recognition

Chun-Yi He and Jen-Tzung Chien
Institute of Electrical and Computer Engineering, National Yang Ming Chiao Tung University, Hsinchu, Taiwan

***Abstract*—Multilingual code-switching speech recognition has been an emerging research direction in real-world applications since most of speakers are bilingual or multilingual. A code-switching sentence is the mixing of two or more languages especially within the same sentence. It is crucial to work out a multilingual speech recognition via a code-switching scheme based on a parameter-efficient learning by utilizing a pre-trained encoder. Using this scheme, it is essential to identify the languages within a single spoken utterance for code-switching speech recognition. However, collecting speech data from monolingual language is easier than collecting code-switching speech in multiple languages. This study develops a new code-switching Mandarin-English speech recognition by utilizing a large-scale pre-trained backbone model containing 53 single-code languages. The fine-tuning of backbone model is implemented by introducing the controllable language or task adapters and incorporating small number of Mandarin-English code-switching speech where the backbone model is frozen and only individual adapters for Mandarin and English are estimated. A limited amount of controllable parameters can be sufficiently calculated. Experiments on code-switching speech recognition for Taiwanese Mandarin and English shows the merit of the proposed method.**

I. Introduction

In the task of speech recognition, it is often faced with speech processing over two or more languages at the same time because most speakers are bilingual or multilingual. It has been demanding to develop multilingual automatic speech recognition (ASR) for a variety of applications. Generally speaking, an utterance or a sentence containing more than one language is seen as code-switching (CS) or code-mixing speech. There have been a number of works explored to handle the challenging task in a code-switching speech recognition system [1], [2]. A traditional ASR method was developed with three components consisting of acoustic model, word lexicon and language model [3], [4], [5], [6]. Acoustic model converts the input audio signal into a sequence of phonemes, word lexicon converts the phonemes generated by acoustic model into words, and language model combines the individual words into sentences. Modern ASR system is built via an end-to-end (E2E) model which requires only a single composite neural network. This network is exploited to optimize the probability of an output word string given an input speech sequence for sequence-to-sequence learning. E2E model has become a main stream method for ASR. E2E model can directly map an input speech signal to an output sequence of phones, characters or words. There are three categories of E2E models. The first one is the method of using the encoder and the connectionist temporal classification (CTC) [7], [8]. The second one is the solution of using an encoder-decoder framework with attention [9], [10]. The third one is the method based on the recurrent neural network (RNN) transducer which jointly estimates encoder and prediction networks [11]. These E2E ASR models have achieved remarkable performance in monolingual task for Mandarin [12], English [13], German. Recently, it was even more challenging to carry out multilingual multispeaker ASR tasks [14], [15] based on E2E setting which have obtained state-of-the-art performance.

In general, the challenge that code-switching ASR will encounter is the lack of code-switching speech data. A reasonable solution to handle insufficient code-switching data is to conduct the transfer learning [16], [17] based on the pre-trained models by using abundant speech data from monolingual Mandarin and English. In addition, a practical approach to handle multilingual ASR was to add the language-specific vectors to multilingual model to enhance the performance in individual languages [14], [18]. A similar strategy was also proposed in [19]. In these works, there was a dedicated layer for a specific language and a shared layer for different languages. The output ratio of two layers was determined through the gating decision process. The language-specific information was only captured in the encoder or from the output layer of a deep neural network. In addition to characterizing the language-specific information, another strategy was proposed to implement the multi-task learning by jointly training the ASR acoustic model and the language identifier [20]. Further, in code-switching ASR, it is difficult to identify target language corresponding to a speech segment [21] since different languages have similar pronunciations. To cope with this issue, language identification could be incorporated into a bilingual ASR model. In [22], the language identification (LID) tags was introduced in an augmented dictionary by adding the LID tokens "CH" and "EN" as the outputs of a model for Chinese and English, respectively. When a code-switching point in a speech signal was encountered, the decoder first predicted which language it was sensing, and subsequently recognized the word tokens corresponding to the selected language. Summarizing the two approaches mentioned above, the first one is to solve the problem of insufficient code-switching data by using monolingual language data training, and the second is to solve the problem of language identification errors by applying the multi-task learning or identifying the language specific information through LID tokens. This paper presents a parameter-efficient learning for bilingual Mandarin and English ASR under an E2E framework.

The rest of the paper is organized as follows. In Section II, we present the issue of data sparseness in implementation of code-switching ASR system. In Section III, the method which incorporates LID into an E2E model using CTC with the proposed language-specific adapters is addressed. The experiments on bilingual Mandarin and English ASR are evaluated and analyzed in Section IV. The conclusions drawn from this study are given in Section V.

II. Code-Switching Speech Recognition

A traditional way to code-switching ASR [23], [24] was developed through language boundary detection and identification. In the procedure, the languages in various speech frames were first identified. The speech frames were then recognized by using the corresponding monolingual speech recognizer. However, this method was highly affected by the performance of boundary detection and language identification. In [25], an improved method based on deep neural network was proposed. More intuitively, the end-to-end methods were developed to relax the requirement of language boundary detection in a code-switching ASR system [26], [27]. In [28], it was proposed to use multiple encoders to capture the properties of individual languages. The acoustic representation of individual languages could be improved. The method in [29] presented a solution to accent-adaptive ASR by jointly learn the accent ID and the acoustic model so as to enhance the performance of accent speech recognition. This paper develops an E2E code-switching method where the parameter-efficient learning based on language-specific adapters is designed and implemented.

In particular, this study aims to handle the issue of data sparseness in a code-switching speech recognition system in presence of Mandarin and English speech with Taiwan accent. The issue is severe because the bilingual speech data with Taiwan accent are limited. A parameter-efficient learning is developed to build a low-resource bilingual ASR. A strong backbone model based on wav2vec architecture [30] is utilized in a transfer learning task where only a limited number of trainable parameters due to two language-dependent adapters are estimated for bilingual speech recognition. Language or task adapters could be pre-trained from monolingual languages with sufficient data. Some shared information in both languages is learned in a code-switching ASR. The requirement for fine-tuning the pre-trained model using code-switching speech data with target accent can be significantly reduced. Basically, using adapters allows efficient parameter tuning from the pre-trained models. Compared with fine-tuning a large-scaled pre-trained model, the lightweight adapters for both languages could be flexibly estimated and utilized to adjust the pre-trained model to a target task. In an E2E implementation, this paper employs the wav2vec2.0 [30] as a pre-trained encoder and incorporates the language adapters into a unified set of encoders and decoders in different layers for code-switching speech recognition. Experiments on the CS corpus ASCEND and NTUT-AB01 [31] show that the proposed model can distinguish the mixed languages while solving the training data scarcity problem.

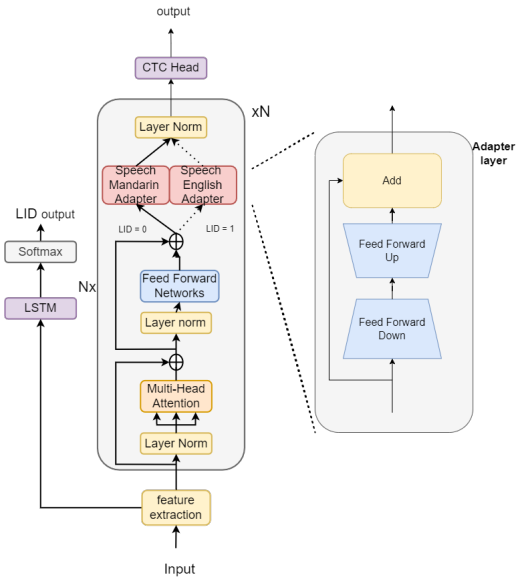

Fig. 1. An overview of the proposed method for code-switching speech recognition. The input speech frames are first passed through a long short-term memory (LSTM) and a softmax layer to find LID outputs for individual frames. The encoder accordingly switches between the corresponding adapters based on LID outputs.

III. Learning Adapters for Code-Switching ASR

Figure 1 overviews an architecture of adding language-specific adapters on a pre-trained backbone model. Language identifier for individual frames is implemented. LID outputs are used to perform language switch in encoder layers. The connectionist temporal classification (CTC) head is employed before finding output sequence. The detailed description of individual components in this work is provided.

A. Connectionist Temporal Classification

In this study, the connectionist temporal classification (CTC) is employed to handle time alignment between input speech signal and output word string in a sequence-to-sequence learning task. CTC network basically contains a linear layer and a softmax output layer with a dimension corresponding to the dictionary size. The dictionary is augmented with an additional "blank" token. In general, CTC calculates the probability distribution of the possible output sequence. The goal of CTC network is to maximize the conditional probability of finding the correct word labels by given the input speech frames. However, it is not always that each frame has a corresponding word label. The blank token is introduced to reflect those silence frames. Let $\mathbf{x} = \{\mathbf{x}_t\}$ denote the input speech frames, $l = \{l_t\}$ denote the output word labels, π denote the CTC path, Θ denote the network parameters, $B^{-1}(l)$ indicates all possible CTC paths from l extension. The CTC loss function is defined as the sum of the negative log probabilities of correct labels given by speech frames $\mathbf{x} = \{\mathbf{x}_t\}$ as

$$\mathcal{L}_{\text{CTC}} = -\log p_\Theta(\mathbf{l}|\mathbf{x}) = -\log \sum_{\pi \in B^{-1}(\mathbf{l})} p_\Theta(\pi|\mathbf{x}). \quad (1)$$

Based on the assumption of conditional independence for output units along T frames, the probability $p_\Theta(\pi|\mathbf{x})$ can be decomposed to a product of conditional probabilities from each time step t as follows

$$p_\Theta(\pi|\mathbf{x}) = \prod_{t=1}^{T} p_\Theta\left(\pi_t|\mathbf{x}_t\right) \tag{2}$$

where $\mathbf{x}_t$ is the input speech frame at time t, π_t is the output unit at time t, and T is the sequence length in frames.

B. Language Identification

This study implements a language identifier in sequence-to-sequence learning for bilingual ASR based on the connectionist temporal classification. In the proposed code-switching ASR, the problem encountered is that similar-sounding words in different languages are likely to be misrecognized. To tackle this issue, a language identification (LID) task is considered. In the implementation, the multilingual pre-trained models are utilized to provide language-related information through the pre-trained speech representations. Therefore, the code-switching ASR is handled by identifying LID for individual frames and then fulfilling a switching scheme between language-related adapters. In [32], [33], the utterance-level LID was proposed. But, in code-switching speech, there will be more than one language in a single utterance. It is necessary to carry out frame-level LID for code-switching ASR. However, the length of speech frames is usually short. It is still difficult to assure a reliable ASR performance based on frame-level LID, Nevertheless, this study integrates speech recognition and language classification where the frame-level LID is merged in a multi-task learning framework. The resulting LID accuracy is likely enhanced to improve learning representation in a joint optimization. For the task of LID, a recurrent neural network using bidirectional LSTM (BLSTM) [34], [35] is merged. Here, BLSTM and CTC models utilize the shared encoder. BLSTM is employed to compute the predicted LID outputs. Given the one-hot LID labels, the cross-entropy loss $\mathcal{L}_{\text{CE}}$ is calculated in an optimization procedure.

C. Adapter Learning

Importantly, this study incorporates individual adapter networks for Mandarin and English for code-switching speech recognition. Adapter network basically consists of a residual layer and two feedforward networks which are connected in a shape which is similar to extracting the bottleneck features. As shown by the shape in right-hand-side of Figure 1, the dimension of intermediate features between two feedforward networks is considerably reduced. A large number of parameters from a backbone model which were originally pre-trained are shared among different tasks, and only a small number of parameters from language-specific adapters are updated according to different objectives or tasks. Using the adapters as an alternative to fine-tuning all parameters of the pre-trained model has the advantage of retaining a large amount of knowledge of the pre-trained model and learning the schemes for specific tasks. When using adapters, only the parameters of the augmented module with adapters are changed, and all the other pre-trained parameters remain unchanged. Therefore, only a small amount of data are required to allow the efficiency in model convergence, and at the same time, avoid the weakness in model fitting due to the limited data. For the application of multilingual speech recognition [36], the adapters corresponding to different languages can be arranged. Adding adapters is also helpful for low-resource language modeling in multilingual machine translation [37]. A shared model could be learned from multiple language resources, and the adapters for low-resource languages are trained on top of the shared model. Different from the previous methods, this paper deals with the Mandarin-English code-switching speech recognition. A parameter-efficient learning based on adapters is proposed. To handle the spoken languages of Mandarin and English, a backbone pre-trained model from a number of different languages is utilized. The adapter-based code-switching speech recognition is built by training the adapters separately from individual languages. The multi-task learning for language identification and speech recognition is performed as detailed in what follows. First, each individual frame in an audio signal is classified as silence, Mandarin or English by using bidirectional LSTM with a linear classifier layer. In the encoder layer based on transformer [38], [39], [40], the audio signal is passed through the feature extraction layer to obtain latent features. These features are then passed through the multi-head attention layer and feedforward layer. Layer normalization is always performed. After that, depending on the LID label of an audio frame, the corresponding adapter is applied to find the word token based on CTC scheme using a CTC head. In case of detecting the input frame as silence, the outputs of transformer layer are not passed through any adapter and will be directly forwarding to CTC module for code-switching speech recognition. The multi-task learning is performed according to the following hybrid objectives

$$\mathcal{L} = (1-\lambda)\mathcal{L}_{\text{CTC}} + \lambda\mathcal{L}_{\text{CE}} \tag{3}$$

where λ is a regularization term to control the contribution of cross entropy loss due to language identification when compared with CTC loss due to speech recognition.

IV. Experiments

The proposed method was evaluated for a code-switching speech recognition under a low-resource setting where only a limited amount of code-switching Mandarin-English speech data with Taiwan accent was incorporated.

A. Experimental Data

In the following experiments, the Mandarin-English code-switching speech datasets including ASCEND [31] and NTUT-AB01 (a public-domain dataset obtained from the Association for Computational Linguistics and Chinese Language Processing (ACLCLP)) were used. ASCEND was a public-domain dataset containing Mandarin-English code-switching conversational speech with China accent. ASCEND consisted

of 10.62 hours of clean speech, collected from 23 bilingual speakers of Mandarin and English from Mainland China. The whole utterances in ASCEND were partitioned into training set, validation set and test set with the proportionals approximately 0.8, 0.1 and 0.1, respectively. In the partition, the total number of audio data for each gender were balanced. Table I summarizes the statistics of training, validation and test sets in ASCEND dataset.

NTUT-AB01 contained Mandarin, English, and Mandarin-English mixed speech which were collected as the reading speech in Taiwan. The Mandarin content was sampled from Chinese books, the English content was re-recorded from the ARCTIC corpus, and the code-switching speech was collected from common Mandarin-English mixed sentences collected from internet. This dataset could be also used to implement a code-switching speech synthesis system. There were 500, 105 and 376 minutes of speech in Taiwan accent for Mandarin, English and mixed Mandarin-English speech data.

TABLE I
SUMMARY OF TRAIN, VALIDATION, AND TEST DATA IN ASCEND.

Gender	Utterance				Duration(hr)			
	Train	Val	Test	Total	Train	Val	Test	Total
Female	4,591	484	861	5,936	4.04	0.46	0.48	4.98
Male	5,278	646	454	6,378	4.74	0.46	0.44	5.63

B. Experimental Settings

Before training the model, the dictionary based on the collected datasets was generated while some unnecessary characters and symbols were removed from the transcription data. This dictionary was used to expand the pre-trained tokenizer which was attached to the model. To enhance the model robustness, the data augmentation using SpecAugment [41] was applied by using the hyperparameter settings including 0.004 for the frequency masking probability, 0.065 for the time masking probability and 2 for the time masking length. The sampling rate of audio signals in ASCEND and NTUT-AB01 datasets was 16K Hz and 44K Hz, respectively, and the NTUT-AB01 dataset was accordingly downsampled as 16K Hz. Forced alignment was applied to automatically align the spoken recordings with the transcripts at the segment level. These schemes significantly reduced the time required to prepare data for speech analysis. The frame-level LID was performed to classify each frame as silent, Mandarin or English where each frame was windowed as 20ms. The frame labels of LID in training phase were obtained by forced alignment.

For the code-switching ASR task, this paper used the pre-trained XLSR-53 [42] which was known as a large-scaled pre-trained model from 53 languages definitely including Mandarin and English. Notably, those multilingual training utterances were *not* mixed or code-switching. The wav2vec 2.0 BASE and LARGE [30] had 95M and 317M parameters, respectively, which were pre-trained from 960 hours on the LibriSpeech [43]. For the language identification task, the module based on bidirectional LSTM was used. In the experiments, all of the models in the comparison were investigated through the HuggingFaces [44] framework.

C. Results on Language Identification

Language identification was configured by a bidirectional LSTM added by a single classifier layer and the fully connected (FC) feedforward classification network. FC network contained 4 hidden layers with the architecture 1024-2048-2048-512. Bidirectional LSTM (BLSTM) network had 2 hidden layers with 1024 nodes per direction in each layer. Table II reports the frame-level performance of LID model based on the extracted features using three backbone models wav2vec BASE, wav2vec LARGE and XLSR where FC and BLSTM are compared in case of using small amount of NTUT-AB01 training data. Test data in NTUT-AB01 are used. The results show that using BLSTM for different feature extractors achieves better accuracy than using FC. BLSTM is superior to FC when modeling time-series data. In addition, it is found that there are no significant gap in accuracy among three backbone models. Although the XLSR pre-trained model contains the knowledge of English and Mandarin, and the wav2vec 2.0 Base and Large pre-trained models contain only English, all these models can distinguish different languages in each sentence. It is because that these three feature extractors basically capture the characteristics of sound and have nothing to do with the labels of language ID. Table III further shows the same comparison but the training data from both ASCEND and NTUT-AB01 are used. LID is improved by considering increased amount of domain-related data.

TABLE II
COMPARISON OF FRAME-LEVEL ACCURACY (%) OF LID USING DIFFERENT METHODS. NTUT-AB01 IS USED AS TRAINING DATA.

Method	Accuracy%
Base + FC	66
Base + BLSTM	77
Large + FC	66
Large + BLSTM	77
XLSR + FC	67
XLSR + BLSTM	78

TABLE III
COMPARISON OF FRAME-LEVEL ACCURACY (%) OF LID USING DIFFERENT METHODS. BOTH ASCEND AND NTUT-AB01 ARE USED AS TRAINING DATA.

Method	Accuracy%
Base + FC	70
Base + BLSTM	81
Large + FC	70
Large + BLSTM	82
XLSR + FC	72
XLSR + BLSTM	82

D. Results on Code-Switching Speech Recognition

This study works on Mandarin-English Code-Switching ASR where the Mandarin and English utterances in ASEND and NTUT-AB01 are used. The character error rate (CER) and

word error rate (WER) were used as the metrics to evaluate ASR in presence of Chinese and English, respectively. For code-switching ASR, the mixed error rate (MER) is used in the evaluation where CER for Mandarin and WER for English are merged. In this set of experiments, XLSR trained from common voice [45] is used as the pre-trained backbone model since both ASCEND and NTUT-AB01 contained most of speech data in Mandarin rather than the backbone model wav2vec which was trained from English.

TABLE IV
ABLATION STUDY ON CODE-SWITCHING ASR WITH FINE-TUNING AND PARAMETER-EFFICIENT LEARNING USING LANGUAGE IDENTIFIER AND ADAPTER IN TERMS OF MERS AND PERCENTAGES OF CONTROLLED PARAMETERS. NTUT-AB01 IS USED AS TRAINING DATA.

Method	MER	Param
XLSR + FT	30.7%	100%
XLSR + adapter	30.0%	0.67%
XLSR + LID + adapter	28.7%	0.80%

TABLE V
ABLATION STUDY ON CODE-SWITCHING ASR WITH FINE-TUNING AND PARAMETER-EFFICIENT LEARNING USING LANGUAGE IDENTIFIER AND ADAPTER IN TERMS OF MERS AND PERCENTAGES OF CONTROLLED PARAMETERS. BOTH ASCEND AND NTUT-AB01 ARE USED AS TRAINING DATA.

Method	MER	Param
XLSR + FT	30.1%	100%
XLSR + adapter	29.2%	0.64%
XLSR + LID + adapter	28.1%	0.78%

Tables IV and V show the ablation studies on code-switching ASR using MER for different methods where the effects on parameter-fining (FT) and parameter-efficient learning with language identifier and adaptation [46], [47] are evaluated. The percentage of controlled parameters is investigated. The proposed hybrid method using language adapter combined with language identifier is compared with baseline fine-tuning method using XLSR and the baseline XLSR with adapter. This set of experiments would like to see how multi-task learning is beneficial to train an adaptive encoder via adapter to find correct text via correct language. The results show that the proposed method does improve speech recognition performance. Using LID as an auxiliary task [20] allows the model to likely catch the time frames to switch languages, From the analysis of results, it is found that the baseline system is prone to mis-identify language at the points where code-switching happens. The resulting prediction of an utterance become more likely an utterance with either monolingual Mandarin or English and less likely an code-switching utterance. Therefore, using LID is helpful to deal with this issue by coming out a distribution of output tokens which is more likely code-switched. Using multiple encoders to learn information from different languages is helpful for speech recognition. Different from [28] using two encoders for two languages, this study arranges two adapters in a single encoder where the number of controlled parameters is significantly reduced. Compared with the results using parameter-fining for all parameters, the proposed parameter-efficient learning with hybrid LID and adapter obtains lower mixed error rates in presence of very small percentage of controlled parameters.

V. CONCLUSIONS

This paper presented a parameter-efficient learning approach to handle Mandarin-English code-switching speech recognition by learning the language identifier for different languages and the language-specific adapters based on a pre-trained backbone model. The end-to-end speech recognition was implemented by using connectionist temporal classification. A multi-task learning with bilingual CTC loss and frame-level LID loss was implemented. The pre-trained model from a large amount of training data with a variety of languages was utilized to reduce the mis-prediction of code-switching points. A single encoder with augmentation of two small-scaled adapters was efficiently implemented. A shared backbone model was used to represent different languages. Only adapters were individual for languages. Experimental results on Mandarin-English code-switching speech recognition using ASCEND and NTUT-AB01 data demonstrated the effectiveness of the proposed method. Future study will be extended by improving the accuracy of language identification which considerably affect the performance of adapter-based code-switching speech recognition. The code-switching speech recognition over Mandarin, Taiwanese and English will be investigated.

***Abstract*—Voice conversion (VC) is the speech-to-speech (STS) synthesis process that converts the vocal identity of a source speaker to a target speaker by keeping the linguistic content unaltered. In recent years, VC research has been explored using generative adversarial network (GAN) models. However, a substantial difference exists between the real and the state-of-the-art (SOTA) VC model-generated speech samples as far as naturalness is concerned. This work proposes an improved GAN model for non-parallel VC to enhance the naturalness of the generated speech samples. The improved GAN model is integrated with a region-wise positional normalization technique in the generator, a relativistic mechanism-based discriminator, and a Fréchet inception distance (FID) based loss function. We tested the proposed model on VCC 2018, CMU Arctic, and a dysarthric speech dataset. The experimental results revealed the superiority of the proposed FID-RPRGAN-VC model over the SOTA MaskCycleGAN-VC model.**

***Index Terms*—Generative Adversarial Network (GAN), Voice Conversion (VC), Region Wise Positional Normalization Technique, Relativistic Mechanism, Fréchet Inception Distance (FID) loss.**

I. Introduction

Voice conversion (VC) [1] is a speech synthesis process that converts the vocal texture of a source speaker similar to a target speaker by keeping the linguistic content unchanged. Recently, the domain of VC has been majorly explored using deep learning (DL) models. Among the DL models, generative adversarial networks (GANs) [2] have been widely used for the VC task due to their capability of performing efficient style transfer of the target features on the source content.

Based on the linguistic contents of the speech datasets, a VC system can be categorized as a parallel or nonparallel VC [1]. In parallel VC, the speech content of both the source and target speakers are considered as same. Whereas for non-parallel VC, dissimilar speech contents are considered in the VC process [3]. On the other hand, based on the type of mapping from the source-to-target domain, it is divided into the following categories: one-to-one, one-to-many, many-to-many, etc. VC. In the early stage of the developments of VC, statistical models such as gaussian mixture models (GMMs) [4], phonetic posteriorgram (PPG) based models [5], non-negative matrix factorization based models [6], vector quantization (VQ) based models [7] etc., were widely used. Eventually, due to the progressive developments in the field of artificial intelligence (AI), the deep learning (DL) models appeared as a better alternative to the statistical models [8].

From the preceding works of GAN-based VC [1], it is observed that the successive models of CycleGAN-VC [8]–[10] have the potential ability to perform the VC task. Although, most of these models rely on multiple speech features for the VC process [11], [12]. This limits the ability of the VC models because of multi-feature dependency of a single VC model. In this context, MaskCycleGAN-VC [13] showed notable performance improvement by considering mel-spectrogram as the only input feature. Although, there is still a significant difference between the real and the existing VC model-generated speech samples in terms of speaker similarity and speech quality. To generate more natural-sounding speech, in this work, we put forth an improved GAN model with region-wise positional normalization technique in the generator, a relativistic mechanism based discriminator, and a Fréchet inception distance (FID) based loss function. The proposed model is named as FID loss-based region-wise position normalized relativistic GAN-VC (i.e., FID-RPRGAN-VC).

In our proposed FID-RPRGAN-VC model, the objective of using the region-wise positional normalization technique is to compute the normalization statistics at all the spatial positions independently by reducing the internal covariate shift [14], [15]. The internal covariate shift is the phenomenon of significant change in the distribution of the layers of a neural network model due to the change in network parameters during training. Most of the preceding works on GAN-based VC [8], [9], [13] have been explored using the instance normalization technique. However, based on the literature

of [14], [15], it is well observed that region normalization and positional normalization provide superior performance over instance normalization (IN) and other normalization techniques in image synthesis task [14], [15]. Moreover, an improvised version of gated linear unit (GLU) called gaussian error gated linear unit (GEGLU) [16], is incorporated into the proposed FID-RPRGAN-VC model to improve the performance of the model. Furthermore, the reason behind inclusion of a relativistic discriminator is to trace the similarity between the latent representation of real and generated mel-spectrogram. In addition to that, FID [17], [18] metric is used in the proposed model as a loss function for obtaining better quality generated speech samples. An Inception-v3 [19] architecture is incorporated to the proposed model to obtain the latent representation of real and generated mel-spectrogram for computing the FID loss.

The performance evaluation of the proposed FID-RPRGAN-VC model is conducted on VCC 2018 [20], and CMU Arctic dataset [21] using objective and subjective evaluation metrics. In addition to that the performance of the proposed model is also compared with MaskCycleGAN-VC for dysarthric-to-normal speech conversion, based on a dysarthric speech dataset called EasyCall corpus [22]. Based on the obtained results, it is observed that the proposed FID-RPRGAN-VC model performed superior to the state-of-the-art (SOTA) MaskCycleGAN-VC model. Our work is specifically compared with GAN-based VC model. The objective of considering MaskCycleGAN-VC for the performance comparison is that, among the other CycleGAN based VC models Mask-CycleGAN-VC has shown the most significant results [13].

The rest of the paper is organized as follows. Section II presents the proposed FID-RPRGAN-VC model in detail. Section III describes the details of the datasets and the experimental setups. In Section IV, the results obtained from the objective and subjective evaluations are discussed. Finally, Section V provides the conclusion and gives good scope for future research.

II. Proposed Model

We provide a detailed description of the framework of the proposed FID-RPRGAN-VC model and the loss functions described here in detail. As shown in Fig. 1, $\mathrm{x} \in \mathrm{X}$ is the mel-spectrogram of the source speaker and m is the mask such that $\mathrm{x}, \mathrm{m} \in \mathbb{R}^{\mathrm{C} \times \mathrm{H} \times \mathrm{W}}$ (where C, H, W are channel, height, and width respectively) used for obtaining the masked mel-spectrogram $\mathrm{x}^{'}$. The mask m contains values zero and one, where zero indicates the masked region (the black region in Fig. 1) and one indicates the unmasked region (the white region in Fig. 1). The masked mel-spectrogram $\mathrm{x}^{'}$ of the source speaker is obtained by element-wise multiplication between x and m (i.e. $\mathrm{x}^{'} = \mathrm{x} \odot \mathrm{m}$). Similarly the masked mel-spectrogram of the target speaker $\mathrm{y}^{'}$ is obtained by element-wise multiplication between y and m (i.e. $\mathrm{y}^{'} = \mathrm{y} \odot \mathrm{m}$).

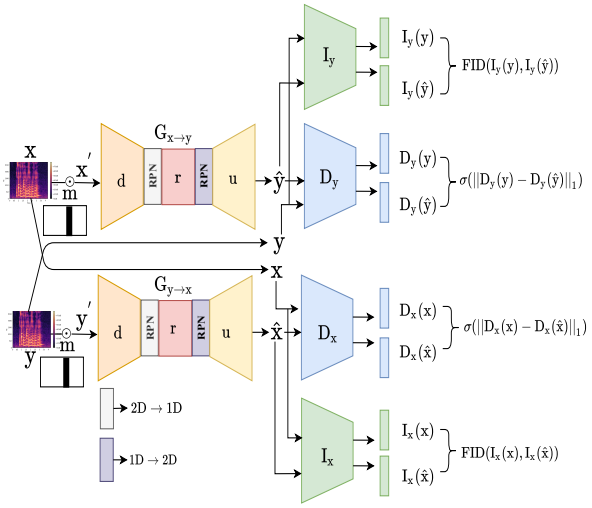

Fig. 1: The schematic overview of the proposed FID-RPRGAN-VC model.

As presented in Fig. 1, generator $\mathrm{G}_{\mathrm{X} \to \mathrm{Y}}$ maps $\mathrm{x}^{'}$ from source domain X to target domain Y, and generate the synthesized mel-spectrogram $\hat{\mathrm{y}}$. Likewise, $\mathrm{G}_{\mathrm{Y} \to \mathrm{X}}$ maps $\mathrm{y}^{'}$ from source domain Y to target domain X and generate $\hat{\mathrm{x}}$. Both $\mathrm{G}_{\mathrm{X} \to \mathrm{Y}}$ and $\mathrm{G}_{\mathrm{Y} \to \mathrm{X}}$ are region-wise positional normalization technique-based generators. And the discriminators D_{X} and D_{Y} of the proposed model are relativistic mechanism-based discriminators that estimate the similarity between the given real data and the synthesized data. In addition to that, Inception-v3 [19] architecture-based deep convolutional neural network (DCNN) model I_{X} and I_{Y} are incorporated in the FID-RPRGAN-VC model to compute the FID loss.

A. Region Wise Positional Normalization Technique-based Generator

The architectural framework of the proposed FID-RPRGAN-VC generators ($\mathrm{G}_{\mathrm{X} \to \mathrm{Y}}$ and $\mathrm{G}_{\mathrm{Y} \to \mathrm{X}}$) consists of downsample block $\mathrm{d}(.)$, residual block $\mathrm{r}(.)$ and upsample block $\mathrm{u}(.)$. Moreover, in between downsample and residual block, 2D $\to$ 1D CNN ($\mathrm{d}_{2 \to 1}(.)$) block is used. Similarly, in the intermediate stage of residual and downsample block, 1D $\to$ 2D CNN ($\mathrm{u}_{1 \to 2}(.)$) block is used. The region wise positional normalization technique is incorporated in both $\mathrm{d}_{2 \to 1}(.)$ and $\mathrm{u}_{1 \to 2}(.)$ block.

The components of $\mathrm{G}(.)$ consists of basic operations such as convolution operation ($\mathrm{Conv}(.)$), instance normalization ($\mathrm{IN}(.)$) [23], gaussian error gated linear unit ($\mathrm{GEGLU}(.)$) [16], [24], region wise positional normalization ($\mathrm{RPN}(.)$) [14], [15], and pixel shuffler ($\mathrm{PS}(.)$) [25].

The architectural framework of FID-RPRGAN-VC generator $\mathrm{G}(.)$ (i.e. both $\mathrm{G}_{\mathrm{X} \to \mathrm{Y}}$ and $\mathrm{G}_{\mathrm{Y} \to \mathrm{X}}$) is expressed in Eq. (1),

$$\mathrm{G}(.) \to \mathrm{u}(\mathrm{u}_{1 \to 2}(\mathrm{r}(\mathrm{d}_{2 \to 1}(\mathrm{d}(.))))). \tag{1}$$

The components of $G(.)$ are represented mathematically below,

$$\mathrm{d}(.) \rightarrow \mathrm{GEGLU}(\mathrm{IN}(\mathrm{Conv2D}(.))),$$
$$\mathrm{d}_{2\rightarrow1}(.) \rightarrow \mathrm{RPN}(\mathrm{Conv1D}(.)),$$
$$\mathrm{r}^{\mathrm{i}} \rightarrow \mathrm{r}^{\mathrm{i}-1} \oplus \mathrm{IN}(\mathrm{Conv1D}(\mathrm{GEGLU}(\mathrm{IN}(\mathrm{Conv1D}(\mathrm{r}^{\mathrm{i}-1}))))),$$

here, r^i indicates the i^{th} residual block.

$$\mathrm{u}_{1\rightarrow2}(.) \rightarrow \mathrm{RPN}(\mathrm{Conv1D}(.)),$$
$$\mathrm{u}(.) \rightarrow \mathrm{GEGLU}(\mathrm{IN}(\mathrm{PS}(\mathrm{Conv2D}(.)))).$$

1) Gaussian Error Gated Linear Unit (GEGLU): GLU [26] is a widely used gating mechanism in the field of language modeling and VC. However, one of the recent variants of GLU called GEGLU [24] has shown significant improvement in sequence-to-sequence modeling. Therefore, in the generator network of the proposed FID-RPRGAN-VC model, GEGLU is used to improve the model's performance for obtaining better quality generated speech samples. The mathematical expression of GEGLU is formulated below,

$$\mathrm{GEGLU}(\mathrm{x}^{'}, \mathrm{W}_1, \mathrm{W}_2, \mathrm{b}_1, \mathrm{b}_2) \rightarrow \mathrm{GELU}(\mathrm{x}^{'}\mathrm{W}_1 + \mathrm{b}_1) \otimes (\mathrm{x}^{'}\mathrm{W}_2 + \mathrm{b}_2),$$
$$\mathrm{GELU}(\mathrm{x}^{'}\mathrm{W}_1 + \mathrm{b}_1) \rightarrow (\mathrm{x}^{'}\mathrm{W}_1 + \mathrm{b}_1) \times \sigma(1.702 \times (\mathrm{x}^{'}\mathrm{W}_1 + \mathrm{b}_1)). \quad (2)$$

As shown in Eq. (2), GEGLU uses the activation function GELU [24]. And $\mathrm{x}^{'}$ is the input vector that passes through two learned linear transformations. Here W_1, W_2, are two different weight matrices and b_1, b_2 are two different bias vectors respectively.

2) Region Wise Positional Normalization (RPN): The RPN technique used in the reshaping block $\mathrm{d}_{2\rightarrow1}(.)$ and $\mathrm{u}_{1\rightarrow2}(.)$ utilize the positional normalization technique [14] in both the masked and unmasked regions of the input matrix. As shown in Fig. 1, the RPN technique is applied on the transformed output of the downsample block $\mathrm{d}(.)$ and the residual block $\mathrm{r}(.)$ respectively. The RPN(.) input matrix is divided into k regions as shown below.

$$\mathrm{x}^{'} = \mathrm{R}^1 \cup \mathrm{R}^2 \cup .... \cup \mathrm{R}^{\mathrm{k}}.$$

Here R^{k} is the k^{th} region of the input matrix $\mathrm{x}^{'}$. However, in this proposed work, k is set as 2 in order to consider masked and unmasked regions. Thereafter, the positional normalization technique is applied to each region (i.e., masked and unmasked). The computation of region wise positional normalization technique is shown through Eq. (3),

$$\hat{\mathrm{R}}^{\mathrm{k}}_{\mathrm{c,h,w}} = \frac{1}{\sigma^{\mathrm{k}}_{\mathrm{h,w}}}(\mathrm{R}^{\mathrm{k}}_{\mathrm{c,h,w}} - \mu^{\mathrm{k}}_{\mathrm{h,w}}),$$
$$\mu^{\mathrm{k}}_{\mathrm{h,w}} = \frac{1}{\mathrm{C}}\Sigma^{\mathrm{C}}_{\mathrm{c=1}}\mathrm{R}^{\mathrm{k}}_{\mathrm{c,h,w}}, \quad (3)$$
$$\sigma^{\mathrm{k}}_{\mathrm{h,w}} = \sqrt{\frac{1}{\mathrm{C}}\Sigma^{\mathrm{C}}_{\mathrm{c=1}}(\mathrm{R}^{\mathrm{k}}_{\mathrm{c,h,w}} - \mu^{\mathrm{k}}_{\mathrm{h,w}})^2}.$$

As per Eq. (3), $\mathrm{R}^{\mathrm{k}}_{\mathrm{c,h,w}}$ is an element of the matrix R^{k}. Whereas, $\hat{\mathrm{R}}^{\mathrm{k}}_{\mathrm{c,h,w}}$ is its corresponding normalized element. Likewise, the positional normalization technique is applied to each of the elements of R^{k} to obtain the normalized matrix $\hat{\mathrm{R}}^{\mathrm{k}}$. In the positional normalization technique, the mean (i.e., $\mu^{\mathrm{k}}_{\mathrm{h,w}}$) and standard deviation (i.e., $\sigma^{\mathrm{k}}_{\mathrm{h,w}}$) are calculated for each one of the elements along all channels for the given matrix. Finally, each normalized region is merged to obtain the final matrix. In this proposed work, the primary objective behind the fusion of positional normalization and region normalization techniques [14], [15] is to tackle the problem of covariate shift in a finer manner. The positional normalization technique computes the normalization statistics independently at all spatial positions and makes the statistics translation, scaling, and rational invariant. This results in better quality generated mel-spectrograms.

B. Relativistic Discriminator

The architectural framework of the relativistic discriminator $\mathrm{D}(.)$ (i.e. both $\mathrm{D_X}$ and $\mathrm{D_Y}$) can be written as follows,

$$\mathrm{D}(.) \rightarrow \mathrm{Conv2D}(\mathrm{d_l}(\mathrm{GEGLU}(\mathrm{Conv2D}(.)))),$$
$$\mathrm{d_l}(.) \rightarrow \mathrm{d_{l-1}}(.). \quad (4)$$

In Eq. (4), $\mathrm{d_l}(.)$ represents l numbers of $\mathrm{d}(.)$ blocks (in this work, l is considered as 4). The outputs of $\mathrm{D_X}$ and $\mathrm{D_Y}$ are the last layer flatten vector (i.e., the latent representation of the input feature) of the corresponding discriminators. The relativistic discriminator incorporated in the FID-RPRGAN-VC model works as a critic that measures the similarity between real and generated speech features. As shown in Eq. (5),

$$\mathcal{L}^{\mathrm{rel_X}}_{\mathrm{disc}} = \sigma(\|\mathrm{D_X}(\mathrm{x}) - \mathrm{D_X}(\hat{\mathrm{x}})\|_1), \quad (5)$$

the last layer flattened vector corresponding to real and synthesized mel-spectrograms are compared to compute the relativistic loss $\mathcal{L}^{\mathrm{rel_X}}_{\mathrm{disc}}$ [27]. Similarly, $\mathcal{L}^{\mathrm{rel_Y}}_{\mathrm{disc}}$ can be computed. The sigmoid activation function σ used in Eq. (5) normalizes the L_1 similarity between the latent representation of real and synthesized mel-spectrograms. Therefore, if the value of σ approaches 0.5, it indicates high similarity, whereas a value higher than 0.5 indicates high dissimilarity. The relativistic loss helps the discriminator to measure the similarity between the latent representations of the real and the synthesized mel-spectrograms.

C. Fréchet inception distance (FID) loss.

The FID metric is a widely used evaluation metric in the field of computer vision and it provides a similarity score between the real and the generated images. However, there is a scope to incorporate FID metric in VC models as a loss function in order to trace the similarity between original and generated samples, while training the generative model. In this work, mel-spectrograms are represented as a matrix of three-dimensional image format (i.e. $2 \times 80 \times 64$). Therefore, in the proposed FID-RPRGAN-VC model, FID metric [17], [18] is

incorporated as a loss function to trace the similarity between original and generated mel-spectrograms. The mathematical formulation of the FID metric is provided below:

$$\mathcal{L}_{\text{fid}}^{\text{X}} = \text{FID}(\text{I}_{\text{x}}(\text{x}), \text{I}_{\text{x}}(\hat{\text{x}})),$$
$$\text{FID}(\text{I}_{\text{x}}(\text{x}), \text{I}_{\text{x}}(\hat{\text{x}})) = ||\mu_{\text{I}_{\text{x}}(\text{x})} - \mu_{\text{I}_{\text{x}}(\hat{\text{x}})}||^2 + \text{T}_{\text{r}}(\Sigma_{\text{I}_{\text{x}}(\text{x})} + \Sigma_{\text{I}_{\text{x}}(\hat{\text{x}})} - 2(\Sigma_{\text{I}_{\text{x}}(\text{x})}\Sigma_{\text{I}_{\text{x}}(\hat{\text{x}})})^{1/2}). \quad (6)$$

Here, $\mathcal{L}_{\text{fid}}^{\text{X}}$ indicates the FID loss between the latent vectors $\text{I}_{\text{x}}(\text{x})$ and $\text{I}_{\text{x}}(\hat{\text{x}})$ that are obtained using Inception-v3 [19] architecture based DCNN model, as depicted in Fig. 1. In Eq. (6), the first term computes the mean difference, whereas the second term computes the covariance difference between $\text{I}_{\text{x}}(\text{x})$ and $\text{I}_{\text{x}}(\hat{\text{x}})$. The minimization of FID improves the similarity between the original and the generated mel-spectrograms, and helps in obtaining the formant information in a better manner. Though, both relativistic and FID loss compute the difference in latent space. But, the additional advantage of FID-loss is that it incentivizes the generator to generate mel-spectrograms by maintaining the feature correlation [17]. Apart from relativistic loss and FID loss, adversarial loss, cycle-consistency loss, and identity loss are also used in FID-RPRGAN-VC, keeping it same as MaskCycleGAN-VC [13]. However, in this work, the FID loss is utilized as an additional generator training loss.

III. Experimental Design

A. Dataset Description

The considered models are trained and tested on VCC 2018 [20], and CMU Arctic [21] dataset. For the VCC 2018 dataset, the considered speakers are VCC2TM1, VCC2SM3, VCC2TF1, and VCC2SF3. Whereas, for the CMU Arctic dataset, the regarded speakers are cmu-us-bld-Arctic, cmu-us-rms-Arctic, cmu-us-clb-Arctic, and cmu-us-slt-Arctic. For both the datasets, 81 speech samples and 35 speech samples were considered for training and testing, respectively. For CMU Arctic [21] dataset (out of 539 belonging to each speakers) we have considered 116 (i.e. 81 for training and 35 for testing) speech samples for each speakers such that the utterances are disjoint. The particular setting is considered for making the training process non-parallel. Additionally, we evaluated the performance of the proposed model for Easycall Dysarthric dataset [22]. The Easycall dataset contains parallel speech content for both normal and dysarthric speakers. Here, four speakers belonging to the male and female genders are considered. For each of the speakers, 264 samples were considered for training, and 66 samples considered for testing.

B. Network Architecture of FID-RPRGAN-VC

The FID-RPRGAN-VC model consists of region wise positional normalization technique based generator and relativistic discriminator. The baseline architecture of the generator is similar to MaskCycleGAN-VC. In the generator two $\text{d}(.)$ and $\text{u}(.)$ blocks are present. Moreover, the generator is comprise of one $\text{u}_{1\rightarrow 2}(.)$ and $\text{d}_{2\rightarrow 1}(.)$ block. In addition to that, six $\text{r}(.)$ blocks are incorporated in the generator. Whereas the discriminator consists of four $\text{d}(.)$ blocks. The architectural framework of the Inception-v3 model adapted to this work is based on [19] for the calculation of FID-loss.

C. Training Details

For training the FID-RPRGAN-VC model, Adam optimizer [28] is used with learning rate 1×10^{-4}. The proposed model is trained for 1×10^3 epochs (i.e. 8×10^5 iterations). The mini-batch size is considered as 1. In this work, pretrained MelGAN vocoder [29] is used for mel-spectrogram to audible speech synthesis. The size of the mel-spectrograms considered here is $2 \times 80 \times 64$, and the number of samples is 64. The mask size here is taken as 25% of the input size (along horizontal axis i.e. width). This value is considered based on the experimental results of MaskCycleGAN-VC [13].

D. Experimental Setup

The complete execution of the proposed FID-RPRGAN-VC model is carried out in the Dell precision 7820 workstation configured with ubuntu 18.04 64 bit Operating System, Intel Xeon Gold 5215 2.5GHz processor, 96GB RAM, and Nvidia 16GB Quadro RTX5000 graphics. All the experiments of this work are implemented in Python 3.6.9 using Pytorch 1.1.2 and Numpy 1.19.5. The audible speech data are preprocessed by using Librosa 0.9.1.

IV. Results and Discussion

A. Objective Evaluation

The average mel cepstral distortion (MCD) [30], modulation spectra distance (MSD) [31], and F_0 root mean square error (F_0 RMSE) [32], [33] values of the proposed FID-RPRGAN-VC and MaskCycleGAN-VC model-generated speech samples are provided in Table I,

TABLE I: MCD, MSD and F_0 RMSE values for VCC 2018 and CMU-Arctic dataset

Dataset	Models	M-M	F-F	M-F	F-M
MCD					
VCC 2018	**FID-RPRGAN-VC**	**6.40**	**6.45**	**6.53**	**6.73**
	MaskCycleGAN-VC	7.45	6.85	6.76	7.84
CMU-Arctic	**FID-RPRGAN-VC**	**6.97**	**7.48**	**8.09**	**7.97**
	MaskCycleGAN-VC	7.12	7.81	8.20	8.07
MSD					
VCC 2018	**FID-RPRGAN-VC**	**1.15**	**1.14**	**1.21**	**1.16**
	MaskCycleGAN-VC	1.17	1.18	1.50	1.24
CMU-Arctic	**FID-RPRGAN-VC**	**1.16**	**1.15**	**1.28**	**1.26**
	MaskCycleGAN-VC	1.18	1.19	1.32	1.29
F_0 RMSE					
VCC 2018	**FID-RPRGAN-VC**	**18.17**	**27.22**	**32.20**	**36.78**
	MaskCycleGAN-VC	18.77	28.37	34.20	38.43
CMU-Arctic	**FID-RPRGAN-VC**	**15.10**	**21.81**	**31.71**	**31.93**
	MaskCycleGAN-VC	15.25	23.62	35.12	34.98

for both VCC 2018 and CMU Arctic dataset[1]. In the case of the objective evaluation metrics, a lower value indicates high speaker similarity and vice versa. As shown in Table I,

[1]All the generated speech samples and the code implementation of our proposal can be downloaded from http://surl.li/fqgpz

for both intra-gender and inter-gender VC the obtained MCD values of FID-RPRGAN-VC is less than MaskCycleGAN-VC. Considering the average of MCD values from Table I, it can be observed that the performance improvement is 6.09%. Similarly, from Table I, it can also be found that FID-RPRGAN-VC performed superior to MaskCycleGAN-VC in terms of MSD and F_0 RMSE. Based on the average of MSD and F_0 RMSE values, the performance improvement is 2.58% and 5.31%, respectively.

We also report an ablation study to evaluate the performance of the proposed FID-RPRGAN-VC model for each contribution using the VCC 2018 dataset. In Table II, ABS(1)

TABLE II: MCD, MSD and F_0 RMSE values for ablation study

Models	M-M	F-F	M-F	F-M
MCD				
FID-RPRGAN-VC	**6.40**	**6.45**	**6.53**	**6.73**
ABS(1)	6.42	6.47	6.57	6.76
ABS(2)	6.56	6.72	6.75	7.09
ABS(3)	6.46	6.54	6.60	6.98
ABS(4)	6.50	6.61	6.69	7.11
MSD				
FID-RPRGAN-VC	**1.15**	**1.14**	**1.21**	**1.16**
ABS(1)	1.16	1.16	1.23	1.17
ABS(2)	1.23	1.27	1.30	1.28
ABS(3)	1.20	1.16	1.24	1.23
ABS(4)	1.21	1.23	1.24	1.21
F_0 RMSE				
FID-RPRGAN-VC	**18.17**	**27.22**	**32.20**	**36.78**
ABS(1)	18.23	27.30	32.28	36.87
ABS(2)	18.54	27.65	32.82	38.38
ABS(3)	18.35	28.02	32.61	38.46
ABS(4)	18.41	27.97	32.70	38.47

indicates the FID-RPRGAN-VC model without GEGLU (replaced by GLU of MaskCycleGAN-VC). ABS(2) indicates the FID-RPRGAN-VC model without RPN based generator (replaced by TFAN [34] of MaskCycleGAN-VC). ABS(3) denotes the FID-RPRGAN-VC model without relativistic discriminator (replaced by MaskCycleGAN-VC discriminator). And, ABS(4) denotes the FID-RPRGAN-VC model without FID loss. Here, the term ABS indicates the models for ablation study.

In Table III, based on the percentage ($\%$) of increment of MCD and MSD values w.r.t FID-RPRGAN-VC, the models ABS(1), ABS(2), ABS(3), and ABS(4) can be ranked as rank: 1, rank: 4, rank: 2, rank: 3, respectively. Since lower MCD and MSD values signify a greater degree of speaker similarity, the model achieving the lowest MCD and MSD is assigned the rank of 1, and so forth. It can be observed from Table III that for both MCD and MSD metrics, the models ABS(4) and ABS(2) obtained the rank: 3 and rank: 4 respectively, which implies the significance of FID loss and the RPN based generator in the proposed model. The removal of these two components significantly degraded the performance of the proposed model. It is also observable from Table III that in terms of F_0 RMSE ($\%$ of increment of F_0 RMSE) the models ABS(4) and ABS(2) obtained the rank: 4 and rank: 3 respectively. This indicates that the removal of these two components also degraded the results in terms of F_0 fundamental frequency or prosody.

TABLE III: MCD, MSD and F_0 RMSE values for ablation study

MCD							
ABS(1)	Rank	ABS(2)	Rank	ABS(3)	Rank	ABS(4)	Rank
0.41%	1	3.82%	4	1.77%	2	3.02%	3
MSD							
ABS(1)	Rank	ABS(2)	Rank	ABS(3)	Rank	ABS(4)	Rank
1.25%	1	9.03%	4	3.64%	2	4.95%	3
F_0 RMSE							
ABS(1)	Rank	ABS(2)	Rank	ABS(3)	Rank	ABS(4)	Rank
0.28%	1	2.46%	3	2.44%	2	2.55%	4

Apart from non-parallel uni-lingual VC, the performance of the proposed FID-RPRGAN-VC model is also evaluated for disordered speech to normal speech conversion considering a dysarthric speech dataset named as Easycall dataset [22], in a parallel setting. In Fig. (2), the schematic overview of the dysarthric to normal speech conversion process using FID-RPRGAN-VC model is shown. In Fig. (3), the visual

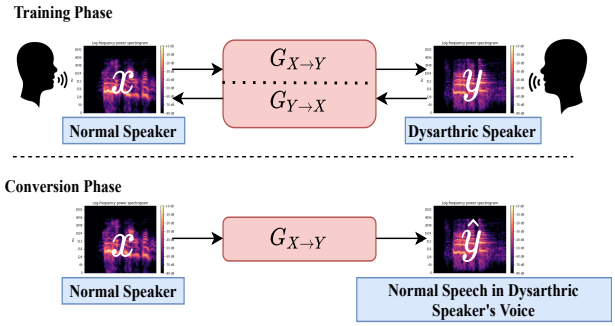

Fig. 2: Schematic overview of the dysarthric to normal speech conversion using FID-RPRGAN-VC model.

comparison of mel-spectrograms for MaskCycleGAN-VC and FID-RPRGAN-VC generated dysarthric to normal speech samples are provided. From the visual comparison (pointed with arrows and elliptical marker) of the mel-spectrograms it is well observed that the proposed FID-RPRGAN-VC generated mel-spectrograms are more similar to the normal speaker's mel-spectrograms as compared to MaskCycleGAN-VC generated samples. The FID-RPRGAN-VC generated mel-spectrograms captures well defined formant structures of the normal speech as compared to the MaskCycleGAN-VC as shown by the annotations 2, 3 and 4, in Fig. (3). We can also see that the generated spectrogram by MaskCycleGAN-VC is noisy (denoted by 1), whereas FID-RPRGAN-VC has obtained similar structures with respect to the target.

B. Subjective Evaluation

The subjective evaluations are conducted to measure the naturalness of the generated speech samples in terms of

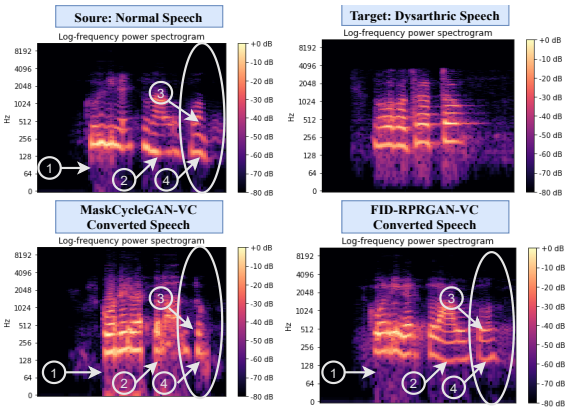

Fig. 3: Visual comparison of mel-spectrograms for MaskCycleGAN-VC and FID-RPRGAN-VC converted speech.

MOS [35]. To obtain the MOS values, 17 volunteers are considered. In order to collect the MOS values, 35 generated speech samples from both the datasets are taken. Each of the volunteers scored any randomly picked speech samples (for each categories i.e. M-M, F-F, M-F and F-M) in a range between 1-5 as per the standard MOS calculation method [35]. The MOS test is conducted for original speech samples, FID-RPRGAN-VC generated speech samples and MaskCycleGAN-VC-generated speech samples. The MOS values with 95% confidence intervals are provided in Table IV for both VCC 2018 and CMU-Arctic datasets.

TABLE IV: MOS for naturalness with 95% confidence intervals

Dataset	Models	M-M	F-F	M-F	F-M
VCC 2018	**FID-RPRGAN-VC**	**3.9±0.29**	**3.8±0.18**	**3.1±0.35**	**3.4±0.51**
	MaskCycleGAN-VC	3.1±0.32	2.9±0.42	2.6±0.23	2.9±0.24
CMU-Arctic	**FID-RPRGAN-VC**	**3.7±0.36**	**3.8±0.18**	**3.5±0.23**	**3.8±0.26**
	MaskCycleGAN-VC	2.9±0.15	3.1±0.41	3±0.04	3±0.05

Table IV shows that the MOS values for FID-RPRGAN-VC generated speech samples are higher than MaskCycleGAN-VC generated speech samples. This implies the superiority of the proposed FID-RPRGAN-VC model over MaskCycleGAN-VC in terms of subjective evaluation.

V. CONCLUSION

In this work, we proposed an improved GAN model for mel-spectrogram based VC and referred to it as the FID-RPRGAN-VC model that consists of a region-wise positional normalized generator, a relativistic discriminator, and a FID loss function. These modifications aim to generate mel-spectrograms that capture the target distribution better than the SOTA MaskCycleGAN-VC model. The proposed model is tested on VCC 2018, CMU Arctic, and Easycall speech datasets. The objective and subjective evaluation of the FID-RPRGAN-VC generated samples indicates the superiority of the proposed model. In the future, the GAN-based VC model can also be investigated for speech enhancement purposes. Moreover, there is also a scope to explore the model for multi-lingual VC.

***Abstract*— The key to the video super-resolution algorithm is to capture the information of adjacent frames to supplement the reconstruction of the current frame. It is necessary to apply the alignment operation to compensate the displacements of objects in different frames. We propose an innovative deformable aligned fusion block (DAFB) to exploit the complementary information from adjacent frames more efficiently. We also model the offsets of deformable alignments as probabilistic distributions to augment the robustness of a DAFB. Our proposed model outperforms state-of-the-art CNN-based models on benchmark testing datasets, including Vid4 and UDM10.**

I. Introduction

The super-resolution technique takes one or more input low-resolution images to recover the corresponding high-resolution image. The single image super resolution (SISR) restores the high-resolution image through a low-resolution image, and the advantage of the video super-resolution (VSR) over SISR is to utilize the adjacent frames to help restore the current frame.

Obtaining the complementary information from the adjacent frames is critical. There are different fusion strategies proposed for the VSR task. Direct fusion [1, 2, 3] exploits the convolutional layers to merge the features in multiple input images at the early stage of the network. Yi *et al.* [4, 5] propose the progressive fusion residual block (PFRB), which utilizes the convolutional layers to capture the temporal correlations between frames. By stacking multiple layers of PFRBs, their proposed network progressively fuses the adjacent feature maps. However, the aforementioned methods lack consideration of the motions between frames. When the motions are large, it is hard for the convolutional layers with small receptive fields to acquire the complementary information from the adjacent frames. Grabbing uncorrelated information results in poor reconstructions.

Dai *et al.* [6] first propose the deformable convolution, in which additional intra-frame offsets are learned to capture information beyond their local neighborhoods, enhancing the capability of convolutions. Tian *et al.* [7] utilize the deformable convolution to achieve the temporal alignment. They dynamically predict the inter-frame offsets of objects between different features maps, and leverage the deformable convolution on adjacent feature maps to align temporally by the predicted offsets. This method is referred to as the deformable alignment. Recent VSR methods [7, 8, 9, 10, 11, 12] utilize the deformable alignment to address the issue of object displacement between frames. Chan *et al.* [13] show that the performance of deformable alignment improves as the number of offset groups increases.

In this study, to mitigate the problem of misalignment, we design the deformable aligned fusion blocks (DAFB) by incorporating the deformable alignment module [7, 13] into the PFRB [4, 5] to better fuse the adjacent feature maps. Compared with prior fusion methods, the DAFB can utilize the alignment module to process object features with larger and more complex motion vectors.

We further model the offsets of deformable alignment as Gaussian distributions. Some prior image processing studies [14, 15, 16] utilize probability distributions to represent the uncertainty in predictions, helping neural networks to be more robust to noisy input data. However, there hasn't been a similar approach in the field of video super-resolution. The modified block, named DAFB-p, estimates the uncertainty of multiple groups of Gaussian distributed offsets, and accordingly find the most probable group as input to the deformable convolution. Through extensive experiments, we find that for the networks with fewer offset groups, the DAFB-p outperforms the DAFB.

Our main contributions are listed as follows.

1) We propose the deformable aligned fusion block, which progressively aligns and fuses neighboring feature maps. The alignment enhances the efficiency of capturing temporal information by the convolutional layers in the PFRB.
2) We measure the uncertainty of multiple offset groups using probability distributions, thereby increasing the tolerance for inaccurate offset estimations.

The rest of this paper is organized as follows. Section II reviews the related works. Section III details the proposed networks and the corresponding loss functions. Section IV

presents our experimental results and ablation studies. Section V concludes this work.

II. Related works

Most VSR models [7, 8, 9, 10, 11, 17, 18, 19, 20] employ alignment operation to capture the temporal correlations between frames. The alignment methods of VSR tasks can be classified into three categories: image-level flow alignment [17], feature-level flow alignment [18, 19, 20] and deformable alignment [7, 8, 9, 10, 11].

The image-level flow alignment first estimates the optical flow between frames and then warps the neighboring frames. The BasicVSR [20] points out that warping frames at the image level inevitably destroys the original details of the images and results in blurring. The feature-level flow alignment warps the features from adjacent frames, and significantly improves the reconstruction performance.

The most commonly adopted alignment approach recently is the deformable alignment. Chan *et al.* [13] mention that the main advantage of the deformable alignment over the flow alignments comes from the offset diversity. In some areas that are difficult to recover, such as image boundaries or fast-moving objects, the deformable convolution improves alignment via multiple groups of offsets. The TDAN [7] is the fisrt method to incorporate the deformable alignment in VSR framework. The EDVR [9] designs a pyramid-shaped alignment module, which performs in a coarse-to-fine manner to process complex motions. Chan *et al.* [11] design a flow-guided alignment module that helps alleviate the burden of offsets learning in deformable alignment by using the optical flow as base offsets.

III. Methodology

A. deformable aligned fusion block

As shown in Fig. 1, the proposed VSR architecture, deformable aligned fusion network (DAFN) is based on the bidirectional recurrent neural network from GOVSR [5] and formed by stacking multiple layers of DAFB. Fig. 2 illustrates the DAFB in the n-th layer, including three input paths for the past feature map F_{t-1}^{n-1}, the present feature map F_t^{n-1} and the future feature map F_{t+1}^{n-1}, respectively. The deformable alignment on the future path utilizes a layer of convolution $(\mathrm{C^o}, \mathrm{C^m})$ to generate the residual offsets $\hat{o}_{t+1,k,g}^n$ and masks $\hat{m}_{t+1,k,g}^n$ from the concatenated feature maps,

$$\hat{o}_{t+1,k,g}^n = \mathrm{C^o}(\{F_{t+1}^{n-1}, F_t^{n-1}\}), \tag{1}$$

$$\hat{m}_{t+1,k,g}^n = \mathrm{C^m}(\{F_{t+1}^{n-1}, F_t^{n-1}\}), \tag{2}$$

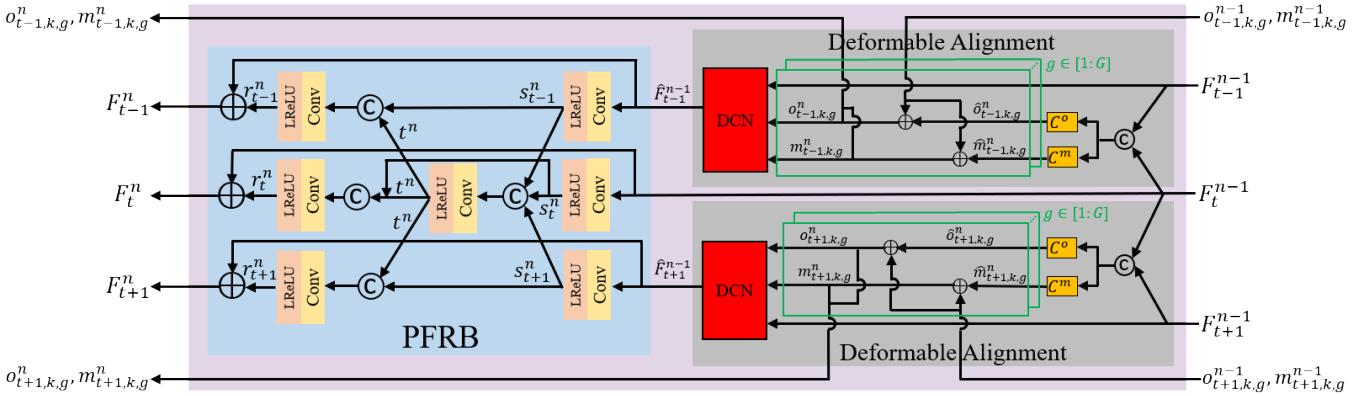

Fig. 2: Our proposed deformable aligned fusion block (DAFB) at the n^{th} layer.

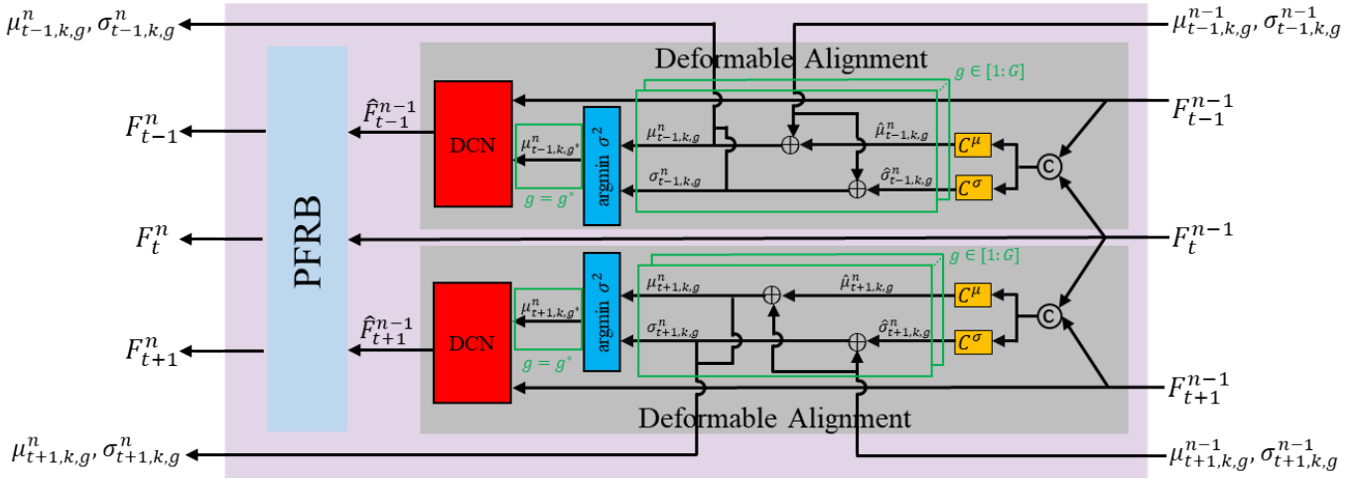

Fig. 3: Our proposed DAFB-p at the n^{th} layer.

for the k-th sampling point of the deformable convolution network (DCN) in the g-th group of offsets and masks.

The offsets and masks in the DAFB of different layers are similar since multi-layer deformable alignments are to align features in the same image. The residual offsets $\hat{o}^n_{t+1,k,g}$ and masks $\hat{m}^n_{t+1,k,g}$ of the current deformable alignment are element-wise added to the offsets $o^{n-1}_{t+1,k,g}$ and masks $m^{n-1}_{t+1,k,g}$ propagated from the previous deformable alignment,

$$o^n_{t+1,k,g} = o^{n-1}_{t+1,k,g} + \hat{o}^n_{t+1,k,g}, \tag{3}$$

$$m^n_{t+1,k,g} = m^{n-1}_{t+1,k,g} + \hat{m}^n_{t+1,k,g}. \tag{4}$$

The offsets $o^n_{t+1,k,g}$ and the masks $m^n_{t+1,k,g}$ are then fed into the DCN to generate the aligned feature $\hat{F}^{n-1}_{t+1}$. The DCN determines the sampling locations of the convolution kernel through the offsets, and the masks are regarded as attention maps to calculate the importance of sampling locations,

$$\hat{F}^{n-1}_{t+1}(p) = \sum_{k=1}^{s^2} w(q_k) \cdot F^{n-1}_{t+1}(p+q_k+o^n_{t+1,k,g}) \cdot m^n_{t+1,k,g}, \tag{5}$$

where s is the kernel size, p is the current position, and q_k is the k-th sampling offset of the convolution. For example, if kernel size $s = 3$, then $q_k \in \{(-1,-1),(-1,0),\ldots,(1,1)\}$. The offset $o^n_{t+1,k,g}$ and the mask $m^n_{t+1,k,g}$ are predicted for the position $p + q_k$.

As shown in Fig. 2, we adopt the PFRB [4, 5] to gradually fuse features. The PFRB extracts the intra-frame spatial information $s^n_{t-1}, s^n_t, s^n_{t+1}$ from the input feature maps $\hat{F}^{n-1}_{t-1}, F^{n-1}_t, \hat{F}^{n-1}_{t+1}$, respectively. These spatial information are then concatenated into a convolutional layer to capture the inter-frame temporal information t^n. Since the adjacent feature maps $\hat{F}^{n-1}_{t-1}, \hat{F}^{n-1}_{t+1}$ are pre-aligned to the current one F^{n-1}_t, the convolutional layer captures the temporal information t^n more efficiently. The temporal information t^n is sent back to each path, and individually fused with the spatial information $s^n_{t-1}, s^n_t, s^n_{t+1}$ through a convolutional layer to obtain the temporal-spatial information $r^n_{t-1}, r^n_t, r^n_{t+1}$. The PFRB outputs the summation of these temporal-spatial information and the input feature maps,

$$F^n_{t-1}, F^n_t, F^n_{t+1} = \mathrm{PFRB}(\hat{F}^{n-1}_{t-1}, F^{n-1}_t, \hat{F}^{n-1}_{t+1}). \tag{6}$$

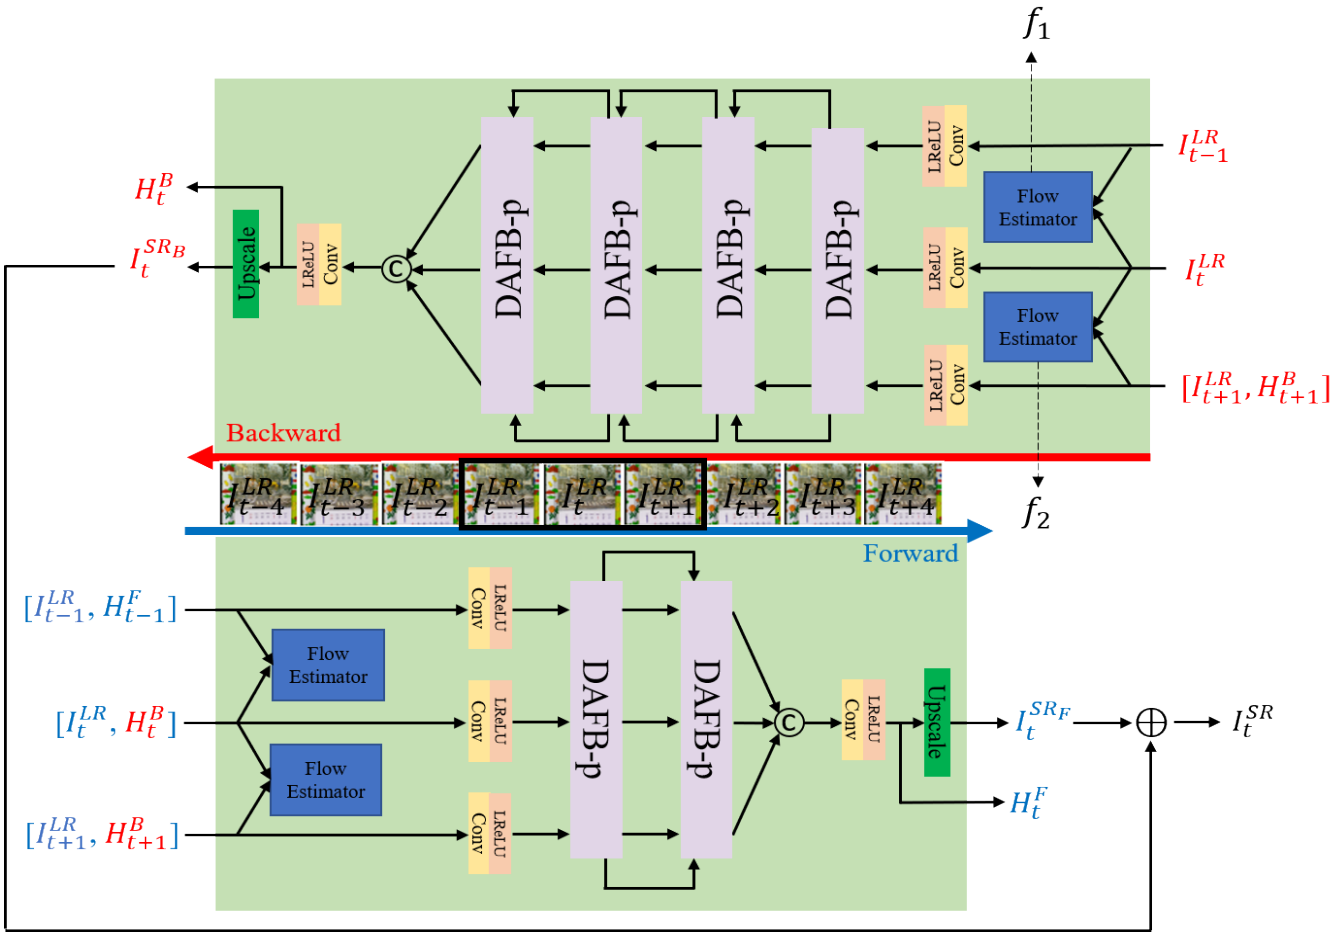

Fig. 4: Our proposed DAFN-p.

As shown in Fig. 1, the DAFN is stacked by a series of DAFB to progressively align and fuse the adjacent feature maps. The DAFN is a bidirectional recurrent neural network, and the final reconstructed image I_t^{SR} is the summation of the output of the backward network and that of the forward network,

$$I_t^{SR} = I_t^{SR_B} + I_t^{SR_F}. \tag{7}$$

We set the loss function by following the approach proposed by Yi *et al.* [5], who choose the Charbonnier loss function during training since it better handles outliers,

$$L = \sqrt{(I_t^{HR} - I_t^{SR})^2 + \varepsilon^2} + \alpha\sqrt{(I_t^{HR} - I_t^{SR_B})^2 + \varepsilon^2}, \tag{8}$$

where I_t^{HR} is the ground truth image, $\varepsilon = 10^{-3}$. We set the weighting factor $\alpha = 0.01$.

B. DAFB with probabilistic offsets

To measure the uncertainty of the offsets, the DAFB-p represents the offsets probabilistically rather than deterministically. Fig. 3 illustrates the DAFB-p in the n-th layer. For convenience, we simply model the distribution of the offsets $o_{t+1,k,g}^n$ as Gaussian distributions with mean $\mu_{t+1,k,g}^n$ and variance $\sigma_{t+1,k,g}^n$, and the deformable alignment utilizes a layer of convolution $(\mathrm{C}^\mu, \mathrm{C}^\sigma)$ to generate the residual mean and variance,

$$\hat{\mu}_{t+1,k,g}^n = \mathrm{C}^\mu(\{F_{t+1}^{n-1}, F_t^{n-1}\}), \tag{9}$$

$$\hat{\sigma}_{t+1,k,g}^n = \mathrm{C}^\sigma(\{F_{t+1}^{n-1}, F_t^{n-1}\}), \tag{10}$$

for the k-th sampling point of the deformable convolution network (DCN) in the g-th group. They are element-wise added to the mean $\mu_{t+1,k,g}^{n-1}$ and variance $\sigma_{t+1,k,g}^{n-1}$ propagated from the previous deformable alignment,

$$\mu_{t+1,k,g}^n = \mu_{t+1,k,g}^{n-1} + \hat{\mu}_{t+1,k,g}^n, \tag{11}$$

$$\sigma_{t+1,k,g}^n = \sigma_{t+1,k,g}^{n-1} + \hat{\sigma}_{t+1,k,g}^n. \tag{12}$$

The variance $\sigma_{t+1,k,g}^n$ may represent the uncertainty of the offset $o_{t+1,k,g}^n$. The smaller variance indicates the higher confidence. In Fig. 3, we select the offset with the minimum variance from G groups as the representative $N(\mu_{t+1,k,g^*}^n, \sigma_{t+1,k,g^*}^n)$,

$$g^* = \arg\min_g \ \sigma_{t+1,k,g}^n. \tag{13}$$

TABLE I: Quantitative comparison (PSNR (dB) / SSIM) on Vid4 [21] and UDM10 [4] for $4\times$ VSR. Red text indicates the best performance and blue indicates the second best.

GOVSR [5]	7.1	81.2	40.14 / 0.9713	28.41 / 0.8724
ETDM [30]	8.7	70	40.11 / 0.9707	28.81 / 0.8725
DAFN (Ours)	4.85	53	40.21 / 0.9695	28.77 / 0.8787
DAFN-p (Ours)	5.46	57	40.31 / 0.9699	28.51 / 0.8755
DAFN-l (Ours)	9.39	103	40.53 / 0.9713	29.13 / 0.8828

We treat the mean μ^n_{t+1,k,g^*} as the offset to be input into the DCN,

$$\hat{F}^{n-1}_{t+1} = \mathrm{DCN}(F^{n-1}_{t+1}; \mu^n_{t+1,k,g^*}). \tag{14}$$

Similar to the DAFB, we leverage the PFRB to gradually fuse features as Eq. (6).

The model DAFN-p shown in Fig. 4 replaces the DAFB with the DAFB-p. Note that we have no groundtruth of the offsets. Chan *et al.* [13] point out that the offsets and the optical flow are similar and can both be regarded as the motion vectors of objects between frames. They adopt optical flow to constrain the offsets so that they do not deviate much from the optical flow. In Fig. 4, to train for a better prediction of variances, we introduce a flow estimator to generate the optical flows,

$$\begin{aligned} f_1 &= \mathrm{FE}(I^{LR}_{t-1}, I^{LR}_t), \\ f_2 &= \mathrm{FE}(I^{LR}_{t+1}, I^{LR}_t). \end{aligned} \tag{15}$$

We set the target deviations as the differences,

$$\begin{aligned} d_1 &= |\mu^1_{t-1,k,g} - f_1|, \\ d_2 &= |\mu^1_{t+1,k,g} - f_2|, \end{aligned} \tag{16}$$

and include the second loss term L_{var},

$$\begin{aligned} L_{var} = &\sqrt{(\sigma^1_{t-1,k,g} - d_1)^2 + \varepsilon^2} \\ &+ \sqrt{(\sigma^1_{t+1,k,g} - d_2)^2 + \varepsilon^2}. \end{aligned} \tag{17}$$

The DAFN-p is trained by minimizing the overall loss function L_p,

$$L_p = L + \beta L_{var}, \tag{18}$$

where $\beta = 0.001$.

IV. Experimental Results

A. Experimental details

We select the same training dataset as previous studies [4, 5, 23], called MM522, which contains 522 groups of consecutive video frames of various scenes, including human, animal, natural and urban views. Diverse scenarios make the network robust when testing different datasets.

For BD (blur and downsampling) images, like existing approaches [2, 9, 27], we first blur the high-resolution video frames through a Gaussian filter with a standard deviation of 1.6 and convolution kernel of size 13×13, and then downsample frames through bicubic interpolation. The evaluation metrics, PSNR and SSIM values, are calculated only on the Y channel of YCbCr color space with skipping the first and last two frames.

The LR patches with the fixed size of 64×64 are randomly cropped from the BD images as the inputs, and the total number of iterations is 400 K. The initial learning rate is set to 10^{-3}, and gradually decays to 10^{-4} until the end. We set the batch size to 16 and the length of training video sequence

to 9 frames. All the experiments are implemented on Python 3.6.8, PyTorch 1.7.1 and V100 Tesla GPU.

B. Comparisons with other VSR models

Table I provides the quantitative evaluation for scale 4 to compare with several SOTA VSR methods. Since most methods train on different datasets, it would be unfair to solely compare results reported on their papers. This paper refers to performances evalutaed in OVSR [5], where those methods are re-trained on the MM522 dataset. The inference speed (Runtime) is measured on a V100 Tesla GPU by restoring images of HR size 1280×720.

To surpass the SOTA VSR methods, we double the number of DAFB in the DAFN, called DAFN-l. In Table I, the DAFN-l outperforms the ETDM [30], the latest VSR model, by up to 0.36 dB in PSNR. Even compared to OVSR [5], the baseline of our work, the DAFN improves PSNR by about 0.2 dB with 32% fewer parameters.

The qualitative comparisons with other SOTA methods are shown in Fig. 5. Our restoration images successfully recover more clear details than other images. For example, the city scene in the Vid4 dataset is restored particularly well. Areas that are difficult to restore, such as texture of the building, are well recovered.

C. Ablation study on DAFB and offsets propagation

We further provide some quantitative comparisons to demonstrate the effectiveness of our designs. As shown in Table II, model (a) solely stacks the PFRB for propagation. Although features from different frames are still gradually fused, the fusion performance is often disappointing since the different feature maps are not perfectly aligned.

In model (b), we replace the PFRB with our DAFB. Its performance (PSNR) is nearly 0.5 dB better than that of model (a). The improvement indicates that our proposed DAFB achieves superior restoration performance. Model (c) further passes the offsets predicted in the previous deformable alignment module to be the initial values of the current module. The performance is even improved by about 0.3dB in average, confirming the effectiveness of the offset propagations.

D. Comparisons between DAFN and DAFN-p

In Table III, we compare the restoration performance of the DAFN and DAFN-p with various offset groups $G = 2, 4, 8$. The DAFN-p outperforms the DAFN for the offset groups $G = 2$ and $G = 4$. But as the number of offset groups increases, the advantage of DAFN-p gradually becomes less significant. When the number of offset groups $G = 8$, the DAFN-p even performs slightly inferior to the DAFN. For more offset groups, even without the probability distribution, the DAFN exhibits robustness to imprecise predictions of offsets through the increase in diversity.

V. Conclusions

Most existing VSR methods rely on concatenating neighboring feature maps to obtain the complementary information from temporal correlations. In this work, we design a deformable aligned fusion block to align the neighboring feature maps and fuse the information. The proposed DAFN outperforms the SOTA models by up to 0.36 dB in PSNR on Vid4 and UDM10 datasets. We further increase the tolerance for inaccurate offsets by modeling them as probability distributions. By comparing two versions of deformable aligned fusion blocks, we observe that as the number of offset groups increases, a probabilistic model provides less advantage for robustness than a deterministic model with diversity. For future work, we need to explore more plausible combinations, including the type of probability distribution, and the number of offset groups

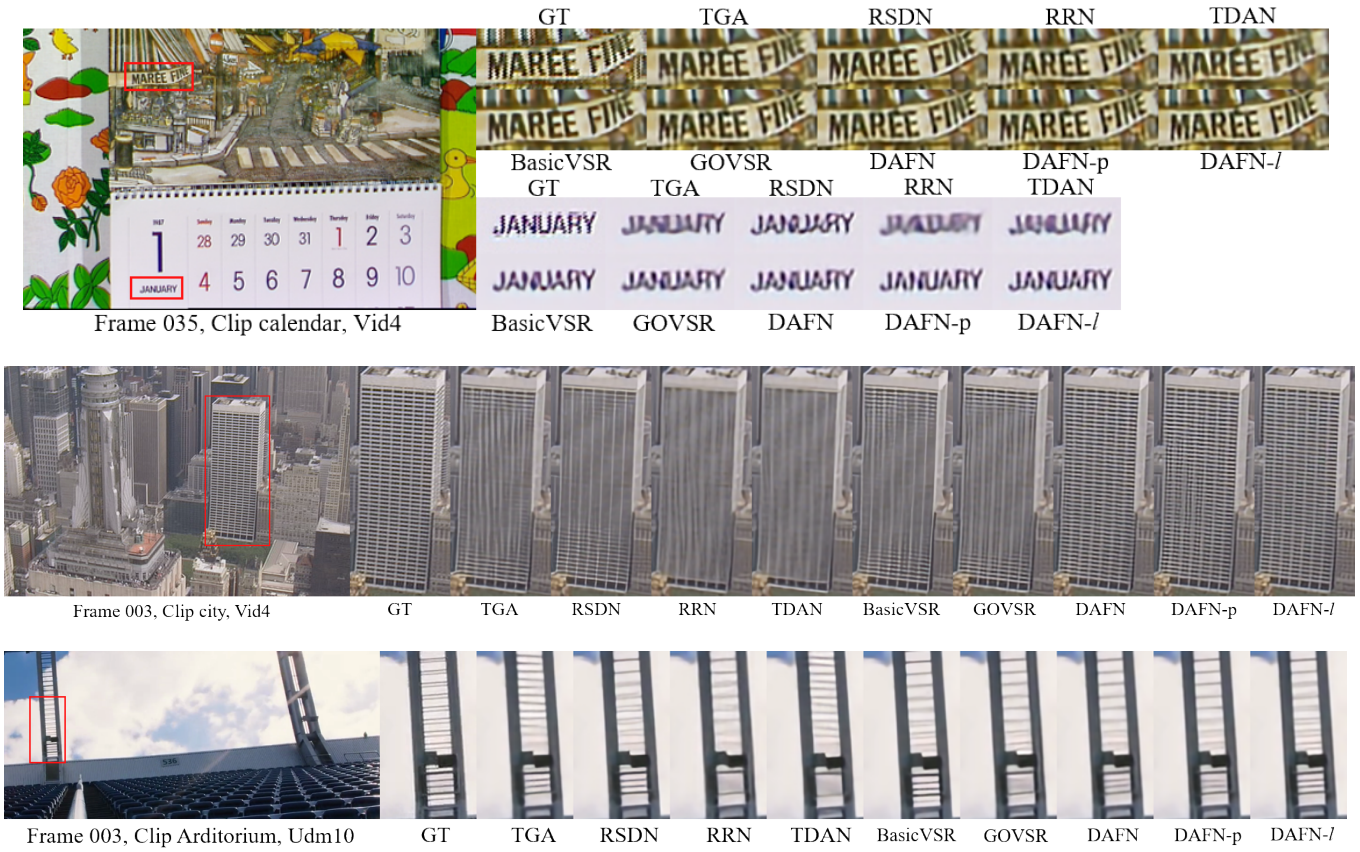

Fig. 5: Visual comparisons with other state-of-the-art VSR (X4) models.

generated through convolutional layers or selected for input into deformable convolutions.

***Abstract* — Bad weather conditions (e.g., rain or hazy) may significantly degrade the visual quality of captured images/videos and the performances of related applications (e.g., outdoor visual surveillance). To solve this problem, this paper presents to learn rain steak removal from a single image. By using the ECNet (Embedding Consistency Network, by Li *et al*., 2022) as our basis network architecture, a deep encoder-decoder-based network with channel attention and the proposed multi-scale pixel attention module (MSPAM) is presented to single image rain streak removal, *i.e.*, deraining. Together with the "Rain Embedding Consistency" mechanism used in the ECNet, we have shown that the channel attention can be used to enhance the extracted features before being fed into the encoder, and our MSPAM can be embedded into the skip connection between the encoder and the decoder for further boosting the features to achieve better image reconstruction. Experimental results have demonstrated that the proposed framework outperforms the ECNet quantitatively and qualitatively.**

I. INTRODUCTION

Bad weather conditions, such as rain, haze, or snow, may significantly degrade the visual quality of outdoor-captured images/videos, and the performances of applications inspired by outdoor visual information [1], [2]. Therefore, single image-based deraining *i.e*., removing rain streaks from a single image, has received much attention recently [3], [4]. We have proposed the first research work for single image deraining in the literature, which is based on sparse signal decomposition without needing rain/non-rain image pairs [5], [6] (with extension to video-based rain streak removal in [7]). This work [5] was also further improved by introducing context-aware image segmentation [8], [9], and visual saliency detection [10], [11], respectively. Moreover, similar to sparse coding, the low-rank-based optimization mechanism was also popular to be used for single image deraining [12]. In addition, non-negative matrix factorization has also been shown to be effective to single image rain removal in [13].

As the advancement of deep learning techniques has achieved significant improvement in various perceptual tasks, such as image restoration [14], image classification [15], object detection [16], and several vision-based applications (e.g., autonomous driving [17]), and sufficient datasets of rain/non-rain image pairs have been available (e.g., [18]-[20]), several deep learning-based single image deraining frameworks have been presented [18]–[27]. The deep learning-based approaches have been shown to achieve state-of-the-art performances in single image deraining, which will be briefly reviewed in Sec. II.

To achieve better image deraining performance, an encoder-decoder-based single image rain removal framework with deep attention mechanism is proposed in this paper. By leveraging the rain embedding consistency mechanism presented in ECNet [27], the encoder can encode a higher quality rain embedding for better decoding performance. In the proposed framework, we have shown that applying channel attention to the feature map before being fed into the encoder would be beneficial for extracting rain streak features. Moreover, embedding the proposed MSPAM (multi-scale pixel attention module) into the skip connections between the encoder and the decoder would be useful for extracting the rain-attentive features for better reconstructing rain streaks $\hat{R}$. The finally rain streak-removed image can be obtained by $I - \hat{R}$, where I denotes the input rainy image.

The rest of this paper is organized as follows. Sec. II briefly reviews related works in deep learning-based single image rain streak removal. In Sec. III, we address the proposed deep encoder-decoder network with our MSPAM for rain streak removal from a single image. Experimental results are demonstrated in Sec. IV. Finally, Sec. V concludes this paper.

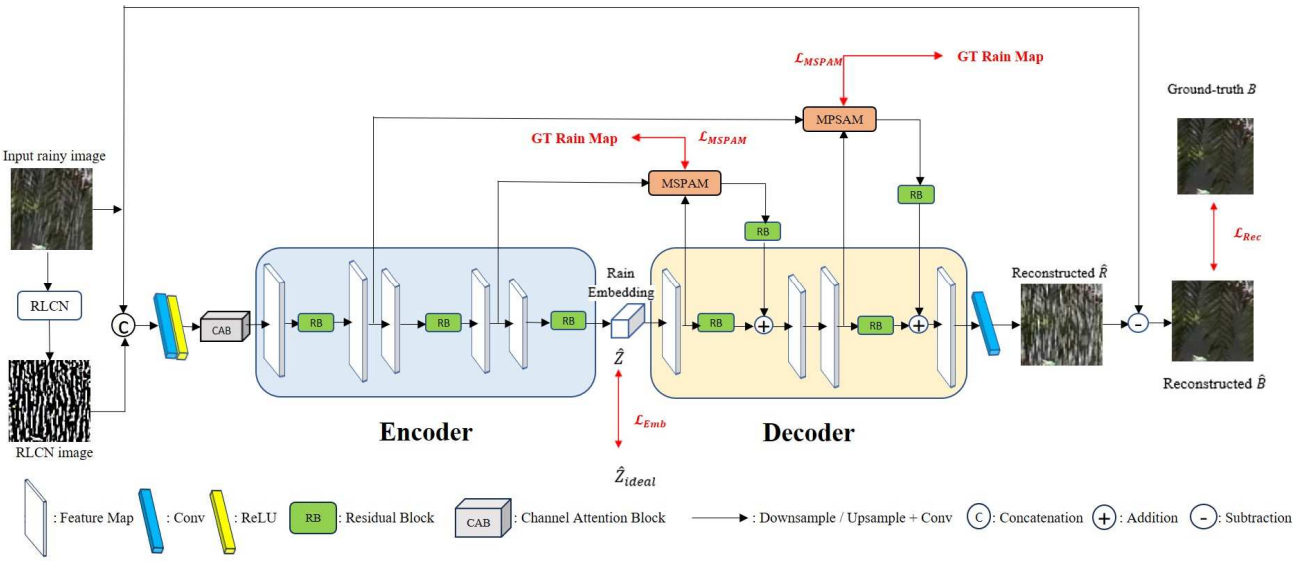

Fig. 1. Proposed deep encoder-decoder network for single image rain streak removal (modified from [27]).

II. Related Works

A. Deep Learning-based Single Image Deraining

A deep convolutional neural network (CNN) model, trained based on the mapping between paired images, embedded in an image decomposition framework (similar to [5]) was proposed for single image deraining in [21]. Moreover, a multi-task deep learning network was presented in [22] for detection and removal of rain streaks from a single rain image by learning the map of binary rain streaks, the appearance of rain streaks, and the clean background. Moreover, we have proposed a sequential dual attention-based single image deraining deep network (SSDRNet) [24] relying on a two-stage training strategy designed for capturing the rain streak distribution in a rainy image. On the other hand, a conditional generative adversarial networks (GAN)-based single image deraining framework was proposed in [23].

B. Embedding Consistency Network (ECNet)

In ECNet [27], an encoder-decoder architecture was presented to learn rain streaks, where the key is to include a "Rain Embedding Consistency" mechanism. The idea is to use the ideal encoded rain embedding obtained by an autoencoder and try to maintain the consistency between the ideal embedding and the real rain embedding derived by the network encoder. A rain embedding loss was used to supervise this encoding process, and a RLCN (rectified local contrast normalization) module was used to guide the extraction of candidate rain pixels. In this paper, by using ECNet as our basis, we propose to apply channel attention and the presented MSPAM (multi-scale pixel attention module) to further boost the feature extraction and the decoding process, described in Sec. III.

III. Proposed Single Image Deraining Framework

A. Overview of the Proposed Framework

As shown in Fig. 1, we adopt an encoder-decoder-based deep network architecture, where the residual block (RB) [28] is used for feature extraction, based on [27]. At the input side, each input rainy image I and its image I_L of candidate rain pixels obtained by the RLCN module presented in [27] are concatenated, denoted by $I_J = Concat(I, I_L)$. The map I_J is then fed into a convolution layer including the ReLU (rectified linear units) function [29], denoted by $J = \text{ReLU}\left(Conv(I_J)\right)$. Moreover, the input image I is also delivered through a skip connection to subtract the finally learned rain streak map $\hat{R}$ to get the finally rain streak-removed result, denoted by $\hat{B} = I - \hat{R}$. Different from [27], before feeding the feature map J into the encoder, we first apply the channel attention block (CAB) presented in [30] to obtain the channel-attentive feature map, denoted by $\text{CAB}(J)$. Then the encoder E encodes the feature map $\text{CAB}(J)$ to obtain the rain embedding, denoted by $\hat{Z} = E\left(\text{CAB}(J)\right)$. To learn the rain embedding, the autoencoder presented in [27] is used to generate the ideal rain embedding $\hat{Z}_{ideal}$. Then, the predicted rain streak map $\hat{R}$ can be obtained by the decoder D, denoted by $\hat{R} = D(\hat{Z})$. Moreover, for each skip connection between the encoder and the decoder, we

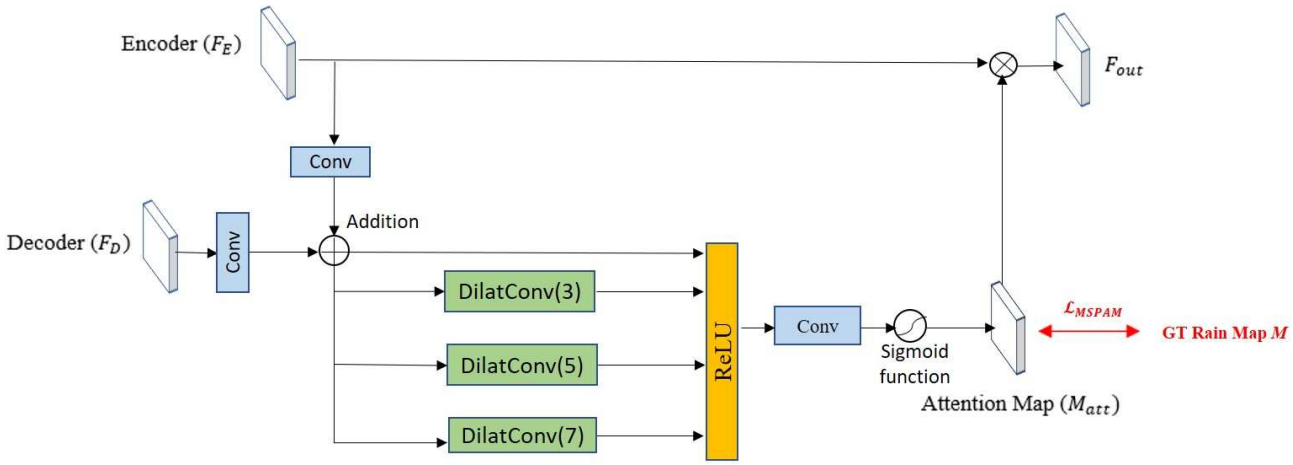

Fig. 2. Proposed multi-scale pixel attention module (MSPAM), where DilatConv(x) denotes the dilated convolution operation with the dilation rate of x.

embed the proposed MSPAM (described in Sec. III.B) to obtain the rain-attentive feature map for better enhancing the decoding process.

B. *Proposed Multi-Scale Pixel Attention Module*

The proposed multi-scale pixel attention module (MSPAM) is used to generate a pixel-level attention map to further refine the features, especially for suppressing possibly unexpected features extracted from the RLCN image which may include some non-rain pixels. As shown in Fig. 2, both of the feature maps F_E and F_D, respectively, from the encoder and the decoder first go through the convolution layers, and then are added. Then, we apply the dilated convolution operations (DilatConv) of the four different dilation rates to extract multi-scale features, followed by the ReLU and convolution operations. Then, the Sigmoid function is used to adjust the feature values to the range between 0 and 1 for generating the attention map M_{att}. The attention map is then used to generate the rain attentive-feature map, denoted by $F_{out} = F_E \otimes M_{att}$, where $\otimes$ is the element-wise multiplication operation.

C. *Leaning the Proposed Deep Model*

To learn the proposed deep model for single image deraining, the loss function is defined as follows. To supervise the reconstruction of background (rain-removed) image $\hat{B}$, the loss function is defined by

$$L_{Rec} = -SSIM(B, \hat{B}), \quad (1)$$

where $SSIM$ denotes the structural similarity (SSIM) index [31] between B and $\hat{B}$, and B is the ground truth (GT)/clean image. In addition, to guide our MSPAM to generate the rain-attentive feature map, the loss L_{MSPAM} between the ground truth of rain streak map/mask M and the predicted attention map M_{att} is defined accordingly. Moreover, the ideal rain embedding $\hat{Z}_{ideal}$ generated by the autoencoder is used to supervise the encoded rain embedding $\hat{Z}$, where the loss between them is denoted by L_{Emb}. As a result, the used total loss function is defined as

$$L = \lambda_{Rec} L_{Rec} + \lambda_{MSPAM} L_{MSPAM} + \lambda_{Emb} L_{Emb}, \quad (2)$$

where λ_{Rec}, λ_{MSPAM}, and λ_{Emb} are the respective weighting coefficients, empirically set to 1, 0.1, and 0.02, respectively.

IV. Experimental Results

To evaluate the proposed deep learning framework for single image deraining, the Rain100H dataset [18], Rain200H dataset [18], and Rain800 dataset [23] were used for training and testing our deep model. The Rain100H dataset contains 1800 training image pairs and 100 testing image pairs. The Rain200H dataset contains 1800 training image pairs and 200 testing image pairs. The Rain800 dataset contains 700 training image pairs and 98 testing image pairs. The patch size of 96×96 was used in the training process. The Adam optimizer [32] was used for model optimization (by 100 epochs) with the batch size set to 4, and the learning rate initialized to 0.001, which is decayed by multiplying 0.2 in every 25 epochs. We quantitatively (in terms of PSNR (in dB) and SSIM [31]) and qualitatively compared our method with the three state-of-the-art methods, PReNet [19], MPRNet [26], and ECNet [27]. The quantitative results were shown in Tables I-III, and the qualitative results were shown in Figs. 3-7. It has been shown that the proposed method recovers more image details while removing the rain streaks, and exhibits better quantitative results.

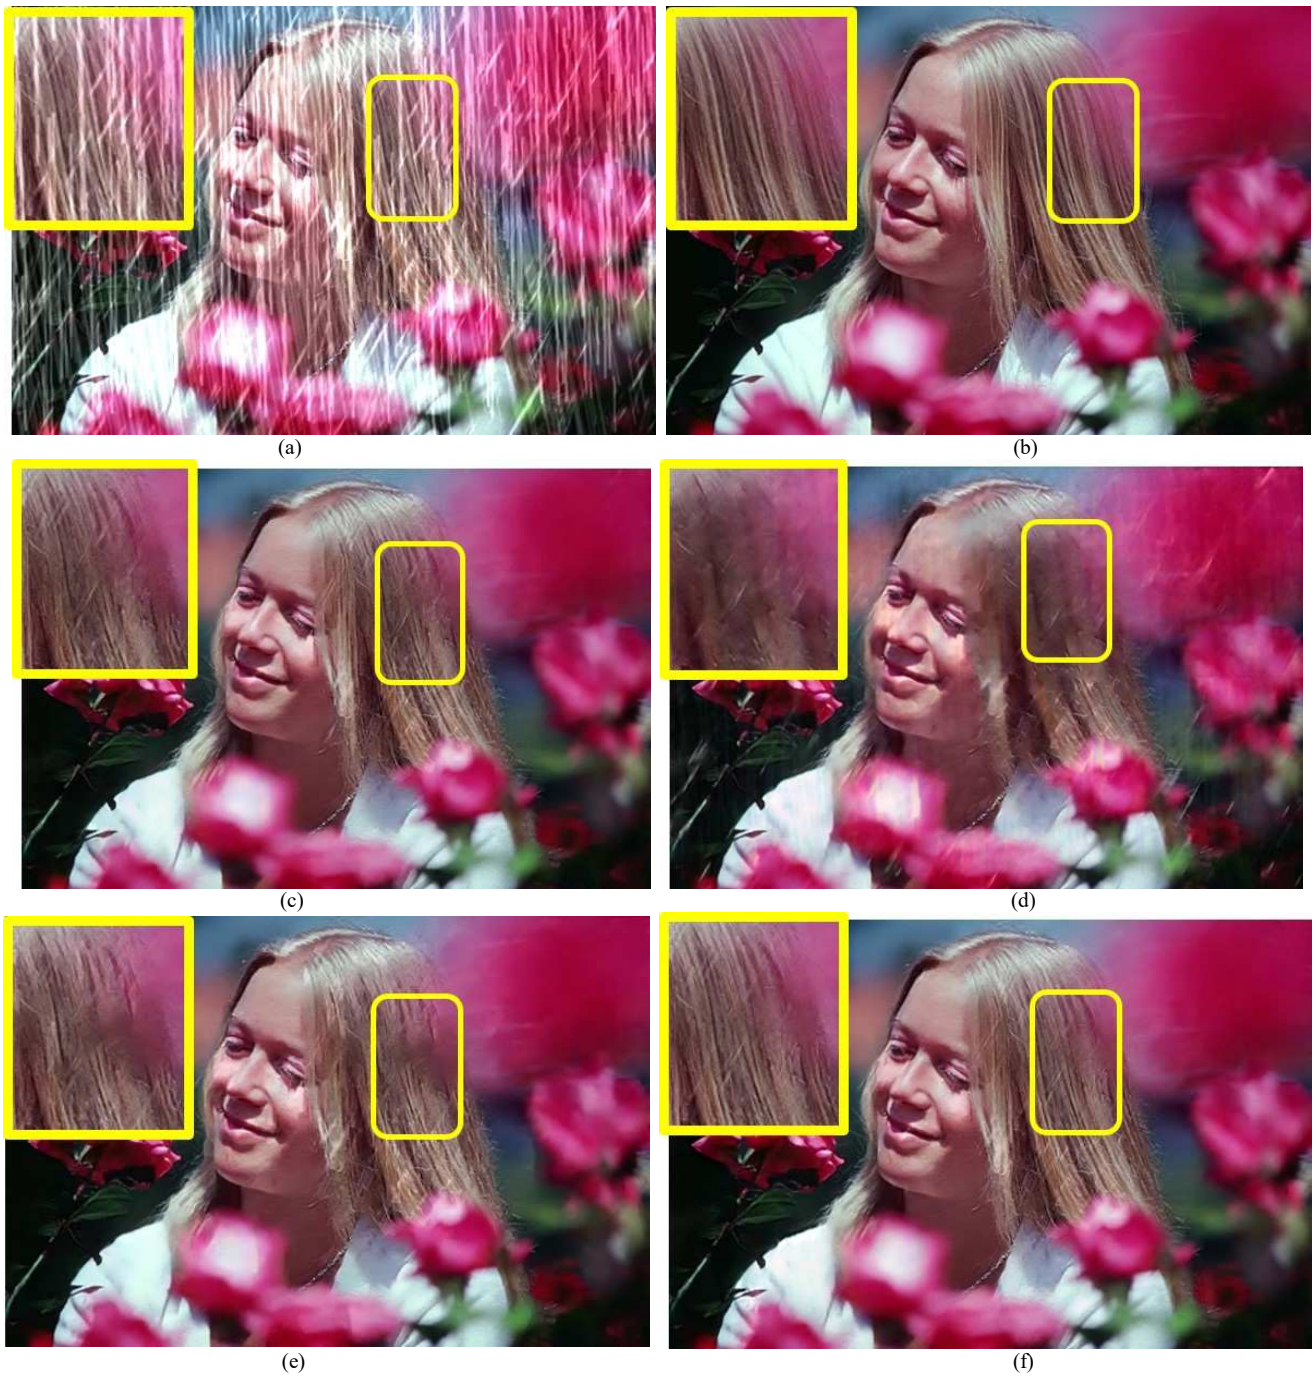

Fig. 3. Qualitative results on the Rain100H dataset: (a) rainy image; (b) ground truth; (c) PReNet [19]; (d) MPRNet [26], (e) ECNet [27]; and (f) proposed method.

Moreover, to evaluate the effectiveness of the embedded CAB (channel attention block) and the proposed MSPAM (multi-scale pixel attention module), we conducted the ablation studies by removing either CAB or MSPAM from the proposed deep rain streak removal framework, and evaluated the corresponding deraining performances, reported in Tables IV and V. Based on Tables IV and V, removing either CAB or MSPAM will degrade the deraining performances, and the proposed complete deep deraining network exhibits the best performance, which verifies the effectiveness of the two modules, CAB and MSPAM.

V. Conclusions

In this paper, we have proposed a deep learning-based encoder-decoder framework to learn rain steaks for single image-based deraining. By using ECNet [27] as our basis, an

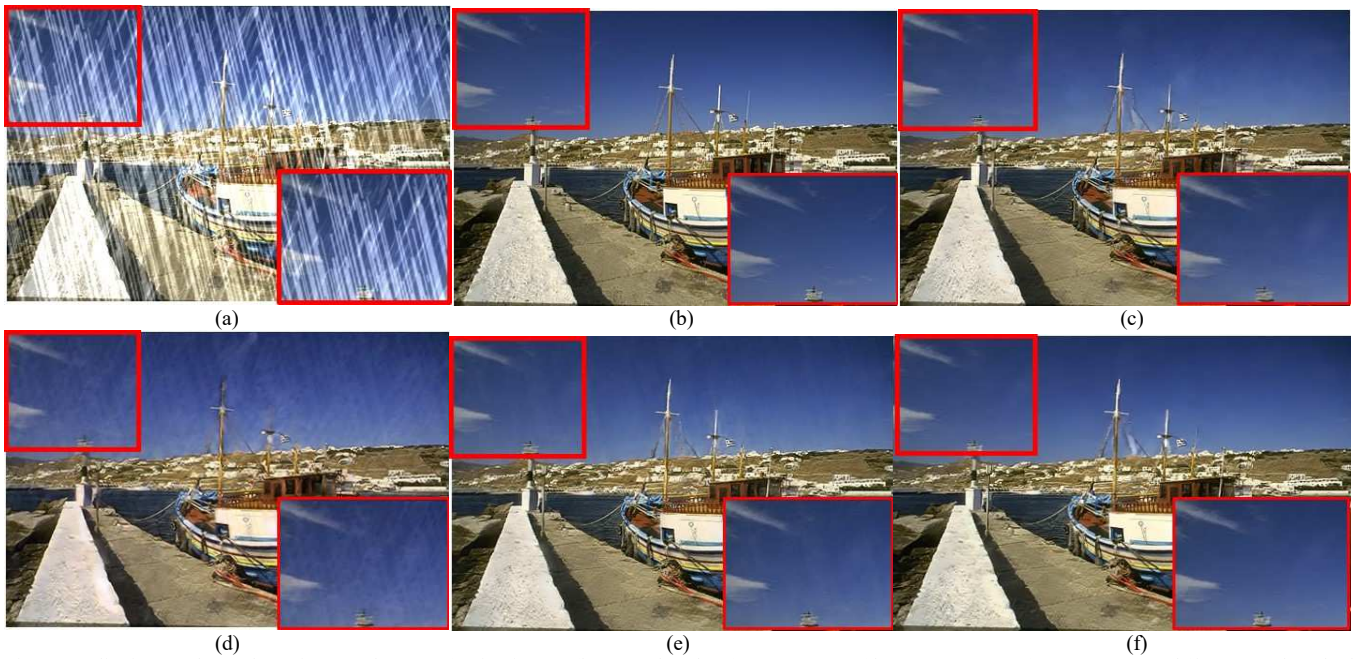

Fig. 4. Qualitative results on the Rain200H dataset: (a) rainy image; (b) ground truth; (c) PReNet [19]; (d) MPRNet [26], (e) ECNet [27]; and (f) proposed method.

encoder-decoder-based network with channel attention and the proposed multi-scale pixel attention module (MSPAM) was presented. Together with the "Rain Embedding Consistency" mechanism presented in the ECNet, we have shown that the channel attention can be used to enhance the extracted features before being fed into the encoder, and our MSPAM can be embedded into the skip connection between the encoder and the decoder for further boosting the features to achieve better image reconstruction. Experimental results have demonstrated that the proposed framework outperforms the three compared state-of-the-art deep learning-based deraining methods quantitatively and qualitatively.

E-mail: {40947038s, myeh}@gapps.ntnu.edu.tw

***Abstract*—This paper proposes a fully transformer-based method for building an end-to-end model dedicated to tiny object detection. Our approach eliminates the components which are difficult to be designed in detecting tiny objects, such as anchor generation and non-maximum suppression. Additionally, we address the issue of receptive fields for tiny objects in convolutional neural networks through self-attention. The model named Swin-Deformable DEtection TRansformer (SD DETR) integrates Swin Transformer [1] and Deformable DETR [2]. Furthermore, we have introduced architectural enhancements and optimized the loss function to improve the model's ability in detecting tiny objects. Experimental results on the AI-TOD [3] dataset demonstrate that SD DETR achieves 10.9 AP for very tiny objects with only 2 to 4 pixels, showcasing a significant improvement of +1.2 AP compared to the current state-of-the-art model. The code is available at https://github.com/kai271828/SD-DERT**

I. Introduction

With the increasing maturity of drone aerial photography and satellite imaging technology, the demand for object detection in aerial images is rapidly growing. In recent years, significant progress has been made in the field of object detection, but the current main achievements are focused on detecting objects of general size. Successfully detecting tiny objects that often appear in aerial images is a challenging problem. Unlike detecting objects of general size, several difficulties exist in detecting tiny objects smaller than 64 pixels [3], including being easily affected by background noise, insufficient training samples, the limitation of using bounding boxes for tiny objects, and the downsampling process tpyically in convolutional neural network methods causing tiny objects to disappear in the final feature map. All of the factors mentioned above result in a significant decrease in the performance of detecting tiny objects.

Currently, the most representative solutions to the problem of detecting tiny objects include Normalized Gaussian Wasserstein Distance (NWD) [4] and Gaussian Receptive Field based Label Assignment (RFLA) [5]. Both methods utilize probabilistic modeling to alleviate the issue of imbalanced positive and negative samples caused by the IoU metric in the task of detecting tiny objects, enabling the model to successfully learn the features of tiny objects. While these methods have shown some success, overall, the task of object detection becomes more complex by incorporating additional probabilistic modeling in those hand-designed modules. Furthermore, there are still unresolved issues related to feature extraction, especially from images containing tiny objects.

We have observed that DETR [6] applied the Transformer model [7]—commonly used in natural language processing—to the field of object detection. Benefiting from the architecture of Transformer, DETR does not contain modules such as anchor generation, label assignment, and non-maximum suppression, which pose design challenges in the task of detecting tiny objects. Nevertheless, the DETR model performs poorly on small objects and has a slower convergence speed, as experimented and evidenced in [6]. To address these issues, many improved methods have been proposed, including Deformable DETR [2]. The multi-scale deformable attention mechanism proposed in [2] improves performance on small objects without using the Feature Pyramid Network (FPN) [8]. In addition, the Deformable DETR model modifies the self-attention mechanism by referring to Deformable Convolutional Networks [9] to accelerate model convergence. However, the performance on tiny objects still needs further investigation.

In addition, Transformers have recently been shown to be very effective backbone networks and outperform traditional convolutional neural networks in various visual tasks. For instance, Swin Transformer [1] uses a hierarchical design and shifted windows calculation to address the issues of Vision Transformer (ViT) [10] in object detection and image segmentation. Experimental results have shown that, under comparable model sizes, extensive pretraining allows the Swin Transformer to outperform commonly used backbone networks like ResNet [11]. We hypothesize that, in this study, the global self-attention mechanism of the Transformer contributes to mitigating the challenges associated with feature extraction for tiny objects.

Given the significant utility of detecting tiny objects and the potential of Transformers in object detection development, this paper aims to demonstrate that by using the elegant design of the DETR series models we can abandon hand-designed modules and achieve a concise and powerful end-to-end model for detecting tiny objects. Additionally, we investigate how the DETR series models can be improved for the detection of tiny objects.

A. Tiny Object Detection

Small objects typically occupy very few pixels in size. The current IoU-based metrics are very sensitive to variations in the position of small objects, which significantly affect the effectiveness of training. To alleviate this issue, Wang *et al.* [4] proposed a new metric based on Wasserstein distance. Specifically, bounding boxes (BBoxes) are modeled as Gaussian distributions, and a new measurement called Normalized Wasserstein Distance (NWD) is used to measure the similarity between the corresponding Gaussian distributions. NWD can be easily integrated into the label assignment, non-maximum suppression, and loss function of any anchor-based detector, replacing the commonly used IoU metrics.

Additionally, Xu *et al.* [5] made two observations. First, for tiny objects, existing label assignment methods heavily rely on overlapping areas. The ground truth hardly overlaps with any anchor boxes (i.e., IoU = 0), resulting in lack of positive samples for tiny objects. Therefore, heuristic methods are employed to ensure more positive samples are obtained for tiny objects. However, the allocator often struggles to compensate for positive samples based on zero-value IoU or centrality, leading to reduced attention to learning tiny objects. Second, the prior region follows a uniform distribution and treats each position within the prior region equally. However, prior information is essentially used to assist in label and feature point assignments. When mapping the feature points' receptive field back to the input image, the effective receptive field becomes a Gaussian distribution. The discrepancy between the uniform distribution of the prior and the Gaussian distribution of the receptive field causes a mismatch between the ground truth and the assigned receptive field for feature points.

To alleviate those issues, prior information based on Gaussian distribution is proposed and a label assignment strategy based on Gaussian Receptive Field is established [5], which is more beneficial for tiny objects.

B. Deformable DETR

DETR [6] has realized an end-to-end object detection model using transformers. Even after removing some modules that require lots of prior knowledge, DETR still performs remarkably well. However, this model also exhibits notable issues that need to be addressed, including poor detection performance for small objects and slow convergence speed. Therefore, Zhu *et al.* [2] proposed Deformable DETR, which effectively processes the features of images by only calculating a small number of key points through multi-scale deformable self-attention modules. Deformable DETR solves the problems of poor detection performance for small objects and slow convergence speed. It can surpass the performance of DETR with only one-tenth of the training times. Therefore, we developed our object detector based on this detection model.

C. Swin Transformer

Liu *et al.* [1] proposed shifted windows based on ViT [10]. By restricting the computation of self-attention mechanisms to non-overlapping regions while allowing cross-region connections, Swin Transformer can extract global features from images. The computational complexity is also reduced from being quadratic with respect to the input size to linearly related. In addition, the hierarchical structure enables Swin Transformer to extract multi-scale features, making it possible to use the transformer as a backbone network for various computer vision tasks. Experimental results also show that with sufficient pre-training, Swin Transformer performs well as a backbone network for object detection and semantic segmentation tasks. In this study, we investigate the effectiveness of this backbone for tiny object detection.

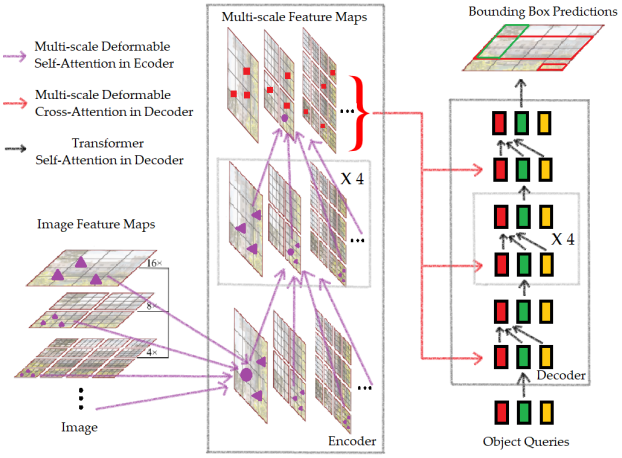

Fig. 1. Model architecture of the proposed tiny object detector. This model combines Swin Transformer [1] and Deformable DETR [2].

III. Method

The proposed tiny object detection model is developed upon Swin Transformer [1] and Deformable DETR [2], as displayed in Fig. 1. In the following we describe the technical details of our implementation.

A. Feature Extraction

As a backbone network, the Swin Transformer divides the input 800×800 image into 4×4 patches. Each patch is then transformed into a token through linear embedding. However, directly feeding these long tokens into the Transformer would result in excessively long computation time for self-attention, which is clearly unacceptable. Therefore, within a Swin Transformer Block, the tensor is divided into several 7×7 windows, and the self-attention computation is performed only within each window. As a result, the length of the tokens is fixed at 49. Subsequently, the windows are shifted, and another round of self-attention computation is performed to facilitate information exchange between windows. Finally, an output tensor of the same dimension is obtained, which serves as part of the feature map input for the subsequent Transformer model.

To incorporate features from other scales, the output tensor undergoes Patch Merging, which is essentially an interval

sampling technique. The output tensor is divided into four parts, and these parts are concatenated along the channel dimension. Subsequently, a 1×1 convolution is applied to adjust the dimension. This process is analogous to pooling in convolutional neural networks, and the resulting tensor can be used for further computations in the subsequent stages. This procedure is repeated several times in our model to obtain feature maps at four different levels.

B. Tiny Object Detection

We developed our tiny object detector based on Deformable DETR [2]. The model first applies positional encoding to the feature maps at four different scales. Then, the encoder utilizes the mechanism of deformable attention to determine the positions of keys that each query requires. This is achieved by learning the offset Δp_{mqk}. The computation of the deformable attention is:

$$\begin{aligned}&\mathrm{DeformAttn}\big(z_q, p_z, \mathbf{x}\big)\\&\quad=\sum_{m=1}^{M} W_m\left[\sum_{k=1}^{K} A_{mqk}\cdot {W'}_m x(p_q+\Delta p_{mqk})\right](1)\,,\end{aligned}$$

where x represents a feature map, z_q represents a query with index q, p_q represents a two-dimensional reference position, m is the index of attention heads, k is the index of sampling points, and A_{mqk} represents the weight of the self-attention. When applied to multi-scale features, the calculation becomes:

$$\begin{aligned}&\mathrm{MSDeformAttn}(z_q, p_z, \{x^l\}_{l=1}^{L})\\&=\sum_{m=1}^{M} W_m\left[\sum_{l=1}^{L}\sum_{k=1}^{K} A_{mlqk}\cdot {W'}_m x^l(\phi_l(\hat{p}_q)+\Delta p_{mlqk})\right](2)\,,\end{aligned}$$

where l represents the index of the multi-scale feature map, $\hat{p}_q$ is normalized 2D coordinates, ϕ_l is used for re-scaling the normalized coordinates, and the remaining symbols are previously described. If the model is enabled with a two-stage approach, an additional encoder-only Deformable DETR is employed to generate region proposals. However, during this process, non-maximum suppression is not required.

Finally, 1,500 learnable object queries—together with the output of the encoder—are fed into the decoder for the standard self-attention computation. The feed-forward network then utilizes the decoder's output to perform predictions for class label and bounding box. To train an effective tiny object detector, we optimized the model by using the focal loss[12], together with the regression loss of the bounding boxes being a combination of the smooth L1 loss and the NWD loss. The NWD loss can address the issue of IoU-based metrics being sensitive to the location deviation of tiny objects.

IV. Experiments

A. Dataset

We evaluated the proposed method on the AI-TOD dataset [3], which contains 28,036 high-quality aerial/satellite images. AI-TOD consists of target objects that do not exceed 64 pixels in size. A single image in this dataset may contain thousands of objects, as shown in Fig. 2, making it more challenging compared to traditional object detection datasets. AI-TOD is divided into two versions—v1 and v2—, in both versions the images are identical, but the annotations in v2 have been improved based on v1[13]. Additionally, objects are categorized based on their sizes in this dataset. Objects ranging from 2 to 8 pixels are referred to as "very tiny" (vt), from 8 to 16 pixels as "tiny" (t), from 16 to 32 pixels as "small" (s), and from 32 to 64 pixels as "medium" (m). Objects are also classified based on their categories, including airplanes (AP), bridges (BR), storage tanks (ST), ships (SH), swimming pools (SP), vehicles (VE), people (PE), and windmill houses (WM).

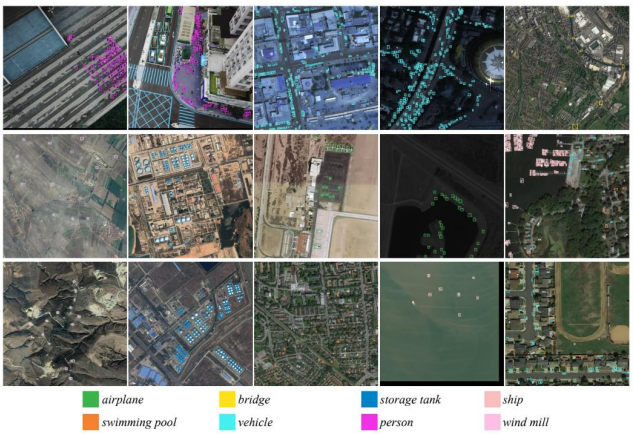

Fig. 2. A few samples in the AI-TOD dataset.

B. Implementation Details

We trained our models on a computer with eight NVIDIA Tesla V100 GPUs. The models were developed based on the MMdetection code library [14].We trained the models for 60 epochs on the AI-TOD-v1 and the AI-TOD-v2 train sets, respectively. In addition, the number of object queries was set to 1,500 to accommodate the dense nature of objects in AI-TOD. The number of feature levels was set to 4. Other hyper-parameter settings and training strategies mainly followed those in Deformable DETR [2].

C. Faster R-CNN and DETR Baselines

We first report the performance of the traditional object detection approach, Faster R-CNN [15], on AI-TOD v1. As shown in Table I, the performance of the Faster R-CNN baseline on AI-TOD is disappointing. While increasing the depth of the backbone network can enhance the overall AP slightly, it does not lead to an improvement in AP for detecting very tiny objects. In fact, the models fails to detect these tiny objects, resulting in an AP of zero. This limitation is a major problem for the Faster R-CNN baseline and other traditional object detection models.

On the other hand, the performance of the original DETR on AI-TOD is even worse. The original DETR does not have

TABLE I
RESULTS OF FASTER R-CNN AND DETR ON AI-TOD V1

Method	Backbone	AP	$AP_{0.5}$	$AP_{0.75}$	AP_{vt}	AP_t	AP_s	AP_m	Epochs
Faster R-CNN	ResNet34	8.9	22.0	5.6	0.0	5.8	18.9	27.8	12
Faster R-CNN	ResNet50	10.1	24.2	6.9	0.0	6.9	21.3	31.1	12
Faster R-CNN	ResNet101	13.1	30.7	9.2	0.0	9.7	24.6	35.5	12
DETR	ResNet50	0.0	0.0	0.0	0.0	0.0	0.0	0.0	150

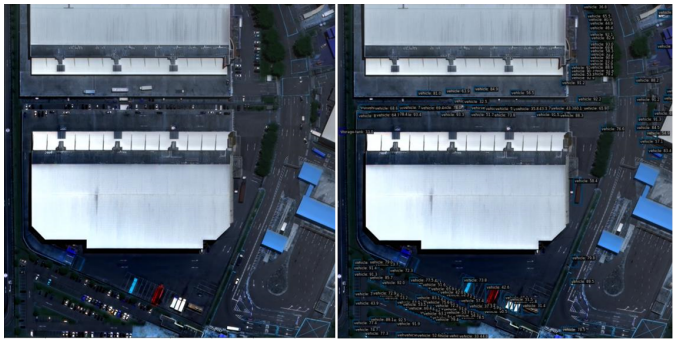

Fig. 3. Visualization of the detection result on AI-TOD v2. Left: the original image, right: the detection result obtained using SD DETR.

a network architecture for handling multi-scale features, and it generates only 100 object queries. Nevertheless, many images in AI-TOD contain a larger number of objects than this limit. It is expected that DETR would perform poorly in detecting tiny objects. However, experimental results show much more extreme outcomes, as the model fails to converge even after training for 150 epochs.

D. Comparison with State-of-the-Art Methods

Tables 2 and 3 compare the performance of our proposed method with state-of-the-art models on AI-TOD v1 and v2, respectively. After applying NWD-RKA [13] or RFLA, many models show significant improvements compared to the baselines. Our proposed models achieve APs that approach the level of state-of-the-art models. It is worth noting that the models outperform the state-of-the-art models on very tiny objects, with an improvement of 1 AP or more. An example of the visualization results of our models on the AI-TOD v2 is shown in Fig. 3.

E. Comparison with Other Designs

Table 4 presents the performance differences brought about by different model designs. Compared to the original deformable DETR, the proposed method performs better on AI-TOD v2 without using a two-stage approach. When incorporating the two-stage approach, the gap in AP widens even further. This improvement is particularly significant for detecting very tiny objects, with an increase of 4.8 AP, which is a notable enhancement.

V. CONCLUSION

We propose SD DETR, a Transformer-based efficient framework for tiny object detection. Addressing the challenges of detecting tiny objects, SD DETR introduces novel ideas and solutions that differ from previous related works. We achieve improved detection performance by directly discarding difficult-to-design modules in tiny object detection and enhancing feature extraction. Experimental results confirm the feasibility and effectiveness of our approach. On AI-TOD, SD DETR achieves comparable performance to state-of-the-art models and even surpasses them in detecting very tiny objects.

Abstract — **The rapid advancement of technology has led to the increasing adoption of deep neural networks on edge computing and mobile devices. However, these devices face challenges in effectively handling the extensive parameters and operations associated with neural networks. This study aims to address this challenge by utilizing knowledge distillation methods and integrating them into a table tennis sports analysis system. Specifically, our focus is to enhance the accuracy of a lightweight model designed for edge devices, specifically for ball bouncing point detection in table tennis. Through comprehensive experimentation, we demonstrate the effectiveness of our proposed learnable teaching materials in improving the model's performance. On average, our approach achieves a 1% accuracy improvement compared to the baseline model before knowledge distillation, with the best performance achieving an accuracy of 91.3%.**

I. INTRODUCTION

In recent years, deep learning has witnessed remarkable advancements, leading to the proposal of diverse model architectures with high accuracy. However, these models often rely on computationally expensive parameters, posing challenges when deploying them on low-end hardware devices such as edge computing devices. To address this issue and achieve fast inference times without compromising accuracy, model compression techniques are crucial. Various approaches, including pruning [1-5], model quantization [6-8], and knowledge distillation [8-17], have been proposed for compressing neural networks.

Pruning [1-5] involves removing weights or channels from the model, making it smaller and faster, resulting in reduced storage requirements and accelerated inference. Model quantization [6-8], on the other hand, quantifies the model weights to achieve lightweight models, albeit with a potential reduction in accuracy. Knowledge distillation [8-21] is not a direct model compression method but aims to achieve similar goals and effects. It involves transferring knowledge from a large, accurate teacher model to a smaller, lightweight student model, enabling the latter to attain comparable accuracy levels.

In this work, we focus primarily on knowledge distillation techniques and practices for model compression. Knowledge distillation involves leveraging the knowledge learned by a high-precision teacher model with a large number of parameters and transferring this knowledge to a smaller, lightweight student model. Numerous knowledge distillation methods have been proposed, with many focusing on extracting appropriate lightweight student networks from complex teacher networks [8-17]. However, these methods often require substantial computational resources and entail prolonged training times.

Additionally, some methods explore loss functions that effectively utilize the transferred knowledge [18-19]. While these methods have lower training costs and time requirements, they are limited to specific tasks. For instance, loss functions designed for classification tasks may not be applicable to object detection tasks.

Through long-term knowledge distillation experiments, we have observed that augmenting the simple knowledge distillation approach with supplementary teaching materials can further enhance teaching quality, accuracy, and fine-grained details of the student model. In Section 3, we present the proposed methods, while Section 4 delves into the experimental results, providing a comprehensive explanation of these advancements.

II. RELATED WORK

Machine vision and deep learning have become popular areas of research in ball sports events, as the speed of the ball

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

makes it challenging for human vision to keep up. Intelligent systems that can gather more information to assist in judgments have been developed. One such system is TTNet [20], which focuses on table tennis and includes scene analysis, ball track detection, and ball bounce event detection.

Given our specific research conditions, which involve strict restrictions and the goal of real-time detection of the table tennis ball's drop point on an edge computing device, we employ lower resolution inputs and a lightweight model to tackle this challenge. The scene recognition in our study is subject to numerous limitations, and we are unable to obtain training data from any publicly available datasets. Therefore, we curated a private dataset to train our model.

Traditional object detection methods typically involve inputting an RGB image and using a network to determine the object's position and type within the image. However, detecting the precise moment when a ball bounces off a table presents a significant challenge for these traditional methods. To overcome this challenge, we curated a private dataset that collects trajectory maps generated by the ball's movement over short intervals. By analyzing these trajectory maps, our goal is to detect the presence of a bounce point. Among the various one-stage detectors available, anchor-free methods [21-30] offer the advantage of lower computational burden and faster inference. One branch of anchor-free detection methods is the keypoint-based approach [25, 27, 28], which involves detecting objects by identifying key points. The Centernet method [27] aligns closely with our objective (refer to Figure 3). Its process is straightforward, directly predicting the coordinates of the center point and subsequently estimating the length and width of the bounding box based on the center point's features. This notion of predicting the key center point of an object aligns with our task of detecting the ball's drop point. Consequently, we design our detection head to predict the center keypoint as part of our approach.

In the realm of knowledge transfer between different networks, Hinton et al. [31] introduced a novel concept of utilizing soft labels in conjunction with hard labels for simultaneous training. Soft labels represent the predicted output probability values from a larger model, while hard labels correspond to the original ground truth labels. This probability distribution provides the neural network with implicit information about the similarity between different categories, moving beyond a binary right-or-wrong approach. By incorporating soft labels, the smaller model can learn more effectively from the teacher model and exhibit improved generalization during training.

Since then, numerous studies have explored the idea of distillation from intermediate layers. Knowledge extraction is not limited to the output of the last layer in the teacher network; instead, it can be derived from multiple layers throughout the network. This enables the teacher to transfer knowledge to the student through feature maps from intermediate layers, facilitating faster and better initialization of the student network. Consequently, extending distillation from logit to intermediate layers has become a common approach in knowledge distillation. Examples include Fitnets proposed by Romero et al. [32] and AT (Attention Transfer) proposed by Zagoruyko et al. [33].

Fitnets suggest that directly fitting the output of a large model to a small model is a challenging task. Therefore, it is recommended to enhance the supervision signal in the intermediate layers, aligning the intermediate layers of the small model with those of the large model. This approach involves the small model emulating an intermediate learning step of the large model. On the other hand, the method proposed by Zagoruyko et al. [33] focuses on distilling knowledge about feature relationships between layers rather than solely focusing on the output. The student model is guided by extracting the attention map generated by the teacher model, ensuring that the student model's attention map closely resembles that of the teacher model. This method enables the student model to not only learn feature information but also learn how to refine feature information. Notably, the attention map differs from the feature map, but the number of channels remains consistent between the teacher and student models, facilitating a more intuitive transfer of knowledge.

III. Proposed Method

In this study, we propose a method based on knowledge distillation. The concept of knowledge distillation involves transferring the final predicted logit of the teacher model to the student model for the classification task, as proposed by Hinton et al. [38]. Our approach follows a similar principle, where the final output of our model takes the form of a heat map that predicts the central point of the ball trajectory upon bouncing. Figure 1 provides an illustration of our training process, which includes computing the loss function using the output heatmaps from both the teacher and student models, in which FCOS[26] architecture is employed and its lightweight model is constructed as shown in Fig. 2.

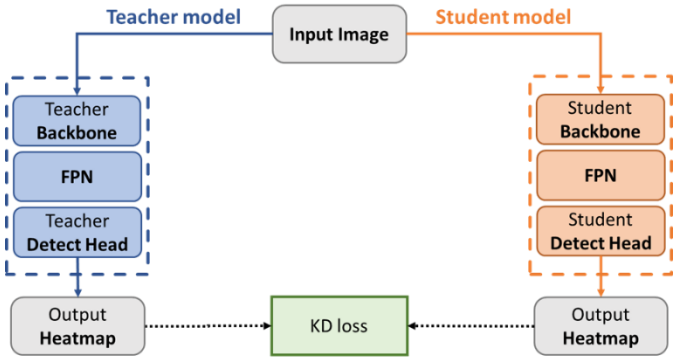

Fig. 1. Training structure of distillation from output layer.

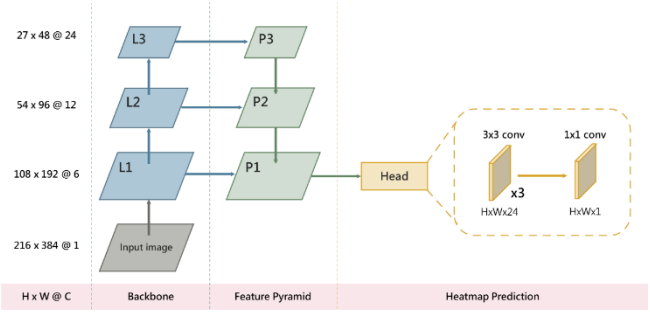

Fig.2. Our lightweight network architecture based on FCOS[26].

The loss functions for our proposed knowledge distillation mechanism are defined as follows:

$$\mathcal{L}_{out_{teach}} = \frac{1}{n}\sum_{i=1}^{n}(\hat{y}_t - \hat{y}_s)^2, \quad (1)$$

$$\mathcal{L}_{output\ layer-KD} = \mathcal{L}_{out_{teach}} + \mathcal{L}_{ori}, \quad (2)$$

where $\mathcal{L}_{output\ layer-KD}$ is the total loss of this part, where the distillation loss $\mathcal{L}_{out_{teach}}$ is the L2 norm, $\hat{y}_t$ and $\hat{y}_s$ are the prediction from teacher and student models, respectively. $\mathcal{L}_{ori}$ is the supervised loss calculated from ground truth. In addition, a loss function for the center response point is added, which is defined as

$$\mathcal{L}_{heatmap} = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2, \quad (3)$$

$$\mathcal{L}_{coordinate} = \frac{\left(C_x - \hat{C}_x\right)^2 + \left(C_y - \hat{C}_y\right)^2}{2}, \quad (4)$$

$$\mathcal{L}_{ori} = \mathcal{L}_{heatmap} + \mathcal{L}_{coordinate}, \quad (5)$$

where $\mathcal{L}_{heatmap}$ is the loss of heatmap, $\mathcal{L}_{coordinate}$ is the MSE loss of predicted coordinate of central response point, C_x, $\hat{C}_x$, C_y, $\hat{C}_y$ is the predicted x-axis coordinate, the ground truth x-axis coordinate, the predicted y-axis coordinate, and the ground truth y-axis coordinate, respectively.

To optimize the learning process of Knowledge Distillation (KD), we introduce the concept of Learnable Teaching Material (LTM) as illustrated in Fig. 3. The key characteristic of LTM lies in its capacity to accommodate an unlimited number of parameters for the learnable materials, depending on the layer of interaction with the teacher model. In Fig. 3, the pre-trained weights of the teacher model remain fixed, while the teaching materials are updated alongside the student model. The initial values of the materials correspond to the initialized weights, which vary according to different interaction patterns within the framework.

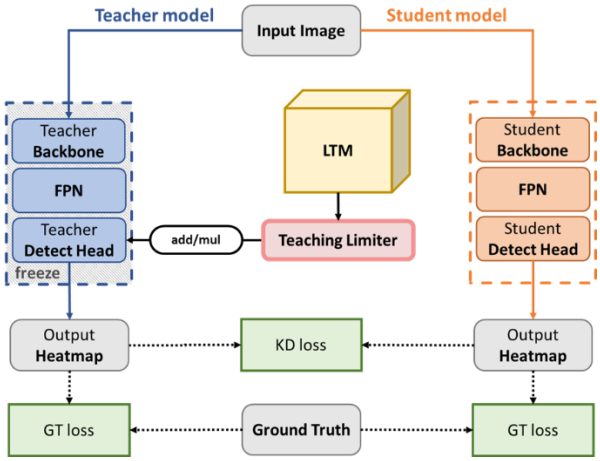

Fig. 3. Training structure of distillation with learnable teaching material.

The rationale behind freezing the pre-trained weights of the teacher model and solely updating the teaching material is to refine the teaching knowledge based on the students' learning progress, while preserving the foundational knowledge already acquired by the model. This approach allows for fine-tuning without directly modifying the existing knowledge. However, it is important to note that certain limitations are imposed on the teaching material as well by

$$\mathcal{T} = \mathcal{M}(LTM) = \gamma \cdot tan\,h(LTM)\,. \quad (6)$$

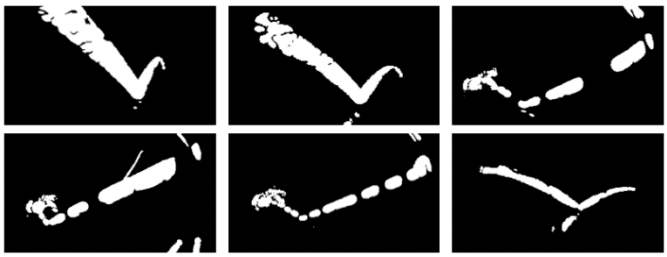
$\mathcal{M}(\cdot)$ is the teaching limiter, $\mathcal{T} \in [-\gamma \sim \gamma]$ is the output of the limiter, which can effectively fine-tune the underlying knowledge of the teacher model, and under the action of the limiter, LTM will not completely change the full structure of the knowledge. The related loss function is defined as

$$\mathcal{L}_{LTM-KD} = \mathcal{L}_{teacher_ori} + \mathcal{L}_{output\ layer-KD}\,. \quad (7)$$

In the whole training process, LTM will be trained and updated together. Therefore, the total loss $\mathcal{L}_{LTM-KD}$ also contains the loss $\mathcal{L}_{teacher_ori}$ from the output of the teacher model.

IV. Experiment Results

Our dataset is collected using the "Cumulative Frame Difference" (CFD) [34] method, which can detect bounce points by a single cumulative map. Examples of the original CFD and 8-bit CFD are demonstrated in Fig. 4 and Fig. 5, respectively.



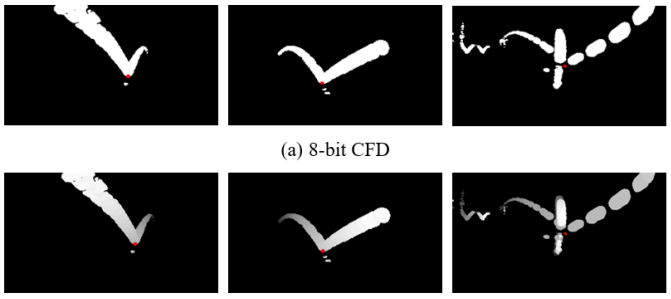


Fig. 4. Demonstration of the original CFD

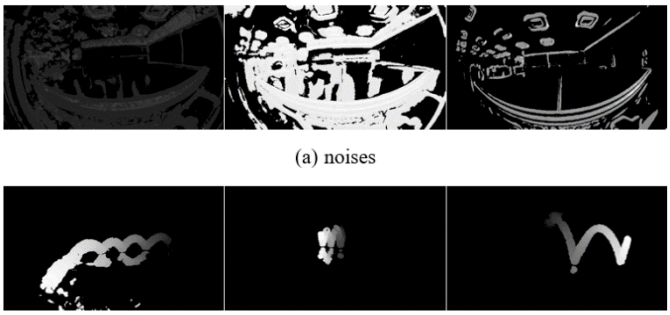

(a) 8-bit CFD

(b) 8-bit CFD w/ temporal

Fig. 5. Demonstration of 8-CFD

In our study, we obtained a comprehensive dataset from 23 private videos, which yielded a total of 7,467 original training images encompassing all employed methods. To enhance the quality of our results, we implemented diverse data augmentation techniques during the training process. These techniques involved common methods like "rotation" and "horizontal flip." Furthermore, we proactively considered potential challenges that may arise in real-time inference, such as camera shake and unexpected re-bouncing of the ball. To tackle these challenges, we employed the "copy-paste" method to create more intricate data augmentations, aiming to bolster the resilience of our training results. Remarkably, previous research [35] has demonstrated the significant performance improvement achievable through the simple act of copying data. Inspired by this insight, we developed a similar process to generate our augmented images.

To organize our training dataset, we divided it into two distinct categories: positive samples and negative samples. Positive samples consisted of images capturing bouncing points, whereas negative samples solely contained background and noise. We further categorized the negative samples into "noises" and "re-bounced ball" subcategories. Fig. 6 provides an example showcasing a negative sample.

(a) noises

(b) re-bounced balls

Fig. 6. Demonstration of negative samples.

We proceeded to develop three merging methods to combine positive and negative samples, resulting in new training data. The merging methods were as follows:

(a) Randomly selecting a "noises" negative sample and a chosen positive sample, and then summing the two samples. (b) Randomly selecting a "re-bounced ball" negative sample and a chosen positive sample, and then summing the two samples. (c) Randomly selecting a "noises" negative sample, a "re-bounced ball" negative sample, and a chosen positive sample, and then summing the three samples. To maintain diversity within the negative samples, we performed various transformations on them before combining the images. These transformations included random rotation, horizontal flip, random zooming, and random panning. Following the data augmentation process, the training images in the dataset expanded to four times the original size, resulting in a total of 29,868 images. This increase is due to each positive sample undergoing the aforementioned data augmentation techniques.

In our experiments, the system we use for training models is AMD Ryzen™ 9 3900X CPU @ 3.8 GHz, NVIDIA® TITAN RTX™ GPU with 24GB VRAM and 4608-core CUDA, and 128GB DDR4 system memory. In training the baseline of teacher (FCOS ResNet-19 lite) and student (FCOS ResNet-13 lite) models, the batch size is set to 64 and 128 respectively, and in knowledge distillation training, the batch size is set to 32. all the above cases trained 300 epochs. For LTM-KD method, we set the hyperparameter γ of the teaching limiter to 0.5, and use the "multiplying" method to let the teaching material assist the teaching.

In Table 1, the addition of Implicit Knowledge to the teacher model leads to noticeable improvements in the "16-bit" datasets. Specifically, compared to the Baseline, there is an increase of 0.9% and 1.3% in performance, respectively.

However, when it comes to the distilled student model in the "16-bit CFD w/temporal" dataset, the improvement is only 0.5%. On the other hand, LTM-KD demonstrates a 0.9% enhancement in the "16-bit CFD" dataset, achieving the highest accuracy of 91.3%. Despite the fact that the teacher model in LTM-KD has not undergone retraining, it is evident that it has been influenced by the LTM. This influence is demonstrated by the observed results. Interestingly, while the accuracy of the student model improves, the accuracy of the teacher model decreases under the influence of LTM. This observation indicates that the original knowledge of the teacher model is too complex to be directly extracted for effective teaching. However, with the assistance of LTM, this challenging knowledge can be transformed into more suitable and digestible forms for students.

Table 1. Performance comparison between KD using implicit knowledge(IK) and learnable teaching material(LTM)

Distillation Method	Teacher FCOS ResNet-19 lite				Student FCOS ResNet-13 lite			
	8-bit		16-bit		8-bit		16-bit	
	CFD	CFD w/ temporal	CFD	CFD w/ temporal	CFD	CFD w/ temporal	CFD	CFD w/ temporal
Baseline	0.896	0.913	0.917	0.906	0.879	0.862	0.894	0.893
IK-KD	0.890	0.909	0.926	0.919	0.878	0.879	0.892	**0.901**
LTM-KD[1]	0.889	0.897	0.905	0.903	0.880	0.881	**0.913**	0.894

[1] : Unlike other methods, LTM-KD does not retrain a pre-trained teacher model specifically for the corresponding method. Instead, it utilizes a baseline model that has been pre-trained with LTM. In the LTM-KD approach, only the parameters of the LTM are updated during the knowledge distillation process.

V. CONCLUSIONS

In this study, we have successfully tackled the challenge by incorporating knowledge distillation techniques and integrating an ultra-lightweight model into a smart table tennis sports system. Our focus was on enhancing the accuracy of a lightweight model designed for edge devices, specifically for ball bouncing point detection in table tennis. By employing LTM-KD, we have effectively improved the performance of the model. Through extensive experimentation, we have demonstrated the efficacy of our proposed knowledge distillation approach utilizing learnable teaching material (LTM). On average, our method achieves a significant 1% accuracy improvement compared to the baseline model prior to knowledge distillation. The best-performing model achieved an impressive accuracy of 91.3%, highlighting the effectiveness of LTM-KD in real-world environments.

***Abstract*—Deep learning-based sign-language recognition usually requires abundant training videos. This research considers generating valid sign-language data for training the recognition models. MediaPipe is used to acquire the hand skeleton from the sign-language video. Then we analyze several hand skeleton adjustment policies with color-weighting strategies and generate hand masks to simulate different hands. Since miss detections of hands may happen due to motion blurring caused by rapid hand movements, we incorporate optical flows to ensure that the hand movement information is retained in each frame. We employ different spatial and temporal data augmentation strategies to simulate varying hand sizes, filming angles, and hand speeds. The experimental results show that the proposed method improves the accuracy of sign-language recognition in the American Sign Language dataset.**

I. Introduction

Sign language is an essential communication tool for people with hearing loss. Such visual languages are not universally understood as they vary depending on the customs of different regions, even in different cities of the same country. Sign language conveys messages through hand shapes, movements, and even facial expressions. Besides, sign languages usually express the meaning of words, instead of separated alphabets, making the recognition of sign languages require particular training. According to a study by the World Health Organization (WHO), more than 5% of the world's population, or 430 million, have a disability-related hearing loss. According to the Ministry of Health and Welfare of the Executive Yuan, $\%5$ of Taiwan's population, or $124,000$, have hearing impairment. Sign language serves as a bridge for people with hearing loss to receive information and communicate with other people. On the other hand, people who have not learned sign language cannot fully understand what the hearing-impaired person would like to express. Using video comprehension methods on terminal devices (e.g., smartphones, tablets, etc.) to help us analyze the gestures made by hearing-impaired persons will significantly reduce communication difficulty.

Traditional sign-language recognition research often requires a wearable device or a depth camera to help extract hand features, thus requiring considerable hardware costs. It also demands a series of image processing procedures to extract hand features, which is time-consuming and labor-intensive. In this research, we adopt deep-learning models to replace the traditional ways of using assistive devices and to effectively extract hand information like bounding boxes of hands or skeletons of hands. We employ hand masks, hand skeletons, and optical flows of sign language videos as the input to a deep learning network. By testing with different experiments, we analyze several hand skeleton adjustments and color weighting strategies and generate hand masks from the skeletons to simulate different hands. The experimental results show that the proposed methods improve recognition accuracy when testing on the American sign language dataset.

II. Related Work

For the related work of sign-language recognition, we first describe the available datasets and the potential solutions.

A. Datasets

There is a wide variety of sign languages; collecting data to form a feasible sign language dataset is not trivial. The publicly available sign-language datasets can be classified into isolated sign-language (ISL) datasets, as shown in Table I, and continuous sign–language (CSL) datasets, as shown in Table II. ISL datasets contain videos demonstrating the signing expression of single words, while CSL datasets consist of multiple words in each video. Each dataset may provide different data and labeling methods. The common data types are raw videos with RGB frames, with probably additional depth information. Such datasets as How2Sign [1] even contain sign-language videos of the same scene captured from different filming angles. Among the datasets, WLASL (Word-Level American Sign Language) [2] has quite complete data on American sign language. Some examples are shown in Fig. 1. There are four different subsets, WLASL100, WLASL300, WLASL1000, and WLASL2000, containing 100, 300, 1000, and 2000 sign language words respectively. We will use WLASL100 in this study.

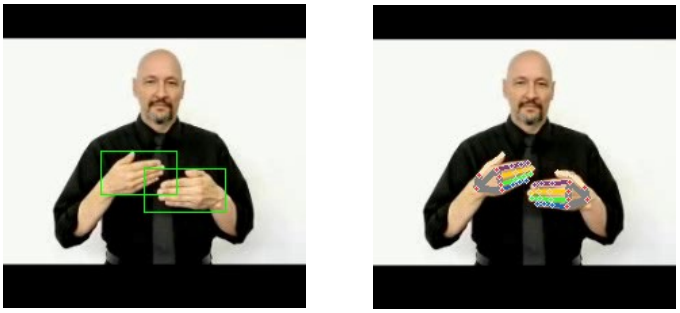
B. Classifications of Sign Language Recognition

Sign language recognition is also divided into ISL recognition and CSL recognition. The methodologies are classified into traditional signal processing and deep learning methods. Early vision-based methods for sign-language recognition used manually crafted hand features [3] to represent gestures. For example, SIFT-based features [4], HOG-based features [5], and other features in the frequency domain may be employed. Auxiliary hardware such as Kinect was often installed to help capture hand gestures. The temporal relationships in the video sequences are then examined by the Hidden Markov Model (HMM) [6]. Finally, machine learning techniques such as SVM, template matching [7], instance-based learning, and decision tree [8] are used to classify the sign language videos. The effectiveness of traditional methods for sign language recognition is usually doubted due to high computational complexity, unpopularity of using additional hardware, and lack of generality of using a single setting for varying videos.

Deep learning methods for sign-language recognition attract much attention as more data are available, and the features can be extracted via training. Karen Simonyan proposed dual-stream convolutional neural networks [9], which could be the first scheme to leverage the feature extraction capability of deep learning techniques. The dual-stream convolutional neural network architecture includes both spatial and temporal networks to deal with the pixel-domain and temporal-domain data. The optical flows are extracted from the videos as the network input. The SVM is used as the classifier. No manual labeling is required. Reasonably good results are achieved on the task of UCF-101 [10] and HMDB-51 [11] datasets. To better establish the temporal relationship between visual features, Jeff Dona proposed LRCN [12], which extracts features from each video frame and models the hidden states by Conditional Random Field (CRF). LSTM is employed to learn the sequential dynamics. Another CNN+LSTM architecture was proposed by Ng et al. [13]. To explore different convolutional feature pooling architectures, feature pooling is used to maximize the collection of local messages. Feature aggregation is applied from frame to frame. A 2D CNN+LSTM-based sign-language video recognition was proposed by Li et al. [2]. The spatial features are extracted using VGG16 trained by ImageNet and then serve as the input to a stack of RNN-routed GRUs to process the temporal domain dependencies for recognition. Hara made use of Kinetics [14] to train a 3D ResNet network [15], replicating the success of 2D CNN on ImageNet. The model I3D [16] was also trained on ImageNet first and then fine-tuned on Kinetics-400 [14]. The results demonstrated that the fine-tuned I3D can better extract the features of sign-language videos. In addition to using RGB images or frames as the input, extracting skeletons is a common approach since many human behavior recognition applications use localized key points for pose analysis. The pose keypoint-based sign language recognition is often adopted in transformer-based single-word sign language recognition systems [17]. They

first estimated human pose key points and introduced a so-called pose normalization approach to process the skeletons. Several joint rotation strategies were proposed to apply the data augmentation on the hand skeletons to improve the model accuracy further.



C. Feature Extraction

Traditional image processing methods to extract hands usually rely on a series of complex procedures. Edge detection can be applied first, followed by binarization and adjusting the thresholds to remove noises and further sharpen edge lines. The contours of the binarized images are then plotted, combined with the convex polygon detection and background removal. In addition to image processing methods, adopting special hardware assistance is also a feasible approach. RGB-D camera, Kinect, sensor gloves, etc. can be employed to obtain more information beyond color pixels. RGB-D cameras can use hand colors and depths to eliminate the background noises to better capture hands. Kinect is equipped with an RGB camera, an infrared emitter, and an infrared CMOS composed of a 3D structured light depth sensor. Kinect can scan the scene with an IR sensor emitting infrared. Kinect can also convert the detected depth images to the skeleton tracking system to facilitate the extraction of hand skeletons. Many open-source platforms integrate mainstream deep learning algorithms into a single library, allowing developers to call different modules using APIs, without markup or with only a small amount of markup, and using pre-trained models, which can significantly reduce development time. Detectron2 [18] is an object detection platform based on the Pytorch framework, developed by AI research in Facebook. As a combination of predecessor Detectron and MaskRCNN-benchmark [19], Detectron2 provides state-of-the-art object detection and object segmentation algorithms, such as Fast RCNN [20], Faster RCNN [21], Mask RCNN [22], which can be used to localize the hand positions. Mask RCNN can also be used to segment the hand and generate hand masks. Mediapipe [23] is a collection of frameworks that can be built on different platforms. Mediapipe supports a variety of different model inferences. It also provides solutions for vision tasks such as object detection, multiple hand tracking, face detection, and hair segmentation, etc. We use the hand detection/tracking module and a skeleton detection module to acquire the information of hands.

III. Proposed Method

It is well known that the regions of interest in frames of sign-language videos should be hands. We utilize Mediapipe to help capture all the hands in videos. Both the hand and skeleton detection modules in Mediapipe are considered to locate the bounding boxes of the hands and the joints of the skeleton of the hand, as shown in Fig. 2.

With the hand skeleton key points, we apply the dilation to expand the joints, draw contours surrounding all the hand key points, and then fill the contours to acquire the hand mask, as shown in Fig. 3. The masks are used to preserve or show the

(a) Bounding Box (b) Multi-Color Skeleton

Fig. 2. The examples of hand extraction by Mediapipe.

pixels of hands only and remove all the inferences from other objects, including other parts of a person or the background. In our opinion, hands look much similar for different persons, compared with other portions of bodies. When the dataset is not large, we have to keep hands only and then use data augmentation to increase the types of content.

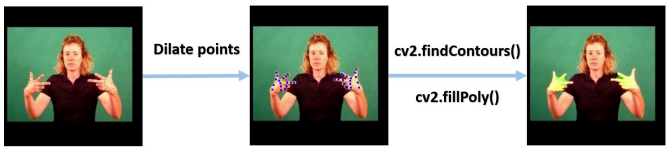


Fig. 3. The procedure of generating hand masks.

It should be noted that Mediapipe may fail to detect the hands when they move too fast or are too close to the face, which has similar skin colors. It is possible that both hands disappear and the whole frame becomes empty. We thus choose to calculate the optical flows to ensure that hand movement information is preserved in every frame, as shown in Fig. 4.

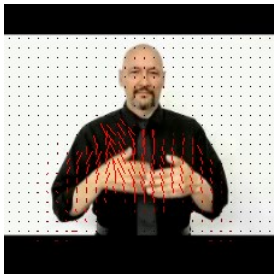

Fig. 4. Optical flows on one frame.

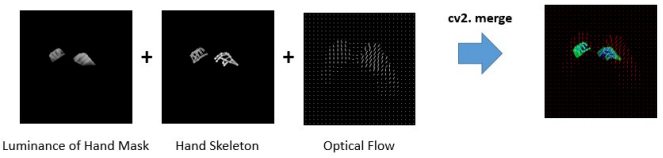
With a small sign-language training set, using a single feature extracted from the sign-language video may result in poor performance due to the limited data that the model can learn from. We examine different hand features in the three input channels of the model. The schematic diagram of the synthesized data is shown in Fig. 5. We have tried several combinations of possible input data, including different color information of hands combined with the optical flows, as



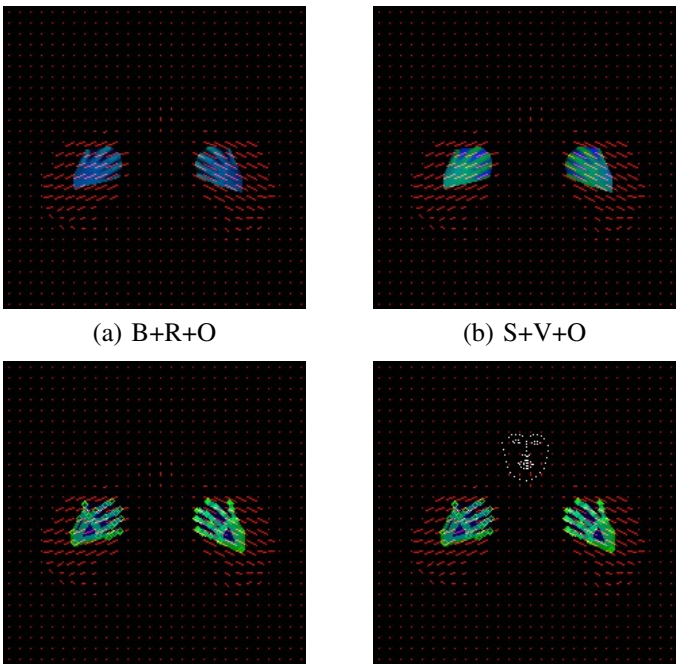


Fig. 5. The procedure of synthesizing the training data.

demonstrated in Fig. 6. The first attempt was to select two channels in the original RGB color space of videos and then integrate the optical flows as the input data. We also convert the videos from the RGB color space to HSV and replace the Hue channel with the optical flows as the input data. Then we train the hand skeletons and hand masks together, combined with the optical flows. We found that this combination yields better performance. Finally, we add the face landmarks into the input by extracting 68 features of the face and merging these features into the three channels, i.e., the hand mask, the hand skeleton, and the optical flows. However, the accuracy is not improved by adding the face landmarks.

(a) B+R+O (b) S+V+O

(c) L+Skeleton+O (d) L+Skeleton+O+F

Fig. 6. Examples of different combinations of input. **O** denotes Optical flow between two frames. **B** and **R** denote the Blue channel and the Red channel in RGB color space, respectively. **S** and **V** denote the Saturation channel and the Value channel in HSV color space respectively. **L** and **F** denotes Luminance of mask and Face Landmark respectively.

In order to simulate the situation where the hand is partially blurred due to fast movement and to let the model learn the different shapes of the hand, our idea is to reveal different pixels of the original hand. We implement this idea by changing the shape of the hand mask. We add noises to the hand skeleton's key points to change the shapes of hand masks. The steps are as follows:

1. Select a hand skeleton joint and choose a random value x in the range [0, X].
2. Randomly choose a direction y in the set {up, down, left, right, top-left, bottom-left, top-right, bottom-right}.
3. Move the joint to a point x unit away from the original joint in the direction y.

Through the steps mentioned above, different hand skeletons can be produced, and then hand masks are generated accordingly. We examine the following four hand skeleton adjustment strategies, as shown in Figure 7.

- **Random Noises**: The most intuitive step is to randomly adjust the data. We randomly pick 0 to 21 points from the 21 joints of the palm; each key point is randomly assigned with a distance value x, direction y, and then move the joint x unit away from the original joint in direction y.
- **Fingertip Noises**: Besides random adjustments, we start with applying minor adjustments on skeletons. Adjusting the fingertips should be the slightest change, compared with moving the whole fingers or retracting the entire palm. The strategy is randomly selecting 0 to 5 fingertips from the five fingers. The selected fingertip key points are randomly assigned with a value of distance x and a direction y. The key points are moved the joint x unit away from the original joint in direction y.
- **Move Fingers**: We randomly select 0 to 5 fingers, and the selected fingers are randomly assigned with a value of distance x and direction y. The key points of the same finger will move in the same direction.
- **Shrink Palm**: We fix our fingers and fingertips, but zoom in or zoom-out on the key points of the palm, and randomly select the distance value x and direction y.

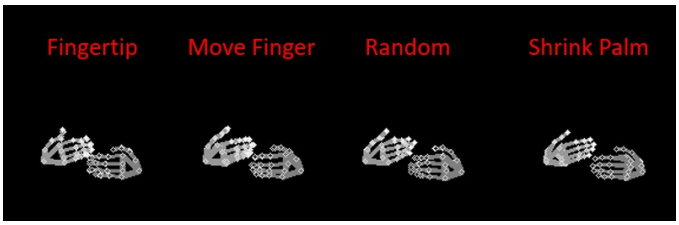

Fig. 7. Applying different skeleton adjustments.

ResNet is a well-known framework and has shown decent performance in image classification. Increasing the time dimension of all the convolutional kernels of ResNet into 3 dimensions, i.e., 3D ResNet, is considered in this research. Such 3D CNN can better combine the spatial and temporal domain features than 2D CNNs with dual-stream networks. In this study, we use a very basic 3D ResNet framework [15] to train a sign-language classification or recognition model. By doing so, the effectiveness of selecting suitable data inputs can be more obvious.

The data augmentation in the spatial domain is to simulate different positions of the hands, the brightness and darkness

of the scene, the size of the hands, and different filming angles, etc. We have applied the following spatial-domain data augmentation by introducing the brightness changes, displacement, scaling, slight rotation, contrast changes, and saturation, as shown in Fig. 8.

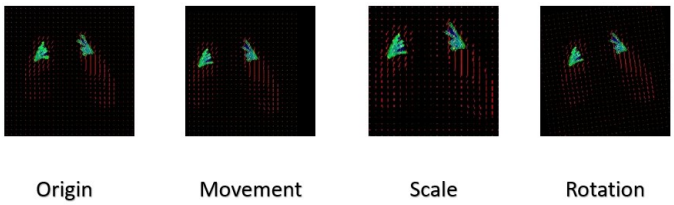

Fig. 8. Spatial augmentations.

The time-domain data augmentation simulates the varying speed of sign-language users. Selecting a few frames for processing reduces the memory burden of training the full video. We first calculated the average frame rate of the entire American Sign Language dataset, which is around 30 frames. We randomly selected 25 frames in American Sign Language videos and restricted the distance between the first and last frame with no more than the min_size set $\{15, 20, 25\}$ frames. If we select more than 25 frames, we randomly drop some frames until 25 frames are left; if the total number of selected frames is less than 25 frames, we randomly repeat some frames until 25 frames are reached. We use the following four different time domain sampling strategies:

1. Average Crop: Randomly select the start frame in the sign-language video interval $[1, min_size/2]$, then randomly select the step x from $\{2, 3\}$, and start sampling with step x from the start frame until 25 frames are selected.
2. Center Crop: First, take the middle frame of the sign-language video, then choose (index of the middle frame - min_size)/2 as the starting frame, and the last frame of the video as the ending frame. Randomly select 25 frames from this interval.
3. Random Crop: From the first to the last frames of the sign language video, we randomly pick 25 frames.
4. Begin Crop: In the sign language video interval $[1, min_size/2]$, pick a random number as the starting frame and sample 25 frames backward.

IV. Experimental Results

A. Implementation Details

This study was developed using Python version 3.6. The deep learning framework uses PyTorch 1.8.0 and Cuda 10.1, CuDNN 7. The operating system is Ubuntu 18.04 LTS. The system is equipped with Intel CoreTM i9-9900K CPU@3.6GHz, 64GB RAM, with Nvidia RTX Titan 24GB GPU.

B. Baseline

We use Mediapipe as the hand extractor to obtain the bounding boxes and skeletons of hands. Then, we use the hand skeleton to generate a hand mask. We train the hand bounding box, hand skeleton, and hand mask as benchmarks for improving sign language recognition accuracy.

According to the experimental results in Table III, the skeleton has the highest accuracy in the Top-1 ranking. Skeleton and Mask have the same accuracy in Top-3, and Mask has the highest accuracy in the Top-5 and Top-10 rankings. It can be found that Skeleton and Mask have their own advantages, while the accuracy of Bounding Box is relatively low. Therefore, we will use Skeleton and Mask for further improvement.

TABLE III
Single Feature Tests

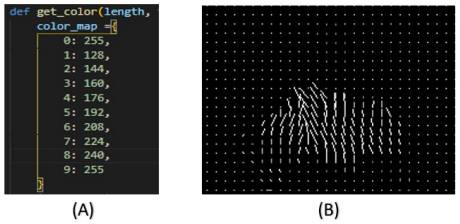
Data type	Top-1 Accuracy	Top-3 Accuracy	Top-5 Accuracy	Top-10 Accuracy
Bbox	62.40%	79.07%	83.72%	87.21%
Mask	70.54%	**84.88%**	**89.92%**	**93.41%**
Skeleton	**72.87%**	**84.88%**	89.15%	91.86%

C. Comparison with different input data

To ensure that hand movement information is preserved in each frame and to integrate the optical flows into the training data, we tried different inputs as shown in Table IV. Mask+Skeleton+Optical flow has the best performance among all the accuracy rates. We believe that the decrease in accuracy with Face landmarks is due to the lack of effective data augmentation for facial features. We will then enhance the features of different channels of Luminance of Mask + Skeleton + Optical Flow to improve the recognition accuracy.

D. Mask+Skeleton+Optical flow

Optical flow color adjustment



In sign-language videos, the more the hand moves, the longer the optical flow line is, as shown in Figure 9. We tried to differentiate the luminance value for different optical flow lines by giving a higher luminance value for longer optical flow lines and a lower luminance value for shorter optical flow lines. After examining the optical flows in the American Sign Language dataset, the lengths of most optical flows are lower than 10 pixels. In Experiment 1, we made minor adjustments. Selecting the luminance value from [128, 255] and assigning the values according to Figure 9.1 (A). The effect is shown in Figure 9.1(B). We wonder whether the adjustment is not large enough so similar results are observed. Therefore, Experiment 2 selects the luminance value from [16, 255] and assigns the values according to Figure 9.2 (A) The effect is shown in Figure 9.2 (B). Nevertheless, the accuracy dropped to 71.32%, which indicates that the difference in the optical flows was too large. We thought about keeping only the

TABLE IV
COMPARISON OF DIFFERENT DATA INPUTS

Data type	Top-1 Accuracy	Top-3 Accuracy	Top-5 Accuracy	Top-10 Accuracy
1.S+V+Optical flow	67.44%	82.95%	86.43%	90.31%
2.B+R+Optical flow	68.22%	85.66%	85.27%	91.47%
3.Mask+Skeleton+Optical flow	**74.81%**	**86.05%**	**87.21%**	**92.64%**
4.Mask+Skeleton+Optical flow+Face landmark	67.05%	79.84%	83.72%	88.37%

optical flow lines in the hand region and removing the points in the figure so that the model could focus on the hand region. The assignment of Experiment 3 is shown in Figure 9.3 (A), and the effect is shown in Figure 9.3 (B). The accuracy of Experiment 3 indicates that the dots were effective for sign language recognition. The results seem to show that adjusting the luminance value does not improve the accuracy. Therefore, the luminance value of the optical flow segment is maintained as a fixed value, 255, and the dots of the optical flow figure are retained in the following experiments.

(a) Different colors in joints (b) Same color of the finger

(c) Same fingertip of the hand (d) Brighter and darker hands

Fig. 10. Different skeleton adjustments.

Skeleton color adjustment

Based on the results of Table VI in different types of multi-color skeletons, we believe that adjusting the colors of the skeletons is quite helpful for sign language recognition. Therefore, as shown in Table VII, we conducted the experiments of color adjustment in skeletons for different hand regions, such as fingertips and fingers. The color configuration of Experiment 1 is shown in Figure 10(a). The left and right hands are in the same configuration. Each line of a skeleton and the joint are assigned a different color. The line's color is obtained by averaging the values in adjacent joints. The result of Experiment 1 shows that the accuracy is not always improved by assigning more colors. Figure 10(b) is the color configuration of Experiment 2. We reduced the number of colors. Giving different colors to the left and the right hands increases the recognizability. The model learns the finger-based features by assigning the same color to the same finger. The result of Experiment 2 indicates that the finger-based may be too coarse for the model to learn features. Figure 10(c) also shows that the model can learn the finger positions. Since the fingertips are the most common part of the palm, we dispatch the fingertips with the same color and configuration in Experiment 2. The result shows that our adjustment works correctly. The color configuration of Experiment 3 can improve the accuracy, so we further

TABLE VI
SKELETON COLOR ADJUSTMENT

Data type	Top-1 Accuracy	Top-3 Accuracy	Top-5 Accuracy	Top-10 Accuracy
1.Red line+Red joint	65.89%	82.56%	88.37%	90.31%
2.Red line+Green joint	69.38%	**85.27%**	88.37%	**92.64%**
3.Multi-Color skeleton	**72.87%**	84.88%	**89.15%**	91.86%

TABLE VII
SKELETON ADJUSTMENT EXPERIMENTS

Experiment	# of Colors	Adjustments	Left hand=Right hand	Line color	Top-1 accuracy
1	21	Different in every joint	v	(Sum of Adjacent Joint)/2	74.81%
2	L:7, R:7	2.1.Same color in the same finger 2.2.Right hand is brighter than left hand	x	Left:104, Right:152	74.03%
3	L:7, R:7	3.1.Same color in the same fingertip 3.2.Different colors between fingers	x	Left:104, Right:152	76.36%
4	L:7, R:7	Brighter left hand in Exp3.	x	Left:128, Right:152	**76.74%**

brightened the darker left hand in Experiment 4, as shown in Figure 10(d). Finally, we adjusted the skeleton color to achieve the best accuracy of 76.74%.

Mask shape adjustment

From the results shown in Table VIII, we select the color configuration with the highest accuracy and apply the skeleton adjustment strategy to change the shapes of the hand masks to reveal different pixels of the original hand to improve the robustness of the model. The results in Table VIII show that 79.84% accuracy can be achieved for the model trained with the hand mask generated by the skeleton adjustment strategy for the shrinking palm. In addition, we also validate our method on the larger dataset WLASL300. The results demonstrate the highest accuracy for the skeleton adjustment strategy of the shrinking palm.

TABLE VIII
MASK SHAPE ADJUSTMENT

Skeleton adjust policy	WLASL_100 Top-1 Accuracy	WLASL_300 Top-1 Accuracy
Move whole finger	74.42%	57.34%
Random noise	74.81%	60.48%
Finger noise	75.97%	60.63%
Shrink palm	**79.84%**	**61.08%**

E. Comparison with Other Models

Table IX shows that the accuracy of the proposed method is further improved in WLASL100 compared to the GCN-based, Transformer-based model. Similar improvement can be observed in WLASL300.

TABLE IX
COMPARISON WITH OTHER MODELS

Paper	Model	WLASL_100 Top-1 Accuracy	WLASL_300 Top-1 Accuracy
GCN-BERT	GCN	60.15%	42.18%
SPOTER	Transformer	63.18%	43.78%
WLASL	I3D	65.89%	56.14%
Ours	**3D ResNet**	**79.84%**	**61.08%**

V. CONCLUSION

We utilize Mediapipe to extract the hands and examine several data input combinations to see which combination demonstrates the best performance. We use the American sign language dataset to verify the usage of combining hand masks, hand skeletons, and optical flows, serving as the three channels of the input to the model. We have made different adjustments on each of the three channels, such as introducing the color weighting of the skeletons according to different parts of the hands and changing the shapes of the hand masks to reveal different hand pixels to increase the robustness of the model. Through careful data enhancement and training with a moderate 3D-ResNet model, we can achieve very good accuracy on WLASL100. For future work, we may consider combining multiple sign-language words to form a complete sign-language sentence by applying the proposed method and training with transformer-based models. GAN-related methods can simulate the lost skeletons when the hands move too fast. In addition, the virtual hands could be generated if the skeleton is used to generate more training data.

***Abstract*— Pruning and transfer learning are extensively applied in developing convolutional neural network algorithms, and at times, they are concurrently employed as part of the training model strategy. However, the existing literature has only focused on studying these techniques separately, with no research focusing on the interaction effect between the two technologies. Therefore, we designed several scenarios to test and explore this issue in different target tasks. The experimental results showed significant performance differences among various strategies employed for the same task.**

I. INTRODUCTION

Convolutional neural networks (CNNs) have achieved remarkable success in computer vision. In the design process of these algorithms, increasing the number of convolutional layers is a common approach to improve model performance. However, such design choices can result in challenges related to training model convergence as well as an increase in the number of parameters and computational demands, thereby making it more difficult for algorithm development and deployment. In addition, while most tasks have sufficient training data for model training, certain specific tasks still have limited training data. Model compression [1-5] and transfer learning [6, 7] are the commonly used techniques for addressing these two issues, respectively.

The performance of the model architecture can be improved by increasing its depth, but it may result in redundant parameters [8]. To address this issue, we can employ model compression techniques to simplify the model, thus reducing the required memory space and computational burden. Common methods include low-rank approximation [1, 2], knowledge distillation [3], compact network design [4], and pruning [5], among others. The low-rank approximation [1, 2] reduces the overall number of parameters and computations by decomposing the multiplication operation of two large matrices into multiple smaller matrices. Knowledge distillation [3] refers to the process of using a pre-trained complex network (teacher network) to assist in training a lightweight network (student network), thus reducing the model capacity while maintaining the performance of the teacher network. The compact network design [4] applies the design of lightweight network architectures that enable the model to have extremely low parameters and computational requirements while maintaining high performance. Pruning [5] aims to measure the importance of parameters in a model by designing selection criteria, removing relatively redundant parameters, transforming a dense network into a sparse one, and achieving model simplification.

Transfer learning is derived from the human ability to apply previously learned knowledge to unfamiliar tasks, enabling easier problem-solving and achieving better outcomes. This concept can leverage CNNs to improve convergence speed during model training and achieve better performance [7]. We can transfer the knowledge and features learned from the pre-trained model on the source task as prior knowledge to facilitate the training of the model for the target task.

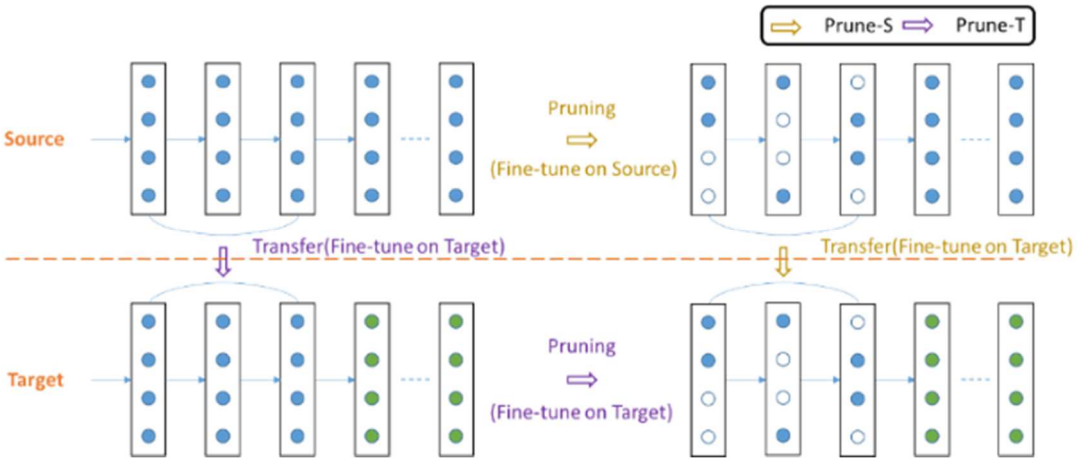

Fig. 1 The operational process of the Prune-S and Prune-T strategies.

Table 1 Integration of information from the source task and the target task.

Transfer Learning	Computer Vision Task	Abbrev.	Image (-centric)	Dataset	Architecture	# of Class	# of Training Data
Source Task	Classification	C	Object	ImageNet	VGG16 [9]	1,000	1.28 M
Target Task	Classification	C1	Object	Flowers-102	VGG16 [9]	102	6.5 k
	Classification	C2	Scene	Indoor-67	VGG16 [9]	67	5.5 k
	Detection	D	Object	Pascal VOC 2007	Faster R-CNN [10]	20	5 k
	Semantic Segmentation	S	Object	Pascal VOC 2012 + SBD	FCN [11]	20	10 k

Typically, we select the shallow convolutional layers of the model for transfer learning since they are responsible for learning distinct types of image features at different levels. Among them, the shallow convolutional layers can learn more general features, while the deep convolutional layers tend to focus on learning task-specific features. In addition to the mentioned advantages, transfer learning can also overcome the problem of insufficient training data [12]. The model can learn to analyze image content from a source task with large data. Then, this model is guided by a smaller amount of data from the target task to learn how to solve the problem of the target task.

Currently, in the development of CNN-based algorithms, it is common to employ not only model compression or transfer learning individually but also both techniques simultaneously. However, to the best of our knowledge, the existing literature predominantly focuses on the investigation of individual techniques, lacking an exploration of the simultaneous application of these two techniques. Therefore, the experiment was conducted with relevant experiments to serve as a reference for researchers in designing training model strategies.

We analyzed the impact of different model simplification strategies on model performance by adjusting three factors: the order of utilizing model compression and transfer learning techniques, the quantity of the target task dataset, and varying compression ratios of the model. During our analysis, we observed that not all model compression techniques could be effectively combined with transfer learning, and such as low-rank approximation, knowledge distillation, and compact network design may not be compatible with transfer learning. These methods require a redesign of the model architecture to simplify the model. As a result, the architectures used in these methods differ significantly from the model architecture of the source task, making the transfer infeasible. Therefore, to work with transfer learning, our experiments use the L1-norm filter structured pruning [5] to compress the model.

II. PROPOSED METHOD

We define the names of two pruning strategies: Prune-S (Prune-on-Source) and Prune-T (Prune-on-Target). Prune-S means pruning the model trained on the source task and fine-tuning it on the target task. Prune-T involves first transferring the model trained on the source task to the target task and then pruning it using the training data of the target task. The operational flow of both strategies is shown in Fig. 1, where the middle orange dashed line serves as a boundary separating the upper and lower sections, representing the source task and the target task individually.

For the selection of the source task, we opted for the commonly used image classification task (C) in transfer learning, along with the widely used VGG16 backbone [9] in classification task architectures. In the target task, we not only selected image classification tasks (C1, C2) similar to the source task but also used object detection (D) and semantic segmentation (S) tasks for evaluation. In selecting the datasets, we considered the image relevance between the source and target tasks to avoid negative transfer during transfer learning. This ensures that the chosen datasets are aligned to minimize any potential negative effects during transfer learning. We have presented detailed information on the source and target tasks in Table 1. Among them, Faster R-CNN [10] and FCN [11] are designed based on the VGG16 architecture. Therefore, we employ these two architectures for tasks D and S, respectively.

Table 2 The result of pruning the source task model

Dataset	Model (VGG-16)		Top-1	Top-5	# of Parameter			FLOPs		
					w/ FC	w/o FC	Times (↓)	w/ FC	w/o FC	Times (↓)
ImageNet	w/o Pruning		71.59	90.38	138.36 M	14.71 M	-	15.61 G	15.36 G	-
	Prune Ratio	25%	70.36	89.68	134.43 M	10.79 M	1.36	9.40 G	9.15 G	1.68
		50%	69.22	89.14	131.44 M	7.8 M	1.89	4.92 G	4.67 G	3.29

Table 3 Hyperparameter configuration for training the model

Hyper-parameters	Source Task	Target Task			
	C	C1	C2	D	S
Optimizer	SGD + momentum				
Weight decay	1e-4	1e-4	1e-4	5e-4	5e-4
Image resolution	224x224	224x224	224x224	Depend on data	Depend on data
Training epoch	-	45	75	22	40
Initial learning rate	-	1e-3	1e-3	1e-3	1e-10

Next, we will explain the data allocation for the target task. Since the limited availability of data for specific tasks compared to others, we simulate this situation by adjusting the amount of data used for the target task. In our experiment, we evaluate the impact of the amount of training data on the Prune-S and Prune-T strategies by using two different configurations, as shown in Fig. 2. First, we fine-tune the model parameters using the entire dataset (100%) of the target task. Second, we randomly select 10% of the data from the dataset and use it for fine-tuning. This allows us to assess the influence of the quantity of training data on the Prune-S and Prune-T strategies.

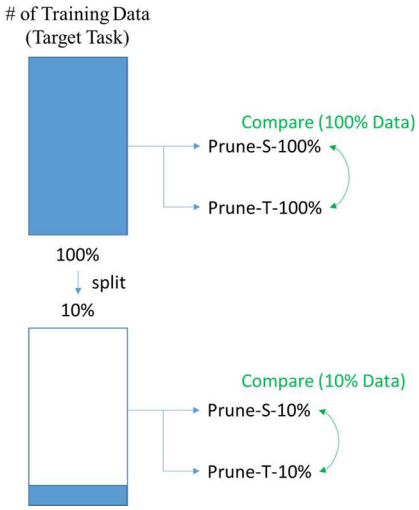

Fig. 2 Illustration of training data splitting.

The model pruning ratio also has a significant effect on the performance of the model. Hence, we will observe the situation when different pruning ratios are used. We applied 25% and 50% pruning ratios to compress the model for the source task, leading to retentions in model parameters by 75% and 50%, respectively. In the following sections, we refer to these as the low pruning ratio (25%) and high pruning ratio (50%). We specifically targeted the first 10 layers of the model for pruning and transfer. This decision was based on the following reasons: 1) As mentioned earlier, shallower convolutional layers tend to learn more generic features. 2) Zhang et al. [1] mention that the parameters in the shallower layers of VGG16 are relatively redundant, making pruning in these layers have a smaller impact on model performance. 3) More than 90% of the computational burden in VGG16 comes from the first 10 convolutional layers, indicating that pruning these layers would be more beneficial. Table 2 presents the results of the pruning on the source task. In Table 2, "w/ FC" indicates that the computed result includes the fully connected layer, while "w/o FC" indicates the exclusion of this layer.

III. Experiment Results

We conducted the experiments on hardware with a CPU Intel i7-7700K and a GPU NVIDIA 2080Ti. Table 3 shows the hyperparameters used during the training of our models, where the model parameters for the source task were obtained from PyTorch [13]. Both the Prune-S and Prune-T strategies were evaluated for the target tasks C1, C2, D, and S. The models were fine-tuned using 100% and 10% of the training data from the target task. Then, their performance was analyzed under different pruning ratios. In the evaluation of model performance, we used Top-n, mAP, and mIoU as the evaluation metrics for image classification (C), object detection (D), and semantic segmentation (S) tasks, respectively. The experimental results are shown in Table 4, which presents the accuracy differences obtained by subtracting the performance of the Prune-T from the Prune-S strategies.

The experimental results confirm that the Prune-S strategy outperforms Prune-T in most conditions, especially in the case of C2 and S, where it demonstrates a significant advantage over Prune-T. The experimental results confirm that the Prune-S strategy outperforms Prune-T in most conditions, especially in the case of C2 and S, where it demonstrates a significant advantage over Prune-T. We can notice that only target task D has better results for Prune-T at low pruning ratios.

We attribute this to the high pruning ratio in the Prune-S strategy, which results in the convolutional layers extracting more generic features which apply to all tasks. Therefore, Prune-S outperforms Prune-T in all cases of high pruning ratios. In contrast, the convolutional layer of the low pruning ratio model in the Prune-S strategy captures not only the general features but also the redundant ones for the target task. These redundant features have a negative impact on the training of the target task, resulting in better performance of Prune-T. When there is low object relevance between the source task and the target task, and a model with a low pruning ratio is employed, it is difficult to determine which strategy is superior for training the target task.

Table 4 The results of the accuracy difference between Prune-S and Prune-T on the target task.

# of Training Data	Prune Ratio	Low pruning ratio (25%)				High pruning ratio (50%)			
	Target Task	C1	C2	D	S	C1	C2	D	S
100%	Prune-S − Prune-T	0.09	0.1	−0.48	0.28	0.33	3.63	0.69	1.31
10%	Prune-S − Prune-T	0.73	0.8	−0.64	0.6	0.71	4.86	0.46	4.94

Finally, we will discuss the time required for model compression under the conditions of 100% data volume and a high pruning ratio. In our experiments, it takes 15 days to prune the model for the source task (C), 1.5 hours for the target tasks C1 and C2, and 1.5 days for the target tasks D and S. The significant difference in time cost is due to the iterative process involved in the pruning and compressing of the model. The algorithm iteratively identifies and removes the unimportant parameters in the model until the assigned pruning ratio is achieved. As a result, the size of the dataset used during the compression process will impact the time required to compress the model. While the compression time for the source task model is several times longer than target tasks, the compressed model can be transferred to other target tasks, reducing the development time for algorithms.

IV. CONCLUSIONS

This study explores the simultaneous application of transfer learning and pruning techniques in convolutional neural networks, aiming to investigate their combined impact on model simplification strategies. Following the analysis of experimental results, we recommend the combination of the Prune-S strategy and a high pruning ratio model because it is more suitable for application across various target tasks. Despite the model compression process for the source task in Prune-S requiring much more time compared to Prune-T, the advantage is that it only needs to be performed once and can be applied to other tasks. Furthermore, the compressed model allows for the development of algorithms with lower hardware requirements, effectively reducing the development time.

***Abstract*— Restoring damaged old photos to their original state can enhance the viewing and comprehension of the historical context and time period captured by these photos. Recent studies attempted to restore these photos using proposed methods, but the results often suffer from blurring and loss of details. Therefore, we propose a restoration model designed explicitly for damaged old photos in this paper. Furthermore, due to the limited quantity of damaged old photos compared to other task datasets, we employ data augmentation techniques to increase the quantity and diversity of training data for the restoration method. The experimental results demonstrate that our restoration method surpasses existing methods across various evaluation metrics and provides a satisfying viewing experience.**

I. INTRODUCTION

Old photos preserve scenes from the past, allowing future generations to reminisce about the lives and events of that time. Unfortunately, many photos preserved until today often suffer from damage such as creases, mold, and insect infestation due to poor storage. Removing these damages from the photos would significantly enhance their visual quality and make viewing more enjoyable.

The most straightforward restoration method is to infer the damaged content based on the intact portions and use appropriate tools to restore the photos accordingly. In the restoration process, besides directly repairing physical photographs, we can scan them into digital files and use digital editing software to modify damaged areas. Although this practice improves the viewing quality of the photos, the restoration results heavily rely on the prior knowledge of the operator, and the entire process can be time-consuming.

The advancement of deep learning has led to improvements in addressing this issue, as demonstrated in recent inpainting methods [1, 2]. These methods can generate missing image content by analyzing the manually annotated regions where content is missing and the surrounding image context. Liu et al. [1] proposed the partial convolution structure, which uses a mask of the input region to be restored, allowing the model to avoid referencing incorrect information during the image analysis. Yu et al. [2] designed gated convolution to analyze the features of each layer to generate the corresponding masks, allowing the model to preserve the semantic structure and details of the image while filling in the missing regions. Inpainting methods can produce results more quickly than manual restoration, but the process of manual annotation remains laborious and prone to errors.

To solve this problem, [3, 4] proposed restoration methods that only require the input of damaged images to obtain restored results. Wan et al. [3] designed a module to remove damaged features of the image in the latent space and obtained the results by converting restored features back to the image space. Although [3] can save significant time and labor costs, we also note that this method has limitations in identifying damages. It may mistakenly consider objects in the image as damaged areas and remove them.

In our previous research [4], we developed an automatic recovery system to address the shortcomings of existing methods. This system consists of a damage detection model and a restoration model. The damage detection model would identify the damaged areas in old damaged photos and then utilizes existing restoration methods to obtain the restored photo. Despite the effective damage detection achieved in [4], the restored regions using existing restoration models still suffer from blurriness and loss of detail. The reason is that these restoration methods are designed for modern images and thus cannot effectively analyze the content of old photos.

To obtain results with more details, we proposed a restoration method designed explicitly for damaged old photos and combined it with our previous research [4]. In the development process, we noticed that the limited quantity and diversity of old photos constrained the performance of the model. Therefore, we apply style transfer technology to transfer modern images into old-style images, thus increasing the amount of training data.

II. PROPOSED METHOD

The flowchart of the old photo recovery system is shown in Fig. 1. In the damage detection step, we use the detection model proposed in [4] to generate the damaged area mask, then combine it with the damaged image as inputs for restoration model, which predicts and generates the content of the damaged regions. Additionally, before training the restoration model, we employ our designed data augmentation model to generate many old-style images, expanding the training data for the restoration model.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

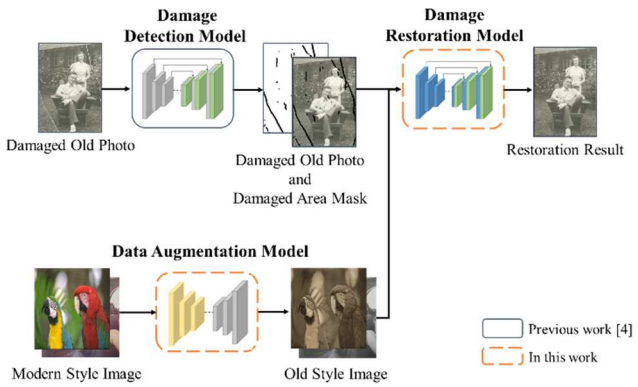

Fig. 1 Flowchart of our old photo recovery system

A. *Damaged Restoration Model*

Our restoration model is based on generative adversarial networks (GANs), as shown in Fig. 2. The adversarial learning between the generator and the discriminator is employed to enhance the realism of the restoration results. We adopt U-Net [5] as the generator backbone architecture because it effectively handles the details of the image. Instead of the standard convolutional blocks in U-Net, we replace them with a combination of Residual Dense Blocks (RDB) [6] and Partial Convolution (PConv) [1] to improve the capability of analyzing damages. RDB allows the model to retain more information from shallow features and accurately predicts the content of the damaged regions by fusing these features. In addition, dense connections and residual learning improve the convergence speed and stability of the deep network. The formula for the partial convolution is written in Eq.(1). The concept is to exploit masks to aid in model restoration, where x' means output feature, W and b represent the weight and bias of the convolution filter, X represents pixel values or feature values at the location of the current convolution filter, M denotes the corresponding binary mask, $sum(1)$ and $sum(M)$ indicate the number of valid pixels and the number of the total pixels in the convolution window, and $\odot$ denotes the element-wise product. The mask needs to be updated while restoring, and the method for the updated mask m' is shown in Eq. (2) which means the center of the convolution window sets to a valid pixel as long as the within region of the convolution window has a valid pixel.

$$x' = \begin{cases} W^T(X \odot M)\dfrac{sum(1)}{sum(M)} + b, & if\ sum(M) > 0 \\ 0, & otherwise \end{cases} \quad (1)$$

$$m' = \begin{cases} 1, if\ sum(M) > 0 \\ 0, \quad otherwise \end{cases} \quad (2)$$

We adopt the Patch-GAN [7] as discriminator. Unlike typical discriminators of GAN that judge the realism of an entire image, Patch-GAN divides the image into multiple N×N patches and evaluates the realism of each patch. This design allows for effectively identifying inconsistencies in different regions of the generated images, improving the image quality produced by the generator.

B. *Data Augmentation Model*

To expand the training data for our model, we designed a data augmentation model based on the architecture of Cycle-GAN [8], as shown in Fig. 3. We used it to learn how to transform images in a modern style into the style of old photos, thus generating old-style images with diverse contents.

Compared to other style transfer network [7], Cycle-GAN does not require paired image datasets for training, which reduces the difficulty of data collection and model training in this case. To enhance the ability of model to perform style transfer, we replaced the transposed convolution used in the original Cycle-GAN with sub-pixel convolution [9]. This substitution helps to avoid generating images with noise or checkerboard artifacts. Sub-pixel convolution rearranges deep features to generate high-resolution features, improving the level of detail in the generated images.

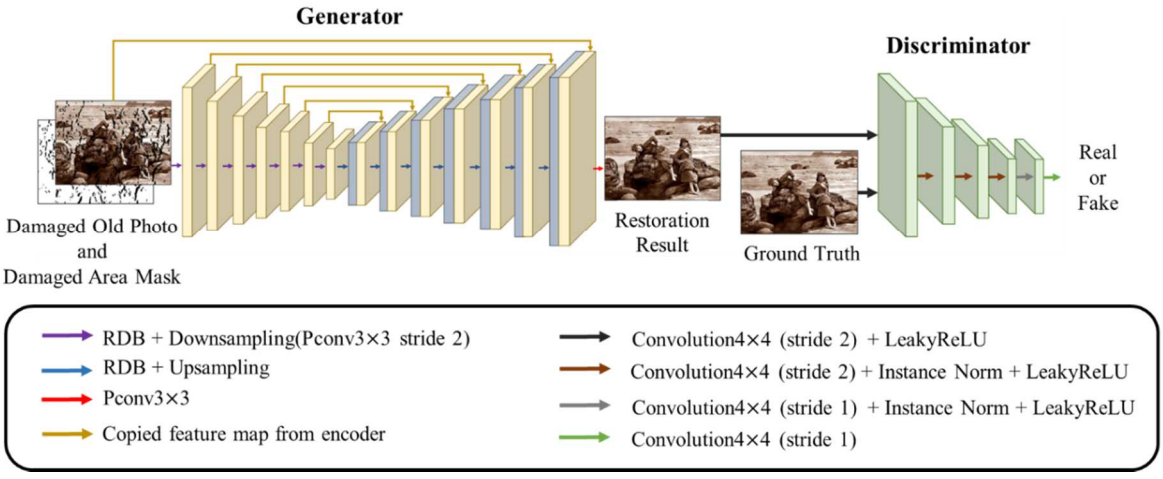

Fig. 2 Architecture of the image restoration model

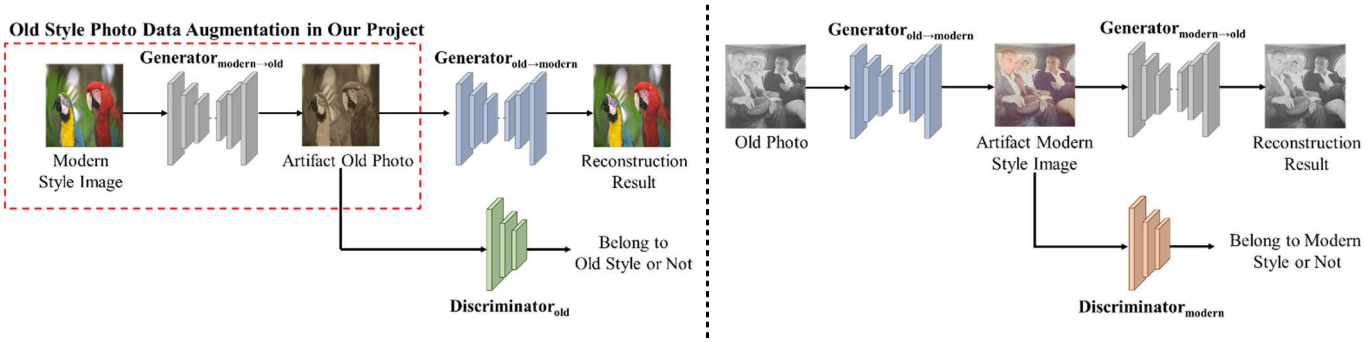

Fig. 3 Architecture of the data augmentation model

We collected modern-style images as our training dataset for the training style transfer model. These images were used separately as the input and target style datasets for the data augmentation model. Specifically, within the target style dataset, we divided the images into two subsets: yellowish style and monochromatic style. We trained the corresponding data augmentation models using these two subsets. This approach was adopted to avoid interference between the two styles and to prevent the generated results from containing both color tones simultaneously.

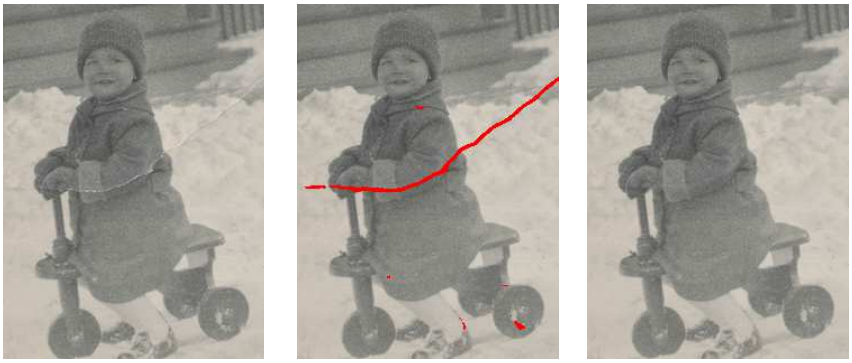
The Eq. (3) presents the loss function $L_{restoration}$ for our restoration model, which consists of six terms. The valid loss L_{valid} and hole loss L_{hole} are employed to measure the differences between the restored image and the ground truth image in the non-damaged and damaged regions, respectively. The perceptual loss $L_{perceptual}$ compares the feature differences between the transformed images in the feature domain. The style loss. L_{style} evaluates the similarity of styles between images in the feature space. The variation loss L_{tv} is used to assess the smoothness of the boundaries between the damaged and non-damaged regions to ensure seamless blending. The adversarial loss L_{GAN} is employed for the discriminator to determine the authenticity of the generated content. Parameters for each loss term in $L_{restoration}$ are set based on the reference [1].

$$L_{restoration} = L_{valid} + 6L_{hole} + 0.05L_{perceptual} + 120L_{style} + 0.1L_{tv} + 0.01L_{GAN} \quad (3)$$

We utilize Eq. (4) as the loss function, denoted as $L_{transfer}$, for training the two data augmentation models. This loss function consists of an adversarial loss L_{GAN} and a cycle consistency loss L_{cyc}. The cycle consistency loss L_{cyc} ensures that the stylized images preserve the content from the input images. The adversarial loss L_{GAN} helps improve the realism of the stylized images after the style transfer process.

$$L_{transfer} = 10L_{cyc} + L_{GAN} \quad (4)$$

III. Experiment Result



Our experiments were conducted on hardware consisting of a CPU E5-2698 and a GPU TESLA V100. We used four widely used metrics, namely PSNR, SSIM, LPIPS [10], and FID [11], to evaluate the performance of restoration system. Higher values for the first two metrics indicate better results, while lower values for the latter two metrics indicate better results. We obtained synthesized damaged old photos in the same manner as the training process to create a testing dataset for evaluating the restoration method.

Table I presents the results of our method compared to [1-3]. It can be seen that our restoration method outperforms other methods in all metrics, and the performance is further improved with the addition of data augmentation. Furthermore, it is notable that Wan et al. [3] show significant differences in the evaluation results compared to other methods. This is because their approach modifies the undamaged regions during the restoration process, resulting in a substantial discrepancy between the generated images and the ground truth.

Table I Comparison of restoration results

Method	PSNR↑	SSIM↑	LPIPS↓	FID↓
Liu et al. [1]	40.35	0.98	0.0102	6.97
Yu et al. [2]	38.25	0.98	0.0678	19.24
Wan et al. [3]	22.30	0.72	0.173	80.22
Our method w/o DA	41.66	0.99	0.0066	4.54
Our method w/ DA	**41.78**	**0.99**	**0.0063**	**4.40**

We show the restored results of different models applied to real damaged old photos in Fig. 4 and Fig. 5. Since there is no corresponding ground truth available for real damaged old photos, we relied on subjective evaluations to evaluate restoration results. In Fig. 4, our method can effectively restore the damage on the sleeve, while restored content of other methods appears more blurry.

Fig. 4 The restored result of different models applied to real monochromatic style damaged old photo

(a) Damaged old photo (b) Damage detection (c) Our method

(d) Liu et al. [1] (e) Yu et al. [2] (f) Wan et al. [3]

Fig. 5 The restored result of different models applied to real yellowish style damaged old photo

Fig. 5 shows the results of restoration methods applied to a yellowish-style photo. The content restoration applied to the shoulder area in [2] is significantly inconsistent with the surrounding regions. Wan et al. [3] causes the hand of the baby to appear blurry and indistinguishable, and adjusted the overall tone of the image. In contrast, our method does not have these problems. Overall, our method can distinguish between the damaged patterns and the objects, allowing the restoration method to predict more accurate restoring content that closely resembles the original image texture.

IV. CONCLUSIONS

We proposed a damaged old photo restoration model based on generative adversarial networks (GANs). We combine residual dense blocks and partial convolution to enhance the restoration effect on the details of the damaged areas. In the data augmentation method, we optimize the architecture of Cycle-GAN to generate various old-style images to increase the training data and then improve the generalization capability of the model. In the experiments, we demonstrated that our restoration method produces better image quality and viewing quality than other methods when applied to damaged old photos.

Abstract — **Climate change greatly affects human life. According to previous studies, the biggest cause of climate change is the increase of greenhouse gases in the atmosphere. In order to effectively reduce carbon emissions, many countries not only formulate many carbon reduction policies, but also focus on developing green energy. Green energy, e.g., solar energy and wind energy, is a solution to reduce carbon emission; however, it is difficult for green electricity to provide stable energy supply due to climate factors. In this paper, we proposed a long short-term memory (LSTM) deep learning model based sustainable energy scheduling system to control the energy usage between green power and utility power. The proposed system analyzes the data of green power generation and weather conditions, and based on the weather forecast and the results calculated by this system, predicts the power generation status of solar and wind energy in the next few days. According to the experimental results, by using the proposed system, the goals of stable power supply and minimization of carbon emissions from energy consumption can be achieved.**

I. INTRODUCTION

In recent years, the issue of global warming has led to a surge in severe weather conditions, consequently driving up electricity consumption. To minimize the environmental repercussions of energy usage, many countries tried to provide various sustainable solutions, with a particular focus on green energy sources, including hydropower, solar energy, wind energy, biomass energy, geothermal energy, etc. According to the estimations of the International Energy Agency (IEA), by the year 2050, green energy can potentially contribute to more than 70% of the world's electricity supply [1]. Several countries have already pledged to achieve zero carbon emissions, emphasizing their commitment to reducing carbon footprints and transitioning away from fossil fuels towards 100% renewable energy.

Even though solar energy and wind power are two main sources of green energy, the intermittent nature of solar and wind power poses a challenge in maintaining a consistent power supply due to climate variability. To maximize the generation of green electricity, numerous wind-solar hybrid systems have been proposed [2-4]. Several wind-solar hybrid products are also available in the market that incorporate energy storage batteries. These innovative solutions, e.g., street lamps and small power supplies, have been designed and implemented to harness the combined potential of wind and solar energy. By integrating different technologies, the hybrid systems can optimize energy production and storage, providing a reliable and sustainable source of electricity.

The objective of this study is to reduce the impact of climate-related variables on the stability of green power supply. To address this issue, in this paper, a deep learning based sustainable energy scheduling method is proposed. The proposed method involves the integration and analysis of solar and wind power generation data in conjunction with diverse weather patterns. The collected data is then visualized and utilized in a long short-term memory (LSTM) forecasting model. By using deep learning techniques, the model compares various weather patterns, the predicted electricity outputs, and actual monitored electricity data to predict the power generation status of solar and wind energy in the next few days.

The experimental results demonstrate the effectiveness of the proposed method in controlling the storage capacity of green power. By accurately forecasting power generation, the method enables the optimized utilization of green power resources, even during adverse weather conditions, so as to enhance the overall efficiency and reliability of green power systems.

II. RELATED STUDIES

Various studies [5-10] have been conducted to enhance the effective utilization of green energy. Chen *et al*. [5] conducted a comprehensive review focusing on the application of electric power in wind energy systems. They examined different types

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

of wind turbines, highlighting variations in performance and controllability. Among these, the SCIG (Squirrel Cage Induction Generator) incorporating the VSC-HVDC (Voltage Source Converter-High Voltage Direct Current) concept demonstrated remarkable adaptability to grid faults. Wang *et al*. [6] addressed the fan configuration of wind farms in their research. As wind passes through the turbines, the blades absorb the wind's kinetic energy, inducing turbulence and reducing wind speed, which is known as the wake effect. Wang's paper introduced a novel non-linear wake expansion model suitable for flat or slightly undulating terrains and offshore wind farms. Additionally, the model incorporated cost-benefit calculations to determine the most economically efficient arrangement of wind turbines in a wind power field.

Bukala *et al*. [7] addressed the issue of small wind turbines, primarily catering to individuals and small-scale users. They recognized that wind turbine sellers often fail to provide customers with crucial performance data, including environmental parameters, technical specifications, and power output. Consequently, their objective was to develop a concise framework capable of describing the factors influencing wind turbines. Touafek *et al*. [8] focused on enhancing solar radiation power through solar energy concentration. The efficiency of the concentrator relied on the radiation concentration and the temperature difference between the absorber and the surrounding air, where the latter contributes to inevitable heat loss. This heat loss directly impacted the overall efficiency, necessitating further investigation into materials that can minimize it. Their study introduced a novel approach by employing two reflectors on a hybrid PhotoVoltaic Thermal (PVT) collector to concentrate solar energy and improve production efficiency.

Bedreddine *et al*. [9] conducted research on parabolic solar panel concentrators, aiming to achieve a focal point temperature of 400 degrees Celsius. They identified various parameters and validated their findings by assessing the performance of zinc oxide thin film batteries at different temperatures. Compared to traditional methods, their approach demonstrated higher safety and efficiency in converting green energy. Reza [10] developed a solar tracking system utilizing Arduino as a development board. This system continuously monitored the sun's position and adjusted the solar panel accordingly to optimal conversion efficiency. Implementing a single-axis solar tracking system on a 10W solar panel resulted in an average power increase of approximately 1W per hour. Furthermore, when applied to a 100W battery, the power output improved by up to 80W.

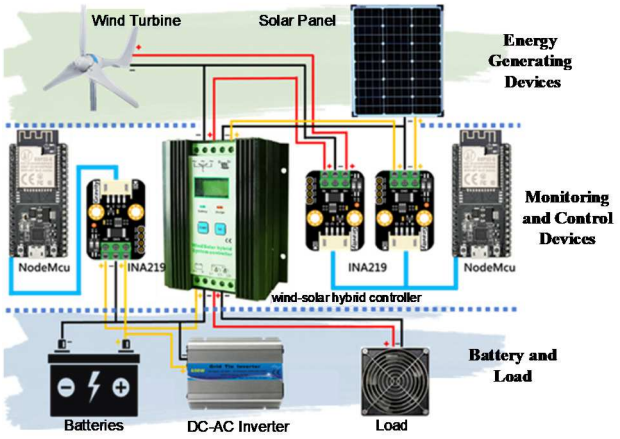

Fig. 1 System Architecture of proposed wind-solar hybrid system.

While the aforementioned papers presented promising solutions, there is still room for improvement in maximizing the efficiency of green energy utilization, particularly in light of climate-related challenges. Therefore, the primary focus of this paper is to introduce a method aimed at optimizing the efficiency of green energy usage.

III. WIND-SOLAR HYBRID SYSTEM ARCHITECTURE

The system architecture, shown in Fig. 1, comprises three main levels: the energy generating devices, the monitoring and control devices, and the storage and load end. At the production side, solar panels and wind turbines are employed to generate electricity. The monitoring and control side facilitates the combination of wind and solar power and ensures the battery is charged without the risk of overcharging. This is achieved through the utilization of voltage and current sensors, which collect data. The collected information is then transmitted to a computer via Wi-Fi using the NodeMCU platform. The data, including voltage, current, and power, is transmitted using the MQTT protocol and Python is employed to connect to the MQTT Broker for data acquisition. Simultaneously, a database is generated to facilitate research and analysis. The storage and load end encompass key components such as batteries, DC-AC inverters, and fan loads. Monitoring between the battery and the wind-solar hybrid is conducted using INA219 voltage and current sensors. These sensors provide insights into the voltage and power status of the battery. The subsequent sections provide a detailed description of each system component.

A. Energy Generating Device

In terms of energy collection, this paper utilizes two components.

(1) Wind Turbine: The energy collection system incorporates a set of 100W five-blade wind generators. These

generators operate based on the principle of converting wind power into electrical energy. The rotation of the five blades is driven by the force of the wind, and the wind turbine head facilitates the conversion of wind energy into electrical energy. To optimize energy generation, the empennage is designed to adjust the wind turbine's direction according to the prevailing wind direction.

(2) Small Monocrystalline Silicon Solar Panel: The energy collection system incorporates a 50W solar panel, specifically utilizing monocrystalline silicon technology. Solar panels can be classified into different types based on the materials and manufacturing methods employed, including silicon, compound, and organic semiconductor types. Among these, silicon-based panels are the most commonly used. Polysilicon panels are cost-effective due to their simpler manufacturing process, but they exhibit lower conversion efficiency. On the other hand, monocrystalline silicon panels offer higher power generation efficiency (>20% module efficiency) and longer lifespan due to the higher purity of the silicon element used.

It is worth noting that the temperature has a notable influence on the efficiency of solar power generation. Lower temperatures lead to slower current drop rates, resulting in more stable current output compared to high temperatures. With increasing temperature, the output voltage and maximum power of the solar cell decrease. Consequently, it becomes necessary to monitor the actual power generated by the solar cells under varying conditions. Weather data is recorded as sample data, allowing for a comparison between weather types and their respective impact on power generation. This analysis aims to determine the degree of correlation between weather conditions and the power generated by the solar cells in different environments.

B. Monitoring and Control Devices

The monitoring and control end of the system encompasses a wind-solar hybrid controller and power sensors. The wind-solar hybrid controller performs the crucial tasks of transmitting and storing power generated by both wind turbines and solar energy sources. It effectively manages and balances the power generation status of both sources to achieve a synergistic and efficient power storage effect. This controller is designed to automatically adjust the power generation operations of the wind turbines and solar energy systems.

During daylight hours, power is generated simultaneously by both solar energy and wind turbines. Conversely, during nighttime hours, only wind turbines generate electricity, as solar energy is limited to daytime generation. The wind-solar hybrid controller optimizes the utilization of both energy sources, ensuring a continuous and balanced power supply while maximizing energy storage capabilities.

C. Battery and Load

One of the batteries used in the proposed system is the Yuasa REC22-12, which is a 12V/22Ah battery. This battery is specifically designed for uninterruptible power supply (UPS) systems. It exhibits exceptional recovery performance after deep discharge and demonstrates an ultra-low self-discharge rate. The maximum charging current for this battery is 5.5A.

The charge-discharge rate of a battery is defined as the ratio of the current during charging or discharging to the rated capacity of the battery. It represents the speed at which the battery can be charged or discharged. This rate is commonly denoted by "C" and is expressed in units of time. For example, a 1C discharge signifies that the battery is discharged in one hour, while a discharge rate of 0.2C indicates that the battery is discharged over a period of five hours. The charge-discharge rate is calculated using formula (1), where I represents the charge-discharge current, Cap represents the rated capacity of the battery, and C_{Rate} represents the charge-discharge rate.

$$C_{Rate} = \frac{I}{Cap} \tag{1}$$

The load side of the system comprises a DC-AC converter and a fan. The DC-AC converter is responsible for converting the DC power generated by the battery into AC power, producing an analog sine wave. This converter is designed to ensure compatibility with connected devices, such as motors, without causing any damage to their components. By directly connecting the devices to the battery, uninterrupted power supply requirements are met, guaranteeing a continuous power source. This requirement is also extended to the NodeMCU, which requires a stable voltage supply for real-time data transmission and updates.

D. Energy Collection and Monitoring Methods

In order to maximize the role of green electricity and ensure a stable power supply, we have developed a sustainable energy utilization and deployment system based on a hybrid of wind and solar power. Fig. 2 provides an actual layout diagram. The system's production capacity encompasses both solar energy and wind energy, with an energy storage battery being charged through a wind-solar hybrid controller.

The wind-solar hybridization offers several advantages. During periods when there is no wind but ample sunlight during the day, the solar panels take charge of power supply and also recharge the energy storage battery. Conversely, the solar panels are inactive at night. In the presence of wind, the power generation is facilitated by wind energy. However, if

Fig. 2 Implement of the proposed system.

there is insufficient wind or no wind at all, the energy storage batteries serve as a backup power source. Furthermore, our system is capable of monitoring weather conditions during the deployment of wind and solar energy. By integrating weather data with algorithms, it can assess weather patterns and optimize power generation accordingly.

The key functionalities of the proposed system include:

(a) Energy Use and Conversion: Our system optimizes the deployment of solar energy by utilizing wind and solar complementarity. This ensures efficient conversion of solar energy into electrical energy, which is then stored for later use. By improving the energy conversion efficiency, the energy of the system is optimized.

(b) Research and Analysis of Electricity Storage and Discharge: To facilitate effective management of electricity storage, we record the hourly electricity storage status and conduct detailed analysis. This analysis incorporates various weather factors such as weather conditions and wind strength. By considering these factors, we can accurately predict the usage of electric energy and make informed decisions regarding its discharge.

(c) Data Monitoring and Transmission: For comprehensive monitoring, we employ the NodeMCU system equipped with the INA219 sensor. This combination allows us to monitor voltage, current, and power parameters. Additionally, we incorporate the MQTT transmission protocol to facilitate efficient and organized data transmission. The monitored data, including voltage, current, and power information, is transmitted every 10 seconds via wireless transmission to a server for storage. The server then generates a data file containing essential information such as voltage and current, enabling further analysis, calculations, and recording of power storage data and weather conditions. Table 1 lists the monitored battery voltage, current, and power.

E. Weather Pattern

Web crawling, an automated process of extracting data from webpages, was employed in this study using the Spyder (Anaconda2) Python programming language. The weather data utilized in this research was obtained from the weather.com website. The crawler program was developed to retrieve weather-related information from the Weather.com webpage and store it in an Excel file format. The extracted data encompasses various parameters including forecast time, temperature, rainfall, UV index, cloud cover, and more. Subsequently, this data was analyzed and visualized to enhance the weather forecasting program.

F. Long Short-Term Memory Model

The LSTM (Long Short-Term Memory) model which is a recurrent neural network (RNN), aimed to deal with the vanishing gradient problem, is a valuable approach for data analysis and forecasting, particularly when examining the correlation between historical data and predicted future data. It is applicable to classification, processing and predicting data based on time series. It leverages the concept of time series analysis to address the irregularity inherent in monitoring systems influenced by varying weather conditions on a daily basis. A common LSTM unit is composed of a cell, an input gate, an output gate and a forget gate. The cell remembers values over arbitrary time intervals and the three gates regulate the flow of information into and out of the cell.

With different weather patterns corresponding to each time point, the complexity of the problem requires a more advanced approach like time series analysis. By considering the sequential nature of the data, the LSTM model used in the proposed system captures temporal dependencies and patterns that may exist within the dataset, including the sensed voltage data, current data, power data, and weather data. This enables more accurate predictions and a deeper understanding of the relationship between past observations and future outcomes.

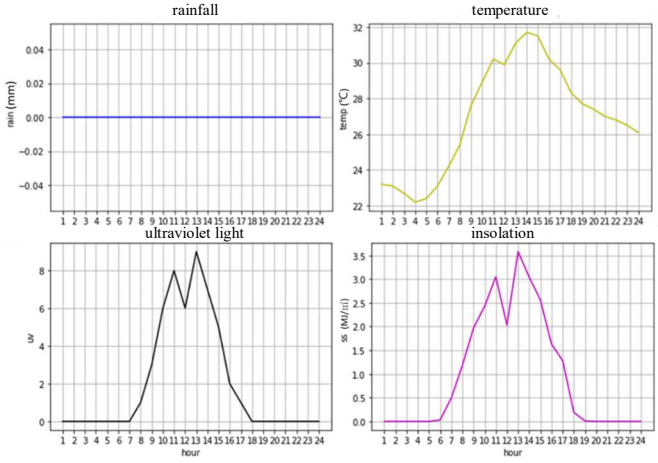

Fig. 3 Weather patterns observed on 2022/04/22.

IV. Experimental Results

A. Weather Patterns

To investigate the impact of weather patterns on the system, this study utilized web crawlers to extract weather pattern data. Fig. 3 displays the weather patterns observed on 2022/04/22. The figure provides the following insights:

(a) The weather conditions were sunny, with no recorded rainfall.

(b) The average temperature exhibited its highest values between 13:00 and 16:00, peaking at 14:00.

(c) Ultraviolet (UV) radiation levels were highest around 13:00 and 14:00, reaching approximately UVI 8.7.

(d) Insolation, which represents the intensity of sunlight, reached its peak at 13:00.

These observations contribute to understanding the specific weather conditions on the mentioned day and their potential impact on the system under study.

B. Solar and Wind Power Generation

Based on the monitoring data, the solar generator's power generation is limited to the time frame from 6:00 am to 6:00 pm. Outside of this period, no power is generated. During unfavorable weather conditions such as cloudy or rainy weather, the voltage, power, and battery voltage decrease noticeably. Using the data from April 22, 2022, as an example, Fig. 4 illustrates the voltage, current, and power curves generated by the solar power system on 2022/04/22.

Upon observing Fig. 4, it is apparent that the voltage begins to rise as it approaches 5 o'clock, indicating the nearing of sunrise. At 6 o'clock, the current and power start to gradually increase, signifying the initiation of the charging process. By around 10 o'clock in the morning, the current and power reach their peak, indicating the highest level of power generation during that day.

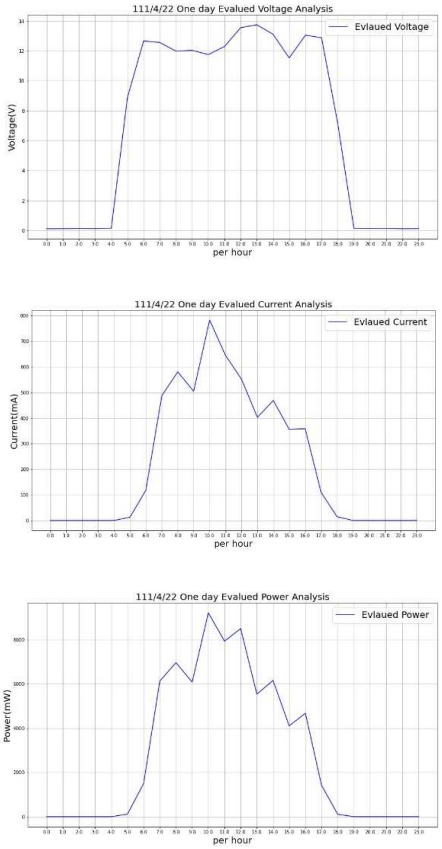

Fig. 4 Voltage, current, and power curves generated by the solar power system on 2022/04/22.

Typically, the voltage tends to stabilize at a certain value, primarily due to limitations imposed by the battery voltage. The current and power, on the other hand, are influenced by the wind-solar hybrid controller to prevent battery overcharging. Consequently, the protection system is activated to maintain optimal operation.

Due to the seasonal and weather-related variability, the power generation status of wind power is relatively unstable. Fig. 5 provides an overview of the wind speed recorded from 2022/04/22 to 2022/04/26. From the figure, it is evident that the wind speed remained relatively low during these five days. Consequently, the corresponding power generation was insufficient to meet the battery charging requirements. This highlights the dependence of wind power generation on favorable wind conditions, which can impact its reliability as a consistent power source.

C. LSTM Prediction

In order to provide comprehensive predictions, training, and comparison of monitored values, we have employed the LSTM prediction model. This model allows us to make accurate forecasts and assess the performance of the system. In

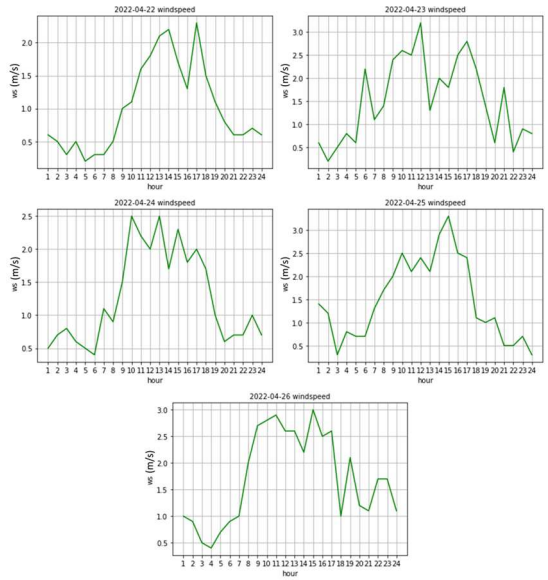

Fig. 5 Wind speed recorded from 2022/04/22 to 2022/04/26.

the generated figures, the blue line represents the actual monitored values, while the red line represents the predicted values.

Fig. 6 illustrates the monitoring data and corresponding forecast for a single day, whereas Fig. 7 displays the monitoring and forecast results for a period of six days. Upon observation, it is evident that the multi-day forecast results align more closely with the actual power generation values. This indicates the effectiveness of the LSTM prediction model in capturing the underlying patterns and trends within the data, leading to improved predictive accuracy and reliability.

D. Discussion

To summarize the above, we utilized the LSTM forecasting model algorithm by incorporating the monitored voltage, current, power, and weather patterns. By feeding the corresponding weather patterns into the LSTM forecasting model algorithm, we observed a certain degree of correlation between the predicted and actual values. Analyzing the resulting curves, we have identified the following findings:

(a) Integral data analysis: We conducted an analysis of the area under the two curves and the time axis. By averaging the differences between the predicted values at each time point, we obtained a value A. Similarly, by averaging the predicted values in the same manner, we obtained a value B. Taking the absolute difference between these two values, we obtained a value of 0.007337. A smaller value indicates a smaller data error and higher reliability.

(b) Analysis of correlation coefficient: The correlation coefficient is used to measure the degree of correlation between two variables, X and Y. Its value ranges from -1 to 1. This coefficient is commonly employed to assess the linear dependence between variables. In our analysis, we calculated the correlation coefficients for voltage, current, and power. The voltage correlation coefficient was found to be 0.7644, the current correlation coefficient was 0.8057, and the power correlation coefficient was 0.8341. These results indicate a high degree of correlation between the predicted and monitored values.

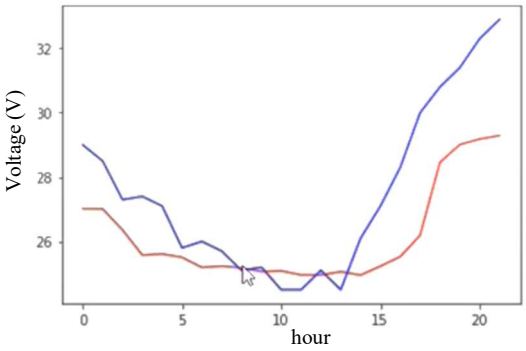

Fig. 6 Monitoring data and corresponding forecast for a single day.

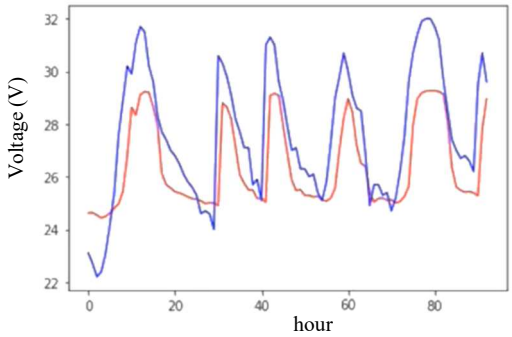

Fig. 7 Monitoring and forecast results for a period of six days.

(c) Analysis of mean square error (MSE): The MSE is a commonly used loss function for regression tasks. It quantifies the deviation between observed and true values. The MSE is calculated as the sum of squared differences between predicted and monitored values. In our analysis, the MSE value between the predicted and monitored values was calculated as 13.267, reflecting the overall deviation between the two sets of values.

Based on the data analysis, it is evident that the power generation of solar energy is significantly influenced by various weather patterns, including cloud cover, ultraviolet rays, temperature, and sunshine hours. By incorporating these impact factors into our linear prediction algorithm, we can establish a strong relationship between weather patterns and power generation. The aforementioned analysis also highlights the credibility of our prediction values.

Similarly, for wind energy, we consider two key weather parameters: wind direction and wind speed. The wind speed

must meet or exceed the minimum startup wind speed of the wind turbine (typically around 5 m/s) to ensure effective power generation. By considering these factors, we can assess the feasibility and potential output of wind energy generation.

Overall, the analysis underscores the importance of considering weather conditions and their impact on power generation when forecasting and optimizing renewable energy systems.

V. CONCLUSION

In this paper, we propose a Deep Learning-based Sustainable Energy Scheduling System that aims to optimize the utilization of green power by leveraging the relationship between solar and wind power generation and weather patterns. Our research focuses on establishing the correlation between green power generation and weather patterns through the collection and analysis of power generation data. To achieve this, we employ a data integration and visualization approach, followed by the utilization of the LSTM forecasting model. By comparing weather patterns, we obtain predicted electricity values and assess their correlation with the actual monitored electricity. Additionally, we utilize weather forecasts to estimate power generation in the coming days, further enhancing the forecasting capabilities of our model.

The experimental results demonstrate the clarity and feasibility of the proposed method. Moving forward, our future work will involve incorporating remote monitoring data and incorporating additional factors that influence green power generation. By developing a more comprehensive model, we aim to enhance the value and effectiveness of sustainable energy optimization. Overall, this paper presents a novel approach to sustainable energy scheduling, leveraging deep learning techniques and the analysis of weather patterns. The findings highlight the potential for maximizing the utilization of green power and pave the way for future research in this area.

***Abstract*—Direct position determination (DPD) technique has been shown its appealing to emitter localization thanks to high estimation accuracy. Motivated by the practical applications, this paper proposed a computational efficient DPD approach using the multiple signal classification (MUSIC) formulation. Whereas, the proposed approach calculates the signal and the noise subspace using the multi-stage Wiener filter (MSWF) without employing the hardware-consuming eigen-decomposition. Hence, the proposed MSWF-DPD can be cheap equipment friendly. And we verify the performance loss is small through the simulations in the end of this paper.**

I. Introduction

Passive localization of emitter has found its significant in various applications, including wireless communication, unmanned aerial vehicle surveillance, Internet of things (IoT) networks [1], [2]. Now days, these techniques can be easily achieved by software defined radio (SDR) equipment. And this may accelerate the development of other possible IoT applications thanks to the cheap price.

The localization approaches are two-folder formulated. The classical approach relies on the well studied two-step notations. At the first step, some intermediate parameters, such as angle of arrival [3], time of arrival [4], Doppler frequency shift [5] and/or signal strength [6], are estimated from the emitter. While at the second step, these intermediate parameters are used to formulate the non-linear equations according to the geometric. The locations are then estimated through solving these non-linear equations. However, these methods are sub-optimal, since the formulation of non-linear equation to a transform linear equation requires some approximation and will introduce a bias to the estimation [4]. Meanwhile, the intermediate parameters are estimated independently without considering the constraint that all the observations relate to the same emitter location [7].

Fortunately, the notation of Direct Position Determination (DPD) approach was firstly proposed in [8], and enables one to achieve the location estimation goal in a single step. Different from the two-step approaches, DPD based approach can directly obtain the location estimation according to the cost function formulated by the radio frequency received signals (sometimes down-converted to the intermediate frequency). By this mean, the estimation error cased by intermediate measurements can be avoided. It is readily shown in [8] that the DPD approaches have a better estimation performance comparing classical two-step counterpart, especially in low signal to noise ratio (SNR) regime.

In fact, the DPD approaches can be directly determined by the maximum likelihood (ML) criteria, which is equivalent to relate the location estimation to the minimized negative log-likelihood function (LLF) While this naive DPD approach has been extensively studied, it fails to work for the multiple emitter regime. On the contrary, spectral based DPD approaches are derived using the eigen-structure of the second-order statistic. So that the eigenvalues with greater values corresponds to the signal subspace while the remaining corresponds to the noise subspace. We can also calculate the expanded steering vector considering the topology of the receivers. Hence, it allows us to estimate the location of the emitter the same manner as the multiple signal classification (MUSIC) used for AOA estimation [9], [10].

Unfortunately, the computational burden of DPD approaches, especially demanded by eigen-decomposition, prohibits us from using this high-precious method. Besides, the eigen-decomposition also consumes vast of hardware resources. Therefore, a low computational complexity approach with slight performance degradation will be more preferable.

In the paper, we develop a new localization approach inherent the improved MUSIC formulation [11]. While the proposed approach can be both computational simple and robust. To achieve this goal, we employ the well-studied multistage orthogonal projection employed in the multi-stage Wiener filter (MSWF) [12] to calculate signal and noise subspace, rather than employing the eigenvectors of the covariance matrix. Finally, a grid searching is employed to yield the localization of the emitter. The computer simulations are conducted to show the feasibility of proposed MSWF-DPD approach.

$Notations$: Throughout this paper, functions/scalars, vectors and matrices are written in lightfaced lowercase, boldfaced lowercase and boldfaced uppercase letters. $\mathrm{j} = \sqrt{-1}$ represents the unit complex. c is a constant representing the speed of light. The $(\cdot)^*$, $(\cdot)^T$ and $(\cdot)^\dagger$ stand for the conjugate, transpose and conjugate transpose operators. $\mathbb{E}\{a\}$ and $\hat{a}$ are the expected value and estimation of a. Given a vector $\boldsymbol{a}$, $|\boldsymbol{a}|_2$ returns its

2-norm. Given a square matrix $\boldsymbol{A}$, $|\boldsymbol{A}|$ and $\mathrm{tr}(\boldsymbol{A})$ are the determinant and trace operator. The $\odot$ represents the Hadamard (element wise) product, while $\otimes$ calculates the Kronecker product. $\boldsymbol{I}_M$ represents the $M \times M$ identity matrix. $\boldsymbol{a}[i]$ stands for the ith entry of the vector $\boldsymbol{a}$, and $[\boldsymbol{A}]_{i,j}$ represents the (i,j)th entry of the matrix $\boldsymbol{A}$. Finally, $\delta_{l,k} = 1$ for $l = k$ and 0, otherwise.

II. Problem Formulation

Consider without loss of generality that L spatially distributed receivers, indexed by l, equipping with M_l omni-directional antenna. For derivation simplicity, we assume $M_l = M$ for all receivers. We then suppose there exist a emitter transmitting the narrow-band unknown signal $s(t)$. The goal of this paper is to determine the location of this emitter.

Denote the unknown source and the known lth receiver location by $\boldsymbol{p}_0$ and $\boldsymbol{p}_l$, respectively. It has been well investigated that according to the geometry, the time of arrival (TOA) and the direction of arrival (DOA) are respectively calculated by

$$\begin{aligned} \tau_l &= \|\boldsymbol{p}_l - \boldsymbol{p}_0\| / c \\ \phi_l &= \frac{\pi}{2} - \arctan\left(\frac{\boldsymbol{p}_l[2] - \boldsymbol{p}_0[2]}{\boldsymbol{p}_l[1] - \boldsymbol{p}_0[1]}\right), \end{aligned} \tag{1}$$

with index $[1]$ indicates the first element of the location and $[2]$ refers to the second element. Hence, the received snapshot of the lth receiver can be formulated by

$$\begin{aligned} \boldsymbol{y}_l(t) &= b_l \boldsymbol{a}_l(\phi_l)\, s(t-\tau_l) + \boldsymbol{\omega}_l(t) \\ &\approx b_l \boldsymbol{a}_l(\phi_l)\, s(t)\, e^{\mathrm{j}2\pi f_0 \tau_l} + \boldsymbol{\omega}_l(t), \end{aligned} \tag{2}$$

where b_l stands for the intensity of the observation, and $\boldsymbol{a}_l(\phi_l)$ is the steering vector corresponds to the array manifold allocated in arbitrary manner. Furthermore, we make the assumption that the sources are located in the far-field regime so that the array manifold is a function of the DOAs only. Therefore, one can denote the total observation from all the sensors by stacking the individual observation into a $L \times M$ vector, so that the total received vectors can be expressed as

$$\begin{aligned} \boldsymbol{y}(t) &= \left[\boldsymbol{y}_1^T(t), \boldsymbol{y}_2^T(t), ..., \boldsymbol{y}_L^T(t)\right]^T \\ &= \mathrm{diag}\{\boldsymbol{b}\} \otimes \boldsymbol{I}_M \boldsymbol{\alpha}(\boldsymbol{p})\, s(t) + \boldsymbol{\omega}, \end{aligned} \tag{3}$$

with noise vector and the extended steering vector being defined as

$$\begin{aligned} \boldsymbol{\omega} &= \left[\boldsymbol{\omega}_1^T(t), \boldsymbol{\omega}_2^T(t), ..., \boldsymbol{\omega}_L^T(t)\right]^T \\ \boldsymbol{\alpha}(\boldsymbol{p}) &= \left[\bar{\boldsymbol{a}}_1^T(\boldsymbol{p}), \bar{\boldsymbol{a}}_2^T(\boldsymbol{p}), ..., \bar{\boldsymbol{a}}_L^T(\boldsymbol{p})\right]^T, \end{aligned} \tag{4}$$

where $\bar{\boldsymbol{a}}_l(\boldsymbol{p}) = \boldsymbol{a}_l(\phi_l)\, e^{-\mathrm{j}2\pi f_0 \tau_l}$.

Meanwhile, we assume the additive noise satisfies the zero-mean circulant Gaussian distribution with variance σ_0^2, i.e. $\omega_l(t) \sim \mathcal{CN}\left(0, \sigma_0^2 \boldsymbol{I}_M\right)$. For derivation convenience, we further assume the additive noise are equal power[1]. The transmitted signal is supposed to have the normalized power $\sum_{t=1}^{N} |s(t)|^2 / N = 1$, while the amplitudes b_l's are jointly stationary zero-mean Gaussian distributed with variance σ_l^2. However, the sensors may spatially coherence so that b_l's are mutually correlated by factor $\rho_{l,k} = \sqrt{\mathbb{E}\{b_l b_k^*\}}$

Under these assumptions, the total observation vector is a complex Gaussian random process with zero mean and the (l,k)th block of the covariance matrix yields

$$\begin{aligned} [\boldsymbol{R}_{\boldsymbol{y}}]_{l,k} &= \mathbb{E}\left\{\boldsymbol{y}_l(t)\, \boldsymbol{y}_k^{\dagger}(t)\right\} \\ &= \rho_{l,k} \boldsymbol{a}_l(\phi_l)\, \boldsymbol{a}_k^{\dagger}(\phi_k)\, e^{\mathrm{j}2\pi f_0(\tau_l - \tau_k)} + \delta_{l,k}\sigma_0^2 \boldsymbol{I}_M, \end{aligned}$$

The likelihood function is then given by

$$f_{\boldsymbol{y}}(\boldsymbol{y}|\boldsymbol{p}_0) \propto |\boldsymbol{R}_{\boldsymbol{y}}|^{-1} \exp\left(-\boldsymbol{y}^H \boldsymbol{R}_{\boldsymbol{y}}^{-1} \boldsymbol{y}\right).$$

The principle of DPD is to estimate the underlying source location by minimizing the negative LLF. However, to the best of our knowledge, the non-linearity equation (1) embedded in LLF under statistic model admits no closed-form representation regarding the location estimation $\hat{\boldsymbol{p}}_0$. Thus, in the sequel, we resort to the grid-search approach and the optimized estimation is in accordance with the grid that minimize (or maximize) the cost function.

Disscussion 1: Under the deterministic model where b_l's are determined yet unknown, one can formulate the cost function by the first-order statistic. The DPD approach is then derivative by nonlinear least square (NLS) estimation criteria regardless the distribution [7], [13]. Whereas, under the statistic model where b_l's are random distributed with zero mean, the covariance matrix is sufficient for computing the cost function. Under this circumstance, one may also access the cost function in the same manner as NLS. However, subspace approaches such as MUSIC are capable to achieve a high resolution estimation. Hence, we formulate the cost function by MUSIC proposed in [9] but recast to a more computational efficient manner.

III. The Proposed DPD without Eigen-Decomposition

In this section, we will present a reduced-rank DPD approach based on MSWF. For comparison purpose, we firstly revisit a recently proposed DPD approach using MUSIC [9], which is under narrow band assumption. We will then present our proposed DPD approach using MSWF to avoid calculating time-consuming eigen-decomposition. In the end of this section, we will summarize our proposed approach.

A. MUSIC DPD

Regarding our received data model, it is non-trivial to decompose the population covariance matrix (PCM) of the received signal by

$$\boldsymbol{R}_{\boldsymbol{y}} = \boldsymbol{U}\boldsymbol{\Lambda}\boldsymbol{U}^{\dagger}$$

where $\boldsymbol{U} = [\boldsymbol{u}_1, \boldsymbol{u}_2, ..., \boldsymbol{u}_{ML}]$ spans the signal and noise subspace. To be concrete, in our *single* source regime, $\boldsymbol{u}_1$ corresponds to the signal vector, while $\boldsymbol{U}_N = [\boldsymbol{u}_2, ..., \boldsymbol{u}_{ML}]$ corresponds the noise subspace.

[1]This assumption is somehow unrealistic, but one can estimate the noise level and "whiten" the received signal. Hence, throughout this paper, we assume the noise level are equal for all receivers.

The principle concept of MUSIC-based approach is that the steering vector lies in the same direction with signal vector, therefore orthogonal with the noise subspace. Thus, the cost function is formulated by

$$\xi_1(\boldsymbol{p}) = \boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\hat{\boldsymbol{U}_N}\hat{\boldsymbol{U}_N}^{\dagger}\boldsymbol{\alpha}(\boldsymbol{p}) \tag{5}$$

where $\hat{\boldsymbol{U}_N}$ is noise subspace of sample covariance matrix (SCM). Here, the nuisance parameter $\boldsymbol{b}$ is substituted by all-one vector since it has no influence on the cost function.

Further, by adopting the asymptotic distribution given by [9], [11], we arrive at

$$\epsilon_i \triangleq \boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\hat{\boldsymbol{u}}_{i+1} \sim \mathcal{N}(0, \gamma_1(\boldsymbol{p})), \forall i = 1, ...ML-1, \tag{6}$$

where $\gamma_1(\boldsymbol{p}) = \boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\boldsymbol{W}\boldsymbol{\alpha}(\boldsymbol{p})$ with $\boldsymbol{W} \propto \boldsymbol{u}_1\boldsymbol{u}_1^{\dagger}$ by a constant scalar $\sigma_0^2\lambda_1/N\left(\sigma_0^2-\lambda_1\right)$. In fact, this scalar can be treated as a weight on the signal subspace for multiple sources. In our single source situation, however, we discard this scalar in $\boldsymbol{W}$ without influencing the global searching for the optimize value. And according to [11], ϵ_i's are asymptotically independent $\mathbb{E}\left\{\epsilon_i\epsilon_j^*\right\} = 0$. Therefore, an improved MUSIC-DPD based cost function is proposed by

$$\xi_2(\boldsymbol{p}) = \frac{\xi_1(\boldsymbol{p})}{\gamma_1(\boldsymbol{p})} = \frac{\boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\hat{\boldsymbol{U}_N}\hat{\boldsymbol{U}_N}^{\dagger}\boldsymbol{\alpha}(\boldsymbol{p})}{\boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\boldsymbol{u}_1\boldsymbol{u}_1^{\dagger}\boldsymbol{\alpha}(\boldsymbol{p})}. \tag{7}$$

Finally, one can calculate the cost function for all possible locations through grid-search. The optimal grid with maximized cost function corresponds to the estimation of source. Whereas, either $\xi_1(\boldsymbol{p})$ or $\xi_2(\boldsymbol{p})$ demands the calculation of eigen-decomposition, thereby requires heavy computational efforts. To cure this problem, we propose a MSWF-based DPD approach to estimate the signal and the noise subspace iteratively, in the following part of this section.

B. Multi-Stage Winier Filter based MUSIC DPD

To begin with, we assume an extra fusion center with single omni-directional antenna. The received signal of the fusion center can be denoted by

$$y_0(t) \approx b_0 s(t)\,\mathrm{e}^{-\mathrm{j}2\pi f_0\tau_0} + \omega_0(t). \tag{8}$$

We define $d_0(t) = y_0(t)$ as the reference, the cross correlation in the fusion center is given by

$$\boldsymbol{r}_0(t) = \mathbb{E}\{\boldsymbol{y}(t)\,d_0^*(t)\} = \mathrm{diag}\{\boldsymbol{c}\} \otimes \boldsymbol{I}_M\boldsymbol{\beta}(\boldsymbol{p}). \tag{9}$$

where $\boldsymbol{c}[l] = b_l b_0^*$, $\boldsymbol{\beta}(\boldsymbol{p}) = \boldsymbol{\alpha}(\boldsymbol{p})\,\mathrm{e}^{\mathrm{j}2\pi f_0\tau_0}$ and the additive noise is eliminated due to the assumption that the noise of each receivers are independent.

[14] indicates this correlation vector can be regarded as matched filter to capture the source information $\boldsymbol{\alpha}(\boldsymbol{p})$. Therefore, we can define a normalized filter by

$$\boldsymbol{h}_1 = \frac{\boldsymbol{r_0}}{\|\boldsymbol{r}_0\|},$$

which partitions the observation by the desired component $d_1(t) = \boldsymbol{h}_1^{\dagger}\boldsymbol{y}(t)$ and orthogonal component $\boldsymbol{y}_1(t) = \boldsymbol{y}(t) - \boldsymbol{h}_1 d(t)$. Similarly, if we partition the signal for the ith stage, which yields

$$\begin{aligned} d_i(t) &= \boldsymbol{h}_i^{\dagger}\boldsymbol{y}_{i-1}(t), \\ \boldsymbol{y}_i(t) &= \boldsymbol{y}_{i-1}(t) - \boldsymbol{h}_i d_i(t). \end{aligned}$$

where the matched filter at ith stage is computed by

$$\boldsymbol{h}_i = \frac{\mathbb{E}\left\{\boldsymbol{y}_{i-1}(t)\,d_{i-1}^*(t)\right\}}{\left\|\mathbb{E}\left\{\boldsymbol{y}_{i-1}(t)\,d_{i-1}^*(t)\right\}\right\|} \tag{10}$$

We can repeat this recursions by ML stages, so that the desired signal forms a vector defined by

$$\boldsymbol{d}(t) \triangleq [d_1(t), d_2(t), ..., d_M(t)]^T = \boldsymbol{H}^{\dagger}\boldsymbol{y}(t),$$

where the unity of matrix $\boldsymbol{H} = [\boldsymbol{h}_1, \boldsymbol{h}_2, ..., \boldsymbol{h}_{ML}]$ has readily proved in [14]. Moreover, [12] has also shown that $\boldsymbol{H}_N = [\boldsymbol{h}_2, ..., \boldsymbol{h}_{ML}]$ spans the noise subspace as $\boldsymbol{U}_N$, for our single source regime.

Following this conclusion, we define the statistic

$$\zeta_i = \boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\hat{\boldsymbol{h}}_{i+1}, \forall i = 1, 2, ..., ML-1,$$

where $\hat{\boldsymbol{h}}_i$ is the data-driven match filter at ith stage and $\boldsymbol{\alpha}(\boldsymbol{p})$ is given by (4). The following proposition provides the statistic property of ζ_i.

Proposition 1: The statistic $\boldsymbol{\zeta} = [\zeta_1, \zeta_2, ..., \zeta_{ML-1}]^T$ are asymptotically joint Gaussian distributed with zero mean, whose i, jth element of covariance matrix is given by

$$\begin{aligned} [\boldsymbol{R}_{\boldsymbol{\zeta}}]_{i,j} &= \mathbb{E}\left\{\zeta_i\zeta_j^*\right\} \\ &= \mathbb{E}\left\{\boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\hat{\boldsymbol{h}}_{i+1}\hat{\boldsymbol{h}}_{j+1}^{\dagger}\boldsymbol{\alpha}(\boldsymbol{p})\right\}, \end{aligned}$$

which is equal to 0 for $i \neq j$ and ML for diagonal elements.

Proof: A detailed proof for the asymptotic Gaussian property in $Proposition1$ will be presented in our future extended paper. Meanwhile, one can easily prove the diagonal property of $\boldsymbol{R}_{\boldsymbol{\zeta}}$ following the orthogonal of $\hat{\boldsymbol{h}}_i$ and $\hat{\boldsymbol{h}}_j$ for $i \neq j$. And the diagonal element can be calculated by noticing $\left\|\hat{\boldsymbol{h}}_i\right\|_2^2 = 1$ and $\|\boldsymbol{\alpha}(\boldsymbol{p})\|_2^2 = ML$. □

Thanks to Proposition 1, we can reformulate the cost function the same manner as (7) by

$$\xi_3(\boldsymbol{p}) = \frac{\boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\hat{\boldsymbol{h}}_1\hat{\boldsymbol{h}}_1^{\dagger}\boldsymbol{\alpha}(\boldsymbol{p})}{\boldsymbol{\alpha}^{\dagger}(\boldsymbol{p})\,\hat{\boldsymbol{H}}_N\hat{\boldsymbol{H}}_N^{\dagger}\boldsymbol{\alpha}(\boldsymbol{p})}. \tag{11}$$

This result is straightforward since $\hat{\boldsymbol{h}}_1$ spans the signal subspace and $\hat{\boldsymbol{H}}_N$ spans the noise subspace. Therefore, we can estimate the location of the emitter by maximize the cost function as one did in (7). Whereas, one can estimate the subspace by iteratively calculate the MSWF stage by stage, instead.

C. A Overview of the Proposed MSWF-DPD Approach

In this paper, we resort to the grid search method by maximize the cost function in (11). Concretely speaking, the section of interest (SOI) will be divided into several square grid with a user-defined resolution. The centers of each girds $\boldsymbol{p}$ are plugged into the cost function, so that one can estimate the location by searching for the maximum value of the cost function, i.e.

$$\hat{\boldsymbol{p}}_0 = \arg\max \xi_3 (\boldsymbol{p}),$$

which corresponds to the optimal location estimation. However, if one search the emitter by a very fine grid at the first stage (say 1×1 grid in 1000×1000 area), the computational load caused by searching (1×10^6) will be very heavy. Hence, one can search the existence of the emitter by a rough resolution and then refine the resolution if the emitter appears in the specific grid.

In summarize, the proposed approach can achieve a refined localization by the algorithm 1.

Algorithm 1 MSWF-MUSIC-DPD

Input:

The SOI, the location of the receivers $\{\boldsymbol{p}_l\}$ and the number of receivers L.

The total received data $\boldsymbol{y}(t)$, number of antenna for each receivers M_l and the number of snapshots N

Output:

The location estimation of emitter $\hat{\boldsymbol{p}}_0$

Initialize: grid size Δ, searching center $\boldsymbol{p}_0^{(1)}$ for the SOI, iterative index $i = 1$, $\boldsymbol{p}_0^{(0)} \leftarrow \boldsymbol{p}_1$

while $\left|\boldsymbol{p}_0^{(i)} - \boldsymbol{p}_0^{(i-1)}\right|_2 > \epsilon_0$ **do**

  $j \leftarrow 0$, $\boldsymbol{y}_0(t) = \boldsymbol{y}(t)$

  Calculate the cross correlation $\boldsymbol{r}_0$ with respect to the fusion center given by (9)

  for $j = 1 : \sum_{l=1}^{L} M_l$ **do**

    $\boldsymbol{h}_j = \boldsymbol{r}_{j-1} / |\boldsymbol{r}_{j-1}|_2$

    $d_j(t) = \boldsymbol{h}_j^{\dagger} \boldsymbol{y}_{j-1}(t)$

    $\boldsymbol{y}_j(t) = \boldsymbol{y}_{j-1}(t) - \boldsymbol{h}_j d_j(t)$

    $\boldsymbol{r}_j = \sum_t \boldsymbol{y}_j(t) d_j^*(t)$

  end for

  $\boldsymbol{p}_0^{(i)} = \arg\max \xi_3 (\boldsymbol{p})$, where ξ_3 is defined in (11)

  $i \leftarrow i + 1$, $\Delta \leftarrow \Delta/2$

end while

IV. Simulation Results

In this section, we report some representative numerical results to investigate the localization performance. The MUSIC-DPD formulated in (7) is adopted as the competitive.

Additionally, each result represents an average of 1×10^3 independent trials. At each run, the gird size is initiated at $10m$. The SOI is a $100m \times 100m$ square centered at the original point. The receivers and the emitter are randomly distributed in this area, as we show in Fig.1 for one run. We assume the emitter transmits the simple pulse modulated by cosine function for illustrative purpose. The duration of the pulse is $50\mu s$. The carrier frequency is assumed to be 2.4GHz. At each run, we assume the receives signals are down convert to the intermediate frequency at 1MHz. The sample rate is twice of the intermediate frequency. So that each receiver can collect 100 snapshots. We evaluate the estimation performance by root mean-squared-error (rMSE) calculated by

$$\text{rMSE} = |\boldsymbol{p}_0 - \hat{\boldsymbol{p}}_0|_2.$$

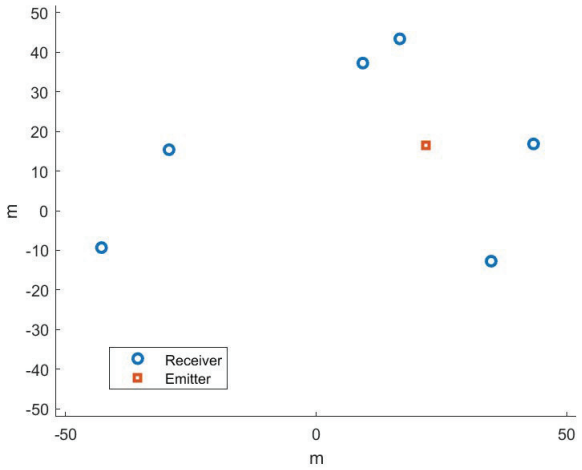

Fig. 1: The randomly generated locations of emitter and receivers for $L = 6$.

We firstly investigate the estimation performance as the function of the SNR. The simulation results is shown in Fig.2, where we assume 6 receivers are randomly distributed in the SOI and each receiver equips 2 antenna except for the fusion center (single channel). It can be observed that the rMSE of both MUSIC-DPD and proposed MSWF-DPD decreases as the SNR increases, and the performance of MSWF-DPD is coverage to the MUSIC-DPD. This is reasonable since the signal component dominates the matched filter in the first stage, i.e. $\boldsymbol{h}_1$, when the SNR is high. Hence, one can have a better estimation of signal subspace using normalized cross correlation (9). In this experiment, we assume the receivers are equipped with 2 antenna because we will extend our result to Universal Software Radio Peripheral (USRP) B210[2] to collect field data in future works. And USRP B210 is designed with 2 receiving channels using AD9361[3].

It can be observe that both approaches have a estimation rMSE for around $5m$ when SNR is equal to 6dB. This result is somehow unsatisfactory, but we can refine this estimation performance by increase either the number of antenna or the number of receiver. Fig.3 and Fig.4 show the rMSE versus number of antenna and receivers, respectively. All the curves decrease as the dimension of total observation, $\boldsymbol{y}(t)$, increases.

[3]visit https://www.analog.com/en/products/ad9361.html for detailed information

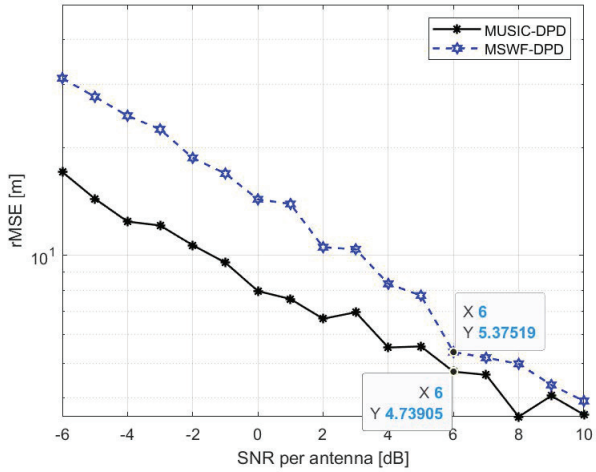

Fig. 2: Localization performance versus SNR with $M = 2$, $L = 6$.

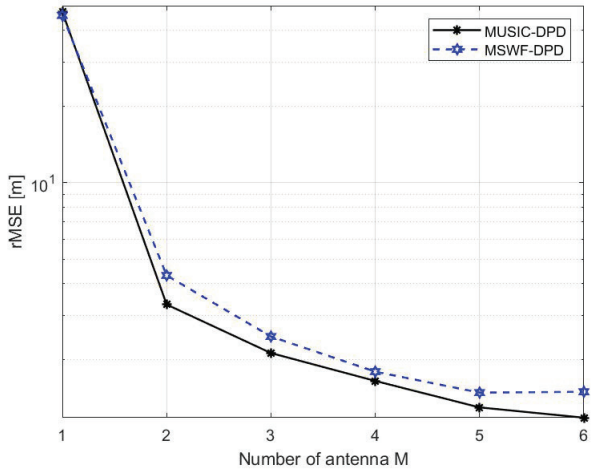

Fig. 3: Localization performance versus M with SNR= 6dB, $L = 6$.

This is because one can have a better estimation of noise subspace as the dimension gets greater. These results are also in accordance with our conclusions in Fig.2.

Although the performance of MSWF-DPD is overwhelmed by MUSIC-DPD, but the computational complexity is significantly decreased [14]. To be specific, the MSWF-DPD spends the most computational effort in computing the covariance matrix. While the MUSIC-DPD requires some extra computational effort in eigen-decomposition, which is $\mathcal{O}\left(M^3L^3\right)$. Hence, the proposed MSWF-DPD can achieve a better estimation efficiency for the centralized location technique.

V. Conclusion and Future Works

In this paper, we proposed a computational efficient method to estimate the localization of a narrow-band emitter. We inherent the grid-search scheme as the MUSIC-DPD.

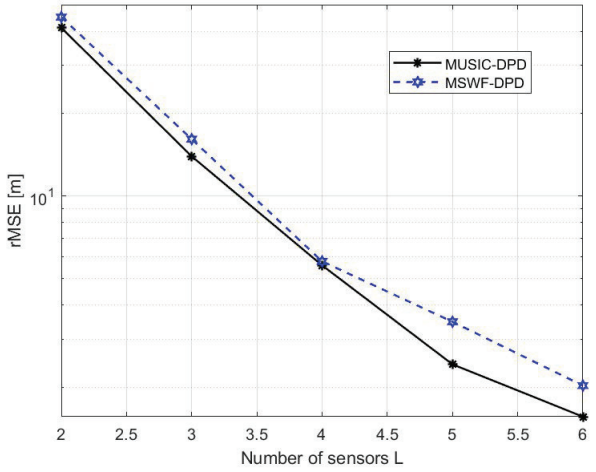

Fig. 4: Localization performance versus L with SNR= 6dB, $M = 6$.

But we achieve the partition without calculating the eigen-decomposition. In the simulation, we present some typical results due to the length constraint. And our method can be easily extended to the multiple emitter regime. For better illustrate our proposed approach, the experiment results using USRP will be presented in our future extended work. Besides, we can further reduce the computational complexity through the selection on the order of MSWF, which require a sophistic trade-off. And the extension to the situation when each emitters is not well calibrated would also left in our future works.

***Abstract*—During a public health crisis like COVID-19, individuals' adoption of protective behaviors, such as self-isolation and wearing masks, can significantly impact the spread of the disease. In the meanwhile, the spread of the disease can also influence individuals' behavioral choices. Moreover, when facing uncertain losses, individuals' decisions tend to be irrational. Therefore, it is critical to study individuals' irrational behavior choices in the context of a pandemic. In this paper, we propose an epidemic-behavior co-evolution model that captures the dynamic interplay between individual decision-making and disease spread. To account for irrational decision-making, we incorporate the Prospect Theory in our individual behavior modeling. We conduct a theoretical analysis of the model, examining the steady states that emerge from the co-evolutionary process. We use simulations to validate our theoretical findings and gain further insights. This investigation aims to enhance our understanding of the complex dynamics between individual behavior and disease spread during a pandemic.**

***Index Terms*—Irrationality, Epidemic, Individual behavior**

I. Introduction

The COVID-19 pandemic has triggered a profound public health crisis and inflicted substantial economic damage. Throughout such public health crisis, individuals' behavior and the pandemic influence each other in a complex way. For instance, individuals' behaviors, such as wearing masks, social distancing, and self-quarantine, can help limit the spread of the disease, while people tend to adopt protective behaviors more readily when the severity of the pandemic becomes apparent. Furthermore, individuals often display irrational behavior during the pandemic, including heightened panic at the early stage of an outbreak or a tendency to underestimate the severity of the disease as it spreads further. These irrational responses can significantly impact people's decision-making processes and ultimately influence the pandemic. Therefore, it is crucial to model individuals' irrational behavior and to analyze its impact on the pandemic.

A. Literature Review

There have been extensive works on user behavior modeling during an epidemic, which we will briefly introduce in the following.

1) Behavior Modeling in Disease Spread: Several previous studies focus on modeling individual behavior during disease outbreaks. The authors of [1]–[3] believe that as the number of infected individuals in a given environment increases, people are more inclined to adopt precautionary measures. Zhang et al. propose that individuals are more inclined to engage in protective behaviors when they have a higher number of infected neighbors [1]. Wu et al. posit that an individual's adoption of protective behaviors is influenced not only by the proportion of infected neighbors but also by the regional and global infection rates [2]. The works in [4]–[8] also propose that information dissemination plays a crucial role in shaping people's protective behavior during disease outbreaks, and individuals who receive relevant information are more likely to adopt precautionary measures in response to the pandemic. Funk et al. believe that infected individuals play a significant role in disseminating information about the disease across networks. This information dissemination can effectively encourage others to adopt protective measures in response to the ongoing spread of the disease [4]. Granell et al. develop a dual network model that incorporates both disease spread and information spread. In their model, one network represents the transmission of the disease, while the other network represents the dissemination of information. Their findings suggest that individuals who receive informational messages are more vigilant and, as a result, exhibit a lower infection rate [5]. However, these studies often overlook a common yet crucial factor: the influence of individual irrationality on decision-making during a pandemic. Understanding and accounting for the impact of irrational behavior are essential as they can greatly shape individuals' responses and actions during an ongoing outbreak.

2) Irrational Behavior Modeling: Individuals often make irrational decisions when faced with risks, such as the risk of being infected during a disease outbreak. The Prospect Theory [9], [10], an influential theory put forth by Nobel laureates Kahneman and Tversky, sheds light on this phenomenon. It says that individuals tend to overestimate the likelihood of low-probability events and underestimate the likelihood of high-probability events. Moreover, individuals demonstrate a heightened sensitivity to potential losses compared to gains [11]. To effectively guide people's behavior during an epidemic and control the spread of the disease, it is of great importance to model such irrational behavior and analyze its impact on the pandemic. The works in [12]–[14] examine the influence of people's irrationality on their vaccination decisions. Vaccination presents a fundamental behavioral choice problem where individuals must make a single binary decision on whether or not to receive a vaccine during an epidemic, wherein opting for vaccination eliminates the risk of infection. However, during an epidemic, individuals also have the option to engage in

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

various protective behaviors, such as wearing masks, practicing hand hygiene, and self-isolation at home. These behaviors are discretionary and may change from time to time depending on the severity of the pandemic. Note that during an epidemic, individuals only decide once on whether to receive the vaccination. But for protective behaviors such as wearing masks, practicing hand hygiene, and self-isolation at home, they have to constantly decide whether to adopt them until the pandemic ends. The dynamic interplay between disease spread and individual behavioral choices occurs continuously throughout the outbreak, highlighting the complex relationship between the two. To our knowledge, no prior work modeled and analyzed the complex interplay between disease spread and behavioral choice with consideration of user irrationality.

B. Our Contribution

The main contributions of this paper are:

- We develop an epidemic-behavior co-evolution model that provides a framework for analyzing the co-evolution of the pandemic and individuals' behavior. This model allows us to study the dynamic interplay between disease spread dynamics and human behavior.
- In our model, we incorporate the concept of individuals' irrationality and specifically model irrational behavior using the Prospect Theory. By considering irrational decision-making processes, we enhance the realism of the model and capture the complex human decision-making process during a pandemic.
- We conduct theoretical analyses of the co-evolution of the pandemic and individuals' behavior. By exploring the dynamics of the model, we identify and characterize the steady states, which provide insights into the long-term behavior patterns and their interplay with the pandemic.

II. The epidemic-behavior co-evolution model

In this section, we model the co-evolution of individual behavioral choices and disease spread during the pandemic. In our model, extending the model in [15], we assume that individuals can choose between 2 possible behaviors: risky behavior a_1 (like going out) and conservative behavior a_2 (like self-isolation). Individuals would choose the behavior according to the severity of the epidemic, and these behavior choices will, in turn, affect the epidemic. We use an undirected graph to model the interpersonal connections among individuals. This graph captures the spread of the disease through the network, and in addition, neighbors in this network influence each other's behavior. To simplify the analysis, in this work, we assume a regular network consisting of N nodes, with degree $\bar{k}$.

Our model contains two parts, the disease spread model and the behavior change model. Given the current actions of all users, the disease spread model quantifies how the pandemic will spread in the network; while given the current number of infected people and their neighbors' current actions, the behavior change model describes how users choose their protective behaviors. We will introduce them one by one in the following.

A. The Disease Spread Model

We adopt the classical Susceptible-Infected-Susceptible (SIS) model to characterize the spread of the disease. In this model, each individual can be in one of two health states: susceptible or infected. In each time slot, a susceptible individual has the potential to become infected by an infected individual, with a given infection rate. Conversely, infected individuals have a chance to recover at a certain recovery rate. To mitigate the risk of infection, susceptible individuals can choose to adopt various protective measures, such as home quarantine, wearing masks, or taking no action. In this study, our focus is primarily on the protective behavior of susceptible individuals. We make the assumption that individuals who are already infected will not engage in such protective behaviors. This assumption is based on the understanding that infected individuals may not have the same motivation or need to adopt protective measures since they are already infected.

Assume that the susceptible individuals have two possible behavioral options a_1 and a_2. Furthermore, we assume that all individuals who choose a_1 have the same infection rate, denoted as β_1, and similarly, all individuals who choose a_2 have the same infection rate β_2. The recovery rate is assumed to be the same for all infected people and is denoted as γ. At time slot t, let $s(t)$ and $i(t)$ represent the fractions of susceptible and infected individuals, respectively. Additionally, let $x_1(t)$ be the fraction of susceptible individuals adopting behavior a_1, and $x_2(t)$ represent the fraction adopting behavior a_2. Consequently, the dynamics of the disease spread can be described by the following differential equations:

$$\begin{aligned} \frac{ds(t)}{dt} &= \gamma i(t) - s(t)i(t)\overline{\beta}\bar{k}, \\ \text{and} \quad \frac{di(t)}{dt} &= s(t)i(t)\overline{\beta}\bar{k} - \gamma i(t), \end{aligned} \tag{1}$$

where $\overline{\beta} = \beta_1 x_1(t) + \beta_2 x_2(t)$. Note that $s(t) + i(t) = 1$, (1) can be rewritten as

$$\frac{di(t)}{dt} = i(t)(1 - i(t))\overline{\beta}\bar{k} - \gamma i(t). \tag{2}$$

B. The Behavior Change Model

The behavior change model quantifies the change in $\{x_1(t), x_2(t)\}$, the proportion of susceptible individuals taking actions $\{a_1, a_2\}$ at time t. The change in $\{x_1(t), x_2(t)\}$ may be due to two possible reasons. First, due to the change in the proportion of the infected individuals, or influenced by their neighbors, susceptible individuals select different actions at time t. We use $E_i(t)$ to denote the change in $x_i(t)$ due to such users' active behavior change, where $i = 1, 2$. Additionally, users' health states may change at time t, causing the change in $x_i(t)$. For example, a susceptible user taking action a_i at time $t-1$ becomes infected at time t, or vice versa. We use $B_i(t)$ to denote the change in $x_i(t)$ due to the change in users'

health states. Thus, we have

$$\frac{dx_i}{dt} = E_i(t) + B_i(t),\ i = 1, 2. \tag{3}$$

In the following, we will discuss $E_i(t)$ and $B_i(t)$ one by one.

1) Analysis of $E_i(t)$: To model users' active behavior change due to their neighbors' influence and the percentage of individuals currently being infected, we use evolutionary game theory to model individuals' decision-making processes. Evolutionary game theory offers a valuable tool for understanding how individuals make choices in response to environmental influences. The fundamental components of the evolutionary game theory include strategy, payoff, and strategy update rules, each of which will be introduced in detail in the following.

Strategy: Each behavior a_i is a strategy. In each time slot, m percent of susceptible individuals are randomly selected as focal individuals. They observe their neighbors' behaviors and choose one possible strategy. Other susceptible individuals keep their actions unchanged.

Payoff: Each individual would get a payoff based on their chosen action and their interactions with their neighbors. To model users' irrationality under conditions of uncertainty, we define the payoffs of different behaviors using the Prospect Theory (PT). The Prospect Theory seeks to explain how individuals make decisions under conditions of uncertainty. PT suggests that people do not always make rational choices, and their decisions can be influenced by various cognitive biases and subjective evaluations. According to PT, if an individual selects a behavior a_i that leads to L potential outcomes $o_1, o_2, ..., o_L$ with corresponding probabilities $p_1, p_2, ..., p_L$, respectively, then the payoff U_i associated with choosing a_i can be defined as follows:

$$U_i = \sum_{i=1...L} u(o_i)\boldsymbol{\omega}(p_i), \tag{4}$$

where $u(x)$ is the value function and $\boldsymbol{\omega}(p)$ is the weighting function, which we will introduce one by one.

For the value function $u(x)$, according to the Prospect Theory, the perceived payoff differs from the actual payoff due to the presence of cognitive biases and subjective evaluations that individuals make when faced with uncertain outcomes. These biases and evaluations influence how individuals perceive and interpret information, leading to deviations from rational decision-making. The value function $u(x)$ models the relationship between the actual payoff x and the perceived payoff $u(x)$. A widely used value function is the power function

$$u(x) = \begin{cases} x^{\sigma}, & if\ x \geq 0 \\ -\lambda(-x)^{\sigma}, & if\ x < 0 \end{cases} \tag{5}$$

where λ reflects the individual's different sensitivity to gain and loss. The sensitivity coefficient $\sigma \in (0, 1]$ determines the shape and curvature of the value function [16].

For the weighting function $\boldsymbol{\omega}(p)$, when facing uncertainty, individuals' perceived probability is different from real probability. Individuals have a tendency to overestimate the probability of small risks, while underestimating the probability of larger risks [17]. According to the work in [18], the weighting function describing the relationship between the perceived probability and the real probability is:

$$\boldsymbol{\omega}(p) = e^{(-(-lnp)^{\alpha})},\quad p \in [0, 1],\ \alpha \in (0, 1], \tag{6}$$

where p is the real probability of a certain outcome, $\boldsymbol{\omega}(p)$ is the perceived probability, and α is the rationality coefficient. A smaller α indicates a higher degree of individuals' irrationality.

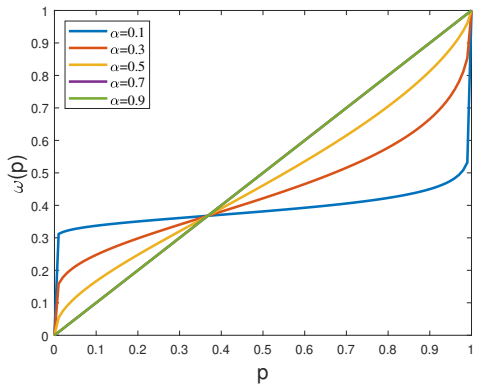

Fig. 1. The weighting function of different rational coefficients α.

Fig.1 plots the weighting function $\boldsymbol{\omega}(p)$ with different α. When the actual probability p is very small, the perceived probability $\boldsymbol{\omega}(p)$ is much larger than the actual probability p, showing the phenomenon that individuals tend to overestimate events/risks with small probabilities. On the contrary, when the actual probability is large, the perceived probability $\boldsymbol{\omega}(p)$ is smaller than the actual probability p, modeling the phenomenon that individuals tend to underestimate events/risks with large probabilities. Also, from Fig.1, a smaller α (that is, a higher degree of individuals' irrationality) intensifies individuals' tendency to overestimate the probability of small risks while simultaneously underestimating the probability of larger risks.

In our model, each susceptible individual who adopts behavior a_i receives a payoff of c_i with probability 1, which is determined by the behavior itself. Also note that an individual taking behavior a_i has an approximate probability of $\bar{k}\beta_i i(t)$ to be infected at time t [19], which incurs an additional loss of c_n (we consider those epidemics with $\beta_i^t \ll 1$, such as SARS, MERS and common influenza[20], and we assume that $\bar{k}\beta_i < 1$). To simplify the analysis, we assume that all individuals have the same form of the utility function $u(x)$ and the weighting function $\boldsymbol{\omega}(p)$. Thus, from (4), the perceived payoff when choosing behavior a_i is

$$U_i = u(c_n) \cdot \boldsymbol{\omega}[\bar{k}\beta_i i(t)] + u(c_i),\ i = 1, 2. \tag{7}$$

Strategy Update Rule: At each time step, m percent of the susceptible individuals are randomly selected as focal individuals and update their actions, while the rest individuals' actions

remain unchanged. These focal individuals are more likely to imitate the behaviors of individuals who have higher payoffs. Following the work in [21], a focal individual with strategy a_i compares its payoff U_i to the payoff U_j of another randomly chosen individual with strategy a_j. The focal individual then updates its strategy to a_j with probability:

$$p(a_i \to a_j) = \frac{1}{2} + \frac{\omega}{2}\frac{1}{U_{max}}(U_j - U_i), \tag{8}$$

where $\omega \in (0, 1]$ measures the strength of selection, and U_{max} is the normalization term.

For the two behavior a_1 and a_2, the probability that $x_1(t)$ increases by $\frac{1}{N_0(t)}$ is:

$$p\left(\Delta x_1 = \frac{1}{N_0(t)}\right) = x_1(t)x_2(t)p(a_2 \to a_1), \tag{9}$$

where $N_0(t)$ is the number of susceptible individuals at t and $N_0(t) = Ns(t)$. Similarly, the probability that $x_1(t)$ decreases by $\frac{1}{N_0(t)}$ is:

$$p\left(\Delta x_1 = -\frac{1}{N_0(t)}\right) = x_1(t)x_2(t)p(a_1 \to a_2). \tag{10}$$

Combining (8), (9) and (10), we have:

$$\begin{aligned} E_1(t) =& mN_0(t)\left\{p\left(\Delta x_1 = \frac{1}{N_0(t)}\right) \times \frac{1}{N_0(t)}\right. \\ & \left. -p\left(\Delta x_1 = -\frac{1}{N_0(t)}\right) \times \frac{1}{N_0(t)}\right\} \\ =& \frac{m\omega}{U_{max}} x_1(t)x_2(t)\left\{u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_1 i(t)]\right. \\ & \left. +u(c_1) - u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_2 i(t)] - u(c_2)\right\}, \end{aligned} \tag{11}$$

where m is the fraction of individuals who are chosen as the focal individuals at each time. We can get $E_2(t)$ in the same way, which is omitted here.

2) Analysis of $B_i(t)$: Even if individuals do not change their behavior, the proportion of different behaviors among susceptible individuals will change over time due to the change of their health states. Let $s_1(t)$ be the fraction of individuals who are both susceptible and adopt behavior a_1 at time t among the entire population, that is, $s_1(t) = s(t)x_1(t)$ where $s(t)$ is the fraction of susceptible individuals and $x_1(t)$ is the fraction of individuals adopting a_1 among all the susceptible individuals. As $s(t) = s_1(t) + s_2(t)$, we have:

$$\begin{aligned} B_1(t) =& \frac{d}{dt}\left(\frac{s_1(t)}{s(t)}\right) = \frac{d}{dt}\left(\frac{s_1(t)}{s_1(t) + s_2(t)}\right) \\ =& \frac{s_1'(t)s_2(t) - s_2'(t)s_1(t)}{s^2(t)}. \end{aligned} \tag{13}$$

Note that $s_1'(t)$, the first order derivative of $s_1(t)$, contains two parts. The first part is the change caused by the infection of susceptible users, while the second part is the change caused by the recovery of infected individuals. For the first part, we have $s_{1a}'(t) = -s_1(t)\beta_1\bar{k}i(t)$, which represents the decrease in the fraction of individuals adopting behavior a_1 due to infection. For the second part, we assume that the recovered individuals would choose their behaviors based on the current ratio of different behaviors in the environment, as defined in [22]. Therefore, we have $s_{1b}'(t) = \gamma x_1(t)i(t)$, which represents the increase in the fraction of individuals adopting behavior a_1 due to the recovery of infected individuals. Combining these two parts, we obtain the overall change in the fraction of individuals adopting behavior a_1 as $s_1'(t) = s_{1a}'(t) + s_{1b}'(t)$. Then we have:

$$\begin{aligned} & s_1(t) = s(t)x_1(t), \\ & s_1'(t) = -s(t)x_1(t)\beta_1\bar{k}i(t) + \gamma x_1(t)i(t). \end{aligned} \tag{14}$$

We can get $s_2(t)$ and $s_2'(t)$ in the same way. Then based on (13) and (14), we have

$$B_1(t) = x_1(t)x_2(t)\bar{k}i(t)(\beta_2 - \beta_1). \tag{15}$$

We can get $B_2(t)$ in the same way, which is omitted here.

Combining (3), (15) and (11), the complete differential equation describing the dynamics of individual behavior change is:

$$\begin{aligned} \frac{dx_1}{dt} =& x_1(t)x_2(t)\bar{k}i(t)(\beta_2 - \beta_1) + \frac{m\omega}{U_{max}}x_1(t)x_2(t) \\ & \cdot\left\{u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_1 i(t)] + u(c_1) - u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_2 i(t)] - u(c_2)\right\}. \end{aligned} \tag{16}$$

Note that $x_1(t) + x_2(t) = 1$, we have $\frac{dx_2}{dt} = -\frac{dx_1}{dt}$.

Combining (2) and (16), we get the epidemic-behavior co-evolution model in (12). The first differential equation represents the dynamics of individuals' health states. The second equation models the changes in the proportions of individuals adopting the risky behavior.

C. Steady State

At the steady states of the above epidemic-behavior co-evolution model, both $i(t)$ and $\{x_1(t), x_2(t)\}$ evolve to a stable state where there are no further changes in the proportions of infected individuals and the choices of different behaviors. As $x_2 = 1 - x_1$, we omit the explicit mention of x_2 in the representation of the steady state, and use (i^*, x_1^*) to represent the steady state. Similar to the work in [22] and the Lyapunov's first method [23], we define the *steady-state* of the epidemic-behavior co-evolution model as follows.

Definition 1: The steady state (i^*, x_1^*) satisfies:

$$\left.\frac{di}{dt}\right|_{i=i^*} = 0, \ \left.\frac{dx}{dt}\right|_{x_1=x_1^*} = 0, \ Re(\lambda_1) < 0, \ Re(\lambda_2) < 0, \tag{17}$$

where λ_1 and λ_2 are the eigenvalues of the Jacobian matrix

$$\left.\begin{pmatrix} \frac{\partial i'}{\partial i} & \frac{\partial i'}{\partial x_1} \\ \frac{\partial x_1'}{\partial i} & \frac{\partial x_1'}{\partial x_1} \end{pmatrix}\right|_{i=i^*, x_1=x_1^*}, \tag{18}$$

and $Re(x)$ means the real part of x.

As (17) are often difficult to solve, we often use numerical methods to find the solution of (17) and the steady states of the co-evolution of disease spread and behavioral choice.

$$\frac{di}{dt} = i(t)(1-i(t))\overline{\beta}\bar{k} - \gamma i(t), \tag{12}$$
$$\frac{dx_1}{dt} = x_1(t)x_2(t)\bar{k}i(t)(\beta_2-\beta_1) + \frac{m\omega}{U_{max}}x_1(t)x_2(t)(u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_1 i(t)] + u(c_1) - u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_2 i(t)] - u(c_2)).$$

III. The steady state Analysis

During the COVID-19 crisis, governments have been promoting home isolation as a crucial measure to contain the spread of the disease. Home isolation helps significantly reduces the risk of being infected and controls the pandemic, while it also leads to substantial economic loss as well as impacts people's physical and mental well-being. During the pandemic, individuals need to choose between high-cost low-risk conservative behavior and low-cost high-risk risky behavior. Their decisions are often influenced by the severity of the epidemic and the potential loss due to home isolation. People tend to choose self-isolation when the pandemic poses a greater threat to their health; while they may be inclined to choose to go out when the loss due to home isolation is too high (e.g., losing their jobs and income).

Therefore, in this section, based on our model in the previous section, we analyze the dynamics of people's choices between two behaviors: risky behavior (going out) represented by a_1, and conservative behavior (home isolation) represented by a_2, and the evolution of the epidemic. We assume that the infection rate for conservative behavior is $\beta_2 = 0$ (as isolation ensures no infection risk).

Then we analyze the steady state of our model. To find the steady state, we first introduce Lemma 1.

Lemma 1: The necessary and sufficient conditions that (i^*, x_1^*) is a steady state is:

$$\begin{aligned} &\frac{di}{dt}\Big|_{i=i^*} = 0,\ \frac{dx_1}{dt}\Big|_{x_1=x_1^*} = 0,\\ &(\frac{\partial i'}{\partial i} + \frac{\partial x_1'}{\partial x_1})\Big|_{i=i^*,x_1=x_1^*} < 0,\\ \text{and}\quad &(\frac{\partial i'}{\partial i}\frac{\partial x_1'}{\partial x_1} - \frac{\partial i'}{\partial x_1}\frac{\partial x_1'}{\partial i})\Big|_{i=i^*,x_1=x_1^*} > 0. \end{aligned} \tag{19}$$

Proof: By the definition of the steady state, we first have $\frac{di}{dt} = 0$ and $\frac{dx_1}{dt} = 0$. For simplicity, we let

$$\begin{aligned} &P(i^*, x_1^*) = (\frac{\partial i'}{\partial i} + \frac{\partial x_1'}{\partial x_1})\Big|_{i=i^*,x_1=x_1^*},\\ \text{and}\quad &Q(i^*, x_1^*) = (\frac{\partial i'}{\partial i}\frac{\partial x_1'}{\partial x_1} - \frac{\partial i'}{\partial x_1}\frac{\partial x_1'}{\partial i})\Big|_{i=i^*,x_1=x_1^*}. \end{aligned} \tag{20}$$

Then we have:

$$\lambda_1 = \frac{P+\sqrt{P^2-4Q}}{2},\ \text{and}\ \lambda_2 = \frac{P-\sqrt{P^2-4Q}}{2}. \tag{21}$$

From (17), the steady state requires $Re(\lambda_1) < 0$ and $Re(\lambda_2) < 0$. If $Q \le 0$, then it implies $Re(\lambda_1) \ge 0$, which contradicts the steady state conditions. Therefore, we must have $Q > 0$. Additionally, since $Q > 0$ and $Re(\lambda_1) < 0$, it follows that $P < 0$. Therefore, we have $P < 0$ and $Q > 0$, which means $\frac{\partial i'}{\partial i} + \frac{\partial x_1'}{\partial x_1} < 0$ and $\frac{\partial i'}{\partial i}\frac{\partial x_1'}{\partial x_1} - \frac{\partial i'}{\partial x_1}\frac{\partial x_1'}{\partial i} > 0$. ■

From Lemma 1, we can have Theorem 1 about the steady state (i^*, x_1^*).

Theorem 1: The steady state (i^*, x_1^*) of (12) satisfies:

$$(i^*, x_1^*) = \begin{cases} (0,1), & \text{if } \bar{k} < \frac{\gamma}{\beta_1},\\ \left(1-\frac{\gamma}{\bar{k}\beta_1}, 1\right), & \text{if } \bar{k} > \frac{\gamma}{\beta_1}, \Phi < 0,\\ \left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right), & \text{if } \bar{k} > \frac{\gamma}{\beta_1}, \Phi \ge 0, \end{cases} \tag{22}$$

where $\Phi \triangleq -k_0(u(c_1)-u(c_2)) - (\gamma - \bar{k}\beta_1) - k_0 u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_1 - \gamma]$, $k_0 = \frac{m\omega}{U_{max}}$, and $i^{(2)}$ is the solution of the equation

$$k_0 u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_1 i^{(2)}] - \bar{k}\beta_1 i^{(2)} + k_0(u(c_1)-u(c_2)) = 0. \tag{23}$$

Proof: By setting $\frac{di}{dt} = 0, \frac{dx_1}{dt} = 0$, we can get four steady state candidates: $(0,0)$, $(0,1)$, $\left(1-\frac{\gamma}{\bar{k}\beta_1}, 1\right)$ and $\left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right)$. Then, we check whether they are stable. Note that in reality, the payoff of going out should be larger than quarantine, we have $c_1 - c_2 > 0$ (that means $u(c_1) - u(c_2) > 0$). Since c_n is the loss of being infected, so $c_n < 0$ (that means $u(c_n) < 0$). Based on Lemma 1, the steady state should satisfy $P(i^*, x_1^*) < 0$ and $Q(i^*, x_1^*) > 0$, where $P(\cdot,\cdot)$ and $Q(\cdot,\cdot)$ are defined in (20). Then we have:

- For the state $(0,0)$, we have $P = k_0(u(c_1)-u(c_2)) - \gamma$ and $Q = -\gamma k_0(u(c_1)-u(c_2))$. Since $u(c_1)-u(c_2) > 0$, $\gamma > 0$ and $k_0 > 0$, we have $Q < 0$. So $(0,0)$ is unstable.
- For the state $(0,1)$, we have $P = -(\gamma - \bar{k}\beta_1) - k_0(u(c_1) - u(c_2))$ and $Q = k_0(\gamma - \bar{k}\beta_1)(u(c_1)-u(c_2))$. As $u(c_1) - u(c_2) > 0$ and $k_0 > 0$, if $Q > 0$, we have $\gamma - \bar{k}\beta_1 > 0$, which is equivalent to $\bar{k} < \frac{\gamma}{\beta_1}$. When $\gamma - \bar{k}\beta_1 > 0$, we also have $P < 0$. Therefore, when $\bar{k} < \frac{\gamma}{\beta_1}$, $(0,1)$ is a steady state.
- For the state $\left(1-\frac{\gamma}{\bar{k}\beta_1}, 1\right)$, we have:

$$\begin{aligned} P =& -k_0(u(c_1)-u(c_2)) - k_0 u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_1 - \gamma],\\ Q =& (\gamma - \bar{k}\beta_1)\{-k_0(u(c_1)-u(c_2))\\ &- (\gamma - \bar{k}\beta_1) - k_0 u(c_n)\cdot\boldsymbol{\omega}[\bar{k}\beta_1 - \gamma]\}. \end{aligned} \tag{24}$$

Since $1 - \frac{\gamma}{\bar{k}\beta_1}$ is the proportion of infected individuals, we have $1 - \frac{\gamma}{\bar{k}\beta_1} > 0$, which is equivalent to $\bar{k} > \frac{\gamma}{\beta_1}$. (If $1 - \frac{\gamma}{\bar{k}\beta_1} = 0$, then the state $\left(1-\frac{\gamma}{\bar{k}\beta_1}, 1\right)$ becomes $(0,1)$,

which we have discussed). To satisfy $P < 0$ and $Q > 0$, we first define

$$\begin{aligned} h_1 &\triangleq -k_0(u(c_1)-u(c_2)) - k_0 u(c_n)\cdot \boldsymbol{\omega}[\bar{k}\beta_1 - \gamma], \\ \text{and } h_2 &\triangleq -k_0(u(c_1)-u(c_2)) - (\gamma - \bar{k}\beta_1) \\ &\quad - k_0 u(c_n)\cdot \boldsymbol{\omega}[\bar{k}\beta_1 - \gamma]. \end{aligned} \tag{25}$$

Note that $P < 0$ and $Q > 0$ are equivalent to $h_1 < 0$ and $h_2 < 0$. It is obvious that $h_1 = h_2 - (\bar{k}\beta_1 - \gamma)$. Since $(\bar{k}\beta_1 - \gamma) > 0$, if $h_2 < 0$, then $h_1 < 0$, and $P < 0$, $Q > 0$. Note that $\Phi = h_2$. Therefore, $\left(1 - \frac{\gamma}{\bar{k}\beta_1}, 1\right)$ is a steady state when $\bar{k} > \frac{\gamma}{\beta_1}$ and $\Phi < 0$.

- First, as $i^{(2)}$ and $\frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}$ are the proportion of infected individuals and the proportion of individuals who choose risky behavior, by definition, we have $0 \le i^{(2)} \le 1$ and $0 \le \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1} \le 1$, which is equivalent to:

$$0 \le i^{(2)} \le 1 - \frac{\gamma}{\bar{k}\beta_1}. \tag{26}$$

From (26), it is obvious that we should have $0 < 1 - \frac{\gamma}{\bar{k}\beta_1}$, which means $\bar{k} > \frac{\gamma}{\beta_1}$ (If $0 = 1 - \frac{\gamma}{\bar{k}\beta_1}$, then the state $\left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right)$ becomes $(0,1)$, which we have discussed). Then, we define $f_2(x) \triangleq k_0 u(c_n)\cdot\boldsymbol{\omega}(\bar{k}\beta_1 x) - \bar{k}\beta_1 x + k_0(u(c_1)-u(c_2))$. From (23), $i^{(2)}$ is the solution of $f_2(x)$ so we have $f_2(i^{(2)}) = 0$. It is obvious that $f_2(x)$ is a monotonically decreasing function of $i^{(2)}$. Then $0 \le i^{(2)} \le 1 - \frac{\gamma}{\bar{k}\beta_1}$ is equivalent to:

$$f_2(0) \ge 0, \quad f_2(1 - \frac{\gamma}{\bar{k}\beta_1}) \le 0. \tag{27}$$

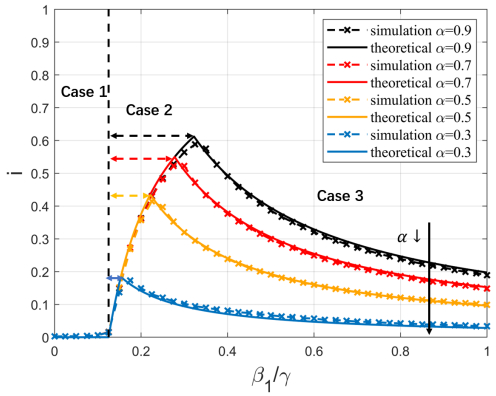
Note that $u(c_1) - u(c_2) > 0$ and $k_0 > 0$. Therefore we have $f_2(0) = k_0(u(c_1)-u(c_2)) > 0$. So when $\bar{k} > \frac{\gamma}{\beta_1}$ and $f_2(1 - \frac{\gamma}{\bar{k}\beta_1}) \le 0$, we have $0 \le i^{(2)} \le 1$ and $0 \le \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1} \le 1$.

Then, if $\left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right)$ is a steady state, it should satisfies $P < 0$ and $Q > 0$, so we have:

$$\begin{aligned} P &= -\gamma + (1-2i^{(2)})\bar{k}\beta_1 x_1^{(2)} = -\bar{k}\beta_1 i^{(2)} x_1^{(2)}, \\ Q &= -\bar{k}\beta_1 i^{(2)} x_1^{(2)}(1-i^{(2)})(1-x_1^{(2)}) \\ &\quad \cdot (k_0 u(c_n)\boldsymbol{\omega}'[\bar{k}\beta_1 i^{(2)}]\bar{k}\beta_1 - \bar{k}\beta_1). \end{aligned} \tag{28}$$

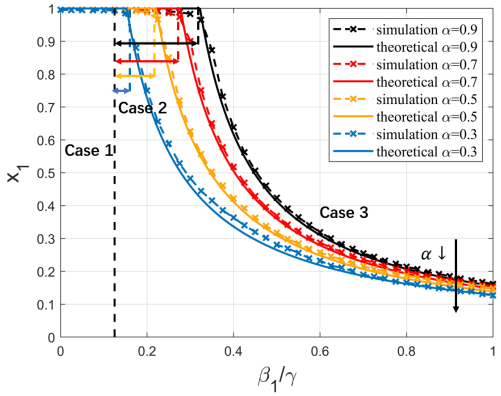
It is obvious that $P < 0$. Since $\boldsymbol{\omega}'[\bar{k}\beta_1 i^{(2)}] > 0$ and $k_0 u(c_n) < 0$, we have $k_0 u(c_n)\boldsymbol{\omega}'[\bar{k}\beta_1 i^{(2)}]\bar{k}\beta_1 - \bar{k}\beta_1 < 0$. So $Q > 0$.

Therefore, when $\bar{k} > \frac{\gamma}{\beta_1}$ and $f_2(1 - \frac{\gamma}{\bar{k}\beta_1}) \le 0$, $\left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right)$ is steady state. Note that $f_2(1 - \frac{\gamma}{\bar{k}\beta_1}) = -\Phi$, therefore, when $\bar{k} > \frac{\gamma}{\beta_1}$ and $\Phi \ge 0$, $\left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right)$ is steady state.



■

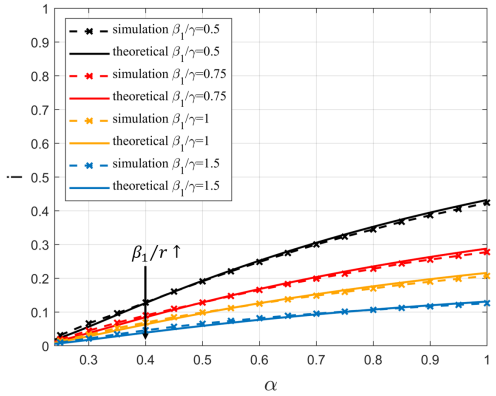
From Theorem 1, our epidemic-behavior co-evolution model has possible three steady states, and each corresponds to a particular situation in reality:



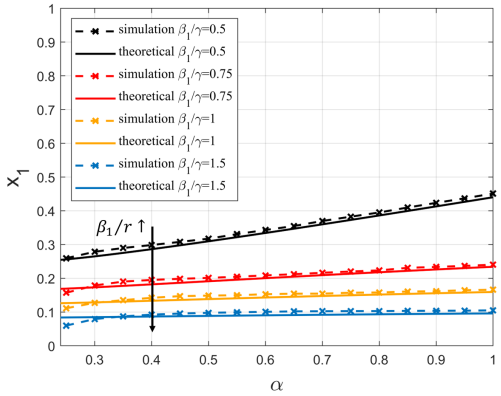
- Case 1: The steady state $(0,1)$ represents an extreme situation where the infection rate is too low, and the disease would eventually die out even without any intervention or change of behavior. In this case, all individuals choose risky behavior. For the steady state $(0,1)$, the stability condition is $\bar{k} < \frac{\gamma}{\beta_1}$, which is equivalent to $\frac{\beta_1}{\gamma} < \frac{1}{\bar{k}}$. Here, $\frac{1}{\bar{k}}$ represents the epidemic threshold of a regular network with degree $\bar{k}$ [24]. If $\frac{\overline{\beta}}{\gamma} < \frac{1}{\bar{k}}$, the epidemic would die out; otherwise, it would spread out [24]. Since $\overline{\beta} \in [0, \beta_1]$, the disease would die out regardless of how people choose their behavior. In this situation, all individuals would choose the risky behavior in the steady state. Therefore, when $\bar{k} < \frac{\gamma}{\beta_1}$, the stable point is $i = 0$ and $x_1 = 1$.
- Case 2: For the steady state $\left(1 - \frac{\gamma}{\bar{k}\beta_1}, 1\right)$, the first constraint is $\bar{k} > \frac{\gamma}{\beta_1}$, which means if all individuals choose the risky behavior, the disease will spread out. The second constraint is $\Phi < 0$. When all individuals choose to go out with $x_1 = 1$, the percentage of infected individuals will reach the stable state $\bar{i} = 1 - \frac{\gamma}{\bar{k}\beta_1}$, which is the maximum extent to which the disease can spread (please refer to Appendix A for a proof). If for all possible i in the range $[0, \bar{i}]$, we have $\frac{dx_1}{dt}|_{x_1 \ne 0,1} > 0$ (if $x_1 = 0$ or 1, $\frac{dx_1}{dt} = 0$), then more people will choose risky behavior as time goes on, and $x_1 = 1$ with all individuals choosing the risky behavior at the steady state. This may happen when the risky behavior's payoff is much higher than the conservative behavior's with $c_1 \gg c_2$, or when the cost of being infected c_n is very low. If $\frac{dx_1}{dt}|_{i=\bar{i}, x_1 \ne 0,1} > 0$, which is equivalent to $\Phi < 0$, then for all $i \in [0, \bar{i}]$, we have $\frac{dx_1}{dt}|_{x_1 \ne 0,1} > 0$. Therefore, when $\bar{k} > \frac{\gamma}{\beta_1}$ and $\Phi < 0$, $\left(1 - \frac{\gamma}{\bar{k}\beta_1}, 1\right)$ is the steady state.
- Case 3: The steady state $\left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right)$ represents the general situation other than the two extreme cases. In this scenario, the disease does not extinct, nor does it spread to the maximum extent, and at the steady state, $0 < i^{(2)} < \bar{i}$ percent of individuals will be infected. Meanwhile, $0 < \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1} < 1$ of susceptible individuals will choose the risky behavior. When $\bar{k} > \frac{\gamma}{\beta_1}$, and $\Phi \ge 0$, the state $\left(i^{(2)}, \frac{\gamma}{(1-i^{(2)})\bar{k}\beta_1}\right)$ is stable.

IV. Simulation Results

In this section, we run simulations to verify our analysis in the above sections. The network we used is a regular network with 500 nodes and a fixed degree of 8. Since the risky behavior of going out is the default behavior that most people take in their daily lives, we set the payoff of this behavior to 0, while the conservative behavior of self-isolation can be regarded as behavior with losses and a negative payoff. As an example, we set the payoff of the risky behavior as $c_1 = 0$, the payoff for the conservative behavior as $c_2 = -1$, and the disease loss as $c_n = -10$. For the value function, we set $\sigma = 0.65$ according to [16]. In our simulations, we set $\lambda = 1$, and observe the same trend for other values of λ.



(a) The proportion of infected individuals



(b) The proportion of individuals choosing risky behavior

Fig. 2. The simulation and theoretical results of steady states with different disease spread ability

(a) The proportion of infected individuals

(b) The proportion of individuals choosing risky behavior

Fig. 3. The simulation and theoretical results of steady states with different disease rationality coefficients α.

Fig. 2 shows the results of steady state with changing $\frac{\beta_1}{\gamma}$ which reflects the spread ability of the disease. A higher value of $\frac{\beta_1}{\gamma}$ indicates a greater ability of the disease to spread within the population. First, from Fig. 2, the theoretical results fit well with the simulation results. The three cases in Theorem 1 can be clearly seen in Fig. 2. When $\frac{\beta_1}{\gamma}$ is low, even if all individuals choose risky behavior, the disease will die out, which corresponds to Case 1 in the figure. When $\frac{\beta_1}{\gamma}$ is high enough so that the disease would spread out, it enters Case 2. As $\frac{\beta_1}{\gamma}$ increases, the proportion of infected individuals in the steady state gradually increases, and at this time, all individuals would still choose risky behaviors since it has a higher payoff. As $\frac{\beta_1}{\gamma}$ continues increasing, it enters Case 3, where more and more people choose self-isolation due to the high risk of infection. In this case, although $\frac{\beta_1}{\gamma}$ become higher, more people choose to self-isolate due to the increased risk of infection, which makes the proportion of infected individuals in the steady state gradually decrease.

Moreover, from Fig. 2, given $\frac{\beta_1}{\gamma}$, individuals with a lower rationality coefficient α (meaning that such individuals are more irrational) have a smaller probability to be in Case 2, which means that irrational individuals are more inclined to choose conservative behaviors during a pandemic. This may be because from the Prospect Theory, irrational users tend to overestimate the small probability of being infected, and thus they tend to be more conservative. We also run simulations on the steady state of Case 3 under different rationality coefficients α and the results are shown in Fig. 3. It can be seen that fewer individuals choose risky behavior when the rational coefficient α is smaller, confirming our previous conclusion about their conservative behavior.

V. Conclusion

In this paper, we propose the epidemic-behavior co-evolution method to capture individuals' behavior during a pandemic and analyze the co-evolution of disease spread and behavior change. We incorporate irrational behavior based on Prospect Theory and examine how it influences people's decision-making processes and, in turn, the spread of the disease. Through rigorous theoretical analysis, we identify three steady states under different scenarios and investigate

their practical implications. To validate our theoretical findings and gain further insights, we conduct simulation experiments. The experimental results align closely with our theoretical predictions, confirming the correctness of our model. Notably, our findings consistently indicate that irrationality tends to steer individuals towards more conservative behavioral choices during a pandemic, effectively mitigating the spread of the disease.

APPENDIX A
PROOF FOR THE MAXIMUM SPREAD EXTENT

For the steady state (i^*, x_1^*), it satisfies $\frac{di}{dt} = 0$. If $i^* \neq 0$, then based on (12), we have:

$$i^* = 1 - \frac{\gamma}{\bar{k}\beta_1 x_1^*}, \tag{29}$$

and i^* is an increasing function of x_1^*, where $x_1^* \in [0, 1]$. Therefore, i^* reaches its maximum value when $x_1^* = 1$. Substituting this value into the equation, we obtain $\bar{i} = 1 - \frac{\gamma}{\bar{k}\beta_1}$.

***Abstract*—In order to improve the performance of pitch detection algorithms in a noisy scenario, we propose a noise-robust pitch detection model based on super-resolution harmonics. The model consists of denoise, integration, and super-resolution modules. The Denoisy module highlights the harmonic structure of speech in the frequency domain to reduce noise interference. The enhanced spectrum is multiplied by an integral matrix to obtain a pitch-harmonic integration spectrum. The super-resolution module adjusts the low-resolution pitch-harmonic integration spectrum and outputs fine results. In addition, dynamic programming is employed for pitch tracking to eliminate those singular spots in the preliminary results. The experimental results show that the proposed model significantly outperforms the referenced approaches, including SWIPE, CREPE, HarmoF0, and HGCN+. The results also show that the model can work well even under low SNR.**

I. Introduction

Pitch often represented by f_0 is an important characteristic of speech. It is widely used in speech applications, such as speech enhancement [1], speech recognition [2], voice conversation [3], and speech synthesis [4], etc.

The traditional approaches can be divided into the time-domain methods (RAPT [5], YIN [6], and pYIN [7]) and the frequency-domain methods (SWIPE [8]). Generally, pitch detection is implemented in two steps. First, the pitch candidates are detected based on the periodicity of voiced segments [5] or the instant of uttering events [9]. Then the pitch tracking adopts dynamic programming [10] or hidden Markov [11] to model temporal continuity constraint. In recent years, pitch detection has been formulated as a supervised learning task. In [12], a supervised learning algorithm to estimate pitch using a convolutional neural network (CNN) and CREPE [13] operates on the waveform to estimate the pitch. [14] proposed a network that jointly detects the voiced segments and pitch. These approaches work well on clean speech, but their performance will decline for noisy speech. can be divided into the time-domain methods (RAPT [5], YIN [6], and pYIN [7]) and the frequency-domain methods (SWIPE [8]). Generally, pitch detection is implemented in two steps. First, the pitch candidates are detected based on the periodicity of voiced segments [5] or the instant of uttering events [9]. Then the pitch tracking adopts dynamic programming [10] or hidden Markov [11] to model temporal continuity constraint. With the introduction of deep learning, pitch detection is formulated as a supervised learning task, and its performance is significantly improved. In [12], a supervised learning algorithm to estimate pitch using a convolutional neural network (CNN) and CREPE [13] operates on the waveform to estimate the pitch. [14] proposed a network that jointly detects the voiced segments and pitch. These approaches work well on clean speech, but their performance will decline for noisy speech. In the speech spectrum, harmonic frequencies are integer multiples of the pitch, where these harmonics show energy peaks locally and present a comb-like structure. Even at low SNR, the harmonic structure is seldom completely masked. HarmoF0 [15] introduced multiple rates dilated causal convolution network [16] to capture the harmonic structure in the logarithmic scale spectrum and then estimate the pitch. Since there is no dedicated module for harmonic enhancement, this approach does not seem to work well at low SNR.

High-resolution fundamental frequencies are essential for speech enhancement and timbre conversion. The high-resolution pitch is verified to be necessary for the use of high-order harmonics. Still, the double error and/or half error are occasionally ignored in our former system (HGCN+ [17]). In HGCN+, a high-resolution harmonic-based pitch detection was proposed and adopted to guide the model for speech enhancement. HGCN+ first performs a coarse spectrum enhancement, and then harmonics integration is utilized to predict the pitch. Finally, the harmonic gating mechanism is used to guide the compensation model to adjust the coarse results from CRN to obtain the refinedly enhanced results. HGCN+ adopts pitch as an additional feature, and the enhanced results would be better with a higher resolution fundamental frequency. The fundamental frequency is often used for prosody modeling in voice conversion. VQMIVC [3] employs vector quantization (VQ) for content encoding and introduces mutual information (MI) as the correlation metric during training to achieve proper disentanglement of content, speaker and pitch representations by reducing their inter-dependencies in an unsupervised manner. High-resolution fundamental frequency enables model prosody to be more precise, resulting in better disentanglement. And the resolution of the estimated pitch can also be improved by a larger frame-size of Fourier transform, in addition to the complexity problem, the over-smoothing problem is also inevitable.

For a practical pitch detection algorithm to run in the real

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

world, there are two issues need to be solved, which include noise robustness and frequency resolution. In this study, starting from the pitch detection module of HGCN+, we improve the integral matrix. Then the U-Net [18] based harmonic enhancement, integral matrix based pitch detection, and super-resolution module are integrated into our network, resulting in a noise-robust high-resolution pitch detection method. We compared our methods with four other advanced ones on both noisy and clean datasets. The outstanding performances with low complexity of the method are verified experimentally.

II. Proposed Method

The overall architecture of the proposed model is shown in Fig. 1, which consists of the harmonic enhancement module (HEM), integral module (IM), and confidence super-resolution module (CSM). The HEM enhances the harmonics of noisy speech. Then IM calculates the pitch-harmonic integration spectrum based on the enhanced magnitude spectrum. Finally, the CSM is used to generate the confidence spectrum. Each module is described as follows.

A. Harmonic Enhancement Module

The harmonic enhancement module (HEM) is designed to highlight the harmonics while suppressing the noise on the magnitude spectrum for more accurate pitch detection. It estimates a mask $\boldsymbol{M}$ from a given noisy magnitude spectrum. And then, the mask is applied to the noisy signal,

$$\boldsymbol{S'} = \boldsymbol{S} \odot \boldsymbol{M} \tag{1}$$

where $\boldsymbol{S'}$ and $\boldsymbol{S}$ are the enhanced and noisy magnitude spectra, respectively. And the $\odot$ denotes the element-wise multiplication. A U-Net based enhancement network is adopted, which is an encoder-decoder architecture. Both encoder and decoder consist of Batch normalization (BN) [19], 2D convolution layer (Conv2d), and Parametric Rectified Linear Unit (PReLU) [20]. Between the encoder and decoder, long short-term memory (LSTM) [21] is inserted to model the temporal dependencies. Additionally, skip connections are utilized to concatenate the output of each encoder layer to the input of the corresponding decoder layer. The channel number of encoder and decoder is $(16, 32, 64, 128, 128, 128)$. And a 512units FC layer after a 128-units LSTM is adopted.

To highlight the harmonics in magnitude spectrum, the training label for HEM is a harmonic enhanced magnitude spectrum, which will be detailed in the section II-E.

B. Integral Module

Harmonics are the key to spectrum-based pitch detection, which appear as comb-like structures in the magnitude spectrum, as peaks are located at integer multiples of the pitch with the locally highest energy. An artificial comb-structure integral matrix $\boldsymbol{K}$ is proposed to mimic the distribution of harmonics, which is adopted as a checklist for different pitches, as shown in Fig. 1.

The integral matrix $\boldsymbol{K}$ is designed as shown in Algorithm 1, where F is the frequency dimension of the magnitude spectrum, and sr is the sample rate. R is the resolution of pitch candidates, which is set artificially. Because the matrix dimension and computational cost increase with higher resolution, R is set to 1 to compromise the computational costs. A total of 360 pitches in 60∼420 Hz are taken as candidates. For special pitch candidate f_c, the energy above $sr/(4 \cdot R \cdot f_c)$ order harmonic has no reference with lower energy. So only the harmonics from 1 to $sr/(4 \cdot R \cdot f_c)$ are allowed to participate in the integration. And to alleviate the double-pitch and half-pitch errors, decaying weighting factors are applied to the integral matrix, and the weight of $(R \cdot f_c \cdot p)^{0.23}$ is applied for the p order harmonic. The weights between $(p-1)$ order and p order harmonic are filled with cosine curves.

Algorithm 1 Integral matrix

$\boldsymbol{K} \leftarrow \boldsymbol{0} \in \mathbb{R}^{[420/R] \times F}$
for $f_c \leftarrow [60/R] \rightarrow [420/R]$ **do**
  $\text{loc}_{\text{last}} \leftarrow 0$; $\text{peak}_{\text{last}} \leftarrow 1$; $j \leftarrow f_c$
  for $p \leftarrow 1 \rightarrow [sr/(4 \cdot R \cdot f_c)]$ **do**
    $\text{loc} \leftarrow [R \cdot f_c \cdot p \cdot F/\,(sr/2)]$
    $\text{peak} \leftarrow 1/(R \cdot f_c \cdot p)^{0.23}$; $\boldsymbol{K}_{j,\text{loc}} \leftarrow \text{peak}$
    if $\text{loc}_{\text{last}} \neq 0$ **then**
      if $\text{loc} - \text{loc}_{\text{last}} > 1$ **then**
        $\text{num}_{\text{iner}} = \text{loc} - \text{loc}_{\text{last}}$
        $\boldsymbol{F}^{\cos} \leftarrow \cos\left(\text{linspace}(0, 2\pi, \text{num}_{\text{iner}})\right)$
        $\boldsymbol{F} \leftarrow \text{linspace}(\text{peak}_{\text{last}}, \text{peak}, \text{num}_{\text{iner}})$
        for $i \leftarrow 1 \rightarrow \text{num}_{\text{iner}}$ **do**
          $\boldsymbol{K}_{j,i+\text{loc}_{\text{last}}} = \boldsymbol{F}_i^{\cos} \cdot \boldsymbol{F}_i$
      else
        $\boldsymbol{K}_{j,\text{loc}} \leftarrow \boldsymbol{K}_{j,\text{loc}} - (\text{peak}_{\text{last}} + \text{peak})/2$
        $\boldsymbol{K}_{j,\text{loc}_{\text{last}}} \leftarrow \boldsymbol{K}_{j,\text{loc}_{\text{last}}} - (\text{peak}_{\text{last}} + \text{peak})/2$
    $\text{loc}_{\text{last}} \leftarrow \text{loc}$; $\text{peak}_{\text{last}} \leftarrow \text{peak}$

As shown in Fig. 1, the enhanced $\boldsymbol{S'}$ is fed into IM to calculate the pitch-harmonic integration spectrum $\boldsymbol{Q}$,

$$\boldsymbol{Q} = \boldsymbol{K} \cdot \boldsymbol{S'} \tag{2}$$

where $\boldsymbol{Q} \in \mathbb{R}^{420 \times 500}$ represents the similarity of the magnitude to the harmonics distribution of different pitch candidates (row of $\boldsymbol{K}$ in Fig. 1).

C. Super-Resolution Module

The super-resolution is adopted to refine the resolution of the given pitch-harmonic integration spectrum with 1 Hz resolution from the IM. The pitch resolution can be increased to 0.2 Hz by the CSM, which is composed of four Conv2d layers and one fully-connected layer (FC). The feature size of the input is $\boldsymbol{Q} \in \mathbb{R}^{420 \times 500}$. The stride of all Conv2d is 1, the kernel size is $(5, 3, 3, 1)$, and the channel number is $(32, 16, 5, 1)$. The first three Conv2d are used to expand the channels up to 5 times. The fourth Conv2d gathers channel features, and the output is flattened into a vector. The vector

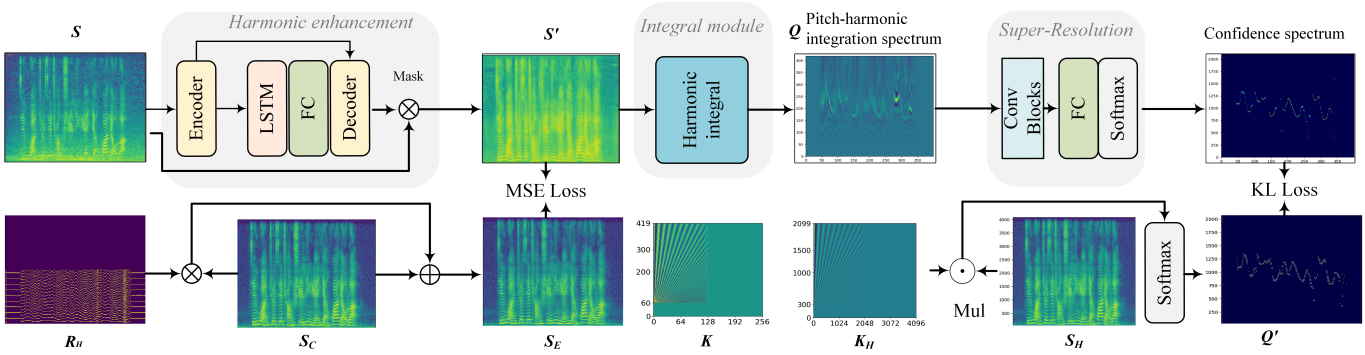

Fig. 1. Architecture of the proposed model.

is fed into FC, resulting in the boosted feature. The activation function of the last FC is softmax. The output of CSM is referred to as the confidence spectrum, which represents the probability of the pitch candidates.

D. Pitch Tracking

The preliminarily detected result may have singular spots without post-processing. Pitch tracking can smooth the expected result by the dynamic programming algorithm. The state probability at each stage is the confidence spectrum. The transfer probability is modeling the temporal continuity constraint, which can be modeled by a normal distribution.

$$p_t(\Delta) = \frac{1}{\sqrt{2\pi}\sigma} exp\left(-\frac{(\Delta-\mu)^2}{2\sigma^2}\right) \tag{3}$$

where Δ represents the pitch change of adjacent frames. Here, we set $\mu = 0$ and $\sigma = 0.1$. The transfer probability reduces as Δ increases, which limits the pitch changing significantly. The dynamic programming algorithm will maximize both state probability at each stage and the transfer probability. Then the final continuous pitch contour is generated by backtracking.

E. Label Generation and Loss Function

There is no pitch annotation on the DNS Challenge dataset [22]. According to Algorithm 1, a high-resolution integra matrix $\boldsymbol{K_H}$ is generated by setting R to 0.2, F to 4097. $\boldsymbol{K_H}$ is shown in Fig 1. A total of 2100 frequencies in 60∼420 Hz are taken as candidates. Then, the matrix $\boldsymbol{K_H}$ is applied to the 4097-dimension magnitude spectrum transformed by the 1024 Hanning window and a hop size of 160. $\boldsymbol{Q'}$ is the target of CSM.

$$\boldsymbol{Q'} = \boldsymbol{K_H} \cdot \boldsymbol{S_H} \tag{4}$$

The KL divergence is used as the loss function to optimize the model. The candidate corresponding to the maximum value in $\boldsymbol{Q'}$ is selected as the pitch, and the corresponding harmonic locations are used as the result $\boldsymbol{R_H} \in \mathbb{R}^{T\times F}$, where the harmonic locations are 1, and the non-harmonic locations are 0.

$$\boldsymbol{S_E} = \boldsymbol{S_C} \odot (\boldsymbol{1} + \boldsymbol{R}_H) \tag{5}$$

$\boldsymbol{S_E}$ denotes the target of the HEM and $\boldsymbol{S_C}$ denotes the spectrum of the clean speech. The MSE loss function is used for HEM.

III. EXPERIMENTAL SETUP

A. Datasets

The proposed model is trained on DNS Challenge (INTERSPEECH 2020) dataset. The DNS Challenge dataset includes 500 hours of clean speech from 2150 speakers and over 180 hours of noise data from 150 classes. For training, we generate 200 hours of noisy speech with DNS noise. The SNR range is -5 dB to 15 dB. And data is divided into training and validation sets at 4: 1. For testing, noisy speech is generated based on PTDB-TUG dataset[23]. The PTDB-TUG dataset comprises 4720 speech and laryngograph recordings of 20 native English speakers (10 males and 10 females) with a total length of 576 minutes. The noises of test data are from the ESC-50, and the SNRs are -5 dB, 0 dB, 5 dB, 10 dB, and 15 dB. A total of 2880 minutes of test audio are generated.

B. Model and Training Setup

The Hamming window of size 512 and a hop size of 160 are used, resulting in the 257 dimension spectral features. The model is trained using Adam [24] with default hyperparameters. And the initial learning rate is 0.001, which will decay to 50% when the validation loss plateau for 5 epochs, and the training is stopped if the loss plateau for 15 epochs. We trained the model with 4 TITAN X GPUs for one day.

C. Evaluation Metrics

Raw Ritch Accuracy (RPA) [25] is used to evaluate and compare the performance of the proposed model with the compared ones. RPA measures the percentage of audio frames where the frequency estimate is accurate within the threshold value. We select 10 cents, 30 cents, and 50 cents as threshold values. The octave is divided into 12 equal parts, which is called a semitone. The semitone is divided into 100 equal parts, and each part is a cent. The higher the RPA is, the better the model performs. Note that RPA ignores voicing errors.

TABLE I
RPA OF DIFFERENT MODELS ON NOISY PTDB-TUG DATASET, TESTED WITH THE 10, 30 AND 50 CENTS THRESHOLD.

Model	10 cents					AVG	30 cents					AVG	50 cents					AVG
	-5db	0db	5db	10db	15db		-5db	0db	5db	10db	15db		-5db	0db	5db	10db	15db

IV. RESULTS AND ANALYSIS

A. Performance in Noisy Conditions

The performance in noisy environments is related to the robustness and the application in real situations. We conduct experiments to validate the performance of the proposed framework on the PTDB-TUG dataset with various noises.

As shown in Table I, our model achieved state-of-the-art accuracy. The RPA of our proposed framework shows $(54.1\%, 12\%, 10.5\%, 9.3\%)$ of relative improvement compared to SWIPE, CREPE, HGCN+, and HarmoF0 with 50 cents threshold. The HGCN+ model enhances the speech coarsely, so it predicts well in the noisy environment. This indicates that the enhancement module is important for the proposed model to predict the fundamental frequency in a noisy environment. A similar trend can be seen in other thresholds. Since the HEM recovers the harmonic structure, the proposed framework is noise-robust.

For the average RPA, the ratios of 10 cent accuracy to 50 cent accuracy of SWIPE, CREPE, HGCN, HarmoF0, and the proposed model are $(38.4\%, 31.4\%, 30\%, 40.3\%, 44.8\%)$, respectively. The detected results of proposed model have a higher proportion within 10 cents, which indicates that the proposed method performs more precisely. This owes to CSM. The detected result may have a rough spot, which can be smoothed by dynamic programming (Fig. 2). Overall, our proposed method achieves better performance under noise scenarios.

B. Pitch Accuracy

For clean speech, the pitch detection performance of the proposed model is depicted in Table II. Our proposed model outperforms other models in different thresholds, which is around 5 million as compared with the CREPE model, which uses 22.2 million parameters. The RTF is second only to the HarmoF0. The RPA of HGCN+, HarmoF0, and the proposed model are similar with 50 cents threshold. The difference of performance becomes more obvious as the threshold decreases, which indicates our method predicts more precisely. To summarize, our proposed model outperforms the compared ones in terms of raw pitch accuracy on PTDB-TUG datasets for clean speech.

TABLE II
RPA ON CLEAN PTDB-TUG DATASET, TESTED WITH THE 10, 30 AND 50 CENTS THRESHOLD

Threshold	Params	RTF	10 cents	30 cents	50 cents
SWIPE	-	0.078	23.1	50.0	60.4
CREPE	22.2M	0.231	25.0	60.0	77.3
HGCN+	3.92M	0.066	18.1	46.4	60.1
HarmoF0	**0.38M**	**0.012**	32.9	64.0	73.4
Proposed	4.45M	0.051	**36.4**	**68.5**	**80.2**

C. Model Analysis

In addition, we further analyze the role of the HEM and CSM. We reduce the HEM and the CSM of the proposed model, respectively, and the results are presented in Table III. The proposed framework significantly outperforms the model without the HEM. Due to the absence of the HEM, the degraded harmonic structure will lead to failing to detect correctly. Without the CSM, the performance is similar with the 50 cents threshold while a gap of 7% with the 10 cents threshold. It indicates that the CSM makes the detected result more precise.

TABLE III
EVALUATION RESULTS OF THE ABLATION STUDY OF PROPOSED MODEL ON 0 SNR ENVIRONMENT.

Threshold	10 cents	30 cents	50 cents
Proposed	35.2	66.6	78.8
w/o HEM	10.8	30.1	45.7
w/o CSM	27.9	50.0	78.5

V. CONCLUSION

This paper proposes a noise-robust pitch detection network, which is based on explicitly modeling harmonics and can estimate pitches with a high resolution. The proposed model outperforms referenced ones like SWIPE, CREPE, HarmoF0, and HGCN+ on the clean PTDU-TUG dataset. Due to the special module (HEM) being set to enhance the harmonic structure from noisy speech, the proposed model is more robust to noise. The performance gap between the proposed model and the referenced counterparts is more significant in noisy

environments. Furthermore, the experimental results show that the model remains high accuracy at a strict evaluation threshold of 10 cents, which mainly owes to the super-resolution module (CSM).

***Abstract*—A joint optimization of sound pressure and particle velocity method has been recently proposed for personal sound zone control, which demonstrates promising performance in terms of reproducing perceptually relevant sound field intensity in the bright zone and reducing the sound pressure in the dark zone. However, this joint optimization method requires a long control filter for the fullband control in reverberant room environments. To make the method suitable for real-time applications, we present in this paper a subband approach to the generation of personal sound zones by joint control of the sound pressure and particle velocity. We show that with the subband filtering strategy, the control filter is shortened so that the computational complexity is reduced. Numerical results demonstrate the superiority and effectiveness of the proposed subband method in comparison with the traditional fullband approach.**

***Index Terms*—personal sound zone, subband filtering, sound pressure, particle velocity**

I. Introduction

Generating personal sound zones (PSZ) is one of the most important topics in sound field control. The objective is to utilize a loudspeaker array to generate spatially separated sound zones for different listeners [1]–[10]. The early work in PSZ is based on pressure matching (PM), which attempts to generate the desired sound pressure at the control points [11], [12]. In order to reproduce a desired sound field in a spatial region, the PM approach requires a large number of control points to achieve satisfying performance.

Sound pressure is only a scalar that describes the sound field at a control point. There are some other important parameters that can be utilized to better characterize the desired sound field, e.g., the particle velocity and sound intensity. The application of such information leads to two new PSZ control approaches, i.e., intensity-based reproduction, and joint optimization of pressure and particle velocity. For example, an intensity-based reproduction method was developed in [13] to reproduce the three-dimensional multizone sound field, in which the amplitude of the loudspeaker control filter is obtained by solving an intensity matching optimization problem. An improved version of this method was developed in [14] where a minimum-phase filter was derived by applying the Hilbert transform, but the resulting control filter is not optimal in terms of phase control.

The particle velocity information has also been explored for PSZ to reproduce the directional information of the sound field in the bright zone [6]. A benefit of using the particle velocity information is that the resulting PSZ system can work with irregularly spaced loudspeaker arrays [14]–[16]. In [6], [17], a multizone sound rendering method was proposed based on the joint control of the sound pressure and particle velocity at the control area contour. It demonstrated that by controlling the radial component of the particle velocity can help improve the reproduction performance. In [18], a particle velocity assisted three-dimensional sound field reproduction method in the modal domain was proposed. Recently, a method with joint control of particle velocity and sound pressure was developed [15], which was shown to work with irregular loudspeaker arrays and can achieve similar performance as the aforementioned methods but with less loudspeakers and less control points. However, this joint optimization method requires a long control filter, particularly in reverberant room environments, which makes it challenging to use in real-time applications.

This paper studies the problem of PSZ production. We present a subband approach to the generation of sound zones by joint optimization of the sound pressure and particle velocity. The control filter is achieved by solving a joint optimization problem in the frequency domain at every subband. The frequency-domain control filter is then transformed to the time domain using the inverse Fourier transform. With the subband filtering strategy, the control filter can be much shorter, making the method computationally more efficient than the fullband control method. As a result, this method is better suited to real-time applications.

II. System Model and Problem Formulation

Consider a loudspeaker array with L loudspeakers to generate a bright zone and a dark zone in a room. In the frequency domain, the sound pressure generated by the loudspeaker array

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

at the control point $\mathbf{x}_m$ is written as

$$p(\mathbf{x}_m,\omega)=\sum_{\ell=1}^{L}S(\omega)w_\ell(\omega)H_\ell^{(p)}(\mathbf{x}_m,\omega)$$
$$=S(\omega)\left[\mathbf{h}^{(p)}(\mathbf{x}_m,\omega)\right]^T\mathbf{w}(\omega), \quad (1)$$

where $S(\omega)$ is the source signal, $w_\ell(\omega)$ is the ℓth loudspeaker control filter, $H_\ell^{(p)}(\mathbf{x}_m,\omega)$ denotes the sound pressure acoustic transfer function (ATF) from the ℓth loudspeaker to the control point $\mathbf{x}_m$, $\omega=2\pi f$ is the angular frequency, and vector

$$\mathbf{h}^{(p)}(\mathbf{x}_m,\omega)=\left[H_1^{(p)}(\mathbf{x}_m,\omega)\ \cdots\ H_L^{(p)}(\mathbf{x}_m,\omega)\right]^T \quad (2)$$

consists of all the loudspeaker sound pressure ATFs.

The sound pressure at all the control points is written as

$$\mathbf{p}(\omega)=\left[\mathbf{p}_{\mathrm{B}}^T(\omega)\quad \mathbf{p}_{\mathrm{D}}^T(\omega)\right]^T$$
$$=S(\omega)\mathbf{H}^{(p)}(\mathbf{x})\mathbf{w}(\omega), \quad (3)$$

where the two vectors $\mathbf{p}_{\mathrm{B}}(\omega)$ and $\mathbf{p}_{\mathrm{D}}(\omega)$ denote the reconstructed sound pressure at the control points in the bright and dark zones respectively, the matrix $\mathbf{H}^{(p)}(\omega)$ denotes the sound pressure ATF matrix, and M_{B} and M_{D} are, respectively, the numbers of control points in the bright and dark zones.

The particle velocity reflects the direction information of the sound field. In the Cartesian coordinate system, the particle velocity generated by the loudspeaker array at the control point $\mathbf{x}_m$ is represented as $\mathbf{v}(\mathbf{x}_m,\omega)=[v^{(x)}(\mathbf{x}_m,\omega)\quad v^{(y)}(\mathbf{x}_m,\omega)\quad v^{(z)}(\mathbf{x}_m,\omega)]^T$. The particle velocity is related to the sound pressure through the following form [19]

$$\mathbf{v}(\mathbf{x}_m,\omega)=-\frac{i}{\omega\rho_0 c}\overrightarrow{\bigtriangledown}p(\mathbf{x}_m,\omega), \quad (4)$$

where ρ_0 is the air density, c is the speed of sound, $p(\mathbf{x}_m,\omega)$ is sound pressure at position $\mathbf{x}_m$, and $\overrightarrow{\bigtriangledown}$ denotes gradient. In practice, the components of $\mathbf{v}(\mathbf{x}_m,\omega)$ can be obtained by using the spatial difference to approximate its derivative in (4). For example, along the x axis, one has

$$v^{(x)}(\mathbf{x}_m,\omega)\approx-\frac{i}{\omega\rho_0 c}\frac{p(\mathbf{x}_m,\omega)-p(\mathbf{x}_{m,x},\omega)}{\Delta R}, \quad (5)$$

where $p(\mathbf{x}_{m,x},\omega)$ is the pressure of the microphone near $\mathbf{x}_m$ along the x axis, and $\Delta R=\|\mathbf{x}_m-\mathbf{x}_{m,x}\|_2$ is the distance between the control point and a closely-spaced microphone in the x axis. In this work, we assume that, at every control point, there is a pressure microphone and three additional microphones located along the $x-$, $y-$ and $z-$axis, which are very close to the control point with a distance of ΔR to estimate the particle velocity.

Similar to (1), (5) can been rewritten as

$$v^{(x)}(\mathbf{x}_m,\omega)=\sum_{\ell=1}^{L}S(\omega)w_\ell(\omega)H_\ell^{(v_x)}(\mathbf{x}_m,\omega)$$
$$=S(\omega)\left[\mathbf{h}^{(v_x)}(\mathbf{x}_m,\omega)\right]^T\mathbf{w}(\omega), \quad (6)$$

where

$$H_\ell^{(v_x)}(\mathbf{x}_m,\omega)=-\frac{i}{\omega\rho_0 c}\frac{H_\ell(\mathbf{x}_m,\omega)-H_\ell(\mathbf{x}_{m,x},\omega)}{\Delta R} \quad (7)$$

is the particle velocity ATF in the x axis, and

$$\mathbf{h}^{(v_x)}(\mathbf{x}_m,\omega)=\left[H_1^{(v_x)}(\mathbf{x}_m,\omega)\quad\cdots\quad H_L^{(v_x)}(\mathbf{x}_m,\omega)\right]^T \quad (8)$$

is the control filter vector. The other particle velocity components $v^{(y)}(\mathbf{x}_m,\omega)$ and $v^{(z)}(\mathbf{x}_m,\omega)$ have similar form to (6).

We write the reproduced particle velocity at the bright zone control points in a vector form as

$$\mathbf{v}(\omega)=S(\omega)\mathbf{H}^{(v)}(\omega)\mathbf{w}(\omega), \quad (9)$$

where

$$\mathbf{H}^{(v)}(\omega)=\Big[\mathbf{h}^{(v_x)}(\mathbf{x}_{1_{\mathrm{B}}})\quad\mathbf{h}^{(v_y)}(\mathbf{x}_{1_{\mathrm{B}}})\quad\mathbf{h}^{(v_z)}(\mathbf{x}_{1_{\mathrm{B}}})\quad\cdots$$
$$\mathbf{h}^{(v_x)}(\mathbf{x}_{M_{\mathrm{B}}})\quad\mathbf{h}^{(v_y)}(\mathbf{x}_{M_{\mathrm{B}}})\quad\mathbf{h}^{(v_z)}(\mathbf{x}_{M_{\mathrm{B}}})\Big]^T. \quad (10)$$

The multi-zone reproduction can be achieved in different ways, which are summarized as follows.

A. Intensity-based Reproduction

Let us first review the frequency-domain sound intensity matching method. The reconstructed intensity at a control point $\mathbf{x}_m$ is $\mathbf{I}(\mathbf{x}_m)=\left[I^{(x)}(\mathbf{x}_m)\ I^{(y)}(\mathbf{x}_m)\ I^{(z)}(\mathbf{x}_m)\right]^T$, where the x component of sound intensity is

$$I^{(x)}(\mathbf{x}_m)=\left(\mathbf{I}^{(x)}\right)^T\overline{\mathbf{w}}, \quad (11)$$

where

$$\mathbf{I}^{(x)}=\left[I_1^{(x)}(\mathbf{x}_m)\ \cdots\ I_L^{(x)}(\mathbf{x}_m)\right]^T, \quad (12)$$
$$\overline{\mathbf{w}}=\left[|\omega_1|^2\quad\cdots\quad|\omega_L|^2\right]^T. \quad (13)$$

We have

$$I_\ell^{(x)}(\mathbf{x}_m)=p_\ell^*(\mathbf{x}_m)v_\ell^{(x)}(\mathbf{x}_m)$$
$$=|S(\omega)|^2\left[H_\ell^{(p)}(\mathbf{x}_m)\right]^*H_\ell^{(v_x)}(\mathbf{x}_m). \quad (14)$$

The intensity can be written in a matrix form as

$$\bar{\mathbf{I}}=\Big[\mathcal{R}\left\{\mathbf{I}^{(x)}(\mathbf{x}_1)\right\}\quad\mathcal{I}\left\{\mathbf{I}^{(x)}(\mathbf{x}_1)\right\}\quad\mathcal{R}\left\{\mathbf{I}^{(y)}(\mathbf{x}_1)\right\}\quad\cdots$$
$$\mathcal{I}\left\{\mathbf{I}^{(y)}(\mathbf{x}_M)\right\}\quad\mathcal{R}\left\{\mathbf{I}^{(z)}(\mathbf{x}_M)\right\}\quad\mathcal{I}\left\{\mathbf{I}^{(z)}(\mathbf{x}_M)\right\}\Big]^T, \quad (15)$$

where $\mathcal{I}\{\cdot\}$ and $\mathcal{R}\{\cdot\}$ denote the imaginary and real parts of a complex vector, respectively, and $M=M_{\mathrm{B}}+M_{\mathrm{D}}$ is the total number of control points within the bright and dark zones. The desired sound intensity at all the control points can also be represented in a vector form as

$$\bar{\mathbf{I}}_{\mathrm{d}}=\Big[\mathcal{R}\left\{I^{(x)}(\mathbf{x}_1)\right\}\quad\mathcal{I}\left\{I^{(x)}(\mathbf{x}_1)\right\}\quad\cdots$$
$$\mathcal{R}\left\{I^{(z)}(\mathbf{x}_M)\right\}\quad\mathcal{I}\left\{I^{(z)}(\mathbf{x}_M)\right\}\Big]^T. \quad (16)$$

Note that here the desired intensity in the dark zone is set to 0 in (16). The amplitude of the control filter can be obtained by minimizing the mean square error between the reconstructed intensity and the desired intensity, which is formulated as

$$\min \|\bar{\mathbf{I}}\overline{\mathbf{w}} - \bar{\mathbf{I}}_{\mathrm{d}}\|^2 \;\; \text{s.t.} \;\; \overline{\mathbf{w}} \geq 0, \tag{17}$$

where the constraint ensures that the elements in the vector $\overline{\mathbf{w}}$ are non-negative. The problem in (17) is a non-negative least squares (NNLS) problem, which can be solved by the Lawson and Hansons method [20]. To make sure that the PSZ control system is causal and stable, a minimum-phase filter is adopted by utilizing the Hilbert transform on the calculated amplitude [14]. As will become clear in Section V, the intensity matching approach is not able to achieve the optimal phase control, leading to insufficient acoustic contrast (AC) between the bright and dark zones.

B. Joint Control of Sound Pressure and Particle Velocity

The desired sound pressure at all the control points is written in a vector form as

$$\mathbf{p}_{\mathrm{d}}(\omega) = [p_{\mathrm{d}}(\mathbf{x}_{1_{\mathrm{B}}}, \omega) \quad \cdots \quad p_{\mathrm{d}}(\mathbf{x}_{M_{\mathrm{B}}}, \omega) \quad \mathbf{0}_{M_{\mathrm{D}}}]^T. \tag{18}$$

The desired particle velocity at the bright-zone control points is also written in a vector form as

$$\mathbf{v}_{\mathrm{d}}(\omega) = \left[\mathbf{v}_{\mathrm{d}}^T(\mathbf{x}_{1_{\mathrm{B}}}, \omega) \quad \mathbf{v}_{\mathrm{d}}^T(\mathbf{x}_{2_{\mathrm{B}}}, \omega) \;\cdots\; \mathbf{v}_{\mathrm{d}}^T(\mathbf{x}_{M_{\mathrm{B}}}, \omega)\right]^T. \tag{19}$$

A frequency-domain method for joint optimization of sound pressure and particle velocity to generate PSZs was developed in [6]. The principle is to reproduce the desired particle velocity and sound pressure within the bright zone and meanwhile keep the dark zone sound pressure as small as possible. The loudspeaker control filter is obtained by solving the following optimization problem:

$$\min_{\mathbf{w}(\omega)} \tau\|\mathbf{p}(\omega) - \mathbf{p}_{\mathrm{d}}(\omega)\|^2 + (1-\tau)\rho(\omega)\|\mathbf{v}(\omega) - \mathbf{v}_{\mathrm{d}}(\omega)\|^2. \tag{20}$$

Let us introduce a frequency dependent normalization term, i.e., $\rho(\omega) = |\omega\rho_0 c\Delta R|^2$, to the particle velocity term in (20). Substituting (3) and (9) into (20) gives the following equivalent optimization problem:

$$\begin{aligned}\min_{\mathbf{w}(\omega)} &\tau\|\mathbf{H}^{(p)}(\omega)\mathbf{w}(\omega) - \mathbf{h}_{\mathrm{d}}^{(p)}(\omega)\|^2 + \\ &(1-\tau)\rho(\omega)\|\mathbf{H}^{(v)}(\omega)\mathbf{w}(\omega) - \mathbf{h}_{\mathrm{d}}^{(v)}(\omega)\|^2,\end{aligned} \tag{21}$$

whose solution is

$$\begin{aligned}&\mathbf{w}(\omega) = \\ &\left\{\tau\left[\mathbf{H}^{(p)}\right]^H \mathbf{H}^{(p)} + (1-\tau)\rho(\omega)\left[\mathbf{H}^{(v)}\right]^H \mathbf{H}^{(v)}\right\}^{-1} \\ &\left\{\tau\left[\mathbf{H}^{(p)}\right]^H \mathbf{h}_{\mathrm{d}}^{(p)} + (1-\tau)\rho(\omega)\left[\mathbf{H}^{(v)}\right]^H \mathbf{h}_{\mathrm{d}}^{(v)}\right\}.\end{aligned} \tag{22}$$

Note that when $\tau = 1$, the filter in (22) becomes the conventional PM method.

The aforementioned joint control method was evaluated in free field environments [6]. When used in real reverberant environments, particularly when reverberation is strong, the control filter has to be long, making the algorithm computationally very expensive. To reduce complexity, we introduce a subband filtering strategy to reduce the length of the control filters in the next section.

III. Subband design for PSZ systems

A. Subband Filtering

We use the quadrature mirror filter (QMF) to fulfil the subband filtering structure [21]. QMF provides a two-band division and achieves an alias-free reconstruction of signals. The QMF subband division method consists of two steps: 1) the analysis step, where the original signal is filtered with the low pass analysis filter f_0 (half-band FIR filter) and the filtered signal is then decimated by two; and 2) the reconstructive step, in which the down-sampled signal is first up-sampled then filtered with the reconstructive filter g_0. The higher frequency band shares a similar process except that the analysis filter is a high-pass filter f_1, and the synthesis filter is g_1. The reconstructed signal is obtained by adding up the synthesized subband signals [21]. Multiband can be obtained by further applying the two-band analysis and synthesis to each subband in a cascaded way.

B. Subband PSZ Method

In the subband method, the ATFs are first converted to subband ATFs. The loudspeaker control filter in the ith subband is then obtained by applying the PSZ control method within this subband where the ith subband loudspeaker control filter is obtained as follows

$$\begin{aligned}\mathbf{w}_i(\omega) = &\left\{\tau\left[\mathbf{H}_i^{(p)}\right]^H \mathbf{H}_i^{(p)} + (1-\tau)\rho\left[\mathbf{H}_i^{(v)}\right]^H \mathbf{H}_i^{(v)}\right\}^{-1} \cdot \\ &\left\{\tau\left[\mathbf{H}_i^{(p)}\right]^H \mathbf{h}_{\mathrm{d},i}^{(p)} + (1-\tau)\rho\left[\overline{\mathbf{H}}_i^{(v)}\right]^H \mathbf{h}_{\mathrm{d},i}^{(v)}\right\},\end{aligned} \tag{23}$$

where $\mathbf{H}_i^{(p)}$, $\mathbf{H}_i^{(v)}$, $\mathbf{h}_{\mathrm{d},i}^{(p)}$ and $\mathbf{h}_{\mathrm{d},i}^{(v)}$ are subband ATFs. To generate the loudspeaker driving signal, the frequency-domain subband control filter $\mathbf{w}_i(\omega)$ is transformed to the time domain using the inverse Fourier transform, thereby giving $\mathbf{w}_i(t)$. The time-domain filter can be truncated to further reduce the filter length. With the subband source audio signal being $\mathbf{s}_i(t)$, the subband loudspeaker driving signal is obtained as $\mathbf{y}_i(t) = \mathbf{s}_i(t) * \mathbf{w}_i(t)$. An example of the subband PSZ control method with 4 subbands is illustrated in Fig. 1.

IV. Performance Measures

In order to evaluate the performance of different PSZ methods, we use acoustic contrast (AC) and reproduced intensity error as performance measures. AC is defined as the ratio of the reproduced signal power at the bright zone to that at the

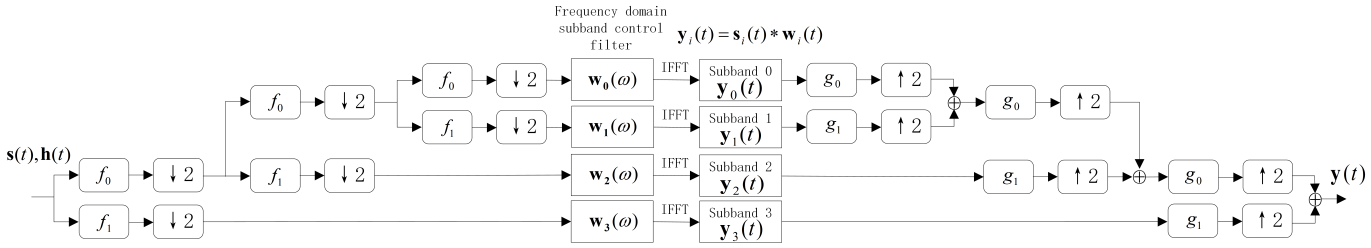

Fig. 1. Illustration of a subband PSZ method.

dark zone, i.e.,

$$\mathrm{AC}(\omega)=\frac{\mathbf{w}^H(\omega)\left[\mathbf{H}_{\mathrm{B}}^{(p)}(\omega)\right]^H\mathbf{H}_{\mathrm{B}}^{(p)}(\omega)\mathbf{w}(\omega)}{\mathbf{w}^H(\omega)\left[\mathbf{H}_{\mathrm{D}}^{(p)}(\omega)\right]^H\mathbf{H}_{\mathrm{D}}^{(p)}(\omega)\mathbf{w}(\omega)}. \tag{24}$$

The normalized mean square error (NMSE) between the reproduced sound intensity and the desired sound intensity in the bright zone is defined as

$$\epsilon(\omega)=\frac{\sum_{m=1}^{M_{\mathrm{B}}}\|\mathbf{I}(\mathbf{x}_m)-\mathbf{I}_{\mathrm{d}}(\mathbf{x}_m)\|^2}{\sum_{m=1}^{M_{\mathrm{B}}}\|\mathbf{I}_{\mathrm{d}}(\mathbf{x}_m)\|^2}, \tag{25}$$

where $\mathbf{I}(\mathbf{x}_m)=p^*(\mathbf{x}_m,\omega)\mathbf{v}(\mathbf{x}_m,\omega)$ and $\mathbf{I}_{\mathrm{d}}(\mathbf{x}_m)=p_{\mathrm{d}}^*(\mathbf{x}_m,\omega)\mathbf{v}_{\mathrm{d}}(\mathbf{x}_m,\omega)$ are, respectively, the reproduced sound intensity and desired sound intensity.

V. Simulation Results

The performance of different PSZ methods are evaluated through numerical simulations. An irregular circle array of 30 loudspeakers are placed in a square room of size $6\ \mathrm{m}\times 6\ \mathrm{m}\times 3\ \mathrm{m}$. The loudspeakers and microphone control points are at the same horizontal plane with a height of $1.5\mathrm{m}$ above the floor. There is a dark zone and a bright zone inside the circular array, and in each zone, we placed 8 control points on the contour of the control area. For each control point, there are extra microphones along the x-, y- and z-axis to obtain the particle velocity estimates. These microphones are $0.01\ \mathrm{m}$ away from the control point. The position of the loudspeakers and microphones are illustrated in Fig. 2. We apply the image source model to simulate the ATFs [22]. The sampling frequency is $8\ \mathrm{kHz}$. The signals are separated into four subbands with the cutoff frequencies being, respectively, $0.5\ \mathrm{kHz}$, $1\ \mathrm{kHz}$, and $2\ \mathrm{kHz}$. For comparison, the reproduction performance based on pressure matching, intensity matching, and the corresponding full-band control are also examined.

In the first simulation, we compare the performance of the joint control PSZ method with the PM and intensity matching method. In order to apply the intensity matching for multizone sound field reproduction, we set the desired sound intensity in the dark zone as zero. A room environment with reverberation time $T_{60}\approx 130\ \mathrm{ms}$ is simulated. From the results shown in Fig. 3, one can see that the joint control method has the smallest reproduced intensity error as compared to both the PM ($\tau=1$) and intensity matching methods at both the control and uncontrolled points. The intensity matching method can obtain acceptable reproduction error at the control point in the bright zone, but almost no AC difference between the bright and dark zones. The underlying reason is that with the intensity matching method, the phase of each control filter is fixed (i.e., a minimum phase as a Hilbert transform of the control filter amplitude), so the required phase control for AC is not guaranteed. The intensity matching method also fails to fulfill the control at the uncontrolled points.

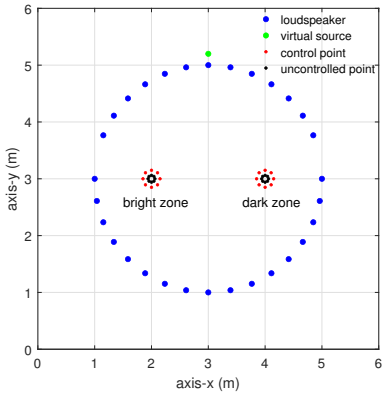

Fig. 2. The simulation setup.

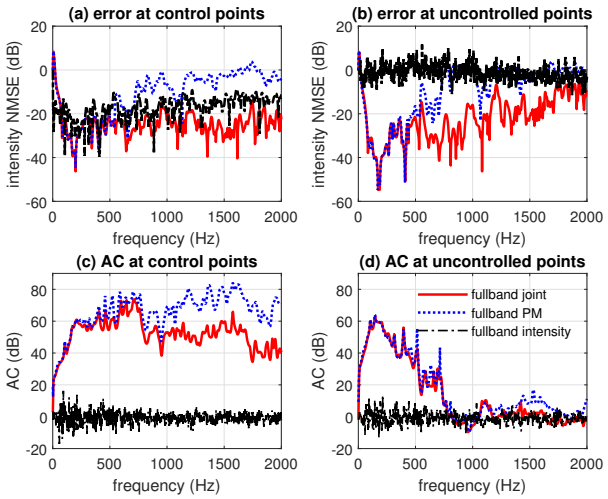

Fig. 3. Performance of the PM method, intensity matching method, and the joint controlled method with $\tau=0.6$.

In the second simulation, the performance of the subband joint control method is studied and compared to the original full-band control method. The results in Fig. 4 show that the subband processing leads to slightly degraded performance compared to its full-band counterpart. However, the subband method has a much shorter filter length. The full-band method requires a filter length of 1800 to obtain good PSZ control

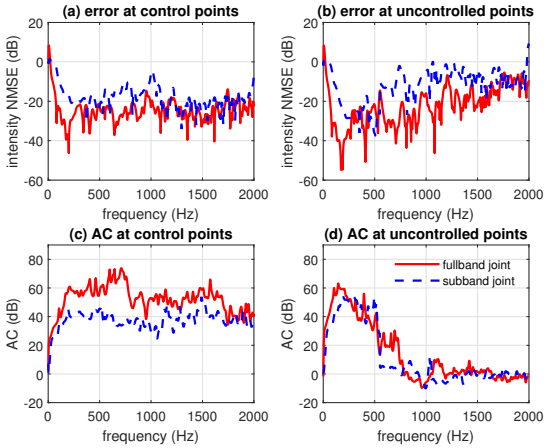

Fig. 4. Performance of the joint control method ($\tau = 0.6$) using fullband and subband filtering strategy.

TABLE I
SUBBAND FILTER LENGTH.

subband (kHz)	0-0.5	0.5-1	1-2	2-4
filter length (samples)	180	180	350	800

performance. In this case, the computational complexity of the full-band method is $(1800)^3$. The filter length of each subband filter is shown in Table. 1. We further shorten the subband filter length by cutting off the points in the tail of the filter which is close to zero. One can see that the subband filter has a much shorter filter length. With the filter length being illustrated in Table 1, the computational complexity of the subband method is $(800)^3 + (350)^3 + 2(180)^3$ which is much less than the full-band method. The less computational complexity of subband PSZ method makes it more appropriate to implement in real applications.

VI. CONCLUSIONS

This paper studied the problem of generating PSZ based on optimization of sound pressure and particle velocity. We first reviewed two state-of-the-art methods, i.e., the frequency-domain intensity matching method and the method with pressure and particle velocity being jointly controlled. Both methods can work with irregular loudspeaker array setups. To reduce the complexity so the joint optimization method can be implemented and applied in reverberant environments, we proposed a subband PSZ control method based on the joint optimization of sound pressure and particle velocity. Simulations show that the intensity matching method, which has no control of reproduced phase, cannot achieve the desired AC. In comparison, the proposed subband method can achieve the desired performance and meanwhile is computationally more efficient since it has a much shorter filter length.

An Multi-evidence Fusion Based on C-Distance with Uncertain Reasoning for Classification

Cuiping Cheng, Pengcheng Yue and Taihao Li*

***Abstract*—Dempster-Shafer (D-S) evidence theory has been extensively used to handle uncertain information. However, evidence fusion remains a challenging problem because counter-intuitive results would occur when combining highly conflicting evidence. To address this issue, we propose a weighted fusion model with multi-evidence uncertainty reasoning based on a novel similarity quantification function. Specifically, we first define a dissimilarity representation function C-distance. This function considers two factors, the angle and the norm of the evidence vector, so that the similarity between evidences can be described more comprehensively. In particular, unlike previous weights defined as the ratio between distances, we use a nonlinear function to fit the weight and the C-distance, which expands the learning space of weights. Based on the above work, we propose a weighted fusion framework. Experiments on real datasets illustrate the excellent performance of the proposed method in information fusion.**

I. Introduction

With the rapid development of science and technology, the types of information are gradually diversified. Information from different sources often helps to comprehensively describe the nature of things, hence, how to integrate multi-source information has attracted much attention [1], [2]. The linear combination formulation works only when there is no high degree of conflict between all tasks, however, such cases are rare. Multiple-evidence learning with conflicts requires a trade-off of weights between tasks that goes beyond what is achieved by linear combinations. Many fusion models have been constructed, such as Dempster-Shafer evidence theory [3], [4] and evidential reasoning [5].

D-S evidence theory [6], [7] has been widely used in many fields such as decision making [8], target recognition and so on [9], [10], [11], [12]. However, counterintuitive results may obtained when using evidence theory to combine highly conflicting evidence [13]. In order to solve this problem, an effective method is to determine the contribution of different evidences in the combined operation by measuring the conflict between the evidences[14]. Many methods to measure the similarity between evidences have been proposed to model the conflict degree [15], [16], [17], among which, the Jousselme $et\ al.$'s distance is relatively simple to calculate and the geometric meaning is clear, it has been widely used to manage conflicts of evidence. Although effective, Jousselme $et\ al.$ diatence is a global similarity measure that cannot capture local differences, which degrades the performance of classification tasks.

To cope with evidence uncertainty and fusion conflicts, we present a novel distance measure to quantify the uncertainty of the belief distribution and the similarity of two evidences, then use the nonlinear constraint relationship to learn the optimal distribution of weights, and finally use the weighted discounted classification results for D-S combination to make the final decision making. In specifically, we first define the C-distance, which estimates the angle and norm difference between evidence vectors, so that it can not only learn local belief structures more sensitively, but also effectively discern non-heterogeneous evidence. Compared with linear weights, dynamic weights [18] can flexibly adjust the sensitivity of conflict, thereby increasing the robustness of the fusion framework and providing decision makers with more space for expression of preferences. We then dynamically learn the optimal weights based on the proposed similarity function. Finally, we design a multi-evidence fusion framework to deal with classification tasks. Specifically, the obtained weight matrix will guide the fusion process to pay more attention to the single evidence with high reliability. We evaluate our model on the challenging dataset, and the empirical results demonstrate the effectiveness of our method. In addition, this paradigm is generalizable and can be extended to more tasks, which is of great significance for improving the performance of fusion decision-making.

In summary, our contributions in this paper are summarized as follows:

- A new similarity measure function is proposed to quantify the angle and modulus length differences of evidence vectors. The proposed measure takes into account the uncertainty of belief distribution and the inclusion relationship between elements, which allows the measure able to handle data where the conflicts between evidences are not significant enough.
- This paper designs a weighted fusion strategy based on C-distance and dynamic weight generation, which gives reliable evidence a higher weight to deal with high-conflict scenarios.
- We conduct extensive experiments on iris dataset and sentiment analysis datasets, the results validate the robustness and effectiveness of our method on the classification task.

II. Related Work

A. Evidence theory

A substantial number of work has been done to deal with the conflict issue from evidence dissimilarity perspectives. One of the classic schemes, Deng $et\ al.$ [19] provide an improved

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

combination averaging method of confidence function based on evidence distance measurement. This method first uses distance to construct a similarity matrix, and then determines the importance of the evidence according to the credibility degree. Fuyuan Xiao [20] presented a new reinforced belief divergence measure in D-S evidence theory for data fusion. The proposed divergence measurement is the first such measure that takes into account the correlations between mass functions and subsets of the sets of belief functions. The credibility of each piece of evidence is obtained by modeling the reinforced belief divergence measure matrix, which is treated as the final weight for each evidence. Kaiyi Zhao $et\ al.$ [21] developed an improved evidence fusion algorithm in multi-sensor systems. First, a new distribution distance measurement method is proposed to obtain the credibility of the evidence. Next, an improved calculating method was introduced to generate the amount of information of the evidence. Finally, modify the credibility of each evidence according to the amount of information to determine the weight of the evidence. There are also many studies focus on the use of entropy and distance to combine conflicting evidence. Chaosheng Zhu $et\ al.$ [14] defined a Hellinger distance for evidence theory. Based on the presented distance, a multisource information fusion method is devised, the proposed method takes both distance between evidences and the uncertainty of the evidences into account. In the proposed belief fusion method, the newly defined distance is used as a tool to measure the distance between two sources of evidence, and the information volume weight of each piece of evidence is calculated by belief entropy.

B. Dynamic weight generation

In [18], an efficient dynamic weight generation scheme was proposed. Given n pieces of evidence, let m_i and m_j be two BPAs on the same frame of discernment Θ.

Step 1: Calculate the dissimilarity representation between all the evidences:

Let

$$d_{sum}(m_i) = \sum_{j=1, j\neq i}^{N} D_C(m_i, m_j) \tag{1}$$

Step 2: Let ω_i be the weight of evidence m_i, the weight ω_i is obtained by minimizing the objective function:

$$minimize \sum_{i=1}^{N} \omega_i^{\tau} d_{sum}(m_i), \tag{2}$$

where $\tau > 1$ is the elasticity coefficient. In order to achieve the result of assigning significant dissimilar evidence with a small weight, optimization is performed by minimizing the objective function. Here, the optimal weight w_i is given by the following equation:

$$argmin_{w_i} \sum_{i=1}^{N} \omega_i^{\tau}(m_i) d_{sum}(m_i) \tag{3}$$

Then, we use the Lagrangian multiplier method to solve this extreme value problem, the Eq.3 has a generalized Lagrangian:

$$\zeta(d_{sum}(m_i), \omega_i(m_i)) = \sum_{i=1}^{N} \omega_i^{\tau}(m_i) d_{sum}(m_i) + \lambda(\sum_{i=1}^{N} \omega_i(m_i) - 1)$$

$$s.t. \sum_{i=1}^{N} \omega_i(m_i) = 1$$

III. The proposed method

A. C-distance

Let us consider an example, m_1, m_2 and m_3 are three BPAs in the $\Theta = \{A, B, C\}$.

$$\begin{aligned} &m_1(A) = 0.5, m_1(B) = 0.2, m_1(C) = 0.3; \\ &m_2(A) = 0.7, m_2(B) = 0.1, m_2(C) = 0.2; \\ &m_3(A) = 0.3, m_3(B) = 0.3, m_3(C) = 0.4. \end{aligned}$$

According to the Jousselme's distance, we have $d_J(m_1, m_2) = d_J(m_3, m_2)$. In this example, m_1 and m_2 have a consistent preference, both support the element A. However, Jousselme's distance fails to capture this information. It is worth noting that, according to information entropy, we can know evidence m_2 has the lowest uncertainty, while m_3 is the most uncertain. More importantly, the norm between the three vectors satisfies the following relationship: $|m_2| > |m_1| > |m_3|$. We therefore propose the following theorem:

Theorem 3.1: The norm of the vector is inversely proportional to its information uncertainty.

Since the Euclidean distance quantifies the global difference, the direction information of the vector is ignored. Especially for high-dimensional vectors, the sparsity of the data is more likely to damage the sensitivity As shown in Fig.1, it can be observed the angle $\theta(\vec{oa}, \vec{ob}) > \theta(\vec{oe}, \vec{of})$ according to Euclidean distance, we have $d_E(\vec{oa}, \vec{ob}) = d_E(\vec{oe}, \vec{of})$. This shows that two sets of vectors with equal Euclidean distances do not mean that their element distributions are also the same. It is necessary to combine the factor of the difference in angle to improve the sensitivity. If the angles and norms of the two sets of vectors are equal, it can be shown that the distance between the two vectors is the same.

In fact, the distance function is a general function of the distribution of random variables, which does not depend on the actual value of the random variable, but only on its belief distribution. Therefore, if the direction difference and value difference can be considered at the same time, the measurement of information similarity will be more reliable. Here, we propose a new conflict measure called C-distance, which overlaps with Euclidean distance and $et\ al.$'s distance, but also extends cosine distance.

Definition 3.1: Given two BPAs $\mathbf{P} = (p_1, p_2, \ldots, p_n)$ and $\mathbf{Q} = (q_1, q_2, \ldots, q_n)$, The C-distance between $\mathbf{P}$ and $\mathbf{Q}$ is

defined as:

$$D_C(\mathbf{P},\mathbf{Q}) = (1 - \frac{\sum_{i=1}^{i=n} p_i \times q_i}{|\mathbf{PS}^P| \times |\mathbf{QS}^Q|})|\mathbf{P}| \times |\mathbf{Q}| \tag{4}$$

where $\mathbf{S}$ is an $1 \times n$ matrix whose elements are

$$\mathbf{S}^P = (\frac{1}{|p_1|}, \frac{1}{|p_2|}, \cdots, \frac{1}{|p_n|})^T$$

where $\mathbf{S}$ is the likelihood ratio matrix whose elements measure the similarity between classified elements, matrix $\mathbf{S}$ reflects the association between each element in the vector, which plays the role of changing the angle between the vectors. Intuitively, the C-distance compares the distance between two vectors in the decision space whose angle is less than or equal to 90 degrees. this measure puts improved robustness and improved similarity conflicts under a common umbrella. This normalization provides effective guidance on which distance metric to use for a given case, depending on the details of the decision task.

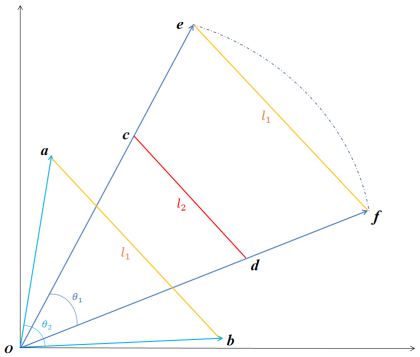

Fig. 1.

B. Evidence weighted fusion

To address the problem of belief theory failing when combined with highly contradictory evidence, in this section, we design a weighted fusion framework, from the aspect of evidence preprocessing. The architecture of presented method is as shown in Fig.2. The framework consists of three modules: formulation of evidence, dynamic weight generation and fusion of weighted beliefs. Our approach provides a new paradigm for fusion learning by combining dynamic evidence outputs from different sources at the decision level.

After obtaining dynamic weights w_i, a weighted average is performed on all the belief functions:

$$\tilde{m}(A) = \sum_i w_i \cdot m_i \tag{5}$$

Suppose two evidences m_1 and m_2, which can be combined into a new evidential body m through Dempster combination rule

$$m(A) = \frac{\sum_{B \cap C = A} m_1(B) m_2(C)}{1 - k} \tag{6}$$

with $k = \sum_{B \cap C = \emptyset} m_1(B) m_2(C)$. Here, k represents the degree of conflict between evidences and also called normalization constant.

Finally, fuse the evidence $\tilde{m}(A)$ $N-1$ times through Dempster's combination rule:

$$m_f(A) = \tilde{m}(A) \oplus \tilde{m}(A) \oplus \cdots \oplus \tilde{m}(A) \tag{7}$$

The output $m_f(A)$ is used for decision making.

IV. EXPERIMENTS

In the following, let us study the properties of our model through numerical examples.

A. Iris dataset

The initial Iris data set comes from the UCI repository of the database. For the credibility and fairness of comparison, we quote the BPAs in [22] for experiments. In the Iris dataset, there are three kinds of Iris flower Setosa, Versicolor and Virginica. and each type of iris has the following four attributes $SepalLength(SL)$, $SepalWidth(SW)$, $PetalLength(PL)$ and $PetalWidth(PW)$. Therefore, the frame of discernment is denoted as $\Psi = \{SE, VC, VI\}$, the BPAs generated based on the Iris dataset is shown in Tab.I. For the purpose of verifying and comparing the performance of models in handling conflicts of evidence, the test data set obtained by adding noise samples is given as Tab.II.

The distance and weight results on the two datasets, as shown in Tab.III, shows the feasibility of our distance measure and weight generation strategy. Our distance is more discriminative for conflicts between conflicting evidence, which contributes to the reliability of weights generated based on distance.

From Tab.IV, for BPA that does not have high conflicts, all methods including our model can assign the highest reliability to the correct sample after fusion. Since our dissimilarity

measurement is more comprehensive, the difference between m_2 and other BPAs is deepened by supplementing preference information. In this example, the reason why we set $\tau = 1.5$ is that when there are highly conflicting data, let $\tau < 2$, it will magnify the difference, the difference would be amplified and the weight of unreliable evidence would be reduced. The comparison results of our strategy and other methods in the noisy dataset are shown in Tab.V. It can be seen that the convergence speed of the proposed method is the fastest. The results obtained by the weighted fusion method are generally better than the Dempster fusion rule, and the weight tendency determined by the proposed method is more obvious. After combining the four pieces of evidence, the presented framework is superior to other methods.

B. EMOCAP dataset

1) Experimental setting: Recent advances in deep neural networks (DNNs) have improved various machine learning problem, but how to effectively fuse massive labeled training data is still the key to improving the accuracy of DNNs [24]. It is worth noting that due to the internal architectures of neural networks are different, for the same data set, the predictive ability of the models learned by different networks is not consistent. Therefore, it is unreasonable to share unified weight parameters in multi-model fusion decision-making. Accordingly, this allows us to conduct multi-model fusion experiment to

ResNet	62.815
VGG	50.565
DenseNet	50.565

illustrate that our approach can effectively mitigate the impact of conflicting data in information fusion, thereby improving the reliability of decision-making. In order to simulate on real datasets, the first step is to build a reasonable belief generation framework to process the outputs of DNNs. DNNs use the softmax operator to convert the continuous activations of the output layer into class probabilities, these probabilities are then compressed into simplex by softmax according to the maximization of the DNNs parameters. Therefore, in this paper, we train the classification probability output by the softmax layer of the neural network as the belief distribution, so that different network models output different evidence to form decision opinions. The output of the softmax operation of the neural network N_i be the predictive distribution m_i:

$$m_i = softmax(N_i)$$

For the evidence given by the ith network model, we can find that the focal element of each evidence is a single subset. It is worth noting that different transformation strategies will have different belief generation results. We chose a one that is simple to calculate while ensuring that the predictions given by the model are not corrupted to the greatest extent.

The evaluation form for EMOCAP contains 10 items (neutral, happy, sad, angry, surprised, fearful, disgusted, depressed, excited, other). We chose 4 of these: angry, happy, neutral and sad, to be consistent with previous research.

2) Results: The result in Tab.VI is the classification accuracy of each neural network model, one may notice that there is a clear gap in accuracy between them. $V-FT$ has the highest accuracy 67.333%, and the gap between the worst-performing G model is greater than 20%. The accuracy of the six models has a certain difference, and the inherent properties may cause the networks to give conflicting decision-making opinions for the same sample. To verify the effectiveness of our model in integrating different and various information sources, we conduct experimental comparisons with existing evidence fusion frameworks on different numbers of models.

TABLE VII
COMPARISON RESULTS OF DIFFERENT METHODS, TO VERIFY THE PROPOSED DISSIMILARITY QUANTIZATION FUNCTION,

Measures	Accuracy result
Dempster [7]	70.287
Murphy's method [23]	67.941
Deng's [19]	70.721
Zhu's [25]	64.292
Proposed	**71.329**

In Fig.VII, we report the results of different methods on the dataset of EMOCAP. We can seen that the accuracy of all model fusion strategies is greatly improved compared with the single model, the performance of ours is better than the comparison models. As can be observed that the performance of multiple models has generally been improved, it may be due to the data enhancement effect of multiple models. Models embedded in evidence theory help characterize the uncertainty of images that are difficult to identify, and the comparison results also demonstrate this advantage. This comparison result verifies the excellent robustness of the proposed model, the reason is that our model is more sensitive to the reliability of the evidence, which can effectively reduce the degree to which conflicting information is considered. Therefore, our model is less dependent on data quality.

V. CONCLUSION

Fusion of conflicting evidence is an open issue of belief function. In this paper, a distance function between evidence vectors is proposed, which not only calculates the angle of the vector, but also considers the norm of the vector. Specifically, in order to make the difference between the evidence more comprehensive, we referred to the cosine function as a prototype to characterize the angle difference, and the norm of the vector was used to solve the shortcoming of the Jousseme $et\ al.$'s. Furthermore, we used the obtained dissimilarity and the constraint condition that the sum of weights is equal to 1 to construct a multivariate function, the solution obtained by calculating this function is used as the optimal fusion weight of each evidence. A set of application simulations has been conducted to demonstrate the effectiveness of the proposed algorithms. We intend to further study the proposed weight determination algorithm in our future work and to extend the proposed method to more applications.

***Abstract*—In recent years, the research of graph signal processing has attracted extensive attention of scholars, especially graph uncertainty principle. The lower bound of uncertainty is closely related to time-frequency resolution, therefore it is of great application value to explore the minimum lower bound of uncertainty in time-frequency analysis, biological data processing and radar imaging. In this paper, we obtain two uncertainty principles of lowband graph signals, basing on matrix theory and operator norm theory. By using the extreme value property of quadratic matrix eigenvalue and the related definition of matrix norm, the basic sparse uncertainty principle and the sparse lower bound of graph uncertainty principle based on multiplicative uncertainty are compared, which shows the superiority of the latter in signal detection performance. Then, examples and numerical comparison results are provided to verify the previous theoretical analysis, showing that the graph uncertainty principle based on multiplicative uncertainty is closer to the time-frequency resolution than the basic sparse uncertainty principle. The application of uncertainty principle involving signal sparsity expansion in compressed sampling is also given.**

I. Introduction

In the field of signal processing, the classical uncertainty principle means that a signal can't be too concentrated in time and space domain and frequency domain at the same time. This means that the resolution of the signal in time domain and frequency domain can't be determined at the same time. The uncertainty principle is not a single theorem, but a group of theorems. The most famous one is Heisenberg's uncertainty principle. Heisenberg inequality [1], [2],

$$\triangle_t^2 \triangle_\omega^2 \geq \frac{1}{4}, \tag{1}$$

as a theoretical tool to measure the resolution in time domain and frequency domain, plays an important role in time-frequency analysis and it is always a research focus. Signals are co-located in time and frequency, and the uncertainty principle represents the resolution trade-off between these two domains. Up to now, in the field of discrete signal processing, the research work on Heisenberg-like uncertainty principle has been very mature. The information characteristics of various stationary signals can be analyzed in detail, and preliminary applications have been made in compressed sensing, image denoising and signal recovery [3], [4]. Among many research results, the Heisenberg inequality is especially widely popularized, mainly involving the spread around a reference point. The related concepts of time spread and frequency spread are introduced below. For a signal $\mathbf{x}(t) \in l^2(R)$,$\langle \mathbf{x}(t), \mathbf{x}(t) \rangle_R = \int_{-\infty}^{\infty} \mathbf{x}^T(t)\mathbf{x}(t)\,dt$, its time spread about a point t_0 is defined by [5]

$$\triangle_t^2 = \frac{\langle (t-t_0)\mathbf{x}(t), (t-t_0)\mathbf{x}(t) \rangle_R}{\langle \mathbf{x}(t), \mathbf{x}(t) \rangle_R}. \tag{2}$$

Similarly, in the classical domain, for a signal $\mathbf{x}(t) \in l^2(R)$, its frequency spread is defined by

$$\triangle_\omega^2 = \frac{\langle \omega\widetilde{\mathbf{x}}(\omega), \omega\widetilde{\mathbf{x}}(\omega) \rangle_R}{2\pi \langle \mathbf{x}(t), \mathbf{x}(t) \rangle_R}. \tag{3}$$

For the classical uncertainty principle in time-frequency domain, see [6], [7], [8].

With the development of digital signal processing theory and the continuous improvement of information analysis ability, more non-stationary and nonlinear signals are encountered in practical application scenarios, such as infrastructure networks, social networks, economic networks and so on. These signals are no longer evenly sampled in time, but exist in the form of graphs. Graph signal includes vector signal, matrix signal and tensor signal. In this paper, we mainly describe vector graph signal. In order to further process and analyze irregular graph signals, it is necessary to extend the basic concepts of Fourier transform, filtering and multi-resolution analysis in classical signals to graph signals. In classical Euclidean space, the underlying domain is homogeneous, and the uncertainty principle applies to all signals, no matter how they are distributed on the coordinate axis. However, in the graph space, the underlying domain is irregular, and its topological structure, the relationship between nodes, needs to be considered. A little change in the structure of each small area on the graph will greatly affect the uncertainty boundary. According to the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

characteristics of the above graph signal, a large number of scholars have successively entered the research field of graph signal uncertainty principle, and put forward the uncertainty principle in different applications. In the following, we mainly introduce two types of common expressions of uncertainty principle on graph signal.

The measurement of the first kind of uncertainty principle mainly involves the spread around a reference point, usually the average position of the energy contained in the signal. For graph signals, it is difficult to extend the definitions of time spread and frequency spread in classical domain to graphs. Because of the structural complexity of graph signal, the extended definition of signal in vertex domain and graph domain is no longer a simple form about the mean or variance of signal. For a signal $\mathbf{x}(t) \in l^2(R)$,$\langle \mathbf{x}, \mathbf{x} \rangle_G = \mathbf{x}^T \mathbf{x}$, its graph spread about a vertex u_0 is defined by [5]

$$\triangle_g^2(\mathbf{x}) = \frac{\mathbf{x}^T \mathbf{P}_{u_0}^2 \mathbf{x}}{\langle \mathbf{x}, \mathbf{x} \rangle_G}, \tag{4}$$

where is $\mathbf{P}_{u_0}$ a diagonal matrix defined as

$$\mathbf{P}_{u_0} = diag\left\{d(u_0, v_1), \ldots, d(u_0, v_N)\right\}, \tag{5}$$

where v_i represents the ith vertex on the graph, $d(u, v)$ represents the shortest distance connecting two vertices. Similarly, for a signal $\mathbf{x}(t) \in l^2(R)$, its spectral spread is defined by

$$\triangle_s^2(\mathbf{x}) = \frac{\mathbf{x}^T \mathbf{L} \mathbf{x}}{\langle \mathbf{x}, \mathbf{x} \rangle_G}, \tag{6}$$

where $\mathbf{L}$ is the Laplace matrix corresponding to Fourier transform on the graph.

Ameya Agaskar and Yue M. Lu [5], [9] introduced the uncertainty principle involving these two concepts and gave the definition of uncertainty curve, which intuitively verified the conditions for realizing the lower bound in the uncertain feasible region. Based on the extension of the extended definition, in this paper, we introduce the first graph uncertainty principle. This indicates that the graph uncertainty principle is only applicable to some weighted graph families, which shows that it has certain limitations. Later, Bastien Pasdeloup [10] and others continued their in-depth research in this field and found a method to extend Ameya Agaskar's work [5] on unweighted graphs. Daniel Lenz [11] and others also studied on weighted graphs, and proved Laplace's principle of low-energy quantitative uncertainty on general weighted graphs. These all belong to the first kind of uncertainty principle. However, the previous work has its limitations. It shows that the extension of the classical uncertainty principle in time-frequency domain on the graph is not simple, which is undoubtedly a major focus of follow-up research.

The second kind of uncertainty principle mainly involves the absolute sparsity or concentration of signals. The research of Oguzhan Teke and Palghat P. Vaidyanathan [12] plays an outstanding role in this category, and its most important contribution is the graph uncertainty principle based on multiplicative uncertainty proposed according to the nonlocal measure of sparsity concept. Specifically, l_0 norm or l_1 norm is the related concept of signal expansion. This method is important because it quantifies the size of signal support. That is, the lower bound of the number of non-zero elements considering the graph signal and its Fourier transform. In order to find the signal that reaches the lower limit of derivation, sparse feature vectors are especially considered. Before this research Michael Elad and Alfred M. Bruckstein first introduced and proved the basic sparse uncertainty principle in early research, which has been widely used and popularized in many subsequent studies. Michael Elad and others also proved the uniqueness of sparse signal representation based on this important result. The above two research is a important achievement in the field of uncertainty principle on graph signals. Although the lower bound of uncertainty is derived from different research angles, they all use graph Laplacian operator to define the properties of graph signals when analyzing graph signals. Because of the importance of basic sparse uncertainty principle and graph uncertainty principle based on multiplicative uncertainty, we want to make a horizontal study and comparison between them.

Specific extension related concepts correspond to specific uncertainty principles, and they all have different applications. In order to further analyze the uncertainty of irregular graph signals, it is necessary to compare different uncertainty principles. The main reason is that if the lower bound is a constant with a parametric variable instead of a constant, it is possible to maximize the time-frequency resolution, thus maximizing the signal detection performance. Therefore, we focus on the basic sparse uncertainty principle and graph uncertainty principle based on multiplicative uncertainty, and deeply studies the minimum lower bound problem by comparing the extreme properties of quadratic matrix eigenvalues and the related definitions of matrix norms. A lowband signal indicates that the adjacent nodes on the graph are similar, and the node characteristics on the graph domain are smooth. In order to better compare the two kinds of uncertainty principle results, we determine to compare the sparse uncertainty boundaries based on l_0 norm on the same kind of lowband graph signals. Finally, the correctness of the previous theoretical derivation is verified by examples and experiments, which shows that the graph uncertainty principle based on multiplicative uncertainty has been improved in signal processing performance. The application of uncertainty principle involving signal sparsity expansion in compressed sampling is given.

II. Comparison of uncertainty principles for lowband graph signals

Graph signal processing is an extension of Fourier analysis. At present, scholars pay attention to the theoretical derivation of various forms of inequalities about Fourier transform of graph signals. In this section, we analyze and compare the uncertainty principle of lowband graph signals.

A. Notation

Given a graph $G(U, E)$, where U represents the set of N nodes in the graph, E is the set of edges. In this paper,

the fundamental structure of a graph G be captured by its adjacency matrix $\mathbf{A}$ of the graph, and each data element corresponds to one edges. Specifically, for any two different nodes $u_i, u_j \in U$ has $\mathbf{A}(i,j) = \omega_{ij}$, where ω_{ij} represents the connection weight value between node u_i and u_j. Given a graph G, the data set constitutes a graph signal, which is defined as a map, $\mathbf{x} : u_n \longrightarrow x_n$. Then the graph signal can be expressed as a vector $\mathbf{x} = [x_1, \ldots, x_N]^T$, which is not only a list, but also a graph.

The Laplacian matrix of a graph is defined as $\mathbf{L} = \mathbf{D} - \mathbf{A}$, where $\mathbf{D}$ is the graph degree matrix and $\mathbf{A}$ is the graph adjacency matrix. Let $\mathbf{L}$ be a real symmetric matrix. According to the theorem, $\mathbf{L}$ can be decomposed into features, $\mathbf{L} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^{-1}$, where $\mathbf{V}$ is an orthogonal matrix, $\mathbf{\Lambda}$ is a diagonal matrix and has non-negative real eigenvalues $0 \leq \lambda_1 \leq \cdots \leq \lambda_N$. Let $\mathbf{V} = (\mathbf{v}_1, \ldots \mathbf{v}_N)$ be the Fourier basis of the graph, then for any signal $\mathbf{x}$ on the graph, the graph Fourier transform is

$$\hat{x}_m = \sum_{i=1}^{N} \mathbf{V}_{mi}^T x_i = \langle \mathbf{v}_m, \mathbf{x} \rangle_G . \tag{7}$$

The Graph Fourier Transform (GFT) $\widehat{\mathbf{x}}$ of a graph signal $\mathbf{x}$ is defined as $\hat{\mathbf{x}} = \mathbf{F}\mathbf{x} = \mathbf{V}^T\mathbf{x}$. Taking the characteristic vector of $\mathbf{L}$ as the Fourier basis and $\hat{x}_m$ as the Fourier coefficient of the signal $\mathbf{x}$ on the m-th Fourier basis. Its essence is the projection on the m-th Fourier basis, which measures the similarity between the graph signal and the Fourier basis, and then connects the graph domain with the spectrum domain.

In order to facilitate the later research, the definition of k-lowband signal is introduced below. If only the first k frequencies in the Fourier transform of a signal are meaningful, where $k \neq 0$, then the signal $\mathbf{x}$ is called a k-lowband signal, that is

$$\hat{\mathbf{x}} = (\hat{x}_1, \ldots, \hat{x}_k, 0, \ldots, 0)^T . \tag{8}$$

The space formed by k-lowband signals is represented as $PW_G(\lambda_k)$ [13]. On the other hand, in the following, $\|\mathbf{x}\|_0$ represents the number of non-zero elements in signal $\mathbf{x}$, $\|\mathbf{A}\|_2$ represents the maximum singular value of matrix $\mathbf{A}$, and $\|\mathbf{A}\|_{max}$ represents the maximum absolute value of elements in matrix $\mathbf{A}$, that is

$$\|\mathbf{A}\|_2 = \max_{x \neq 0} \frac{\|\mathbf{A}\mathbf{x}\|_2}{\|\mathbf{x}\|_2}, \|\mathbf{A}\|_{max} = \max_{i,j} |a_{i,j}| . \tag{9}$$

B. Uncertainty Principles

Theorem 1 (Basic Sparse Uncertainty Principle): Given a vector $\mathbf{S} \in R^N$, for two orthogonal bases $\mathbf{\Phi}$ and $\mathbf{\Psi}$, the vector $\mathbf{S}$ can be expressed as $\mathbf{S} = \mathbf{\Phi}\boldsymbol{\alpha}, \mathbf{S} = \mathbf{\Psi}\boldsymbol{\beta}$. For each pair of $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$, there is:

$$\frac{\|\boldsymbol{\alpha}\|_0 + \|\boldsymbol{\beta}\|_0}{2} \geq \sqrt{\|\boldsymbol{\alpha}\|_0 \|\boldsymbol{\beta}\|_0} \geq \frac{1}{M}, \tag{10}$$

where M is a scalar value, indicating the mutual coherence between bases $\mathbf{\Phi}$ and $\mathbf{\Psi}$ [4].

Applying the above results to the signal $\mathbf{x} \in PW_G(\lambda_k)$, the first coefficient uncertainty boundary is obtained:

$$\|\mathbf{x}\|_0 \|\widehat{\mathbf{x}}\|_0 \geq \frac{1}{\mu_k^2}, \tag{11}$$

where μ_k represents the mutual coherence of the gauge basis. Let $\left(\mathbf{u}^1, \ldots, \mathbf{u}^k\right)$ represent the first k eigenvectors of Laplacian matrix $\mathbf{L}$, then μ_k has the following expression

$$\mu_k = \max_{\substack{1 \leq i \leq N \\ 1 \leq j \leq k}} \left| u_i^j \right| . \tag{12}$$

Definition 2 (Multiplicative Uncertainty): For a graph with GFT $\mathbf{F}$, the multiplicative uncertainty of a nonzero signal $\mathbf{x}$ is:

$$p_0(\mathbf{x}) = \sqrt{\|\mathbf{x}\|_0 \|\mathbf{F}\mathbf{x}\|_0}. \tag{13}$$

And $p_0(\mathbf{x})$ is called multiplicative uncertainty of signal $\mathbf{x}$ [12].

Theorem 2 (Multiplicative Uncertainty Principle): For a graph with (GFT) $\mathbf{F}$, the multiplication uncertainty of a nonzero signal $\mathbf{x}$ is lower bounded as follows [12]:

$$p_0(\mathbf{x}) \geq \frac{1}{\|\mathbf{F}^{-1}\|_2 \|\mathbf{F}\|_{\max}}. \tag{14}$$

C. Comparison of sparse uncertainty principles

In order to compare the two uncertainty principles conveniently, this paper limits the signal. It specifies the graph signal $\mathbf{x} \in PW_G(\lambda_k)$, so $\|\widehat{\mathbf{x}}\|_0 \leq k$. Then there is a lower sparsity bound for (11)

$$\|\mathbf{x}\|_0 \geq \frac{1}{k\mu_k^2}. \tag{15}$$

Remember that this uncertainty boundary is $A(k)$, that is $A(k) = \frac{1}{k\mu_k^2}$. Similarly, for a signal $\mathbf{x} \in PW_G(\lambda_k)$, the multiplicative uncertainty principle (14) also has the corresponding sparsity lower bound

$$\begin{aligned} \|\mathbf{x}\|_0 &\geq \frac{1}{k\left(\|\mathbf{F}^{-1}\|_2 \|\mathbf{F}\|_{\max}\right)^2} \\ &= \frac{1}{k\left(\|\mathbf{V}\|_2 \|\mathbf{V}^{-1}\|_{\max}\right)^2} \end{aligned} . \tag{16}$$

Remember that basic sparse uncertainty boundary is $B(k)$, that is $B(k) = \frac{1}{k\left(\|\mathbf{F}^{-1}\|_2 \|\mathbf{F}\|_{max}\right)^2}$. The main conclusion of this paper is given below.

Theorem 3: For a graph with (GFT) $\mathbf{F}$ and a nonzero signal $\mathbf{x}$, the following inequality holds:

$$A(k) \geq B(k) . \tag{17}$$

Proof: Proving (17) is equivalent to proving that the following inequality holds for any k

$$\left\|\mathbf{F}^{-1}\right\|_2 \|\mathbf{F}\|_{max} \geq \mu_k. \tag{18}$$

For any $\mathbf{F} \in R^{N \times N}$ and $\mathbf{x} \in R^{N \times 1}$, there is

$$max \frac{\mathbf{x}^T \left(\left(\mathbf{F}^{-1}\right)^T \left(\mathbf{F}^{-1}\right)\right) \mathbf{x}}{\mathbf{x}^T\mathbf{x}} = \lambda_{max}\left(\left(\mathbf{F}^{-1}\right)^T \left(\mathbf{F}^{-1}\right)\right). \tag{19}$$

Let the matrix $\mathbf{F}^{-1} = (a_{ij})_{N\times N}$, identity matrix $\mathbf{E}_N = (\mathbf{e}_1, \ldots, \mathbf{e}_N)$, and $\mathbf{x} = \mathbf{e}_i$, we have

$$\lambda_{max}\left(\left(\mathbf{F}^{-1}\right)^T\left(\mathbf{F}^{-1}\right)\right) \geq a_{1i}^2 + \cdots + a_{Ni}^2. \tag{20}$$

Further limit the smaller boundary

$$\sqrt{\lambda_{max}\left(\left(\mathbf{F}^{-1}\right)^T\left(\mathbf{F}^{-1}\right)\right)} \geq \max_{i,j}\left|a_{ij}\right|, \tag{21}$$

hence

$$\left\|\mathbf{F}^{-1}\right\|_2 \geq \left\|\mathbf{F}^{-1}\right\|_{max}. \tag{22}$$

Since $\|\mathbf{F}\|_{max} > 0$, there is

$$\left\|\mathbf{F}^{-1}\right\|_2 \|\mathbf{F}\|_{max} \geq \left\|\mathbf{F}^{-1}\right\|_{max}. \tag{23}$$

For any k, the following inequality holds

$$\left\|\mathbf{F}^{-1}\right\|_2 \|\mathbf{F}\|_{max} \geq \mu_k, \tag{24}$$

namely $A(k) \geq B(k)$.

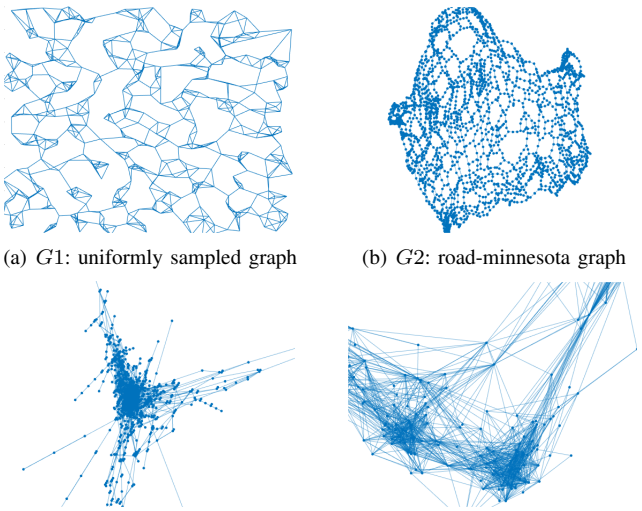
Remark: In the above proof process, (23) shows that Theorem 3 is still valid for non-lowband signals.

III. Experiments

In this section, the basic sparse uncertainty lower bound $A(k)$ and multiplicative uncertainty principle $B(k)$ are compared in the following four different data graphs in order to verify the correctness of the above conclusions. It shows the superiority of multiplicative uncertainty principle in signal detection performance.

(1) $G1$: Uniformly sampled graph 500 positions are generated uniformly and randomly in the unit square, and $G1$ is generated by the 4- nearest neighbor process.

(2) $G2$: Road-minnesota graph $G2$ is a Minnesota road network from the road network class in MatlabBGL library, which consists of 2,642 nodes and 3,304 vertices [14].

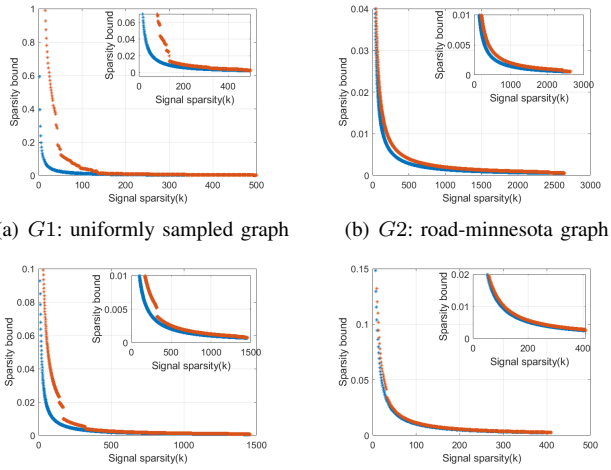


(3) $G3$: Bio-yeast graph $G3$ is a biological yeast graph from the biological network class in MatlabBGL library, which consists of 1458 nodes and 1948 vertices [14].

(4) $G4$:Infect-dublin graph $G4$ is a Dublin infection graph from adjacent network classes in MatlabBGL library, which consists of 410 nodes and 2765 vertices [14].

Fig. 1 shows four experimental graphs. Fig. 2 shows the function change images of two sparse boundaries about k on these graphs, where the orange line represents the lower bound of basic sparse uncertainty $A(k)$ and the blue line represents the lower bound of multiplicative uncertainty principle $B(k)$. As shown in the figure, for each graph studied, the lower bound $A(k)$ is higher than $B(k)$, which reflects the correctness of the conclusion in the previous section. On the one hand, the smaller the lower bound, the higher the time-frequency resolution and the stronger the information processing ability. Obviously, the lower bound $B(k)$ is closer to the limit of time-frequency resolution. Using this relationship, the time-frequency resolution can be maximized and the signal detection performance can be maximized. At the same time, it shows that the multiplicative uncertainty principle improves the signal processing ability on $PW_G(\lambda_k)$ compared with the basic sparse uncertainty principle. On the other hand, the larger the lower bound, the higher the accuracy of time-frequency resolution, so the lower bound $B(k)$ also has certain application value. In addition, as can be seen from the figure, when k tends to N, $A(k) = B(k)$, since $\mu_N = \|\mathbf{V}\|_{max}$ and $\|\mathbf{V}\|_2 = 1$. It shows that these two sparse lower bounds tend to be equal when k approaches N.

IV. Potential Application



Compressive sensing is a technology for signal sampling, which specifically refers to the process of data compression in the sampling process. It breaks through the Nyquist Theorem in the field of signal processing, and achieves the same effect as full sampling with few sampling points in the process of signal sampling. Compressive sensing technology has a wide application prospect. Taking magnetic resonance imaging as an example, the long imaging time is a major defect of MRI. The application of compressed sampling technology not only improves the imaging speed, but also avoids wasting a lot of sampling resources and reduces the cost of signal measurement. Compressive sensing theory mainly includes three parts, which are sparse representation of signal, construction of measurement matrix and design of signal recovery algorithm. The sparse representation of the signal requires that the signal is sparse in a certain change domain. For the signal that meets the sparsity, the noise can be removed by setting the threshold. In [3], David L. Donoho and Xiao M. Huo applied the basic sparse uncertainty principle to compressive sensing and sparse signal processing to define reconstruction conditions. In addition, the uniqueness of sparse representation is proved, and how sparse the representation should be depends on the boundary provided by uncertainty principle. It can be seen from the above results that the multiplicative uncertainty principle improves the sparse boundary. This means that the improved lower bound can be used for compressive sensing

(a) $G1$: uniformly sampled graph (b) $G2$: road-minnesota graph

(c) $G3$: bio-yeast graph (d) $G4$: infect-dublin graph

Fig. 1. Graphs $G1$ to $G4$

(a) $G1$: uniformly sampled graph (b) $G2$: road-minnesota graph

Fig. 2. Function diagram of uncertainty boundaries $A(k)$ and $B(k)$ from $G1$ to $G4$ with respect to k.

to reduce the sparse boundary of reconstruction based on coherence index. It further shows that the uncertainty principle related to signal sparsity expansion has direct application in the model construction of compressed sampling.

The specific application process is given below. Let the graph signal $\mathbf{x} \in PW_G(\lambda_k)$, the sparse matrix $\mathbf{H} \in R^{N\times N}$, then the sparse coefficient is $\mathbf{x} = \mathbf{Hs}$. The measurement matrix $\mathbf{H} \in R^{M\times N}$ is a universal independent gaussian random measurement matrix with the same distribution , which corresponds to the sub-sampling process. The observation signal $\mathbf{y} \in R^M$ obtained by $\mathbf{y} = \mathbf{Ax}$, which is the result of sub-sampling. The problem of reconstructing the graph signal is transformed into the optimization problem of solving linear equations $\mathbf{y} = \mathbf{AHs}$. In general, the number of equations is far less than the number of unknowns. The equation has no definite solution, so the signal cannot be reconstructed. However, if the graph signal is sparse, the unknown quantity can be accurately obtained from the M observed values and the signal reconstruction can be realized. The approximation of signal is obtained generally. According to the reduction of the sparse lower bound, the original signal can find a more sparse and effective expression to improve the reconstruction rate.

V. Conclusions

The lower bound of uncertainty is closely related to the time-frequency resolution, and studying the size of the lower bound is an important way to optimize the performance of signal analysis and processing. In this paper, we mainly study and compare two lower bounds of sparse uncertainty on lowband graph signals. By using the extreme value property of quadratic matrix eigenvalue and the related definition of matrix norm, we compare the basic sparse uncertainty principle of lowband graph signal with the sparse lower bound of graph multiplicative uncertainty principle, which shows that the latter is stricter and closer to time-frequency resolution. The correctness of the previous theoretical derivation is verified by examples and experiments, which shows that the graph uncertainty principle based on multiplicative uncertainty is optimized in signal processing compared with the basic sparse uncertainty principle. Finally, the application of uncertainty principle involving signal sparsity expansion in compressed sampling is given.

***Abstract* - Extracting roads from high-resolution remote sensing image data presents a challenging task in the field of remote sensing image processing, which is of great significance for urban planning, vehicle navigation, and geographic information system updates. In 2018, the champion of the DeepGlobe Road Extraction Challenge proposed a creative solution named as D-LinkNet, which employed a dilated convolution cascade module to expanded the network receptive field and achieved impressive results with a concise network structure. However, D-LinkNet still suffers from low connectivity caused by road breaks. Therefore, based on D-LinkNet, we have made three improvements in this paper: 1) incorporating a strip pooling module to capture long-range anisotropic contextual information, 2) employing a parallel upsampling structure in the decoder to supervise the shallow layers, and 3) introducing a connectivity branch with a connectivity attention module to model local connectivity of roads. We have named the upgraded network as CoA-DLinkNet. Our experimental results have demonstrated that the proposed network significantly improves the prediction accuracy and connectivity of the extracted road.**

I. INTRODUCTION

Roads are the backbone of modern transportation system, and an integral component of modern urban infrastructure and geographic information systems. Directly extracting roads from high-resolution remote sensing (RS) images is an important and efficient approach for updating road databases. However, challenges in extracting road breaks and missing parts arise due to large intra-class variations, small inter-class differences, large spans with small proportions, and shadow occlusions in RS images [1]. With the development of artificial intelligence in recent years, deep learning (DL) algorithms have been widely utilized in the field of RS image processing, and have been initially applied in road extraction tasks with certain breakthroughs and achievements.

Currently, the automatic road extraction tasks based on DL, with CNN as the representative, includes two sub-tasks, namely road segmentation and road centerline extraction. Road segmentation is a narrow road extraction task, which is typically regarded as a two-category semantic segmentation problem, where the roads are considered as the foregrounds and the others as the backgrounds. According to the different models used, methods can be classified into four categories: CNN based models [2], FCN based models [3-5], Encoder-Decoder based models [2, 6-9] and GAN based models [10]. On the other hand, road centerline extraction is to obtain the vector representation of roads, which is a key step in road network extraction and modeling. There are many application prospects in practical applications, such as autonomous driving, urban planning, vehicle navigation, etc. According to the different DL methods used, existing road centerline extraction algorithms can be divided into two categories: methods based on segmentation post-processing [11-13] and methods based on road iterative tracking [14-16]. The former heavily rely on the quality of road segmentation, and segmentation disruptions usually result in low road connectivity. The latter constructs the road network by iteratively predicting road points, offering better connectivity. However, such methods are complicate to the implement, and suffer from missed detection and misalignment due to local receptive field.

D-LinkNet [7] is an important network in the field of road extraction. It adopts an encoder-decoder architecture and incorporates a cascade of dilated convolutions in the middle of the network to expand the receptive field. However, it still exhibits three major problems. Firstly, it has limitations to expand the receptive field by stacking convolution. Secondly, the usage of square convolution kernels would inevitably introduce unwanted background interference. Lastly, the method based on segmentation post-processing predicts that the road is overly refined, resulting in poor road connectivity. To address these limitations, this paper proposes three improvements to the original D-LinkNet, taking the characteristics of narrow and long connected roads into account: 1) A strip pooling module [17] is integrated with the utilization of a long and narrow strip pooling kernel, which can

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

obtain anisotropic long-range context information in the horizontal and vertical directions, effectively expand the receptive field and reduce the background interference. 2) The decoder designs a multi-stage parallel upsampling structure, allowing the fusion of multi-scale features and enabling layer-by-layer depth supervision to refine network predictions. 3) A connectivity branch is introduced to demonstrate the connectivity between the modeled center pixel and the surrounding eight neighboring pixels, thereby improving the connectivity of predicted roads. The improved network is named CoA-DLinkNet. Experimental results shown that the CoA-DLinkNet achieves higher accuracy and improves connectivity in road extraction tasks.

II. PROPOSED METHOD

A. *Network Architecture*

The overall process of the proposed method is shown in Fig. 1. The CoA-DLinkNet is a multi-task learning network, which has SB (segmentation branch) and CB (connectivity branch) in parallel. The SB introduces a strip pooling module based on D-LinkNet, which directly outputs a predicted road extraction result shown in Fig. 2. The CB shown in Fig. 3 introduces several parallel connectivity attention modules [17] to predict the connectivity of among the pixels in eight directions of the road. The two branches improve learning performance through information exchange during the learning process.

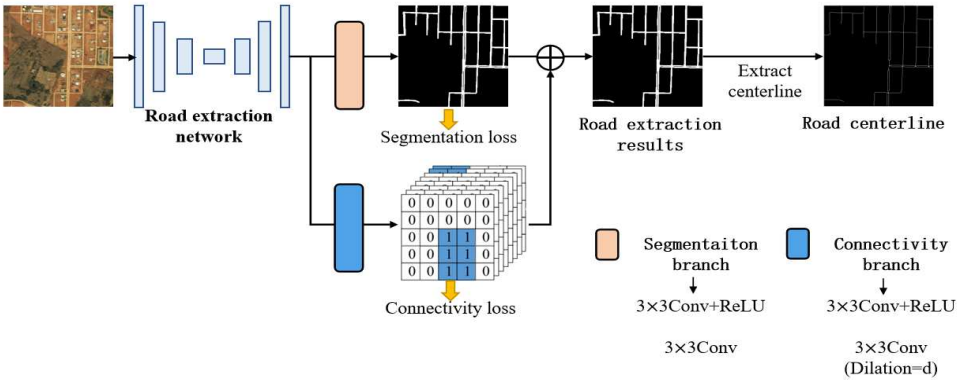

Fig. 1: An overview of SP-DLinkNet-CoA Network

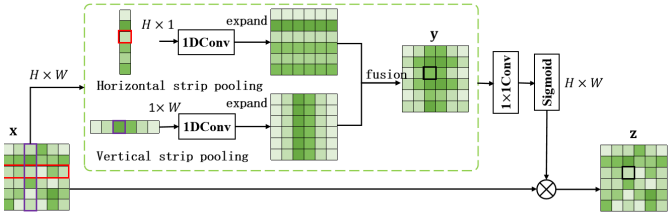

Fig. 2: Strip Pooling Module (SPM)

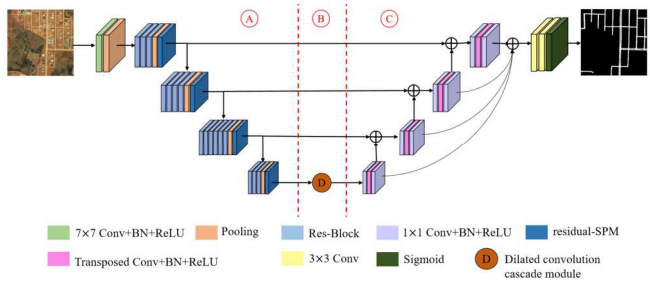

Fig. 3: Segmentation branch of CoA-DLinkNet

In the prediction stage, the final road extraction result can be obtained by the weighted summation of the two branch predictions. Finally, through the post-processing oof the centerline extraction method, the road centerline can be obtained for a wider range of real-world applications.

B. *Strip Pooling Module*

The structure of the Strip Pooling Module (SPM) [16] is shown in Fig. 2, given an input feature $\boldsymbol{x} \in \boldsymbol{R}^{C\times H\times W}$, feed it to two parallel horizontal and vertical strip pooling layers that average the row and column features. Then, it goes through a 1D convolutional layer with a kernel size of three, which is used to obtain the neighborhood features of the current location. In order to obtain the output $\boldsymbol{z} \in \boldsymbol{R}^{C\times H\times W}$ containing the global context information, finally we repeatedly expand the obtained features and combine them together. After the Sigmoid function is multiplied with the original feature $\boldsymbol{x}$, the output feature map $\boldsymbol{z}$ is obtained.

SPM combines horizontal and vertical strip pooling layers, conforming to the general shape of roads in RS images, and it is easy to build long and narrow long-range dependencies. At the same time, since the pooling kernel shape is narrower along the other dimension, it also focuses on capturing local details. SPM can be regarded as a spatial attention mechanism. Through $1\times N$ and $N\times 1$ pooling, each pixel can obtain the average of all pixel features in its row and column, that is, the global context information in the horizontal and vertical directions. Afterwards, close-range local context information can be obtained in the orthogonal direction of pooling through

1D convolution. Multiplying the fused features of the two pools with the original feature map is equivalent to using the correlation between pixels to enhance or weaken the features of each position in the original feature map. Compared with attention-based modules, SPM modules are lightweight and can be easily embedded into any building block to improve the ability to capture long-range spatial dependencies.

The segmentation branch of CoA-DLinkNet is based on D-LinkNet and integrates SPM to obtain long-range context information in a specific direction. To use pretrained ResNet weights, we add residual SPM after each stage. For the irregularly shaped country roads in RS images, their directions are changeable, and it is difficult to use horizontal or vertical pooling to obtain the contextual information of the road. In order to ensure that the pixels of these roads can also obtain sufficient contextual information, we retain the dilated convolution cascade module in the central part of D-LinkNet to expand the receptive field and to perform multi-scale information fusion. In addition, after each stage of the decoder, a multi-stage upsampling (MPU) is designed to restore the feature maps to 1024×1024 through different multiples. At the same time, in order to reduce the memory consumption, the dimension is reduced to a unified dimension and added. After that, it is fused by 3×3 convolution to get the final road prediction. The advantage of parallel upsampling is that it can aggregate multi-scale features, and at the same time, the loss can be directly back-propagated to each stage of the network during training, thereby generating an implicit deep supervision, which can enable the shallow layers of the network to be fully trained and reduce The loss of detailed features, to obtain more accurate road extraction results, also help to train deeper networks.

C. Connectivity Attention Module

The connectivity branch (CB) of CoA-DLinkNet introduces the Connectivity Attention Module (CoA)[18] with local relation perception. The CB consists of several parallel CoA modules at different intervals d . We experiment with CoA modules of $d=1, d=3$ and $d=5$, each supervised by the corresponding ground-truth connectivity cube, respectively. The final predicted connectivity cubes are summed according to the channel direction, and then added to the prediction map of the split branch according to the weight.

The CoA module consists of convolutions and a channel attentions. First, the input feature map is dimensionally reduced by a 3×3 convolution, and the number of channels after dimensionality reduction is 8. Second, the connectivity between the center pixel and the eight neighboring pixels is modeled by a 3×3 dilated convolution with a dilation rate $r=d+1$. Finally, we utilize the channel attention module to recalibrate the connectivity predictions after dilated convolutions. These steps are shown in Fig. 4.

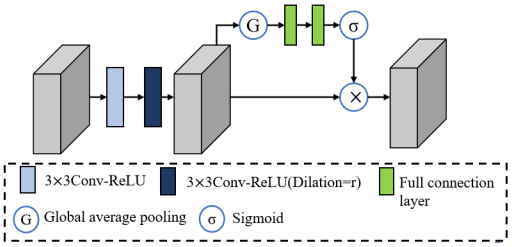

Fig. 4: Connectivity Attention Module (CoA)

The ground-truth connectivity cube $\boldsymbol{O} \in R^{H \times W \times C_0}$ can be generated by using binary ground-truth road labels, where C_0 represents the number of adjacent pixels sampled for a given pixel, and we predict the connectivity of the square neighborhood of a pixel, and set $C_0=8$, the interval between adjacent pixels is d. By traversing to check whether each pixel is connected to the eight neighborhood pixels with interval d, the connectivity of C_1-C_8 position can be obtained, and then the truth connectedness cube $\boldsymbol{O}$ can be obtained. In the connectivity cube $\boldsymbol{O}$, $\boldsymbol{O}_{i,j,c}=1$ represents the connection relation between the central pixel and adjacent pixels, where (i, j) represent the spatial position of pixels, and C represents the orientation $C_1 \rightarrow C_8$, if $\boldsymbol{O}_{i,j,c}=1$, it means that the center pixel (i, j) is connected to the pixel at position c, that is, both pixels are road pixels. We do not predict the connectivity of background pixels, and set the connectivity of pixels with pixel value of 0 in all directions to 0 to reduce irrelevant background noise. After obtaining the connectivity cube of truth value, it can supervise us to predict the connectivity between adjacent pixels through the network.

The predicted connectivity cube can be viewed as a subtask of the road segmentation task, which divides each pixel into foreground and background while ensuring overall semantic rationality and regional smoothness. In the connectivity prediction subtask, each task only classifies pixels in one direction. Therefore, the subtask must not only judge whether the pixel is the foreground or the background, but also judge whether the adjacent pixels in a specific direction are also the foreground, so the network is forced to model the local connectivity of the image and learn more robust features, so that the network predicts Road connectivity is stronger. In addition, the introduction of the connectivity task can explicitly integrate the prediction of the relationship between pixels into the optimization problem, which can be seen as a process of simulating graph inference in the model, which can enable

better preservation of road contours and prevent rough segmentation results. Since connectivity is a symmetric metric, it can be seen as a simple ensemble method that combines the predictions of two corresponding adjacent pixels to determine the connectivity of a pair of pixels.

III. EXPERIMENTS

A. Datasets

Our experiments are performed on the DeepGlobe Road Extraction dataset [19], which includes images from three different cities with pixel-level annotations. The spatial resolution is 0.5 meters, and the image size is 1024×1024. We divide the 6226 images of the official training set into 4226 training images, 1000 validation images, and 1000 test images. To evaluate the connectivity of roads, we skeletonized the road extraction results and used the DP algorithm to simplify the curve to obtain the ground truth of the road centerline.

B. Evaluation metrics

1) Pixel-level metrics: F1-score and IoU are two common metrics to evaluate pixel-level segmentation performance.

2) Graph-Based Metrics: Average Path Length Similarity (APLS)[20] measures the similarity of the average shortest path lengths between all pairs of nodes in the ground truth graph G and the predicted graph $\hat{G}$, and the topological correctness and connectivity of roads can be evaluated in (1).

$$APLS = \frac{1}{N}\sum\left(2\Big/\left(\frac{1}{S_{\hat{G}\to G}}+\frac{1}{S_{G\to\hat{G}}}\right)\right), \tag{1}$$

where N is the total number of images in the dataset, and $S_{\hat{G}\to G}$ measures the similarity of all corresponding node pairs in the ground−truth graph G to the predicted graph $\hat{G}$, defined as (2). $S_{G\to\hat{G}}$ is a symmetric term of $S_{\hat{G}\to G}$ in order to prevent false positive(FP).

$$S_{\hat{G}\to G} = 1-\frac{1}{M}\sum \min\left(1,\frac{\left|L(a,b)-L\left(\hat{a},\hat{b}\right)\right|}{L(a,b)}\right) \tag{2}$$

where M is the number of unique paths in the ground truth map G; a,b are all possible starting and ending points in G; $\hat{a},\hat{b}$ are the points in the predicted map $\hat{G}$ that are closest to the positions of a and b in the ground truth map G; $L(a,b)$ and $L(\hat{a},\hat{b})$ are the path lengths between corresponding nodes in G and $\hat{G}$, respectively.

C. Implementation Details

We train the network using the Adam optimizer[21] with a batch size 8, a maximum epoch of 300 and an initial learning rate of 2e-4. When the loss of the validation set does not decrease for three consecutive epochs, the learning rate is divided by 5, and the training is terminated early when the loss of six consecutive epochs no longer decreases, and the training is also stopped when the learning rate is less than 5e-7.

We perform large-scale data augmentation at training time, including color and spatial transformation. In the testing phase, we performed test-time augmentation by flipping horizontally, vertically, and diagonally, making eight predictions for each image, and averaging the test results of eight images as the final result.

Different from the loss function used by D-LinkNet, the segmentation branch of CoA-DLinkNet adds the SSIM loss [22], which can measure the similarity of the local structure of the image, and the loss function is shown in (3). where the BCE loss evaluates the difference between the predicted map and the ground-truth map at the pixel level, the SSIM loss evaluates the road structure difference at the local level, and the Dice coefficient loss evaluates the performance of the model road extraction at the image global level.

$$L_{seg} = L_{BCE} + \lambda_1 L_{Dice} + \lambda_2 L_{SSIM} \tag{3}$$

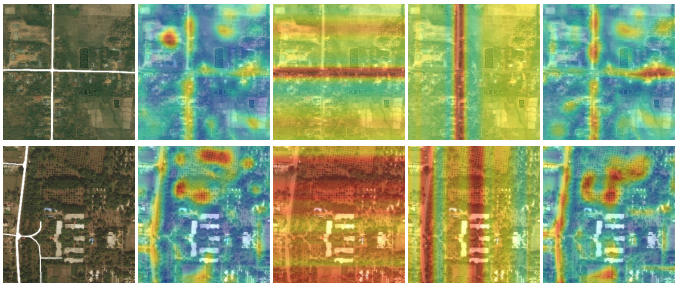
where λ_1, λ_2 are the weight parameters, which are set to 1 in the experiment.

To address the imbalance of positive and negative samples in the connectivity branch, we use the loss function Focal loss [22] for class imbalance. The prediction map of each direction of each connectivity cube uses the Focal loss to calculate the loss separately, so the loss L_{d1} of the CoA module with interval $d=1$ is defined as (4).

$$\begin{aligned} L_{d1} = -\frac{1}{C_o\times N}\sum_{c=1}^{C_o}\sum_{i=1}^{N} \Big[& y_i^c \alpha\left(1-\hat{y}_i^c\right)^{\gamma} y_i^c \log\left(\hat{y}_i^c\right) \\ & +\left(1-y_i^c\right)(1-\alpha)\hat{y}_i^{c\gamma} log\left(1-\hat{y}_i^c\right) \Big] \end{aligned} \tag{4}$$

where $C_o = 8$ and N is the total number of pixels in the image.

Since the task of predicting connectivity cubes can be viewed as a subtask of segmentation, we can recover road segmentation maps from the connectivity branch. Specifically, the predicted connectivity cube $\boldsymbol{O}$ is normalized by Sigmoid, and the threshold t is set for binarization. At the same time, we require that the predictions of the corresponding adjacent pixels (i', j') should be consistent, for example, if and only if $\sigma(\boldsymbol{O})_{i,j,5} > t$ and $\sigma(\boldsymbol{O})_{i,j+1,4} > t$, the two Adjacent pixels are connected.



D. Results and Analysis

We use the original D-LinkNet34 as the baseline model to test each improved method, and the results are shown in Table 1. We first modified the encoder part, and by adding SPM at the end of each stage, F1-score, IoU, and APLS were improved by 0.71%, 0.85%, and 1.33%, respectively. In order to illustrate the role of the SPM module more intuitively, we performed the visualization of the feature map to observe the

distribution of features in the image, as shown in Fig. 5. It can be seen that the two pooling can accurately locate the horizontal and vertical roads, and the characteristics of the road area are significantly enhanced, indicating that the SPM module can effectively identify large-span roads.

Table 1 Ablation study (%) for the proposed strip pooling module (SPM), multi-stage parallel upsampling (MPU), SSIM loss and connected attention module (CoA)

Model	loss	F1-score	IoU	APLS
D-LinkNet	BCE+Dice	77.85	63.74	66.51
D-LinkNet+SPM	BCE+Dice	78.56	64.69	67.92
D-LinkNet+SPM+MPU	BCE+Dice	78.75	64.95	68.33
D-LinkNet+SPM+MPU	BCE+Dice+SSIM	79.56	66.05	70.34
D-LinkNet+SPM+MPU+CoA (CoA-DLinkNet)	BCE+Dice+SSIM	80.41	67.24	73.54

(a) (b) (c) (d) (e)

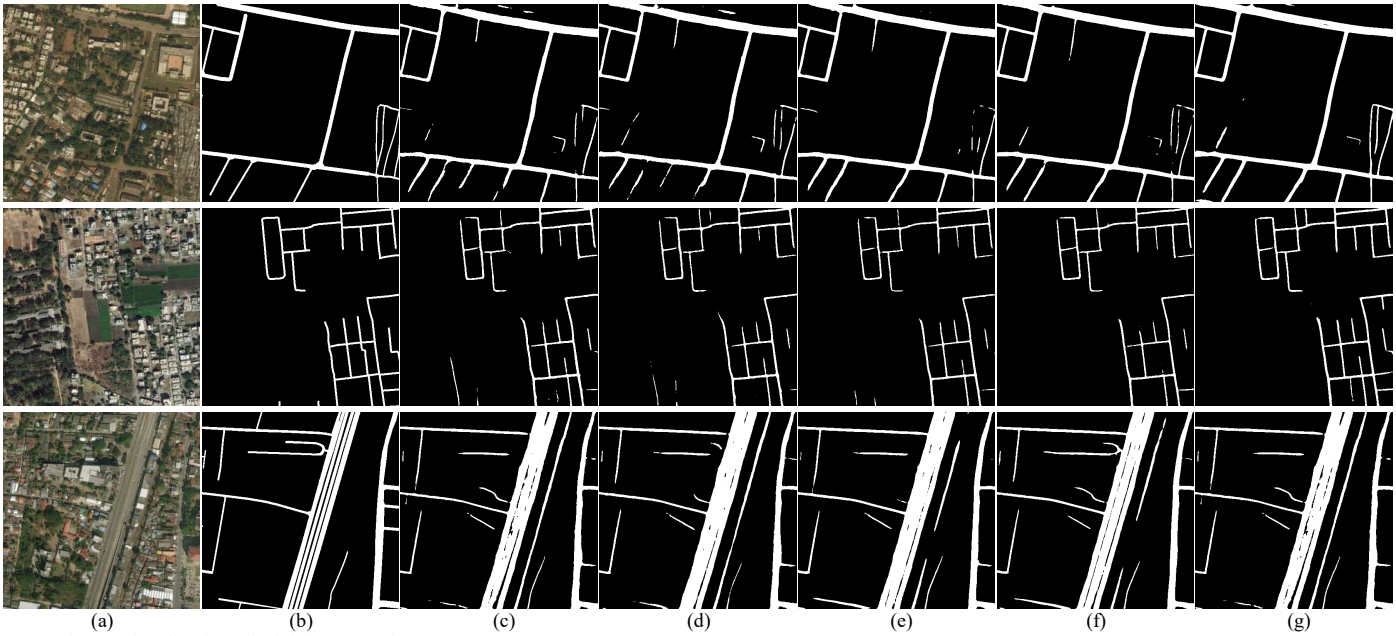


Fig. 5: Feature map visualization after adding SPM module. (a) to (e) correspond to: Image with GT, D-LinkNet, Vertical pooling, Horizontal pooling, and DLinkNet + SPM.

We continued to add the MPU structure at each stage of the decoder, and the F1-score, IoU, and APLS increased by 0.19%, 0.26%, and 0.41%, respectively. When we added the loss function SSIM for network training, the F1-score increased by 0.81%, the IoU increased by 1.10%, and the APLS increased by 2.01%. All metrics have been significantly improved, indicating that the supervision of SSIM loss has been significantly improved. The network's ability to identify road pixels makes the identified road more complete. Finally, the best performance obtained by our CoA-DLinkNet with the added connectivity branch is 80.41% for F1-score, 67.24% for IoU, and 73.54% for APLS, showing that the addition of CoA module to the network makes the predicted road connectivity better, more complete.

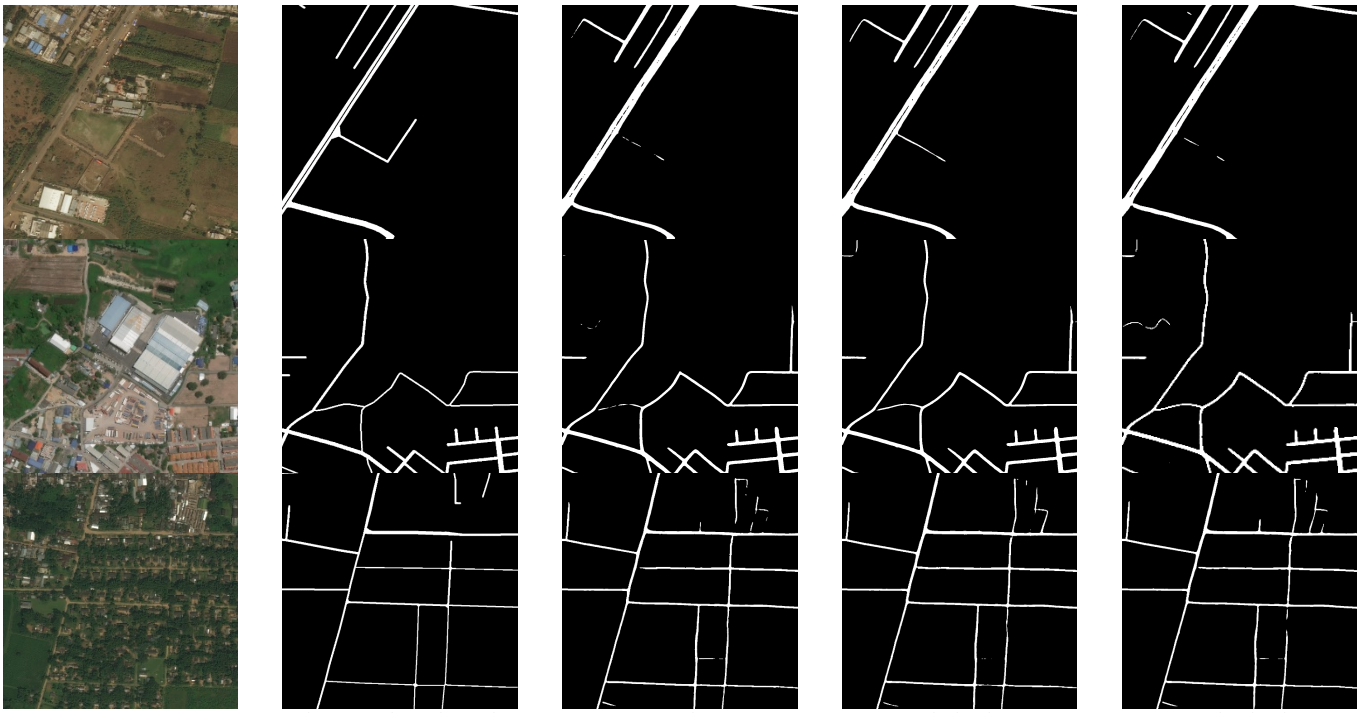
The visualization results of the above methods are shown in Fig. 6. The D-LinkNet can obtain a larger receptive field by dilated convolution, but it still has limitations when it contains the contamination information of irrelevant regions brought by the squared kernel. As shown in Fig. 6(c), when the road is occluded, the entire road segment or several parts of the road are lost. The limitations of D-LinkNet can be alleviated by employing the strip pooling to capture anisotropic long-range contextual information.

After adding SPM in the encoder, D-LinkNet can identify some occluded roads, shown in Fig. 6(d). We add parallel upsampling at each stage of decoder of the D-LinkNet+SPM, as shown in Fig. 6(e). After adding the multi-stage parallel upsampling, the network prediction is more accurate, and the gap recognition ability for two-way lane lines is stronger.

After adding SSIM loss, the network can identify more unidentified road segments, so the overall structure of the

(a) (b) (c) (d) (e) (f) (g)

Fig. 6: Visualization of Ablation Experiments. (a) Input Image, (b) Ground-Truth Mask, (c) D-LinkNet, (d) D-LinkNet+ SPM, (e) D-LinkNet + SPM + MPU, (f) D-LinkNet + SPM + MPU + SSIM Loss, (g) D-LinkNet+SPM+MPU+SSIM Loss + CoA.



road is more complete, as shown in Fig. 6(f). Fig. 6(g) shows the visualization of the connectivity branch road extraction effect after adding CoA modules with d=1 and d=3. It can be seen that after adding the connectivity branch, the road fracture problem has been significantly improved, some obviously broken roads are connected, and the integrity and connectivity of the road have been significantly improved.

In order to explore the impact of connectivity branches of different CoA module configurations on network performance, we experimentally compared the connectivity branches of three different CoA module configurations, as shown in Table 2, where the second column represents the interval d of parallel CoA modules. The loss function used by the default connectivity branch is Focal loss.

When using the connectivity branch containing only the CoA module with $d=1$, the F1-score is improved by 0.76%, the IoU is improved by 1.06%, and the road centerline APLS is improved by 3.01%. When using the connectivity branch including the CoA module with $d=1$ and $d=3$, compared with $d=1$, F1-score, IoU, and APLS are improved by 0.09%, 0.13%, and 0.19%, respectively. This shows that when the multi-scale CoA module is used, the extracted roads are more complete and better road extraction results can be obtained. When using the connectivity branch containing CoA modules with d=1, d=3 and d=5, the F1-score, IoU, and APLS decreased by 0.05%, 0.07%, and 0.27%, respectively, compared to using the two scales. We can analyze the reason through Fig. 7.In Fig. 7(c), when the connectivity branch only contains CoA modules with d=1, the network can improve the situation of some road breaks. However, due to the small interval between adjacent pixels of CoA modules, there are still some broken roads with large intervals that do not be connected. When the connectivity branch contains CoA modules with d=1 and d=3, the number of broken roads in Fig. 7(d) is greatly reduced, part of the broken roads are reconnected, and the connectivity of the roads is improved. When the connectivity branch includes CoA modules with d=1, d=3 and d=5, due to the increase of the distance between pixels, more background information is modeled in the CoA module, resulting in a decrease in the reliability of prediction. In Fig. 7(e), roads with narrower widths will break again due to more surrounding backgrounds, and the network will detect redundant pixels that do not belong to the road.

Table 2 Ablation study of the proposed Connectivity Attention Module (CoA) with different configurations (%). d1, d3, and d5 represent CoA modules with d=1, d=3, and d=5, respectively.

Model	CoA	F1-score	IoU	APLS
CoA-DLinkNet	-	79.56	66.05	70.34
CoA-DLinkNet	1	80.32	67.11	73.35

CoA-DLinkNet	1, 3, 5	80.36	67.17	73.26

(a) RS Image (b) Ground-Truth Mask (c) d1 (d) d1, d3 (e) d1, d3, d5

Fig. 7: Visualizing the effect of different configurations of connectivity branches on road extraction

We compare the performance of CoA-DLinkNet with several state-of-the-art road extraction methods on the DeepGlobe road extraction dataset, including Improved Connectivity [13], ResUNet [6], LinkNet34 [7], D-LinkNet[8] and Deep Road Mapper [11] as shown in Table 3. Among them, Deep Road Mapper and Improved Connectivity utilize complex designed post-processing steps to improve road connectivity, while other methods directly generate extraction results through road skeleton extraction.

Table 3. Performance comparison of different models on DeepGlobe dataset (%)

Model	F1-score	IoU	APLS
DeepRoadMapper[11]	78.06	63.98	65.56
ImprovedConnectivity[13]	79.96	66.58	71.69
ResUNet[6]	75.34	60.96	61.06
LinkNet[7]	77.09	62.32	65.33
D-LinkNet[8]	77.85	63.74	66.51
CoA-DLinkNet	80.41	67.24	73.54

In Table 3, the CoA-DLinkNet algorithm achieves state-of-the-art results in F1-score, IoU, and APLS metrics, achieving 80.41%, 67.24%, and 73.54%, which are 0.68%, 0.66%, and 1.85% higher than the best-performing ImprovedConnectivity algorithm, respectively. Since our proposed CoA-DLinkNet integrates road segmentation and modeling of connectivity between adjacent pixels into one framework, it can more accurately extract roads from RS images. More importantly, the topological connectivity of roads can be further improved by using the CoA module.

IV. CONCLUSION

The CoA-DLinkNet proposed in this paper is a dual branch network based on D-LinkNet, the segmentation branch and the connectivity branch. In the segmentation branch of the network, a strip pooling module is added to the D-LinkNet encoder, enabling the network to capture anisotropic long- range contextual information. Parallel upsampling at each stage in the decoder can deeply supervise the network and make the network prediction more accurate. The connectivity branch models the connectivity between local pixels through the connectivity attention module, which is beneficial to improve the problem of predicting road breaks. Our experiments show that, compared with D-LinkNet, the extracted road by our CoA-DLinkNet network is more accurate, and the connectivity of road centerline is greatly improved, subject to little additional computational cost.

Black-box Lossless Fragile Watermarking Based on Hidden Space Search for DNN Integrity Authentication

Gejian Zhao and Chuan Qin*
University of Shanghai for Science and Technology, Shanghai, PR China
E-mail: 202430387@st.usst.edu.cn, qin@usst.edu.cn

***Abstract*—A lossless and fragile watermarking scheme based on black-box with hidden space search is proposed for DNN. This is a publicized remote verification scheme, any authorized party can generate and verify the watermark of the target model without knowing the internal situation of the model and only by the model ground-truth input and output results. Specifically, we generate some sensitive samples near the decision boundary of the target model and exploit these samples as the fingerprints of the model. Once these target models are attacked or tampered to a certain extent, the labels corresponding to these sensitive samples will be flipped, thus accomplishing the purpose of authentication. Experimental results show that the proposed scheme is sensitive to the some current common model attack schemes, and only a small number of sensitive samples are needed to efficiently identify whether the watermarked model is intact or not.**

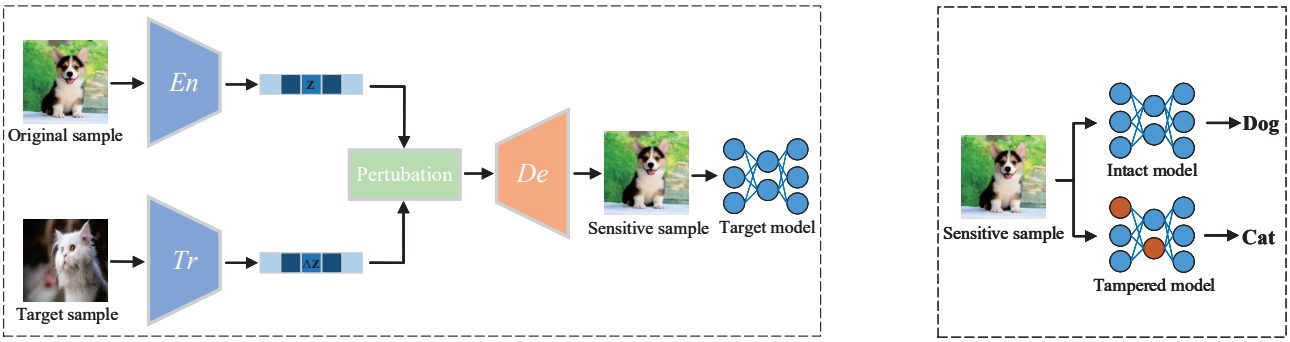
I. Introduction

Today, the theory and technology of deep learning have been gradually improved, the application scenarios has been expanded, and the commercialization of DNN has become more and more mature. Many technology companies choose to provide off-the-shelf models to customers on a subscription or rental basis, mainly through MLaaS (Cloud-enabled Machine Learning as a Service) [1], where the customers only need to request the API (Application programming interface) provided by the cloud service vendors from a remote location. However, potential risks and threats of MLaaS are emerging, such as hackers who can maliciously tamper models with backdoor attacks [2] or Trojan attack [3], and dishonest cloud server providers who degrade models to save storage costs [4], or even embed backdoor through model compression [5].

Model fragile watermarking technology [6], [7] is commonly used as an effective mean of identifying whether a watermarked DNN model has been tampered. An ideal fragile watermarking scheme should be sensitive in the face of various attacks against the model, and any modification will change the watermark information in the target model.

This work was supported in part by the National Natural Science Foundation of China under Grants 62172280, U20B2051 and 62172281, in part by the Natural Science Foundation of Shanghai under Grants 21ZR1444600 and 20ZR1421600, and in part by the STCSM Capability Construction Project for Shanghai Municipal Universities under Grant 20060502300.



There are two mainstream fragile watermarking schemes, one is similar to the image-oriented fragile scheme, called white-box watermarking, where a specified string is embedded as watermark information in the target model by modifying the model parameters. For example, Botta *et al*. [8] proposed a fragile watermarking scheme with tampering localization. This scheme extracts the parameters of the model in order, and uses cryptographic hashing function, linear transformations and genetic algorithms to embed the watermark. Guan *et al.* [9] proposed a model integrity authentication scheme based on reversible watermarking scheme, which first obtained the hashes of model parameters by utilizing SHA-256 cryptographic hashing function, and then embedded the hashes into the host sequence by histogram shifting.

Another mainstream is generation of sensitive samples, called black-box watermarking, where the authentication task is achieved by observing the input-output relationships of the compromised models. He *et al.* [10] first proposed a black-box fragile watermarking scheme, which is able to detect attacks, such as data poisoning attack and backdoor attack, without knowing the priori knowledge of the model.

Black-box fragile watermarking is convenient, efficient and concealed compared to white-box watermarking, and has been gradually gaining attention from researchers in recent years. In this work, a black-box lossless fragile watermarking scheme based on hidden space search is proposed, and the main contributions of the proposed scheme are summarized as follows.

- The scheme does not require any internal information about the target model, or even access to train the model, and any authorized party can generate sensitive samples using the label information returned by the model.
- Design a high-performance VAE-GAN-based mapping and reconstruction model that maps the original samples into hidden space to form the corresponding hidden vectors, which can then be reconstructed into visually satisfactory sensitive samples by the decoder.
- A strategy is designed to search for perturbations in the hidden space on the hidden vector of the original sample, which can keep the search in the direction of the decision boundary of the target model, and in turn generates efficient sensitive samples that can be attached to the vicinity of the decision boundary.

II. The Proposed Fragile Watermarking Scheme

This part explains in detail the process from the generation of sensitive sample to model integrity authentication, and gives the corresponding mathematical optimization.

A. The Overall Flow of The Proposed Scheme

The proposed fragile watermarking scheme based on image hidden space is a black-box watermarking type. For an image classification model f to be protected, referred as target model, the licensees adopt MLaaS approach to generate some sensitive samples locally for the target model by querying it at a remote location. These sensitive samples and associated labels are retained by the licensees as fingerprints of the target model and are exploited as a criterion for determining whether the target model has been tampered. The specific flow of the proposed watermarking scheme is shown in Fig. 1(a).

The framework consists of three main parts, namely encoder En, decoder De and converter Tr. A high-performance encoder En is first trained on the dataset $\mathbf{X}$ with a corresponding decoder De. The purpose of the encoder En is to map an original sample x from dataset to hidden space, thus obtaining the corresponding hidden vector $\mathbf{z}$. Then an image with a different label from the original sample, called target sample x', is fed into the converter Tr to obtain its vector $\Delta\mathbf{z}$. Finally, the output of the target model f is used as the guidance to search perturbation on $\mathbf{z}+\Delta\mathbf{z}$ in the direction of the target sample in the low-dimensional hidden space. After the perturbation search, $\mathbf{z}+\Delta\mathbf{z}$ is fed to the decoder De, which reconstructs the input vector to generate the sensitive sample v. After that, we use the generated sensitive samples and the corresponding labels as the fingerprints $\mathbb{FG}=\{(v_i, f(v_i))\}_{i=1}^{n}$ of the target model, and hand them over to the authorized party for retention.

In the verification session, in the face of a suspicious model f' deployed on a cloud server, the authorized party can access the model f' remotely by using API interface. If there exists $f'(v_i)\neq f(v_i), i\in\{1,\cdots,n\}$, then it can be assumed that the parameters or structure of the model f' has been tampered and its integrity has been compromised, and the verification session is shown in Fig. 1(b).

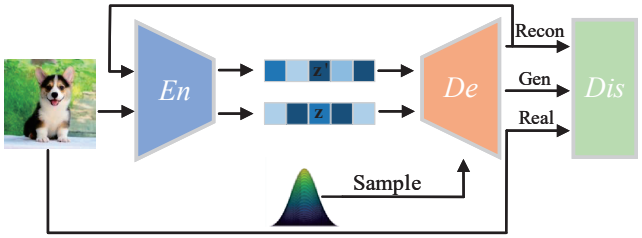

Fig. 2. Structure of VAE-GAN-based mapping and reconstruction model.

B. Generation of sensitive samples

The encoder module consists of several convolutional layers, in the process of the convolutional kernel downsampling the input image, the main features of the image are learned, which maps the input image to a low-dimensional vector, constituting a structure called hidden space $\mathcal{Z}$, and these compressed vectors are called hidden vectors $\mathbf{z}\in\mathcal{Z}$. The decoder consists of a number of transposed convolutional layers, and the effect of the decoder is to reconstruct the low-dimensional hidden vector into the original image.

The encoder-decoder coupling ensures a fixed mapping between the hidden vectors and the image samples, and means that the vectors in the hidden space can be manipulated to generate the new images needed for our task, i.e., the sensitive samples in proposed scheme. However, the samples generated by standard VAE are often blurred and visually poor [11]. To address this issue, we design a high-performance VAE-GAN-based mapping and reconstruction model, which can extract more critical features from the input images and generate images with better visual quality, the specific structure of the model is shown in Fig. 2.

Specifically, for the input original sample x, it is first transformed by the encoder into a low-dimensional vector $\mathbf{z}$, i.e., $\mathbf{z}\sim En(x)=q(\mathbf{z}\mid x)$, after which it is reconstructed by the decoder into reconstruction sample $\widetilde{x}$, i.e., $\widetilde{x}\sim De(\mathbf{z})=p(x\mid\mathbf{z})$. Then VAE model imposes a priori constraint term on the hidden vector $\mathbf{z}$ such that it conforms to $\mathbf{z}\sim\mathcal{N}(0,I)$.

Thus the loss function of VAE can be shown in Eq. (1):

$$\mathcal{L}_{VAE} = -\mathbb{E}_{q(\mathbf{z}|x)}\left[\log \frac{p\left(x \mid \mathbf{z}\right) p\left(\mathbf{z}\right)}{q\left(\mathbf{z} \mid x\right)}\right] = \mathcal{L}_{\text{like}}^{\text{pixel}} + \mathcal{L}_{\text{prior}} \tag{1}$$

$$\mathcal{L}_{\text{like}}^{\text{pixel}} = -\mathbb{E}_{q(\mathbf{z}|x)}\left[\log p\left(x \mid \mathbf{z}\right)\right] \tag{2}$$

$$\mathcal{L}_{\text{prior}} = D_{KL}\left(q\left(\mathbf{z} \mid x\right) \parallel p\left(\mathbf{z}\right)\right) \tag{3}$$

where $\mathcal{L}_{\text{like}}^{\text{pixel}}$ is the reconstruction loss used to keep the reconstructed sample as similar as possible to the original sample, and $\mathcal{L}_{\text{prior}}$ is the KL scatter loss, which measures the similarity between two distributions.

In order to obtain visually better sensitive samples, we adopt the idea of GAN [12] by using the decoder De as the generative network in GAN, which is followed by a discriminator Dis. Detailedly, we sample the gaussian noise $\mathbf{z}_p$ as the input to the decoder De to obtain generated samples $\bar{x}$. Since the distribution $p(\mathbf{z})$ and the distribution $q(\mathbf{z} \mid x)$ tend to differ to some extent, in order to minimize this difference, we feed the real sample x, the reconstructed sample $\widetilde{x}$ and the generated sample $\bar{x}$ together into the discriminator. In the ideal case, the discriminator can not recognize the difference between the three. Besides, in order to generate more accurate sensitive samples after adding perturbations in the hidden space, we need to reduce the difference between the hidden vector $\mathbf{z}'$ obtained from the reconstructed sample $\widetilde{x}$ by the encoder De and the hidden vector $\mathbf{z}$ of the real sample. Therefore, we design the $\mathcal{L}_{\text{GAN}}$ loss and the $\mathcal{L}_{\mathbf{z}}$ loss, as shown in Eq. (4) and Eq. (5), respectively:

$$\begin{aligned}\mathcal{L}_{\text{GAN}} =& log(Dis(x)) + log(1 - Dis(De(\mathbf{z}_p))) + \\ & log(1 - Dis(De(En(x))))\end{aligned} \tag{4}$$

$$\mathcal{L}_{\mathbf{z}} = \left\|\mathbf{z} - \mathbf{z}'\right\|_2 \tag{5}$$

where the $Dis(\cdot)$ in Eq. (4) is the probability that the discriminator can recognize the input true sample as the natural image from the training set.

The difference between the reconstructed sample $\widetilde{x}$ and the generated sample $\bar{x}$ can be captured by the discriminator, so we can obtain a decoder with better reconstruction capability. Therefore, we can optimize the parameters in the encoder, decoder and discriminator simultaneously by Eq. (6).

$$\mathcal{L}_{\text{En-De-Dis}} = \mathcal{L}_{\text{like}}^{\text{pixel}} + \mathcal{L}_{\text{prior}} + \mathcal{L}_{\text{GAN}} + \mathcal{L}_{\mathbf{z}} \tag{6}$$

Through the joint training of encoder, decoder and discriminator, the conditions for the generation of sensitive samples are provided.

C. Strategies for Perturbation Search

After completing training on encoder En and decoder De, both of which have acquired the ability of mapping and reconstructing. Considering the visual quality of sensitive samples, we should impose as little as possible perturbation on original samples, so the selection of target samples is needed. Specifically, we perform Euclidean distance calculation for each available sample that differs from the label of original sample, then select the samples with the closest distance to the original sample as the target samples, see Eq. (7):

$$\min_{l \neq y} \min_{f(x')=l} \left\|x' - x\right\|_2 \tag{7}$$

where $f(\cdot)$ is the target model, x is the original sample, y is the label of the original sample, x' is the target sample, and l is the label of the target sample.

After selecting a suitable target sample x', we fed it into the converter Tr such that the converter extract the key semantic information in the target sample and converts these information into a hidden vector $\Delta\mathbf{z}$. To facilitate the addition of suitable perturbations to the hidden vector, the converter Tr is constructed in the same structure as the decoder En. The input samples are mapped by the encoder to the corresponding hidden vector $\mathbf{z}$, then $\Delta\mathbf{z}$ is superimposed onto the hidden vector $\mathbf{z}$ as a perturbation, and finally $\Delta\mathbf{z} + \mathbf{z}$ is used as the input to the decoder De. The decoder can reconstruct the input from the hidden space to the original sample space to generate the sensitive sample. The core idea of the scheme is to add the perturbation to the hidden vector of the input samples, which makes the samples move closer to the decision boundary of the target model. We can identify the task as a mathematical optimization problem, see Eq. (8):

$$\begin{aligned}\mathcal{L}_{\text{target}} =& \max\left(f(De(\Delta\mathbf{z} + \mathbf{z}))_y - \max f(De(\Delta\mathbf{z} + \mathbf{z}))_{y \neq l}, 0\right) \\ & s.t. \|\Delta\mathbf{z} - \mathbf{z}\|_2 \leq \varepsilon\end{aligned} \tag{8}$$

where $f(\cdot)_y$ denotes the confidence that the output label is y, $\|\cdot\|_2$ is the Euclidean distance, and ε denotes the maximum threshold of perturbation to constrain the visual quality of sensitive samples.

Besides, we should control the direction of the search perturbations in the hidden space towards the location of the target sample. Specifically, the original sample x, the sensitive sample v and the target sample x' are mapped through the encoder En to obtain their corresponding hidden vectors $\mathbf{z}$, $\mathbf{z}_{wmk}$ and $\mathbf{z}_{tgt}$. Then the differential vector $\mathbf{z}_{tgt-ori}$ between the target sample and the original sample and the differential vector $\mathbf{z}_{wmk-ori}$ between the sensitive sample and the original sample can be obtained by Eq. (9) and Eq. (10), respectively.

$$\mathbf{z}_{tgt-ori} = \mathbf{z}_{tgt} - \mathbf{z} \tag{9}$$

$$\mathbf{z}_{wmk-ori} = \mathbf{z}_{wmk} - \mathbf{z} \tag{10}$$

Since the differential vectors $\mathbf{z}_{tgt-ori}$ and $\mathbf{z}_{wmk-ori}$ contain information about the direction in the hidden space, the angle between the two vectors can be measured by calculating the cosine similarity, thus we impose a certain constraint on the search direction of the perturbation, see Eq. (11).

$$\begin{aligned}&\text{Cos}\left(\mathbf{z}_{wmk-ori}, \mathbf{z}_{tgt-ori}\right) = \\ &\frac{\sum_{i=0}^{n}\left(\mathbf{z}_{wmk-ori}^{i} \times \mathbf{z}_{tgt-ori}^{i}\right)}{\sqrt{\sum_{i=0}^{n}\left(\mathbf{z}_{wmk-ori}^{i}\right)^2} \times \sqrt{\sum_{i=0}^{n}\left(\mathbf{z}_{tgt-ori}^{i}\right)^2}}\end{aligned} \tag{11}$$

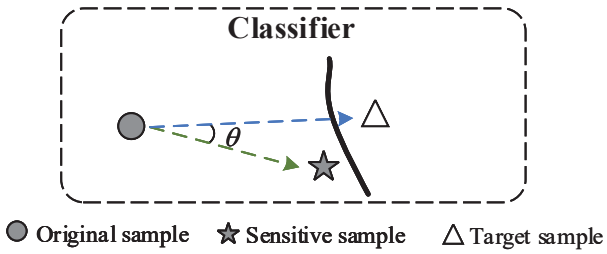

Fig. 3. Diagram of perturbation search direction.

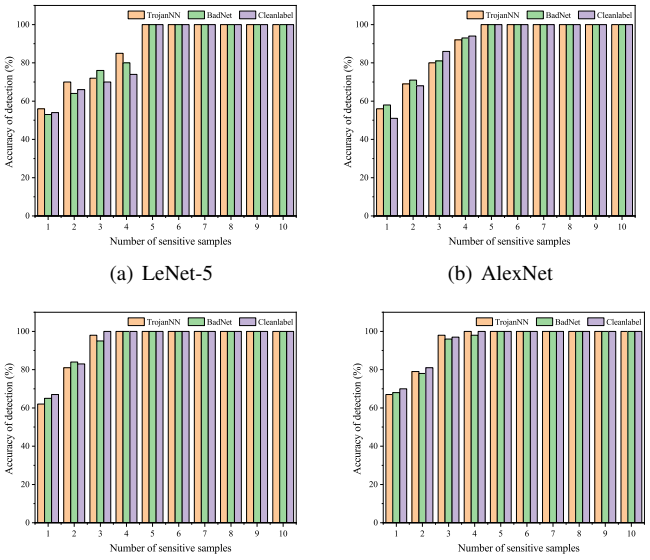
The utilization of cosine similarity allows the search direction of the perturbation to coincide with the direction of $\mathbf{z}_{tgt-ori}$. In the sample space this is expressed as the direction of the perturbation remaining on the line from the original sample to target sample, as shown in Fig. 3.

The visual quality of the sensitive samples need to be maintained while imposing constraints on the direction of perturbation search, so the overall loss function for the perturbation search can be expressed as:

$$\mathcal{L}_{\text{perturbation}} = \mathcal{L}_{\text{target}} + (1 - \text{Cos}\left(\mathbf{z}_{wmk-ori}, \mathbf{z}_{tgt-ori}\right)) + \|v - x\|_2 \tag{12}$$

After the classification information of the target samples are obtained by accessing the model, according to the designed perturbation search strategy, the sensitive samples can be made to reach near the decision boundary of the target model with the loss function $\mathcal{L}_{\text{perturbation}}$.

III. Experimental Results and Analysis



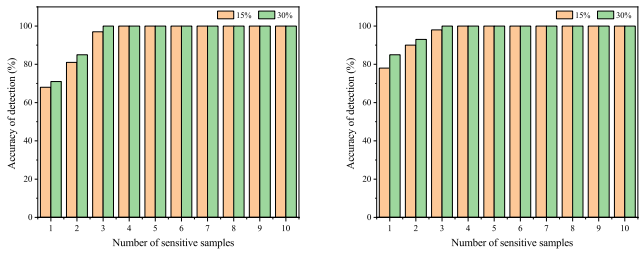
In the following experiments, we selected four typical DNN models, namely LeNet-5, AlexNet, VGGNet19 and ResNet50, with different performance and structural complexity, to demonstrate the fitness of our scheme. To further prove the generalization ability of the schemes, these models were trained and manipulated on two different datasets, namely MNIST and Cifar-10. All experiments were conducted on a computer equipped with NVIDIA TITAN RTX GPU, Intel Xeon W-2123 CPU and 64 GB RAM.

A. Setup

We simulated two different types of attacks against the integrity of the model. For the backdoor attack type, three typical attack schemes, BadNet [2], TrojanNN [3] and Cleanlabel [13], were chosen, all resulting in incorrect output of the model during inference. In this scenario, we assume that the attacker attempts to minimize the prediction accuracy of the target model, as well as to maximize the likelihood of misclassifying samples into the target category, so we adjusted the success rate of three attack schemes to the highest. We use attack intensity to measure the strength of the attack, i.e. the accuracy of successfully outputting a toxic sample as a predefined mislabel. The second type is that the dishonest cloud server provider compresses the target model to save storage costs, and used the compression rate to measure the attack intensity, with the higher the compression rate the higher the attack intensity.

TABLE I
Experimental Models and Attack Settings

Target Model	Attack Type	Dataset	Attack scheme	Attack Intensity
LeNet-5	Backdoor attack	MNIST	BadNet	100%
			TrojanNN	96%
			Cleanlabel	95%
AlexNet	Backdoor attack	Cifar-10	BadNet	100%
			TrojanNN	98%
			Cleanlabel	97%
VGGNet19	Backdoor attack	Cifar-10	BadNet	100%
			TrojanNN	98%
			Cleanlabel	98%
ResNet50	Backdoor attack	Cifar-10	BadNet	100%
			TrojanNN	99%
			Cleanlabel	98%
AlexNet	Compress attack	Cifar-10	Pruning	Compress 15%
VGGNet19	Compress attack	Cifar-10	Pruning	Compress 30%



(a) LeNet-5 (b) AlexNet

(c) VggNet19 (d) ResNet50

Fig. 4. Detection accuracy rate of backdoor attacks for sensitive samples in different models.

The specific attack settings are shown in TABLE I. We conducted backdoor attacks on four different watermarked models with BadNet, TrojanNN and Cleanlabel. 100 attack operations were performed on the watermarked models for each attack scheme, and all the average success rate of each attack are over 95%. In addition, we performed compression attacks on two watermarked models, namely AlexNet and VGGNet19, trained on Cifar-10, by means of pruning attack.

The length of the hidden vector was set to 68, and we trained 300 epochs with Adam optimizer, the learning rate was 0.08, the weight decay was set to 0.005, and the threshold ε was set to 3.5. 20 images of each category from each dataset were randomly selected as the original and target samples for perturbation search.

TABLE II
DIFFERENCES IN THE PROPERTIES OF DIFFERENT FRAGILE WATERMARKING SCHEMES

Scheme	Watermarking type	Performance	Sample generation
RWDCNN [9]	White-box	↓	N/A
SSFDNN [10]	Black-box	=	White-box
NeuNac [8]	White-box	↓	N/A
FNNW [14]	Black-box	↓	Black-box
Proposed	Black-box	=	Black-box

Fig. 6. Visualization of the training process of reconstructed samples.

B. Tampering Detection

To assess the effectiveness of the watermarking scheme in detecting attacks on the integrity of the model, i.e. the fragility of the watermark, we conducted statistics on how the labels associated with the sensitive samples changed after the model was compromised. The experimental results are shown in Fig. 4, where the horizontal coordinates indicate the number of sensitive samples and the vertical coordinates indicate the success rate of identifying tampering attacks. It should be noted that the proposed scheme does not identify the intact models as tampered models, i.e. the false positive rate is 0.

As can be seen from Fig. 4, the correct detection rate for the three backdoor attacks gradually increases with the number of sensitive samples increases. When the number of sensitive samples is set to 5, 100% correct detection rate is achieved on all models, which indicates that the verifier only needs 5 API accesses to be informed of the integrity, thus proving that the proposed scheme has a very high verification efficiency.

In order to verify the effectiveness of the scheme in detecting model compression attacks, AlexNet and VGGNet19 after compression attacks were also tested, the experimental results are shown in Fig. 5. When the number of sensitive samples was set to 3, both AlexNet and VGGNet19 achieved 100% correct detection for 30% pruning attack, and 96% and 98% accuracy for 15% pruning attack, respectively. When the number was set to 4, both models achieved 100% accuracy in detecting different levels of pruning attacks.

C. Comparisons with State-of-the-art Schemes

To verify the superior performance of the proposed scheme, we compared it with some other model fragile watermarking schemes. According to the type of watermarking, NeuNac [8] and RWDCNN [9] can be classified as white-box watermarking, both of which embed a specific string into the model, and inevitably modify some parameters and cause performance degradation. SSFDNNN [10], FNNW [14] and the proposed scheme are black-box watermarking schemes, the FNNW requires the target model for fine-tuning, which also distorts the decision boundaries of the model to some extent. The state-of-the-art scheme SSFDNN does not impact on the performance of the target model, but it requires information of the model during the generation of sensitive samples. TABLE II lists the differences in the properties of these fragile watermarking schemes.

To further demonstrate the effectiveness, we conducted more detailed comparison experiments and analysis between SSFDNN and the proposed scheme. We selected VGGNet19 trained on Cifar-10 as the experimental subject, and generated three different groups of experiments with sensitive sample numbers of 1, 2 and 3 using the SSFDNN and the proposed scheme, respectively. Then we attacked the experimental model 100 times with each of the five attacks in TABLE I. At the authentication end, changes of associated labels were used to determine whether the experimental model had been tampered, as illustrated by the results in TABLE III.

With the number of sensitive samples set to 1, the proposed scheme achieved a higher detection accuracy than SSFDNN. As the number of sensitive samples increases, SSFDNN's effectiveness increased but is still slightly worse than the proposed scheme. Overall, the proposed scheme is able to detect a wide range of attacks with excellent results and does not require any internal information of the target model, and only acquires the output of the model to generate several efficient sensitive samples.

D. Imperceptibility

In addition to the effectiveness, imperceptibility is also a very important evaluation criterion in watermarking schemes. The sensitive sample should have good visual quality, so that the human eye cannot distinguish the difference between the sensitive samples and the original samples. The experiment adopted imperceptibility to measure the visual difference, and imperceptibility can be obtained by Eq. (13):

$$Imperceptibility = \sqrt{\frac{1}{n} \parallel v - x \parallel_2} \tag{13}$$

where n is the number of pixels in the image, v is the sensitive sample and x is the original sample.

A lower imperceptibility indicates a better visual quality for the sensitive sample. We first conducted imperceptibility experiments on the reconstruct effect of VAE-GAN, and we show the reconstructed samples obtained every 30 epochs, as shown in Fig. 6. It can be seen that, the reconstruction process

TABLE III
PERFORMANCE COMPARISON OF THE PROPOSED SCHEME WITH SSFDNN ON THE VGGNET19

	SSFDNN [10]			Proposed		
	1 Sample	2 Samples	3 Samples	1 Sample	2 Samples	3 Samples
BadNet	65%	90%	100%	64%	83%	96%
TrojanNN	68%	87%	98%	62%	80%	98%
Cleanlabel	70%	89%	99%	68%	82%	100%
15% pruning	51%	80%	94%	78%	90%	97%
30% pruning	55%	82%	98%	83%	93%	100%

Fig. 7. Visual quality of sensitive samples on MNIST dataset.

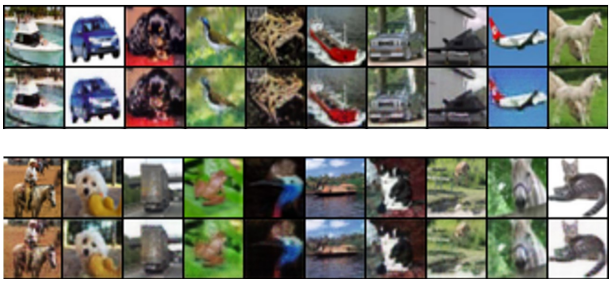

Fig. 8. Visual quality of sensitive samples on Cifar-10 dataset.

gradually enriches from smooth regions at low frequencies to complex details at high frequencies, which is in line with the reconstruction law of deep learning models. After training the model for 300 epochs, the reconstructed samples achieved high visual quality, and the imperceptibility between the reconstructed sample and its original sample is 23.6.

To further verify the imperceptibility of the sensitive samples, AlexNet was selected to trained on MNIST and Cifar-10, respectively. The data in MNIST are simple single-channel images, which allows the model to learn the core features more easily, while the images in Cifar-10 are colourful and more complex, which makes the perturbation search more difficult. In this experiment, we randomly selected 50 original samples from each of the two datasets, which can generate 50 sensitive samples, and then calculated the imperceptibility in pairs, followed by the average mean. After calculation, the mean values of imperceptibility on MNIST and Cifar-10 are 51.25 and 98.83, respectively. Some representative sensitive samples generated from the corresponding datasets are shown in Fig. 7 and Fig. 8.

IV. CONCLUSION

In this paper, a black-box fragile watermarking scheme is proposed, which can generate sensitive samples only by the output results returned by the model. Firstly, a high-performance mapping and reconstruction model is designed, which superimposes the semantic features of the target sample on the hidden vector corresponding to the original sample by searching for perturbations, so that the original samples keep moving towards the decision boundary. After that, the decoder reconstructs the perturbed vector to obtain sensitive samples with good visual quality. Extensive experiments demonstrate that the sensitive samples can effectively detect model backdoor attack and compression attack. In addition, the user only needs a low cost for samples generation and model integrity verification, which has practical application value for image classification models.

***Abstract*—The rise of online medical-related technologies has brought great convenience to doctors and patients. However, electronic patient information may be subject to attacks and tampering during medical transmission, leading to compromised information. Therefore, it is necessary to protect the security of data in medical transmission by authenticated electronic patient information. This paper proposes a high-capacity reversible data hiding technology based on interpolated images, which can successfully protect patients' confidential information and verify received content. By using predictors to generate high-quality cover images, and then using data foding strategy to hide electronic patient information into medical images, the entire scheme can be divided into image preprocessing, data processing, and data embedding processes. Image preprocessing includes generating predicted images and performing boundary value on them to generate high-quality covered images. Data processing encrypts the secret data, divides the encrypted data into n blocks of 3 bits, and converts each block into a decimal number. Before embedding the secret data, these numbers are subjected to data foding strategy operation, and data labeling is carried out to ensure the recovery of secret data. The embedding process divides the cover image into 2x2 blocks and embeds secret data in the non-seed pixel diagonal of each block. Last but not least, a fragile watermark is also embedded in the cover image to determine whether the transmitted information has been tampered with. Experimental results show that the method can achieve a high embedding capacity of an average of 2.25 bits per pixel, while the average peak signal-to-noise ratio of the steganographic image reaches 42dB, which is good compared to existing technologies.**

I. Introduction

E-healthcare has improved healthcare services during pandemics, minimizing disease transmission and reducing morbidity and mortality rates [1]. In order to address the problem of uneven distribution of medical resources, remote healthcare has received extensive attention within the medical industry of the Internet of Things [2]. The security of remote medical data and the protection of patient privacy have always been a key concern [3]–[5]. In the entire remote healthcare system, EPI serves as a medium between doctors and patients, and if there are minor changes it will interfere with the doctor's diagnosis. In this case, researchers have been looking for effective methods to ensure the security of EPI.

Data hiding algorithms are found to be applicable to the remote healthcare system for protecting patient information. The direction of data hiding research can be roughly divided into digital watermarking, steganography and reversible data hiding (RDH) [6], [14]. Due to the special mechanism of RDH, it is impossible to cause any damage to the diagnostic medical images. Therefore, its work and research play an important role in protecting EPI.

II. Literature review

Reversible data hiding algorithms based on image interpolation (IT) has become a new research hot topic. Image interpolation technology is widely used in the field of medical digital image processing [7], [8].A large amount of patient diagnostic information needs to be collected so that doctors can make better diagnoses. Compared with traditional RDH algorithms [15]–[18], IT-based RDH algorithms [13], [19], [20] have the advantages of large single-layer embedding capacity and high visual quality.

Jung et al. [9] first generate interpolated pixels by calculating the average value of neighboring pixel values, this method is called Neighborhood Mean Interpolation (NMI) method, and then embeds secret data of corresponding bit numbers by comparing the relationship between the original pixels and the interpolated pixels. In order to pursue better visual quality, Lee et al. [10] implemented the RDH method through an interpolation of neighboring pixels (INP). A RDH method based on enhanced neighborhood mean interpolation (ENMI) was proposed by Chang et al. [11], which further improves image quality by replacing the diagonal interpolated pixels . At the same time,An improved neighbor mean interpolation (MNMI) method was proposed by Malik et al. [12]. Overall, in terms of visual quality, ENMI and MNMI methods can achieve higher image quality than NMI method. Compared with traditional RDH techniques, IT-based RDH techniques can achieve a high embedding rate of 2.0 or higher because multiple bits of secret data can be embedded in each interpolated pixel block, achieving truly large-capacity secret data embedding. In practical applications, if you need to embed a large amount

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

of secret data in the cover image, the IT-based scheme can be said to be an ideal choice.

We can see that most of the reversible data hiding techniques based on interpolation images have disadvantages such as high computational complexity, low efficiency in EPI transmission, and lack of tampering detection capabilities. As a result, we propose an improved interpolation approach to optimize the EPI transmission efficiency while minimizing the impact on image quality. Encoding the data can reduce differences between pixel values, providing better imperceptibility. Tampering detection capabilities are obtained by inserting fragile watermarks in the spatial domain.The main contributions of this paper are:

- An improved predictor is designed for three types of interpolation pixels. The predictor based on the classification idea of this paper effectively retains the edge texture information of the original image.
- A data double-folding mechanism was developed to map the corresponding data to a fixed sequence of shifted data, resulting in less degradation for a given set of hidden data. The main purpose of data mapping is to reduce the difference between pixel values and achieve high imperceptibility

III. Proposed method

The entire embedding process of this method is shown in Figure 1.

First, the original image generates a cover image through interpolation. As in previous research schemes, the cover image was divided into each block of 3×3, and the seed pixels are kept while the non-seed pixels are predicted using the improved predictor method to ensure reversibility. At the same time, the encrypted bitstream to be embedded is divided into 3-bit blocks, and each block is first composed of decimal equivalents of 0, 1, 2, 3, 4, 5, 6, 7, then converted into -1, 0, 1, 2 representations through data folding and tagged. As later sections show, the encoding mapping system can improve the imperceptibility of the steganographic image by further reducing the difference between pixel values. Border conditions need to be imposed on each pixel block to handle overflow pixel values. The proposed method also has tampering detection capability.

A. Predictor

To generate a cover image for hiding secret information, the predictor generates relevant interpolated pixels by referencing the relationships between neighboring pixels. On the one hand, this ensures reversibility, and on the other hand, it also performs well in terms of image fidelity. We re-considered the reference position of the interpolated image and made it an adaptive process.

B. Predictor computation mechanism

In each block, the pixels within each block are divided into two types of pixels due to different uses, namely reference pixels and interpolation pixels. The classification rule is: the original pixels in each block are classified as reference pixels, and other pixels are classified as virtual pixels. The interpolated pixels are calculated from weighted reference pixels and given parameters. The original pixels located in each block are used to calculate the interpolated pixels because they have a strong local correlation with the predicted interpolated pixels.During the calculation process of weight parameters, different labels are assigned to the calculated pixels, as shown in Figure 2. "C" represents the pixel to be interpolated at this time, "D" represents the reference pixel, and "×" represents the pixels that do not affect the generation of the interpolated pixel.

Types 1 and Type 2: As shown in figure 2, if the interpolated pixel has neighboring pixels on its left and right, or above and below, that are original pixels, we classify this as Type 1 and Type 2 respectively.

The formula for predicting pixel C is: C = PxD_1 + (1-P)xD_2

$$P = \begin{cases} \frac{\text{overnum}_1}{\text{num}}, & \text{if } D_1 > D_2 \\ \frac{\text{overnum}_2}{\text{num}}, & \text{if } D_2 > D_1 \\ \frac{1}{2}, & \text{if } D_1 = D_2 \end{cases} \tag{1}$$

In this formula, P is an adaptive parameter whose value is determined by the difference between the interpolated pixel and its neighboring pixels.D_1 refers to the value of the pixel to the left or above the predicted pixel value, and D_2 refers to the value of the pixel to the right or below the predicted pixel value. num represents the number of non-seed pixels around the predicted pixel. $Overnum_1$ and $Overnum_2$ represent the number of non-seed pixels whose values are greater than the D1 and D2 pixel values, respectively.

For Type 3, as shown in Figure , where the interpolated pixel has no neighboring original pixels on its left, right, above, and below, we classify it as Type 3.

The formula for predicting pixel C is:

$$C = \begin{cases} \frac{D_1+D_4}{2}, \text{ if } |D_1 - D_4| < |D_2 - D_3| \\ \frac{D_2+D_3}{2}, \text{ if } |D_1 - D_4| > |D_2 - D_3| \\ \frac{D_1+D_2+D_3+D_4}{4}, \text{ if } |D_1 - D_4| = |D_2 - D_3| \end{cases} \tag{2}$$

A working example of a simple predictor is presented here. The process of interpolating prediction on the original pixel points with grayscale values [53 42 64 31] is shown in Figure 3. The two pixels with values of 53 and 31 are treated as labels D_1 and D_4, respectively, and the two pixels with values of 42 and 64 are treated as labels D_2 and D_3, respectively. Then, the predicted interpolated pixel "C" is calculated based on different scenarios.

C. Prediction of boundary interpolated pixels

Due to insufficient original pixels, the proposed method cannot predict interpolated pixels at edges. Therefore, in this paper, the following special cases will be handled as follows:

Case 1: Interpolate the first and second-to-last rows of the cover image, or interpolate the pixels in the last row of the cover image, where the boundary pixels at this time are the average of the adjacent left and right pixels.

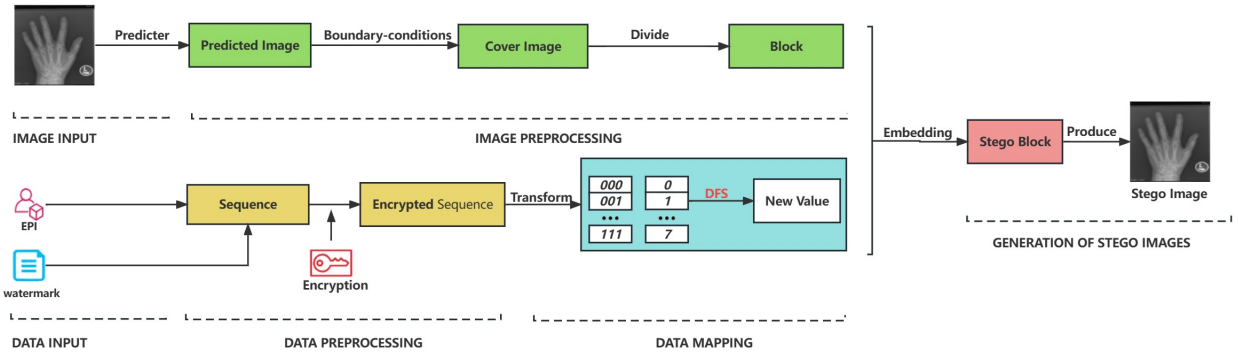

Fig. 1. The flowchart of the proposed scheme.

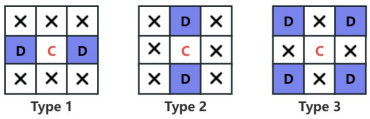

Fig. 2. Different predictor types.

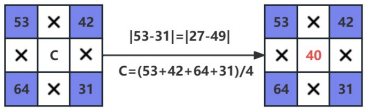

Fig. 3. Pixel prediction using the predictor.

Case 2: Interpolate the pixels in the first and second-to-last columns of the cover image, or interpolate the pixels in the last column of the cover image, where the boundary pixel is the average of the adjacent top and bottom pixels.

After passing the method, we get the cover image that hides the secret data.

D. Encryption and data folding schemes

Security of confidential data is the top priority of telemedicine systems.Various data breaches occur in the medical industry every year, so new mechanisms need to be developed to protect the security and privacy of data. In this scheme, this paper uses the AES-128 encryption scheme to encrypt confidential data to enhance its security. In our scenario, we are using 128-bit key length because it provides faster encryption. After encrypting the data, the previously used method, namely, data left-shift method (LDM), is typically used to embed data into a cover image. Instead, in this paper, we use a data folding scheme (DFS) to optimize the data in the cover image. The scheme enables us to further hide more data while reducing the image degradation level. First, the data D to be embedded is converted into 3-bit blocks, all of which are converted into decimal value data from 0 to 7. Then, these numbers are folded according to a corresponding mapping (such as a formula), and the range of the folded data L is between -4 and 3. Therefore, the data is divided into two parts: the positive part and the negative part. However, we found that the values of each part are still very large, so we need to repeatedly fold each part to obtain new data (New D) with a range of [-2,1] to reduce the difference between pixel values. Embedding data in this way will result in stego images with lower degradation levels compared to the traditional method.

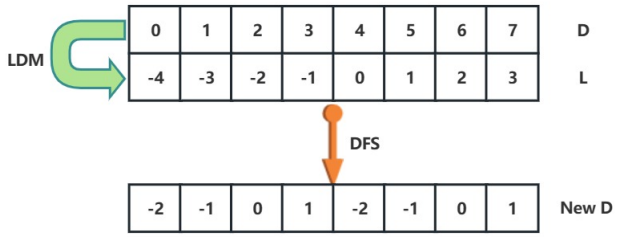

Fig. 4. Proposed implementation of DFS

E. Data Embedding Process

This section will demonstrate embedding confidential data and fragile watermarks in the generated cover image.After being combined with the watermark, the secret data is embedded in the pixels designated on the reverse diagonal while keeping the seed pixels unchanged. For the purpose of authentication,a 64×64 fragile watermark is concatenated with the data to be embedded, with one watermark bit embedded after every 47 bits of confidential data. The purpose of the scheme is to ensure high susceptibility to attacks. See Algorithm 1 for details.

F. Data Extraction Process

This section briefly describes the data extraction process. The data extraction process operates exactly opposite to the data embedding process. The extraction process consists of two parts: extraction of original images and extraction of secret data.The process of extracting the original image, which is done by retaining the seed pixels of the cover image. For data extraction, the algorithm used returns the original values, and

Algorithm 1 Embedding Algorithm.

Require:

secret data SD and Cover image C;

Ensure:

Stego image S;

1: Take n-bits secret data SD and the cover image C.;
2: Divide the cover image of size M×N into 2×2 blocks, each block contains seed pixels and 3 interpolated pixels,where the number of blocks is M×N/4 ;
3: Concatenate watermark bits and the EPI into a sequence ”S” with a size of 6MN. At the same time, select the key K and encrypt the sequence ”S” to get ”E”. The encryption sequence process can be expressed as E=ENC(S,K);
4: Divide the encrypted sequence ”E” into one part every 3 bits, and convert each part from binary to decimal (i.e, 000 through 111 is converted to 0 through 7)
5: Convert these decimal numbers to new value ”X” by data folding strategy;
6: The two decimal-converted secrets are sequentially embedded into the anti-diagonal of each block while preserving the original pixels. The embedding process is: P_i=P+X,where P_i is the pixel value after embedding and P is the pixel value before embedding;
7: Follow steps 1-6 above until you obtain the stego image containing the secret data;

the decrypted information is then obtained by applying the corresponding algorithm.

IV. Results and Discussion

In this section, to evaluate the performance of our proposed algorithm, we randomly tested eight images with a size of 512 × 512 (4 regular images and 4 medical images). The test images shown in Figure 8 are 4 medical images acquired from the Open Access Biomedical Image Search Engine (OPENI) and 4 general images acquired from USC-SIPI. The proposed method extended the images before embedding using a predictor to generate predicted images with a size of 512 × 512. To embed, we used data generated by a pseudorandom function. The experiment was conducted using MATLAB R2014a.

A. The embedding capacity

The embedding capacity is one of the important metrics for reversible data hiding schemes.

The embedding capacity (EC) is defined as follows:

$$EC(bpp) = \frac{\text{The number of bits embedded}}{\text{Total number of pixels}}. \quad (3)$$

Therefore, the method in this paper can hide 2.25bpp after calculation. It should be noted that when fragile watermarks are added, the maximum embeddable EPI is 1.5 bpp.

The payload of the method proposed in this paper has been compared with some related and existing state-of-the-art methods. The results shown in Figure 6 show that our scheme outperforms most techniques in terms of payload.

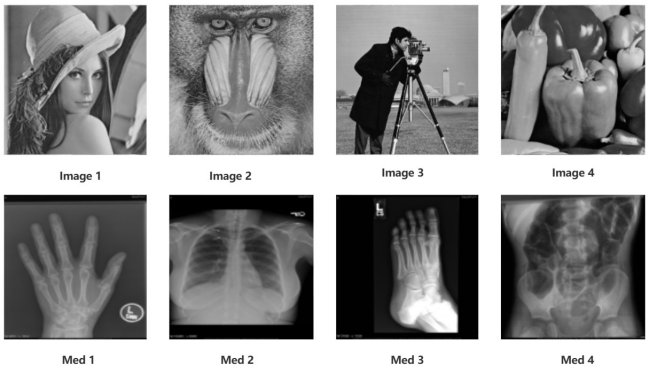

Fig. 5. Test images.

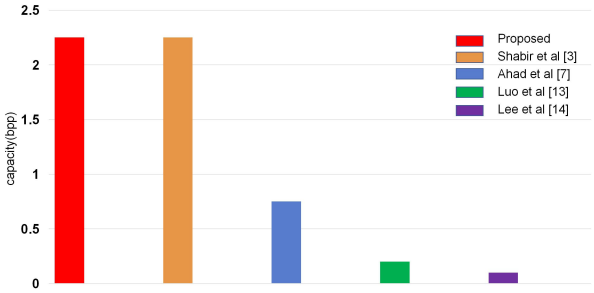

Fig. 6. Payload comparison of images.

TABLE I
Payload(bits), PSNR (dB),SSIM, BER

Images	Payload(bits)	PSNR(dB)	SSIM	BER(%)
Img1	589824	41.96	0.9731	0
Img2	589824	41.88	0.9635	0
Img3	589824	41.75	0.9802	0
Img4	589824	41.94	0.9737	0
Med1	589824	41.99	0.9466	0
Med2	589824	41.92	0.9583	0
Med3	589824	41.96	0.9861	0
Med4	589824	41.99	0.9553	0
Average	**589824**	**41.92**	**0.9671**	**0**

B. imperceptibility analysis

An important criterion for an information embedding system is that even after high-capacity data embedding, the perceptual quality of the image must have a satisfactory result. For imperceptibility, commonly used measurement methods are similarity index (SSIM) and peak signal-to-noise ratio (PSNR).

For a stego image S and an original image C, PSNR is defined as:

$$PSNR \triangleq 10\log_{10}\frac{255^2}{MSE} \quad (4)$$

SSIM is calculated as follows:

$$\text{SSIM} = \frac{(2\mu_{Cl}\mu_S + C_1)(2\sigma_{CS} + C_2)}{(\mu_C^2 + \mu_S^2 + C_1)(\sigma_C^2 + \sigma_S^2 + C_2)} \quad (5)$$

Where C_1 andC_2 are two defined constants. The value of SSIM ranges from 0 to 1. An SSIM value of 0 means that the two images are completely different. At the same time, an SSIM value of 1 means that the two images are identical.

Table 1 shows the average PSNR value of the images to be 41.92 dB, which means the changes in the image are imperceptible to humans through their senses.Table 1 also shows the SSIM values of sample test images, which ranges from 0.9466 to 0.9861. The average SSIM value is 0.9671. The results show that the stego image is almost identical to the cover image.

C. Reversibility analysis

This section discusses the reversibility analysis of the proposed method. The original image and the restored image are shown in Figure 7. The differences between the two images are almost imperceptible to the human eye, but the fact that the pixel values of the original image and the recovered image are exactly the same indicates that our method is completely reversible and the original image can be completely recovered without any loss. We randomly tested two typical images to confirm this, as shown in the figure.

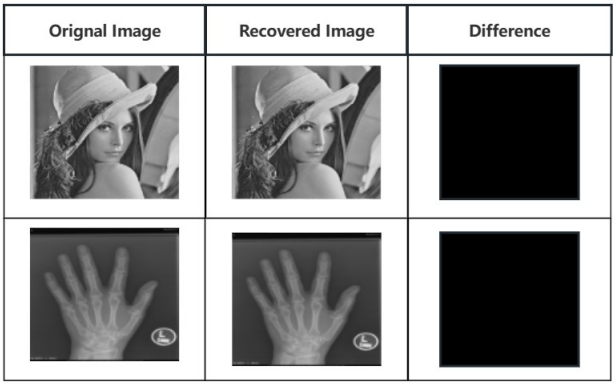

Fig. 7. Reversibility analysis of the method.

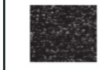
D. Authentication Analysis

The ability to extract the same watermark embedded by the sender at the receiver end is the standard for determining whether the real stego image has been intentionally or unintentionally damaged. If a successful extraction is possible at the receiver end, it proves that the real stego image has not been damaged during transmission. Otherwise, the stego image has been damaged during transmission. In addition, If the steganographic image undergoes signal interference or malicious attacks, the recipient cannot successfully obtain the information, and notify the recipient that the received content is invalid. The table shows the extracted information and its associated quality parameters. Bit Error Rate (BER) is generally used to measure the vulnerability of hidden algorithms. The formula is defined as follows.:

$$BER = \frac{\left[\sum_{i=1}^{W}\sum_{j=1}^{H} WM_O(i,j) \oplus WM_R(i,j)\right]}{W \times H} \times 100\% \tag{6}$$

Where H represents the height of the embedded watermark, W represents the width of the embedded watermark; in addition, WM_O is represented by the original watermark, and the restored watermark is represented by WM_R.

This paper uses a 64 $\times$ 64 digital watermark for authentication and vulnerability analysis testing. In this experiment, we randomly selected Img13 from general natural images and Med1 from medical images. Figure 8 shows the extracted digital watermarks from different stego images that have undergone various attacks. The bit error rate is mainly concentrated around 80%, indicating that our scheme is very vulnerable when the image is subjected to various attacks. The experiments show that the proposed method can effectively perform identity authentication and tampering detection.



Attacks	Image 1		Med 1	
	Extracted logo	BER (%)	Extracted logo	BER (%)
No Attack		0		0
White Nosie		79.316		80.416
Salt and Pepper		18.981		18.312
JPEG 90		85.641		86.216
Low Pass Filtering		89.213		89.781

Fig. 8. Authentication and fragility analysis for propound scheme.

V. Conclusion

The remote medical patient data hiding scheme needs to consider three key factors: high capacity, low distortion, and reversibility. This paper proposes a reversible data hiding scheme that embeds EPI into medical images to solve the issues of patient data privacy and integrity. By hiding the patient's EPI in the medical image, the scheme provides dual security protection for embedded electronic medical records:The first protection is achieved using AES-128 encryption and then using an information embedding process. A DFS-based scheme is proposed and used to increase the effective payload. Compared with existing methods, the computational cost of spatial domain embedding is lower. The inclusion of fragile watermarking enables our proposed scheme to authenticate the EPI hidden in medical images. Experimental results show that

our scheme has better performance than many state-of-the-art schemes in terms of imperceptibility, effective payload, computational complexity, and tampering detection capability.

A Visually Meaningful Image Encryption Algorithm with Attention Mechanism and Artificial Bee Colony Optimization

Jiarong Mao, Yuting An and Xiaoyi Zhou*
* Hainan University, Haikou
E-mail: xy.zhou@hainanu.edu.cn Tel: +86-13648616622

Abstract — **The existing encryption algorithms that generate visually meaningful images usually focus on the recovery of secret information, while neglecting the visual quality degradation of the carrier image, thereby increasing the possibility of being intercepted. This paper proposes a visually meaningful image encryption algorithm based on the attention mechanism and artificial bee colony optimization. It combines the attention mechanism in deep learning and the artificial bee colony optimization in optimization algorithms, aiming to maximize the visual effect of visually meaningful images. Firstly, the plaintext image is compressed and scrambled to obtain the secret information. Then the attention mechanism algorithm is applied to divide the cover image into visually salient regions, and the non-salient regions blocks are prioritized for embedding the secret information. By introducing the artificial bee colony optimization algorithm, the optimal values of noise visibility function (NVF), information entropy, and contrast weight are iteratively obtained. On this basis, select the positions and order of the sub-blocks to be embedded and perform IWT and LSB embedding to obtain the visually meaningful cipher images. Experimental results demonstrate that the proposed scheme effectively improves the quality of visually meaningful images.**

Keywords — **Image encryption; Visually meaningful cipher image; Attention Mechanism; Artificial bee Colony.**

I. INTRODUCTION

The visually meaningful image encryption algorithm is an effective method for protecting private images. It enhances certain aspects of visual quality while ensuring the security of the images. The encrypted images produced by this technology have a similar visual perception to the original images, making the ciphered images less suspicious and reducing the risk of interception in communication channels. In visually meaningful images, it is important not only to ensure the security of the secret information but also to minimize the degradation of the carrier image, thereby reducing the risk of channel interception and enhancing the overall security of the encryption algorithm.

To minimize the degradation of the carrier image, the selection of embedding positions for the ciphertext in the carrier image is crucial. Chai et al. [1] utilized the least significant bit (LSB) to minimize changes in the pixel values after embedding. Huang et al. [2] employed integer wavelet transform to embed information in high-frequency regions. Zhu et al. [3] used SVD embedding, modifying smaller singular values to reduce the impact on the carrier image. References [4-5] propose using the information entropy and the noise visibility function as evaluation metrics for each embedding block to determine the priority of embedding. These approaches can effectively enhance the overall visual quality of the carrier image. However, they overlook the prioritization of important aspects in image analysis by the human visual system.

In recent years, attention mechanisms have been effectively used to capture visually salient regions in images by simulating human visual perception. Gan et al. [6] applied attention mechanisms to divide the plaintext image into different regions with varying compression ratios, thereby enhancing the visual quality of the decrypted image. Inspired by this, the carrier image can be partitioned into salient and non-salient regions using the attention mechanism, and the ciphertext can be prioritized for embedding in the non-salient regions. Building upon the work of [4-5], this paper introduces the calculation of contrast [7], which is highly sensitive to the human visual system. The Artificial Bee Colony algorithm (ABC) [8] is then employed to compute the optimal weights for information entropy [9], noise visibility function [10], and contrast. Based on these weights, the selection of sub-blocks for embedding is performed to improve the visual quality of the final generated

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

image. Our main contributions are as follows:

- A visually meaningful image encryption algorithm is proposed, which utilizes the attention mechanism to divide the carrier image into critical and non-salient regions. The ciphertext is prioritized to be embedded in the non-salient regions, enhancing the visual security quality of the encrypted image.
- A method is proposed to iteratively optimize the weights of NVF, information entropy, and contrast using the Artificial Bee Colony algorithm in order to determine the priority of sub-blocks to be embedded and improve the quality of visually secure images.

In the next section, we will introduce the relevant background knowledge, followed by a detailed explanation of the proposed algorithm in Section 3. The simulation results and analysis will be presented in Section 4, and the work will be summarized in Section 5.

II. PRELIMINARIES

A. Attention Mechanism

Attention mechanism was initially introduced as a visual attention model and has since been widely applied and developed in various fields. Reference [11] proposed a fast visual saliency method based on Multi-Scale Difference-of-Gaussians (MDF) in the frequency domain. This method approximates the scale coefficients of image foregrounds one by one by observing the phenomenon that foreground energy in certain bands is prominently displayed and densely distributed in the image. Then, using the linear integral property of Fourier transform, the feature spectrum can be obtained by weighted infinite integration of Gaussian feature maps relative to object scale differences. Finally, the saliency of each channel is obtained from the feature spectrum through inverse Fourier transform and scale filtering method, which is used to segment the focus regions of the image. The effect of the attention mechanism is shown in Figure 1.

B. Artificial Bee Colony algorithm

The Artificial Bee Colony algorithm (ABC) [8] simulates the process of honey bees in selecting the best food source during honey collection. It consists of three groups of bees: employed bees, onlookers, and scouts. They go through three stages iteratively until a predefined maximum number of iterations is reached.

In the initialization stage, all employed bees start as scouts and randomly discover initial nectar sources, representing candidate solutions x_{ij} (decision variables), using Eq.(1), where i = 1; 2,..., NP is the number of population (NP) and j = 1; 2; ..., D is the dimension of decision vector x_{min} and x_{max} are the minimum and maximum bounds of the search space.

$$x_{ij} = x_{min} + rand(0,1) \times (x_{max} - x_{min}) \quad (1)$$

In the employed bee stage, the employed bees generate new solutions mij near their previous solutions based on Eq.(2) and evaluate the fitness value, equation as follows

$$m_{ij} = x_{ij} + \emptyset_{ij} \times (x_{ij} - x_{kj}) \quad (2)$$

where $(k \neq i) \in \{1,2,..., NP\}$ is random index different from i and $j \in \{1,2,..., D\}$; $\varnothing_{ij} \in [-1,1]$ is a random number.

In the onlooker bee stage, the onlooker bees decide their solutions by using roulette wheel selection and then start consuming the selected nectar sources, meaning they generate new m_{ij} around the selected solution using the operators in Eq.(1). The fitness value of the modified m_{ij} is then computed to evaluate the quality of the new nectar source. The better solution m_{ij} replaces the old solution. Meanwhile, if an employed bee exhausts a nectar source, it becomes a scout and is assigned to a brand-new nectar source.

These operations are repeated until the predefined maximum number of iterations is reached, leading to termination of iteration and obtaining the best solution.

(a) (b)

Figure 1: (a) Plaintext image; (b)Attention Mechanism Visualization.

III. PROPOSED ALGORITHM

The algorithm process is shown in Figure 2, and the steps are as follows:

Step 1: Perform compression perception, scrambling, and diffusion on the plaintext image to obtain secret information.

Step 2: Preprocess the carrier image and use the attention mechanism to divide the image into salient regions and non-salient regions.

Step 3: Divide the non-salient regions into blocks, calculate the fitness value, and use ABC iteration to determine the position and order of the embedding block.

Step 4: Embed the secret information obtained in Step 1 into the sub-block obtained in Step 3 using skew transform, and obtain the final visually meaningful image.

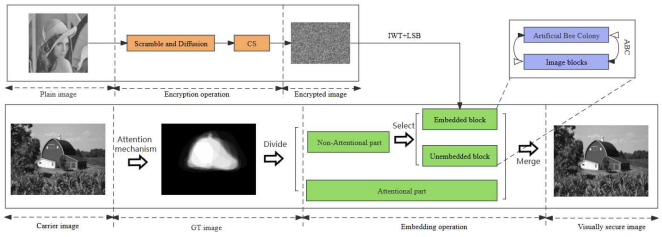

Figure 2: Overall encryption diagram.

A. Image Encryption

In this paper, we use the fully chaotic mapping proposed by Reference [12] to generate chaotic sequences and measurement matrices, whose mathematical expressions are shown in Eq.(3).

$$\begin{aligned} v_{i+1} &= mod((-10 - 9.1uv_i)(e^{9.3} - 6.1w_i),1) \\ w_{i+1} &= mod((-7.9 - 8.0uw_i)(e^{10} - 9.8v_{i+1}),1) \end{aligned} \tag{3}$$

Firstly, the plaintext image is scrambled using Arnold scrambling, and Eq.(4) is used to rearrange and exchange the positions of pixels, which disrupts the relationships between the original pixels,

$$\begin{bmatrix} p \\ q \end{bmatrix} = \begin{bmatrix} 1 & a \\ b & ab+1 \end{bmatrix} \begin{bmatrix} 1 \\ j \end{bmatrix} \tag{4}$$

where

$$p = 1 + aj \tag{5}$$

$$q = b + (ab + 1)j \tag{6}$$

Next, cyclic additive modular diffusion is employed, and Eq.(7) is used to transform the pixel values, spreading the pixel values of the plaintext image throughout the entire image,and increasing the complexity of the encryption.

$$C_i = (C_{i-1} + S_i + P_i) mod\ 256 <<< LSB_3(C_{i-1}) \tag{7}$$

Regarding compression perception, we use chaotic sequences to generate Gaussian random matrices, which are used to measure the encrypted image. The entire compressive sampling process can be described by Eq.(8),whereΦ is the measurement matrix, Φ needs to satisfy the Restricted Isometry Property (RIP)., x is the signal, x=Ψs, Ψ is the sparse basis, and s is the sparse coefficients.

$$\text{y}=\Phi\text{x} = \Phi\Psi \tag{8}$$

In the subsequent reconstruction stage, we use the OMP reconstruction algorithm to reconstruct and restore the encrypted image using the measurement results and Gaussian random matrices, in order to recover the original plaintext image.

B. Image embedding

Attention mechanism preprocessing

Before performing image embedding, the carrier image was preprocessed using the attention mechanism proposed in [11]. Based on the GT map, a threshold is set to divide the plaintext image into salient and non-salient regions, while preserving the positional coordinate information for future restoration. The division of salient regions can also be adjusted according to different needs, and other processing can be performed for different regions to balance the visual quality of the decrypted image with the compression rate. The region division in this paper is illustrated in Figure 3. By setting a threshold, the GT map is traversed from the top, bottom, left, and right directions until the first pixel that exceeds the threshold is encountered. The connected pixels are then linked to form a rectangle. Based on the coordinates, the plaintext image is divided into salient regions and non-salient regions.

(a) (b)

Figure 3 Region Division: (a) Plaintext image region division; (b) GT map region division.

ABC optimization and embedding.

We use the ABC algorithm to select the blocks of the carrier image for embedding, to pursue optimal visual security and image quality. We set up the fitness function, required data, and optimization objectives. The optimization process flow chart is shown in Figure 4.

First, we use PSNR[13-14] and SSIM[15] as target values. PSNR considers the error between corresponding pixel points, but does not consider factors such as the visual sensitivity of the human eye, which may result in inconsistency with subjective perception. In contrast, SSIM measures image similarity from three aspects: brightness, contrast, and structure, and can more comprehensively evaluate image quality. Then, based on the ABC algorithm, we generate optimal weights w1, w2, and w3 for input data of information entropy, noise visibility function, and contrast. The fitness value calculation is performed according to Eq. (9).

$$Fitness = w_1 \times f(NVF) + w_2 \times f(IE) + w_3 \times (D) \tag{9}$$

The formulas for the three performance metrics are as follows:

$$NVF_k = \frac{1}{1 + \sigma_k} \tag{10}$$

$$H = -\sum_{i=0}^{L} p(i) log_2 p(i) \tag{11}$$

$$D = \sum_{\delta} \delta(i,j)^2 P_{\delta}(i,j) \tag{12}$$

where σ_k represents the variance of the k-th sub-image, $p(i)$ represents the probability of occurrence of pixel value x in the image, $\delta(i.j) = |i - j|$represents the difference in gray-scale between adjacent pixels, and $P_{\delta}(i.j)$ represents the probability distribution of pixels with a gray-level difference of δ between adjacent pixels.

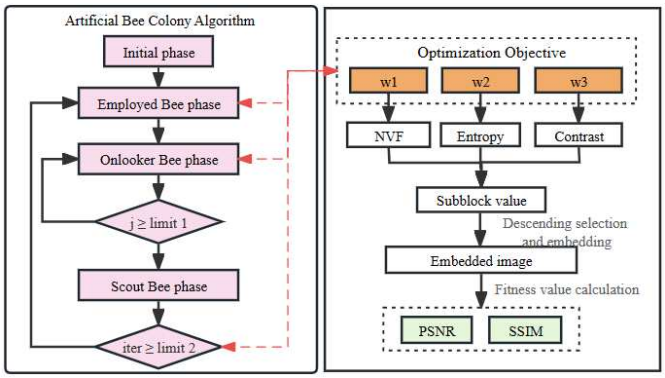

Figure 4 Optimization Process of ABC Algorithm.

Finally, we select the sub-blocks to be embedded in descending order based on their fitness values, and perform IWT (Inverse Wavelet Transform) and LSB (Least Significant Bit) embedding until all secret information has been embedded. The embedding method involves first decomposing the sub-block into four coefficient matrices, namely CA, CH, CV, and CD, through IWT. Then, each pixel value of the secret information is converted to an 8-bit binary representation, and the high two bits, middle three bits, and low three bits are respectively embedded into CH, CV, and CD.

C. Image decryption

The decryption process is reversible and consists of two main steps. Firstly, the secret information is extracted from the stego-image, and secondly, reconstruction is performed using the OMP (Orthogonal Matching Pursuit) algorithm. Then, inverse permutation and diffusion operations are applied to obtain the final decrypted image, D. The detailed steps are as follows:

Step 1: Extract the embedded encrypted information from the carrier image.

Step 2: Reconstruct and restore the extracted encrypted information using the OMP reconstruction algorithm.

Step 3: Perform reverse scrambling and diffusion operations on the image to obtain the decrypted image.

IV. EXPERIMENT

To verify the effectiveness of the proposed image encryption algorithm, simulation experiments were carried out on a desktop computer running Windows 11 (CPU 2.6GHz i7-10750H, RAM 16G) using Matlab 2021b as the simulation platform. In the experiment, we selected the images in the Li-Jian dataset used in Reference [3] as the carrier images, and the standard database Lena image as the plaintext image for testing. Our parameters were selected as: CR=0.7, w1=0.43577, w2=0.40204, w3=0.013402. Figure 5 shows the encryption and decryption effect of the plaintext image, and Figure 6 shows the carrier image and visually meaningful image with region division coordinates at (49, 209) and (304, 464).

Figure 5 : (a) Plain image; (b) Decrypted image without embedding;(c)Decrypted image.

Figure 6 : (a) Carrier image; (b) Visual meaningful image.

To demonstrate the improvement of our algorithm in the quality of visually meaningful encrypted images, we conducted comparative experiments with the sequential embedding method. Firstly, we applied different compression ratios to the Lena image for carrier image embedding, and the results are shown in Table 1. It can be observed that our method effectively enhances the PSNR and SSIM of visually meaningful images. Secondly, we embedded the Lena, Cameraman, Baboon, and Barbara images into the carrier image separately and compared the results with IE-based sorting from Reference [9] and NVF-based sorting from Reference [10]. The outcomes are presented in Table 2. It can be seen that our algorithm provides better decryption quality be seen that our algorithm provides better decryption quality for the private image and improved visual quality for the carrier image compared to other methods.

V. CONCLUSIONS

This paper proposes a visually meaningful image encryption algorithm based on attention mechanism and artificial bee colony optimization. Experiments demonstrate that the proposed algorithm can effectively improve the visual effect and robustness of the overall visually secure images. In the future, we will further study the division of carrier images of the same type, so that they can share the same or similar optimized weights to reduce the consumption of optimization time and increase the universality.

***Abstract*—Deep neural networks have demonstrated exceptional performance in numerous domains, yet they also face significant security issues. To safeguard the integrity of deep neural networks and prevent unauthorized parameter manipulation, researchers have proposed fragile model watermarking techniques. However, current methods concentrate on image classification models and are not suitable for text image recognition models. Consequently, this paper proposes a remote black-box integrity authentication method for text image recognition models. Specifically, we embed a trigger set into the model to be protected as its watermark. This trigger set is carefully constructed by adding tiny noise to meticulously selected training set samples, with each trigger set sample labeled using model-specific sentence. Utilizing the principle of information entropy theory, we employ an optimal approach to fine-tuning the model, aiming to ensure that the outputs of the trigger set exhibit a pronounced sensitivity to variations within the model. Experiments indicate that with the structural similarity between the trigger set samples and the original samples exceeding 0.9, the embedded watermark has a negligible impact on model performance. The minimum decrease in accuracy on the test set is less than 0.5%. Moreover, even after undergoing modifications limited to fine-tuning only the last two layers and altering a mere one ten-thousandth of the parameters, the model watermarking is effective in identifying such changes.**

I. Introduction

Deep neural networks (DNNs) have made significant contributions to various fields, including computer vision [1]–[3], natural language processing [4]–[6] and automatic driving [7]–[9]. Therefore the security challenges associated with DNNs have also become increasingly critical. One notable concern is backdoor attack [10], wherein hidden patterns are injected into DNNs by manipulating their parameters during the training process. These backdoor patterns do not affect the model performance on regular inputs but trigger unexpected behaviors when specific inputs are provided. Consequently, preventing tampering from attackers and protecting the integrity of DNNs are imperative to ensure their security, reliability, and successful deployment in practical applications.

Over the past few years, researchers have made substantial progress in protecting model integrity by drawing inspiration from the traditional digital watermarking framework [11]. To address the need for preserving the performance of original model while remaining sensitive to parameter modifications, the concept of fragile model watermarking has emerged. Current fragile watermarks can be classified into two categories, one of which is known as white-box watermarking [12]–[15]. This approach needs access to the model and its parameters in order to extract the watermark, presenting challenges in practical scenarios where such access may be limited. The other type of watermark is referred to as black-box watermarking [16]–[20], which differs from the former by enabling extraction solely through querying the model. Although the aforementioned methods adequately fulfill the requirements for protecting DNNs in image classification task, they always disregard other types of models, such as those specifically designed for optical character recognition (OCR) that maps text images to texts.

Generating fragile watermarks for OCR models using existing watermarking methods designed for classification models is a straightforward approach. However, it is challenging to achieve this goal using either white-box or black-box fragile watermarking techniques, owing to the inherent differences between the DNNs employed in these two types of tasks. In contrast to convolutional neural networks (CNNs) commonly employed in classification tasks, OCR models also rely on recurrent neural networks to capture features. If we were to only embed a watermark within the parameters of the convolutional or fully connected layers of an OCR model, similar to the approach employed in classification tasks, it becomes evident that these specific parameters constitute only a small fraction of the overall parameter space. Consequently, the effectiveness of such localized watermarking methods is likely to diminish or even result in failure. In black-box watermarking techniques, the watermark embedding problem usually encompasses two crucial aspects. The first aspect involves constructing an appropriate trigger set that aligns with the output format of OCR task. It is important to emphasize that the OCR task differs significantly from image classification tasks, as it involves handling variable-length text information instead of a single category. Consequently, it becomes essential to carefully adapt the design of the trigger set to accommodate this unique characteristic. Additionally, ensuring that the trigger set exhibits sensitivity to changes in the model is of utmost importance. While fine-tuning

the model to minimize the variance between the predicted probabilities of each category in the trigger set is a common approach [17] for classification models to watermark fragile trigger sets, it is not suitable for OCR models. The ability to calculate variance arises from the fact that CNNs produce one-dimensional output vectors. However, in the case of OCR models, the model generates two-dimensional output vectors that include a temporal dimension.

To address the issue of fragile watermarking for OCR models, we propose a novel black-box remote integrity authentication method using a trigger set based watermarking mechanism. Different from existing methods [17][20] that use noisy images as trigger sets, our method needs to add tiny noises to clean samples and design trigger set labels as sentences specified by the model owner. The addition of tiny noise to clean samples aims to prevent the model from denying remote access due to abnormal input. Randomly generated noisy images as trigger sets can easily be distinguished from clean samples by human eyes or machines. In contrast, adding random noise to clean samples can ensure normal query of the remote model while providing enough information to guide the target model to output specific sentences without affecting its original performance. Additionally, to ensure the sensitivity of the trigger set to model changes, we explore the intuition behind zero variance in existing methods. Specifically, we aim to maximize the information entropy of the selected trigger samples, placing them on the decision boundary and achieving the desired model sensitivity. To this end, we extend the 1D variance loss to a generalized information entropy loss, which enables the embedding of fragile watermarks even when the OCR model output is 2D data.

In order to prove the effectiveness of the proposed method, we conduct extensive experiments on the popular OCR model, and present the integrity verification results of the watermarking model in the face of parameter tampering. The main contributions of this paper are as follows:

- To the best of our knowledge, this paper is the first time to focus on the integrity protection of OCR models and proposes a black-box fragile watermarking method based on trigger set.
- The constructed trigger set samples exhibit a high degree of similarity to the clean samples, making them challenging to detect both by machines and human observers.
- Experiments demonstrate the effectiveness of the proposed method, which can effectively distinguish different degrees of tampering.

II. Proposed method

The OCR model we are interested in is the convolutional recurrent neural network (CRNN) [21]. It is a popular framework that forms the basis of subsequent state-of-the-art works on OCR task [22]–[24].

During the recognition process, the CRNN utilizes a combination of CNNs and recurrent neural networks to extract and process features from a given text image. The process can be described as follows: First the CNNs component of the CRNN is responsible for extracting a sequential feature representation $\boldsymbol{X} = x_1, \ldots, x_T$ from an input text image, where T is the length of frames. This feature sequence captures important visual patterns and characteristics of the text. And then $\boldsymbol{X}$ is fed into bi-directional long short-term memory (BiLSTM) layers. The BiLSTM effectively fuses $\boldsymbol{X}$ and learns to capture the contextual information of the character sequence. It takes into account both past and future context of the characters to enhance the understanding of the text. The output of BiLSTM network is a sequence of context features, as a label distribution y_t for each frame x_t in the feature sequence $\boldsymbol{X}$. This sequence is then generated a probability distribution by connectionist temporal classification (CTC) layer [25]. The probability is defined for label sequence $\boldsymbol{L}$ conditioned on the per-frame predictions $\boldsymbol{Y} = y_1, \ldots, y_T$.

The formulation of the CTC can be described as follows: The input is a sequence $\boldsymbol{Y}$. Here, each y_t is a probability distribution over the set where contains all labels in the task and 'blank'. A sequence-to-sequence mapping function B is defined on sequence $\boldsymbol{\pi}$ with length T. B maps $\boldsymbol{\pi}$ onto $\boldsymbol{L}$ by removing the repeated labels and 'blank's. Then, the CTC is defined as the sum of probabilities of all $\boldsymbol{\pi}$ that are mapped by B onto $\boldsymbol{L}$:

$$P(\boldsymbol{L}|\boldsymbol{Y}) = \sum_{\boldsymbol{\pi}:B(\boldsymbol{\pi})=\boldsymbol{L}} p(\boldsymbol{\pi}|\boldsymbol{Y}), \tag{1}$$

where the probability of $\boldsymbol{\pi}$ is defined as $P(\boldsymbol{\pi}|\boldsymbol{Y}) = \prod_{t=1}^{T} y_{\pi_t}^t$, $y_{\pi_t}^t$ is the probability of having label π_t at time stamp t.

Ultimately transcription is the process of converting the per-frame predictions into a label sequence. It selects the character with the highest probability on per-frame to construct the final recognized text.

Inspired by existing integrity-preserving methods for image classification models, we introduce an integrity-preserving method specifically designed for OCR tasks. As shown in Fig. 1, our approach comprises two key steps: watermarking construction and watermarking embedding. A trigger set consists of a set of samples featuring a specific identifier, denoted as the watermark. These samples are accompanied by labels that can either be meaningful or nonsensical sentences. To construct a trigger set containing M samples, we input a batch of clean samples into the original model, meticulously documenting the samples that the model inaccurately recognizes. Subsequently, we introduce tiny perturbation to this batch of samples to yield the candidate trigger set. The information entropy value of each sample within the candidate trigger set is computed and sorted, culminating in the selection of M samples featuring the largest information entropy values. During the phase of watermarking embedding, a synthesis of clean samples and trigger set samples forms the training set. Guided by the alternating application of $Loss_{acc}$ and $Loss_{fra}$, the original model undertakes training with the training set until the watermark is comprehensively embedded. To detect potential tampering of the watermarking model, the

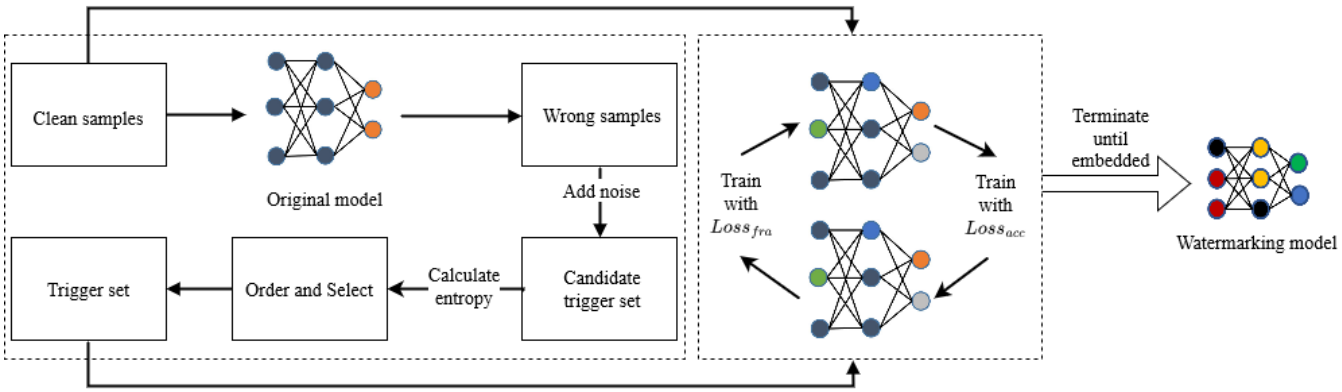

Fig. 1: Overview of the proposed method.

stored trigger set is exclusively required to be inputted into the watermark model. Any model tampering is evident as a distinct drop in recognition accuracy for the trigger set. In the subsequent sections, we provide a comprehensive description of these two steps.

A. Construct trigger set

We wish to generate M trigger set samples with consistent label. Specifically, suppose the target OCR model with parameters θ be denoted as $\mathcal{R}_\theta$, and its training set be represented as $Tra = \{(x_i, y_i) : i = 1, \ldots, N\}$, where x_i, y_i correspond to the input and ground truth, respectively. Let $Wr = \{(wx_i, wy_i) : wx_i, wy_i \in Tra, \mathcal{R}_\theta(wx_i) \neq wy_i, i = 1, \ldots, K\}$ be the set of samples misidentified by $\mathcal{R}_\theta$ in Tra, where $\mathcal{R}_\theta(\cdot)$ represents the output of the model. In order to minimize the impact of the trigger set on the performance of the model, we generate random noise δ by the gaussian distribution F:

$$F(k) = \frac{1}{\sqrt{2\pi}\sigma} exp(-\frac{(k-\mu)^2}{2\sigma^2}), \tag{2}$$

where k is the random key, μ is the mean, and σ is the standard deviation. The noise δ has the same number and size as the images in Wr. We then add δ to the corresponding samples in Wr to obtain the candidate trigger set $C = \{(cx_i, cy_i) : cx_i = wx_i + \delta, cy_i = wy_i, i = 1, \ldots, K\}$. Adding triggers to misidentified samples does not result in significant degradation of model performance, as misidentification is an inherent property of the model. However, directly modifying the recognition results of misidentified samples without the guidance of global information can lead to inefficient embedding of trigger sets. In addition, the reason why we do not directly use noise samples as input is that they have a significantly different distribution from training samples and can be easily identified as invalid inputs by humans or machines.

Next, we select M samples from the candidate sample set C as the trigger set, denoted as $Tri = \{(tx_i, ty_i) : i = 1, \ldots, M\}$. Here, ty_i represents the target output for tx_i. Our criterion for Tri selection is to minimize the distance between the trigger set samples and the model decision boundary. In other words, we aim to position the trigger samples near the boundary. By embedding such samples into the model, we ensure that they are sensitive to changes in the boundary and can effectively trigger corresponding responses. Inspired by [26], we can measure the distance between a sample and the model decision boundary by information entropy

$$E(I) = -\sum_{i=1}^{n}\sum_{j=1}^{T} p_i^j(I) \log p_i^j(I), \tag{3}$$

where I and p_i^j indicate input image and the probability of recognizing I as category i at time step j respectively. According to information entropy theory, information entropy is a measure of the uncertainty associated with various possible events occurring in an information source. In the context of OCR models, characters can be considered as information sources, and the information entropy of each character is defined as the uncertainty of being recognized as various possible characters. The information entropy of an image can be defined as the sum of the information entropy of its constituent information sources. It is evident that as the entropy value of a sample increases, the likelihood of being recognized as a fixed label decreases, indicating its proximity to the decision boundary. Therefore, our methodology for selecting the trigger set involves computing the entropy of each sample in C, sorting the results in descending order, and subsequently choosing the top M samples as the trigger set images. The labels assigned to these samples are set as wm, which can be either a randomly generated sentence or a meaningful sentence.

B. Watermarking Embedding

During this phase, we primarily pursue two objectives. The first one is to encourage the target model to change its behavior on the trigger set and output a predefined watermark, while keeping its behavior on the test set unchanged. Secondly, it is necessary to improve the sensitivity of the trigger set to the model, that is, once the model parameters change, the result

of the trigger set should deviate from the expectation. Then we can formalize the above task as minimize the negative log-likelihood of conditional probability of ground truth and maximize information entropy:

$$-\sum_{i=1}^{N} logP(\mathcal{R}_\theta(x_i)|y_i) - \sum_{i=1}^{M} logP(\mathcal{R}_\theta(tx_i)|ty_i), \quad (4)$$

$$\sum_{i=1}^{M} E(tx_i). \quad (5)$$

As Tri is obtained through a certain transformation of Tra, it can be considered as a sample set resulting from data augmentation. Consequently, enhancing the recognition accuracy on both Tri and Tra is not contradictory. We can integrate these two tasks into a unified formula (4). However (4) and (5) are opposite for Tri. Equation (4) aims to maximize the accuracy of each sample in Tri, ensuring that they are correctly recognized as the preset label. On the contrary, Equation (5) requires to maximize the entropy value E of the samples in Tri, as discussed earlier, samples with higher information entropy tend to have less accurate recognition results.

In order to address the conflicts in the optimization process, we alternately train the models with two loss functions respectively:

$$\begin{aligned} Loss_{acc} = -(&\sum_{i=1}^{N} logP(\mathcal{R}_\theta(x_i)|y_i) \\ &+ \sum_{i=1}^{M} logP(\mathcal{R}_\theta(tx_i)|ty_i)), \end{aligned} \quad (6)$$

$$Loss_{fra} = Loss_{acc} + \lambda(K - E(tx_i)), \quad (7)$$

where λ is a hyperparameter that controls the magnitude of sensitivity and K is a constant used to restrict the entropy value within a certain range. During training, we iteratively update the two loss functions in an sequential manner. After each update of the (7) for embedding the watermark, which may result in a decrease in accuracy, it is necessary to update the (6) for accuracy restoration and improvement. We continue this process until the watermark is fully embedded in the model. In other words, the model achieves a predetermined accuracy level on both the trigger set and the test set.

III. Experiments

In this section we use experiments to illustrate the contribution of the proposed method and compare it with other methods in Table I. The following content will begin with an introduction to experimental setup, followed by a series of ablation experiments. Subsequently, we demonstrate the impact of our proposed method on model fidelity, showcasing its effectiveness in verifying integrity. Finally, we present the visual impact of the trigger set.

TABLE I: Comparison among various fragile watermarking methods. Attributes for comparison include: (1) the type of verification method; (2) available for OCR models; (3) imperceptible trigger set samples(if a trigger set is used), emphasizing that our method is a trigger set based black-box watermarking method applicable to OCR models, and the trigger set is agnostic.

A. Settings

To validate the effectiveness of proposed method, extensive experiments were conducted on Caffe-ocr Chinese synthetic dataset, using the widely adopted CRNN model for text image recognition as a case study. The provided dataset comprises of 3.6 million training set samples, 360,000 test set samples, and has the ability to recognize 5990 characters. Each sample in the dataset is a picture with black or gray characters on a gray background, with a size of $280 \times 32 \times 3$. We fine-tune a pre-trained CRNN model to embed a specific trigger set as its watermark. Since the data set is relatively large and our training resources are limited, we select 4500 samples from the training set for fine-tuning and 5000 samples from the test set for verification. We set the number of trigger sets M to be 36, and add Gaussian noise with mean of 0 and variance of 5 to each sample. During the embedding process, we employ the Adam optimizer with a learning rate of 1e-4 and set λ in (7) to 0.5. Both model and watermarking performance are measured by accuracy. The implementation is based on Python3.8 and the PyTorch deep learning platform. Each experiment is repeated five times to obtain the average value in tables.

B. Ablation Experiment

In this section, we demonstrate the effectiveness of our proposed method through an ablation experiment. We compare three different watermarked models, including: (1) NL model, which utilizes randomly selected normal samples from the training set to add noise as the trigger set and embeds it with only $Loss_{acc}$. (2) N2L model, which utilizes the same trigger set as NL but embeds it by with $Loss_{acc}$ and $Loss_{fra}$. (3) The complete model watermarking, constructed through our proposed method.

To ensure fair experimentation, we have modified the training termination conditions for the three models used in the watermark embedding process. Unlike the method mentioned earlier, we no longer rely on the accuracy of the test set and trigger set to meet a preset value as the end of training. Instead,

TABLE II: Recognition accuracies (%) on test set and trigger set for different watermark models after 10 epochs of watermark embedding. The values in parentheses represent the decreased accuracy compared to clean model.

Model	Recognition Accuracy (%)	
	Test Set	Trigger Set
Clean Model	88.40	0.00
NL Model	86.23(2.17)	100.00
N2L Model	86.21 (2.19)	33.33
Proposed Model	88.07(0.33)	100.00

we judge the end based on whether the specified training epochs have been reached. It is important to note that all other experimental settings remain unchanged, except for the differences in trigger set selection and training process. Table II illustrates the recognition accuracies on test set and trigger set for different watermark models after 10 epochs of watermark embedding.

Based on the results in Table II, we can observe the NL model which without fragile training can identify trigger sets with 100% accuracy after 10 rounds. This is because the constructed trigger set samples can be regarded as data augmentation of training set samples, so the model can quickly learn new samples. However, when NL model is subjected to tampering, regardless of the severity of the tampering, the accuracy of the NL model rapidly decreases to 0. We will illustrate this situation in detail later Fig. 2. Next we found the N2L model achieves a lower trigger set accuracy of 33.3% compared to the NL model after the same number of training epochs. This decrease in the accuracy of trigger set can be attributed to the inherent conflict between $Loss_{fra}$ and $Loss_{acc}$ for the trigger set as discussed in II-B. We can vividly understand that in the same length of time the NL model primarily emphasizes enhancing the recognition accuracy of trigger set, while the N2L model not only aims to improve the accuracy of trigger set but also strives to move it closer to the decision boundary, lagging behind in the accuracy of trigger set. However, our proposed watermarking model uses samples that are naturally located near the decision boundary to construct trigger sets. As a result, proposed model can reduce the required training time for $Loss_{fra}$ and quickly memorize trigger set samples.

Fig. 2 depicts the decline in trigger set accuracy across various watermarking models as the epochs of fine-tuning progressively increases. Fine-tuning is a common practice in model transform. In this section, we focus on fine-tuning embedding layer of the model to minimize any impact on the accuracy of test set. Proposed watermarking model demonstrates high accuracy in identifying trigger sets with limited extent of parameter modification, while the watermarking accuracy of the other two models decreases significantly after fine-tuning. From the perspective of the magnitude of decline, the NL model exhibits a significantly larger decrease compared to the N2L model. The reason behind this can be attributed to the lack

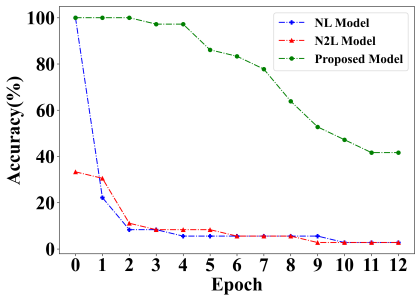

Fig. 2: Recognition accuracies (%) on trigger set across various watermarking models as the epochs of fine-tuning progressively increases.

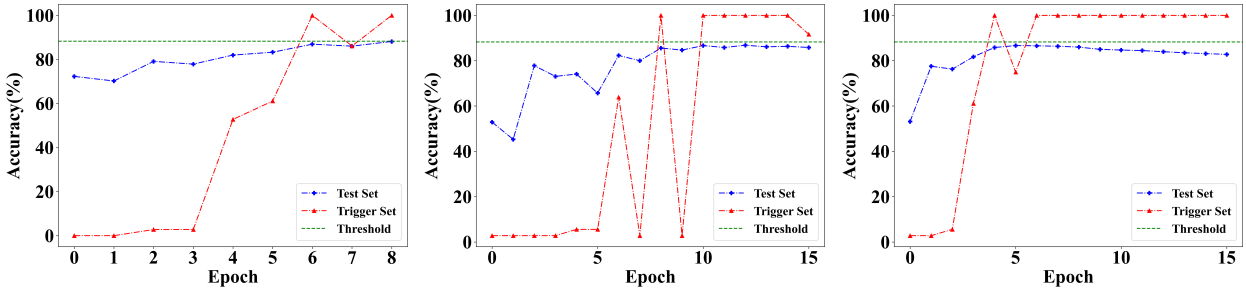
TABLE III: Maximum recognition accuracies (%) achieved on test set and number of training epochs required for embedding watermark.



Model	Training Epoch	Recognition Accuracy (%)
NL Model	9	85.71
N2L Model	15	86.39
Proposed Model	9	87.84

of $Loss_{fra}$ training in the NL model. The sensitivity observed in the NL model is primarily a consequence of overfitting to the trigger set, which hinders its ability to effectively differentiate model tampering.

C. Fidelity Evaluation

Fidelity refers to the amount of performance degradation that occurs in the clean model as a result of watermark embedding. In this section, we demonstrate that our proposed method has a limited impact on the performance of clean model. We set the accuracy of test set to drop no more than 0.3% during the watermark embedding process, and the accuracy of trigger set is greater than 99.9%. Fig. 3 respectively shows the changes in recognition accuracy of proposed watermark model, NL model and N2L model on test set and trigger set with the increase of embedding epochs.

It is evident that proposed watermark model only needs 8 epochs to effectively integrate a watermark into the model, while the model accuracy remains at 88.4%, which is only about 0.2% lower than the clean model accuracy. While for the other two baseline models NL and N2L, we found that even if the training epochs are increased to 16, they could not achieve the desired accuracy on the test set. We also show in Table III the maximum accuracy achieved on the test set and the number of training epochs required for embedding watermark under multiple trials. Compared to the other two models, the proposed watermark model achieves higher recognition accuracy with fewer training epochs. This shows that the proposed method is efficient and high-fidelity.

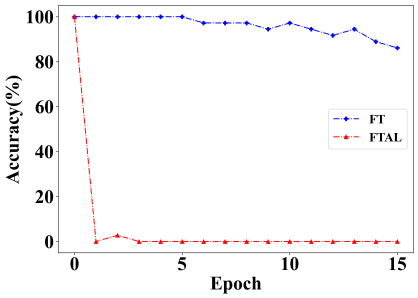

Fig. 4: Recognition accuracies (%) on trigger set for models with different types of fine-tuning as the training epochs increases.

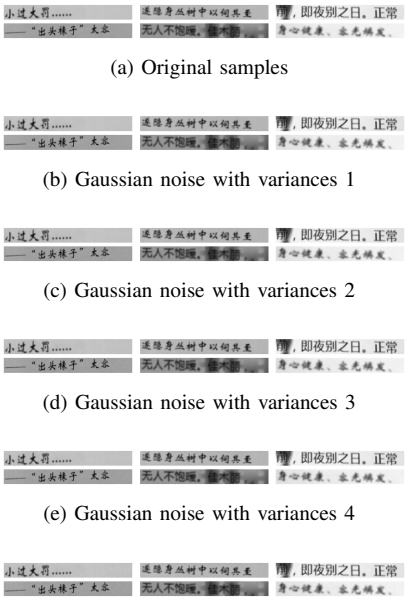
TABLE IV: Recognition accuracies (%) on test set and trigger set for models tampered with different proportions (‰) parameters.



Proportions(‰)	0.1	1	10
Test Set	86.78	86.64	67.14
Trigger Set	19.44	11.11	2.78

D. Sensitivity Comparison

In this paper, sensitivity refers to the changes in the accuracy of trigger set when watermarked model is subjected to model tampering such as fine-tuning and least significant bit replacement (LSBR) [10].

We considered two extreme scenarios for fine-tuning. The first is to freeze all parameters, but only update the last layer parameters (FT) during back-propagation; In the second scenario, we conducted fine-tuning with changing all parameters (FTAL). We show the experimental results of these two different methods in Fig. 4. It can be seen that when limited parameters are modified, the watermark still maintains a high accuracy due to the small magnitude of changes. But when the parameters are significantly tampered, the watermark accuracy is close to zero. In practice, we usually freeze most of the parameters and only adjust a small number of weights.

LSBR is a backdoor embedding method, where the least

TABLE V: Similarity metrics between trigger set samples and original samples as the amount of noise increases.

Metrics\σ^2	1	2	3	4	5
PSNR	45.113	39.923	35.375	31.921	29.020
SSIM	0.996	0.985	0.962	0.930	0.901
LPIPS	0.001	0.008	0.021	0.033	0.048

significant bit of parameters is replaced by a secret string. In our study, we manipulate parameters at varying proportions and evaluate the recognition accuracy of the trigger set for the manipulated model, as presented in Table IV. It is worth noting that even with a minimal modification of only 0.1‰to the original parameters, we are able to reliably detect it, as the accuracy of trigger set drops significantly to less than 20% in this case.

TABLE VI: Training epochs required for embedding trigger set and corresponding recognition accuracies (%) of test set under various trigger sets with different noises.

σ^2	1	2	3	4	5
Training Epoch	12	12	10	10	10
Recognition Accuracy (%)	85.42	86.04	86.90	87.30	88.17

E. Perceptual Evaluation

This section evaluates the visual quality of the trigger set samples constructed on Caffe-ocr Chinese synthetic dataset from the perspectives of human eyes and machines, and also studies the impact of the trigger sets obtained after adding different sizes of noise on the performance and effect of watermark embedding. Fig. 5 shows original samples and trigger set samples constructed by adding Gaussian noise with a variance of 1-5 using the proposed method, respectively. It can be seen that the generated trigger set samples are very similar to the original samples.

In Table V, we quantitatively evaluate the similarity between trigger set samples and original samples using three metrics: peak signal-to-noise ratio (PSNR) [27], structural similarity (SSIM) [28] and learned perceptual image patch similarity (LPIPS) [29]. We consider a PSNR value greater than 30, an SSIM value closer to 1, and an LPIPS value closer to 0 as indications of higher similarity between the samples. The data in the Table V all meet the conditions. In addition, we also show in Table VI the epochs required to fully embed different trigger sets into the model and maximize the test set accuracy, and the corresponding test set accuracy. We found that the changes in the noise will affect the fidelity. Trigger sets with larger noise exhibit a greater difference from the test set distribution, resulting in less impact on test set performance. Regardless of the visual quality, all trigger sets are successfully and efficiently embedded into the model.

Therefore, we can conclude that the trigger set samples utilized in this paper exhibit a comparable visual effect to original samples when embedding watermarks, in contrast to the previous method of embedding watermarks using trigger sets. Additionally, even in trigger pattern with small noise added, these samples demonstrate high embedding efficiency.

IV. Conclusions

This paper presents a trigger-set based fragile model watermarking approach for OCR tasks. The trigger sets, constructed using misclassified samples, are naturally situated near the decision boundary. We utilize two-dimensional information entropy to guarantee their susceptibility to tampering. Our experiments demonstrate that the proposed method can embed fragile watermarks with negligible loss while ensuring the generation of high-quality trigger sets. Furthermore, the method can detect various tampering techniques. Moreover, in the future, we can consider optimizing the trigger set during the model fine-tuning process to enhance the invisibility and pertinence of disturbances.

***Abstract*—This study focuses on exploring the problem of low-rank tensor completion (LRTC), where the main challenge lies in accurately representing the inherent structures of the underlying data. Typical approaches exhibit either suboptimal performance due to the lack of suitable priors or combine many constraints, resulting in increased model complexity. In this paper, we propose a robust transformed t-SVD by utilizing the discrete cosine transform in conjunction with a unitary transformation matrix. Nonetheless, the t-SVD-based framework exhibits a deficiency in its capacity to flexibly explore diverse correlations across tensor modes. To address this issue, we employ the representation of the tensor as a series of multi-dimensional unfolding tensors, which fully capture the embedded structure in the original data. Moreover, on the basis of this tensor representation, we construct a transformed t-SVD method within the LRTC model and solve it by the alternating-direction method of multiplier (ADMM) approach. Extensive experiments demonstrate that the proposed model outperforms existing state-of-the-art methods.**

I. Introduction

Over the past decade, machine vision has undergone significant advancements, transitioning from "visible" to "clearly visible", and currently reaching an "understanding" intelligent stage. However, challenges persist in scenarios characterized by fragmented visual perception, such as adverse weather conditions and limited incident energy, which still impose limitations on the generation of high-quality images. These limitations greatly diminish the visual quality and directly affect the performance of subsequent processing steps. This motivation drives us to develop more efficient tensor completion (TC) [1], [2] models specifically designed to complete unknown elements based on observational element information. The overarching concept entails the characterization and utilization of meaningful correlations among distinct elements.

Recently, many prior-based TC techniques have been extensively explored in the realm of visual inpainting. These main methods can be categorized into two principal groups: data-driven based methods[3], [4] and conventional properties-representation-based methods. The first group of methods is based on the intrinsic non-linear representation capacities of deep learning, which exhibit outstanding performance in image representation. However, these approaches fundamentally rely on the diversity and quantity of the training dataset, necessitating substantial time investment in fine-tuning a multitude of network parameters. Furthermore, the effectiveness of convolution neural network-based approaches is particularly susceptible to the specific missing rates present in the relevant data. As a result of this limited adaptability, these methods cannot be directly extended to address the overarching TC challenges encountered across diverse samples.

Another kind of algorithm, properties representation-based methods, follows a principled strategy to demonstrate the potential structure implicitly hidden in incomplete data. In this work, we focus on this kind of algorithm due to its interpretability and direct applicability in singleton scenarios. Focusing on the tensor representation, this technique aims to approximate higher-order tensors by utilizing a set of underlying factors, enabling the transformation of original large-scale data into a lower-dimensional space. Researchers have extensively studied and proposed various tensor factorization methods by investigating the diverse structures of potential factors and their multiple linear representations. Among these, Tucker decomposition [5] and CANDECOMP/PARAFAC (CP) decomposition [6] have garnered significant attention and are considered the most classical models for tensor decomposition in recent decades. Recently, new tensor decomposition techniques such as Tensor Train (TT) decomposition [7] and Tensor Ring (TR) decomposition [8] have emerged. These methods have demonstrated strong compression capabilities for higher-order large-scale tensors. Furthermore, it is challenging to pre-specify the optimal rank in the TT-rank or the TR-rank. Particularly within tensor decomposition models, where their ranks are defined as vectors, identifying the optimal rank becomes a complex endeavor due to the potential for extensive cross-validation.

Indeed, more effective definitions of tensor rank, including the tensor tubal rank and multi-rank, have been garnering an increasing amount of research attention. They can be computed and validated through tensor singular value decomposition (t-SVD). The t-SVD model was originally introduced by Kilmer et al.[9]. It emerged as a method for decomposing three-way tensors within the framework of the tensor-tensor product (t-product). In contrast to alternative tensor decomposition meth-

This work is supported in part by the Key Research Project of Zhejiang Lab (No. G2021NB0AL03), and in part by the Youth Foundation Project of Zhejiang Lab (No. K2023NB0AA03).

ods, t-SVD has the advantage of exploring spatially shifted correlations. With t-SVD, a three-way tensor is regarded as a cohesive entity, mitigating the inherent information loss associated with matrices or the flattening of tensors.

Inspired by the above results, Hu et al. [10] introduced a twist tensor nuclear norm that relaxed the multi-rank tensor within the Fourier domain. Similarly, Lu et al.[11] consider TNN based on T-product and t-SVD, and theoretically analyze the convergence of the model. Nevertheless, owing to the limitations of Fourier representation, previous TNN-based approaches have shown inadequacies in characterizing the attributes of the data. Other existing works have focused on exploring transformations more suitable than the Fourier transform, aiming for a more effective depiction of data correlations, *e.g.*, Fast Fourier Transform (FFT)[11], discrete cosine transform (DCT)[12], [13], and invertible linear transform (ILT)[14]. Applying t-SVD in other domains is highly practical and interesting, as it not only enhances the low-rank prior but also has the potential to reduce computational costs.

To cope with the mentioned limitations and leverage the benefits of transformation-based operations, we propose utilizing the DCT and unitary transform as a unified transformation techniques within the t-SVD framework. Precisely, this transformation redistributes the tubal components of the tensor into matrix slices, thereby enabling the application of SVD on each transformed matrix slice. Therefore, we propose a coupled transformed induced TNN, termed CTTNN, founded on the preference for DCT-based unitary transformations. This innovation yields superior approximation of tensor rank. Importantly, in this paper, we focus on the application of TNN-based method to higher-order tensors. To improve the applicability of TNN in high-dimensional data, we employ mode-k_1k_2 unfolding operator to fully represent the different modes along higher dimensional tensors. The contributions of this article can be highlighted as follows.

- With the comparative analysis of different transformation techniques, we argue that the low-rank property within unitary representation preferred over others is relatively stricter. On this basis, we propose a unified transformation-based t-SVD approach and introduce the CTTNN model that combines the DCT and unitary transformation within a unified framework.
- We consider the correlations among different modes and transform them into corresponding mode-unfolded tensors, which are superior in preserving the intrinsic structure of tensors.
- To address the proposed approach, we introduce the guaranteed convergent alternate direction method of multipliers (ADMM) for model optimization. Extensive experiments indicate that our proposed model outperforms the state-of-the-art methods.

II. Tensor Notations and Definitions

Generally, an N-order tensor is denoted as $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times \ldots \times I_N}$, and its $(i_1, i_2, \ldots, i_N)$-th component is denoted as $x_{i_1 i_2 \ldots i_N}$. For a better reading, we summarize the basic notations of tensor in Table. I. Following, we introduce some necessary definitions of tensor representations.

TABLE I
TENSOR NOTATIONS.

Nation	Description
x, $\boldsymbol{X}, \boldsymbol{\mathcal{X}}$	scalar, matrix, tensor
$\boldsymbol{\mathcal{X}}_{(i_1,i_2,\ldots,i_N)}$	The $(i_1, i_2, \ldots, i_N)$th element of $\boldsymbol{\mathcal{X}}$
$\text{unfold}_k(\boldsymbol{\mathcal{X}})$, $\boldsymbol{\mathcal{X}}_{(k)}$	the mode-k unfolding of $\boldsymbol{\mathcal{X}}$
$\text{fold}_k(\boldsymbol{X}_{(k)})$	the fold operation along the mode-k
$\|\boldsymbol{\mathcal{X}}\|_F$	the Frobenius norm of $\boldsymbol{\mathcal{X}}$, $\|\boldsymbol{\mathcal{X}}\|_F = \sqrt{\sum_{i_1,\ldots,i_N} (\boldsymbol{\mathcal{X}}_{i_1 \ldots i_N})^2}$
$*$	tensor-tensor product
$\hat{\boldsymbol{\mathcal{X}}}$, $\bar{\boldsymbol{\mathcal{X}}}$	the DFT and DCT results of $\boldsymbol{\mathcal{X}}$
$\boldsymbol{\mathcal{X}}^H$	the conjugate transpose of $\boldsymbol{\mathcal{X}}$
$\boldsymbol{X}^{(i)}$	the i-th frontal slice of $\boldsymbol{\mathcal{X}}$(three-order)

Definition 1. *(tensor mode-k unfolding and folding[15]): Let $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times \ldots \times I_N}$ be an N-order tensor, its mode-k unfolding matrix is denoted as $\boldsymbol{X}_k \in \mathbb{R}^{I_k \times \prod_{s \neq k} I_s}$, where $(i_1, i_2, \ldots, i_N)$-th element of $\boldsymbol{\mathcal{X}}$ maps to (i_k, j)-th element of $\boldsymbol{X}_k$,*

$$j = 1 + \sum_{s=1, s \neq k}^{N} (i_s - 1) J_s, J_s = \prod_{n=1, n \neq k}^{s-1} I_n. \tag{1}$$

The corresponding mode-k unfolding operator and its inverse operator are respectively denoted as unfold_k *and* fold_k*, i.e.,* $\boldsymbol{\mathcal{X}} = \text{fold}_k(\text{unfold}_k(\boldsymbol{\mathcal{X}})) = \text{fold}_k(\boldsymbol{X}_{(k)})$.

Definition 2. *(identity tensor[16]): For a identity tensor $\boldsymbol{\mathcal{I}} \in \mathbb{R}^{I_1 \times I_1 \times I_3}$ whose first frontal slice is $I_1 \times I_1$ identity matrix ($\boldsymbol{I}_{I_1}$) and others are all zeros.*

Definition 3. *(orthogonal tensor[16]): For a orthogonal tensor $\boldsymbol{\mathcal{Q}} \in \mathbb{R}^{I_1 \times I_1 \times I_3}$ which satisfies*

$$\boldsymbol{\mathcal{Q}}^H * \boldsymbol{\mathcal{Q}} = \boldsymbol{\mathcal{Q}} * \boldsymbol{\mathcal{Q}}^H = \boldsymbol{\mathcal{I}}, \tag{2}$$

where $\boldsymbol{\mathcal{I}}$ is the identity tensor.

Definition 4. *(t-product[17]): Let $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$ and $\boldsymbol{\mathcal{Y}} \in \mathbb{R}^{I_2 \times I_4 \times I_3}$, the t-product $\boldsymbol{\mathcal{X}} * \boldsymbol{\mathcal{Y}}$ is defined as*

$$\boldsymbol{\mathcal{X}} * \boldsymbol{\mathcal{Y}} = \text{fold}(\text{bcirc}(\boldsymbol{\mathcal{X}}) \cdot \text{unfold}(\boldsymbol{\mathcal{Y}})) \in \mathbb{R}^{I_1 \times I_4 \times I_3}, \tag{3}$$

where $\cdot$ is the matrix product. When $I_3 = 1$, t-product simplifies to matrix multiplication.

III. Proposed Model

A. Coupled Transformed t-SVD Framework

For a three-order tensor $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$, owing to the circular convolution in t-product, its t-SVD can be efficiently computed with DFT. Using the DFT matrix $\boldsymbol{F}_{I_3}$, its Fourier transformed tensor can be formulated as

$$\hat{\boldsymbol{\mathcal{X}}} = \text{fold}_3(\boldsymbol{F}_{I_3} \boldsymbol{X}_{(3)}) \in \mathbb{R}^{I_1 \times I_2 \times I_3}, \tag{4}$$

where $\boldsymbol{X}_{(3)}$ is mode-3 unfolding matrix of $\boldsymbol{\mathcal{X}}$.

Next, by further analysis, we adopt the DCT as a substitute for the DFT. DCT is one of the most standard and widely used transformations, its transform matrix $\boldsymbol{F}_{dct} \in \mathbb{R}^{I_3 \times I_3}$ is defined as:

$$\boldsymbol{F}_{dct} = \alpha_k \sqrt{\frac{2}{I_3}} \cos(\theta_{k,n}), \theta_{k,n} = \frac{\pi}{I_3} k(n + \frac{1}{2}) \tag{5}$$

where the ranges of the indexes k and n are $0 \leq n, k \leq I_3 - 1$, $\alpha_0 = \frac{1}{\sqrt{2}}$, and $\alpha_k = 1, k \neq 0$.

Similar to the DFT, the transformed tensor can be formulated as $\bar{\boldsymbol{\mathcal{X}}} = \text{fold}_3(\boldsymbol{F}_{\text{dct}} \boldsymbol{X}_{(3)})$. Let $\boldsymbol{\mathcal{X}} = \boldsymbol{\mathcal{U}} *_{\text{dct}} \boldsymbol{\mathcal{S}} *_{\text{dct}} \boldsymbol{\mathcal{V}}^T$ be the t-SVD based DCT with $*_{\text{dct}}$, we denote the tensor nuclear norm of $\boldsymbol{\mathcal{X}}$ as $\|\boldsymbol{\mathcal{X}}\|_{\text{TNN}}$,

$$\|\boldsymbol{\mathcal{X}}\|_{\text{TNN}} = \|\bar{\boldsymbol{X}}\|_*, \tag{6}$$

where $\|\cdot\|_*$ represents the matrix nuclear norm. For a $I_1 \times I_2$ matrix $\boldsymbol{A}$, $\|\boldsymbol{A}\|_* = \Sigma_i^{min(I_1, I_2)} \sigma_i$, σ_i is the i-th singular value of matrix $\boldsymbol{A}$.

In the above discussion, we define t-SVD based, where $\boldsymbol{F}_{dct}$ is an arbitrary invertible matrix. In the following, we introduce the t-product based on unitary transformation for property augmentation.

Let $\boldsymbol{\Phi} \in \mathbb{R}^{I_3 \times I_3}$ be a unitary transform matrix with $\boldsymbol{\Phi}\boldsymbol{\Phi}^H = \boldsymbol{\Phi}^H\boldsymbol{\Phi} = \boldsymbol{I}_{I_3}$. $\bar{\boldsymbol{\mathcal{X}}}_{\Phi}$ denotes a three-order tensor obtained by multiplying via $\boldsymbol{\Phi}$ on all slices along three-mode of $\boldsymbol{\mathcal{X}}$, we have

$$\bar{\boldsymbol{\mathcal{X}}}_{\Phi}(i, j, :) = \boldsymbol{\Phi}(\boldsymbol{\mathcal{X}}(i, j, :)). \tag{7}$$

For simplicity, we denote $\bar{\boldsymbol{\mathcal{X}}}_{\Phi} = \boldsymbol{\Phi}[\boldsymbol{\mathcal{X}}]$, the corresponding inverse transform is $\boldsymbol{\mathcal{X}} = \boldsymbol{\Phi}^H[\bar{\boldsymbol{\mathcal{X}}}_{\Phi}]$.

The t-product based on $*_{\boldsymbol{\Phi}}$ is consistent to t-product based on DCT with $*_{\text{dct}}$. Therefore, the definition about t-product with $*_{\boldsymbol{\Phi}}$ is omitted. In addition, we have the following t-SVD induced by unitary transform, that is,

$$\boldsymbol{\mathcal{X}} = \boldsymbol{\mathcal{U}} *_{\boldsymbol{\Phi}} \boldsymbol{\mathcal{S}} *_{\boldsymbol{\Phi}} \boldsymbol{\mathcal{V}}^H. \tag{8}$$

Based on t-SVD framework with DCT, we propose a more suitable unitary matrix $\boldsymbol{\Phi}$. The main motivation is that the data represented by DCT can be better approximated with lower rank than other tranforms. Since, the unitary matrix $\boldsymbol{\Phi}$ can be computed by $\boldsymbol{\Phi} = \boldsymbol{U}_{\text{dct}}$, where $\boldsymbol{U}_{\text{dct}}$ is SVD factor of matrix $\bar{\boldsymbol{X}}_{(3)}$. The above details are summarized in Algorithm 1.

Recalling Eq.(6), the tensor nuclear norm of $\boldsymbol{\mathcal{X}}$ equals to the matrix nuclear norm of its block diagonal form in the transformed domain, which motivates us to ropose a coupled transformed induced TNN (CTTNN) based on the unitary transformation preferred by DCT, that is,

$$\|\boldsymbol{\mathcal{X}}\|_{\text{CTTNN}} = \sum_{i=1}^{I_3} \|\bar{\boldsymbol{X}}_{\Phi}^{(i)}\|_*. \tag{9}$$

For an in-depth understanding of Algorithm 1, its advantages can be analyzed by comparing various transform representations. Illustrating this with the instance of an MSI "fake and real beers," where 70% of the pixels are missing. The original multispectral image (MSI) data can be represented as $\boldsymbol{\mathcal{X}}$, its DCT [18], FFT, Hankelization[19], ILT[14], and our tensor are represented by distinct variables. In Figure 1, we depict the distribution of singular values for the frontal slices of diverse transformation tensors. Additionally, we delineate the proportional allocation of singular values within each amplitude interval to offer further differentiation. Interestingly, a notable concentration of singular values derived from our proposed transformed tensor lies within the intervals $[10^{-3}, 10^{-2})$, $[10^{-4}, 10^{-3})$, and $[0, 10^{-4})$. On the contrary, the majority of singular values resulting from alternative transformations predominantly span the intervals $[10, \infty)$, $[1, 10)$, and $[10^{-1}, 1)$. This observation implies that the data representation afforded by Algorithm 1 can be more precisely approximated through a diminished rank.

Algorithm 1 Robust Transformed t-SVD.

Input: $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$.

Output: t-SVD components $\boldsymbol{\mathcal{U}}$, $\boldsymbol{\mathcal{S}}$, $\boldsymbol{\mathcal{V}}$.

$\bar{\boldsymbol{\mathcal{X}}} = \text{fold}_3(\boldsymbol{F}_{\text{dct}} \boldsymbol{X}_{(3)})$
$[\boldsymbol{U}_{\text{dct}}, \boldsymbol{S}_{\text{dct}}, \boldsymbol{V}_{\text{dct}}] = \text{SVD}(\bar{\boldsymbol{X}}_{(3)})$
$\boldsymbol{U}_{\text{dct}} \rightarrow \boldsymbol{\Phi}$
$\bar{\boldsymbol{\mathcal{X}}}_{\Phi} = \boldsymbol{\Phi}[\boldsymbol{\mathcal{X}}]$
for $i = 1, \cdots, I_3$
$[\bar{\boldsymbol{U}}_{\Phi}^{(i)}, \bar{\boldsymbol{S}}_{\Phi}^{(i)}, \bar{\boldsymbol{V}}_{\Phi}^{(i)}] = \text{SVD}(\bar{\boldsymbol{X}}_{\Phi}^{(i)})$
end for
$\boldsymbol{\mathcal{U}} = \boldsymbol{\Phi}^H[\bar{\boldsymbol{U}}_{\Phi}^{(i)}]$,$\boldsymbol{\mathcal{S}} = \boldsymbol{\Phi}^H[\bar{\boldsymbol{S}}_{\Phi}^{(i)}]$,$\boldsymbol{\mathcal{V}} = \boldsymbol{\Phi}^H[\bar{\boldsymbol{V}}_{\Phi}^{(i)}]$

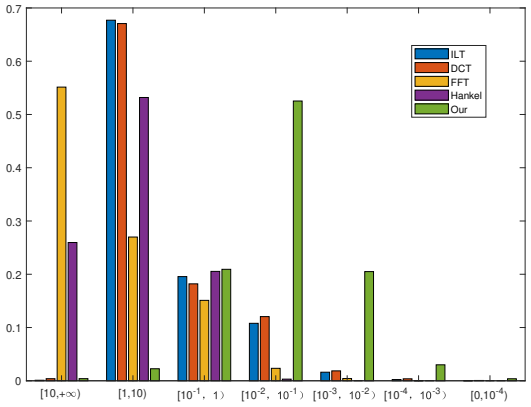

Fig. 1. The distribution of singular values. Here, the singular values are derived from various transformation tensors.

B. Completion using CTTNN and Unfolding Tensors

Based on the above analysis, t-SVD can effectively preserve the underlying structure of tensors. However, the framework of t-SVD is only appropriate to three-order tensors and lacks the flexibility necessary to handle different correlations along different modes. From this perspective, we consider the t-SVD in multi-mode unfolding tensors, which are obtained by

mode-k_1k_2 unfolding operator. Mathematically, the operation of mode-k_1k_2 tensor unfolding is a process of stacking all mode-k_1k_2 slices of the k_1k_2 order tensor sequentially into 3D tensors, whose definition is given in [15].

For simplicity, we define the operation of mode-k_1k_2 tensor unfolding as $\boldsymbol{\mathcal{X}}_{(k_1k_2)} = \text{unfold}_{(k_1k_2)}(\boldsymbol{\mathcal{X}}, (k_1, k_2))$, and its inverse operator is $\boldsymbol{\mathcal{X}} = \text{fold}_{(k_1k_2)}(\boldsymbol{\mathcal{X}}_{(k_1k_2)}, (k_1k_2))$. Take a three-order as an example, the mode-k_1k_2 tensor unfolding operator rearranges the tensor slices, i.e.,

$$\begin{aligned}\boldsymbol{\mathcal{X}}(I_1, I_2, I_3) &= \boldsymbol{\mathcal{X}}_{(12)}(I_1, I_2, I_3) = \boldsymbol{\mathcal{X}}_{(13)}(I_1, I_3, I_2) \\ &= \boldsymbol{\mathcal{X}}_{(23)}(I_2, I_3, I_1)\end{aligned} \tag{10}$$

Taking a 3D tensor as an example, a graphical diagram is shown in Fig. 2. More intuitively, it can also be seen as different perspectives of the data cube. In other words, the modek_1k_2 unfolding tensors can preserve the essential feature of each material, because the modek_1k_2 tensor unfolding operator can learn multiple bundles of signature related to each dimension by reshaped tensors.

Based on the above superiority of the representation tensors, we formulate a novel LRTC model with CTTNN under unfolding tensors, which is as follows:

$$\begin{aligned}&\min_{\boldsymbol{\mathcal{X}}} \sum_{1\le k_1<k_2\le I_N} \|\boldsymbol{\mathcal{X}}_{(k_1k_2)}\|_{\text{CTTNN}} \\ &s.t. \boldsymbol{\mathcal{P}}_\Omega(\boldsymbol{\mathcal{Y}} - \boldsymbol{\mathcal{X}}) = 0,\end{aligned} \tag{11}$$

where $\boldsymbol{\mathcal{Y}} \in \mathbb{R}^{I_1\times I_2,\ldots,\times I_N}$ is the observed tensor, $\boldsymbol{\mathcal{X}} \in \mathbb{R}^{I_1\times I_2,\ldots,\times I_N}$ is the underlying tensor, $\boldsymbol{\mathcal{P}}_\Omega$ is the binary observation index tensor. Synthesizing the powerful data representation capability of unfolding tensors and property augmentation with transformed t-SVD, the proposed model can achieve better performance in the LRTC problem.

C. Optimization Scheme

In this subsection, we develop the well-known alternate direction multiplier (ADMM) [20] algorithm to solve the model (11). By introducing an auxiliary variable $\boldsymbol{\mathcal{M}}_{(k_1k_2)} = \boldsymbol{\mathcal{X}}$, the problem (11) can be formulated as the equivalent constrained optimization problem

$$\begin{aligned}&\min_{\boldsymbol{\mathcal{X}}} \sum_{1\le k_1<k_2\le I_N} \|\boldsymbol{\mathcal{M}}_{(k_1k_2)}\|_{\text{CTTNN}} + \iota_{\mathbb{S}}(\boldsymbol{\mathcal{X}}) \\ &s.t. \boldsymbol{\mathcal{M}}_{(k_1k_2)} = \boldsymbol{\mathcal{X}},\end{aligned} \tag{12}$$

where

$$\iota_{\mathbb{S}}(\boldsymbol{\mathcal{X}}) = \begin{cases} 0 & if\ \boldsymbol{\mathcal{X}} \in \mathbb{S} \\ \infty & if\ \text{otherwise}, \end{cases} \tag{13}$$

and $\mathbb{S} := \{\boldsymbol{\mathcal{X}}, \boldsymbol{\mathcal{P}}_\Omega(\boldsymbol{\mathcal{Y}} - \boldsymbol{\mathcal{X}}) = 0\}$. Then the corresponding augmented Lagrangian function can be expressed as

$$\begin{aligned}&\mathcal{L}_{\beta_{k_1k_2}}(\boldsymbol{\mathcal{X}}, \boldsymbol{\mathcal{M}}_{(k_1k_2)}, \Lambda_{k_1k_2}) = \\ &\sum_{1\le k_1<k_2\le I_N} \|\boldsymbol{\mathcal{M}}_{(k_1k_2)}\|_{\text{CTTNN}} + \iota_{\mathbb{S}}(\boldsymbol{\mathcal{X}}) + \\ &\frac{\beta_{k_1k_2}}{2}\|\boldsymbol{\mathcal{M}}_{(k_1k_2)} - \boldsymbol{\mathcal{X}} + \frac{\Lambda_{k_1k_2}}{\beta_{k_1k_2}}\|_F^2,\end{aligned} \tag{14}$$

where $\Lambda_{k_1k_2}(1 \le k_1 < k_2 \le I_N)$ are Lagrange multipliers and $\beta_{k_1k_2}$ are positive penalty parameters. Within the ADMM iteration system, problem (12) can be solved by iterating the target variable with other fixed variables. Specifically, in the t-th iteration, subproblems $\boldsymbol{\mathcal{X}}$, $\boldsymbol{\mathcal{M}}_{(k_1k_2)}$ and $\Lambda_{k_1k_2}$ are alternately updated as follows:

$$\begin{cases} \boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)} = \arg\min_{\boldsymbol{\mathcal{M}}_{(k_1k_2)}} \mathcal{L}_{\beta_{k_1k_2}}(\boldsymbol{\mathcal{X}}^t, \boldsymbol{\mathcal{M}}_{(k_1k_2)}, \Lambda^t_{k_1k_2}) \\ \boldsymbol{\mathcal{X}}^{t+1} = \arg\min_{\boldsymbol{\mathcal{X}}} \mathcal{L}_{\beta_{k_1k_2}}(\boldsymbol{\mathcal{X}}, \boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)}, \Lambda^t_{k_1k_2}) \\ \Lambda^{t+1}_{k_1k_2} = \arg\min_{\Lambda_{k_1k_2}} \mathcal{L}_{\beta_{k_1k_2}}(\boldsymbol{\mathcal{X}}^{t+1}, \boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)}, \Lambda_{k_1k_2}) \\ \beta_{k_1k_2} = \min(\rho\beta_{k_1k_2}, \beta_{k_1k_2\max}) \end{cases} \tag{15}$$

where $\rho > 1$ denotes a predetermined constant of the penalty.
1) $\boldsymbol{\mathcal{M}}_{(k_1k_2)}$ **sub-problem**: The $\boldsymbol{\mathcal{M}}_{(k_1k_2)}$ at the t-th step is

$$\begin{aligned}\boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)} =& \arg\min_{\boldsymbol{\mathcal{M}}_{(k_1k_2)}} \|\boldsymbol{\mathcal{M}}_{(k_1k_2)}\|_{\text{CTTNN}} \\ &+ \frac{\beta_{k_1k_2}}{2}\|\boldsymbol{\mathcal{M}}_{(k_1k_2)} - \boldsymbol{\mathcal{X}} + \frac{\Lambda_{k_1k_2}}{\beta_{k_1k_2}}\|_F^2.\end{aligned} \tag{16}$$

Similarly to the proximal mapping of the nuclear norm of the matrix, following the tensor singular value thresholding (t-SVT)[21] theorem. The problem (16) can obtain the closed-form solution as,

$$\boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)} = \text{t-SVT}(\mathcal{D}_{\frac{1}{\beta_{k_1k_2}}}(\boldsymbol{\mathcal{X}} - \frac{\Lambda_{k_1k_2}}{\beta_{k_1k_2}}), k_1, k_2), \tag{17}$$

where $\mathcal{D}(\cdot)$is a t-SVT operator.

2) $\boldsymbol{\mathcal{X}}$ **sub-problem**: By fixing $\boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)}$, $\Lambda^t_{k_1k_2}$, the $\boldsymbol{\mathcal{X}}^{t+1}$ can be given by

$$\begin{aligned}\boldsymbol{\mathcal{X}}^{t+1} =& \arg\min_{\boldsymbol{\mathcal{X}}} \iota_{\mathbb{S}}(\boldsymbol{\mathcal{X}}) + \\ &\frac{\beta_{k_1k_2}}{2}\|\boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)} - \boldsymbol{\mathcal{X}} + \frac{\Lambda_{k_1k_2}}{\beta_{k_1k_2}}\|_F^2,\end{aligned} \tag{18}$$

which is differentiable and its closed-form solution can be obtained by

$$\begin{cases} \boldsymbol{\mathcal{P}}_\Omega(\boldsymbol{\mathcal{X}}^{t+1}) = \boldsymbol{\mathcal{P}}_\Omega(\boldsymbol{\mathcal{Y}}) \\ \boldsymbol{\mathcal{P}}_{\Omega^c}(\boldsymbol{\mathcal{X}}^{t+1}) = \boldsymbol{\mathcal{P}}_{\Omega^c}\left(\frac{\sum_{1\le k_1<k_2\le I_N} \beta_{k_1k_2}\left(\boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)} - \frac{\Lambda^t_{k_1k_2}}{\beta_{k_1k_2}}\right)}{\sum_{1\le k_1<k_2\le I_N} \beta_{k_1k_2}}\right), \end{cases} \tag{19}$$

where Ω^c denotes the complement of the index set Ω.

3) $\Lambda_{k_1k_2}$ **sub-problem**: According to the ADMM iteration standard, we update the multiplier $\Lambda_{k_1k_2}$ by

$$\Lambda^{t+1}_{k_1k_2} = \Lambda^t_{k_1k_2} + \beta_{k_1k_2}(\boldsymbol{\mathcal{M}}^{t+1}_{(k_1k_2)} - \boldsymbol{\mathcal{X}}^{t+1}). \tag{20}$$

The whole pseudocode of the ADMM iteration strategy to solve problem (12) is illustrated in Algorithm 2.

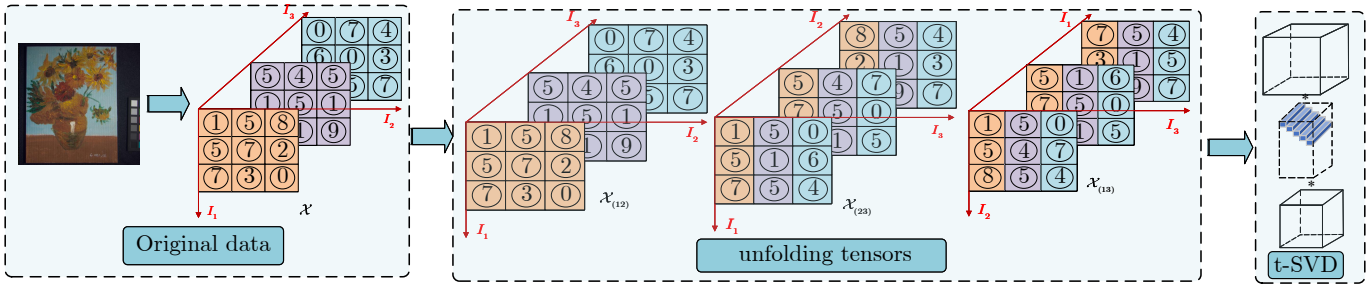

Fig. 2. Illustration of CTTNN, which contains two components: unfolding tensors (middle) and t-SVD (right).

Algorithm 2 ADMM for solving (12).

Input: The incomplete tensor $\mathcal{Y} \in \mathbb{R}^{I_1 \times I_2, \ldots, \times I_N}$, the binary observation index tensor $\mathcal{P}_\Omega$, the positive penalty parameters $\beta_{k_1 k_2}$, the predetermined constant ρ, the maximum number of iterations T.

Output: the completed tensor $\mathcal{X}_\Omega$.

1: **Initialization**: $\mathcal{X}_\Omega = \mathcal{Y}_\Omega$, $\mathcal{X}_{\Omega^c} = 0$, $\mathcal{X}^0_{(k_1 k_2)} = 0$, $\mathcal{M}^0_{(k_1 k_2)} = 0$, $\rho = 1.1$, $T = 500$;
2: **while** not converged and $t \leq T$ **do**:
3: update $\mathcal{M}_{(k_1 k_2)}$ by solving (17);
4: update $\mathcal{X}$ by solving (19);
5: update $\Lambda_{k_1 k_2}$ by solving (20);
6: update $\beta_{k_1 k_2} = \min(\rho \beta_{k_1 k_2}, \beta_{k_1 k_2 \max})$;
7: **end while**

IV. Experimental Results

To illustrate the effectiveness of the proposed CTTNN model, extensive tensor completion experiments on images under two types of tasks, missing-pixel restoration. In these experiments, all Multispectral Images (MSIs) are resized to dimensions of 256×256 pixels, encompassing 31 spectral bands. The entire array of experimental images is depicted in Figure 3. Meanwhile, several state-of-the-art and representative methodologies are enlisted: TRLRF [22], FCTN-TC [23], TNN [21], HFTNN [19], and WSTNN[15]. Among these, TNN follows a scheme grounded in tSVD, while HFTNN and WSTNN are refinements of TNN that employ distinct tensor representation strategies. TRLRF and FCTN-TC are based on tensor decomposition techniques, utilizing the tensor ring and fully-connected tensor ring for low-rank approximation, respectively. To ensure equitable evaluation, the parameters of each competing method are meticulously fine-tuned within the bounds suggested by the original authors, aiming for optimal outcomes. All experimental results are produced in Matlab2020a, and the hardware environment is AMD Ryzen 7 4800H CPU and 16GB RAM.

In this subsection, we apply all methods to six MSIs from the Columbia MultiSpectral Image database[1], i.e., flowers, thread spools, fake and real beers, oil painting, stuffed toys,

[1]http://www.cs.columbia.edu/CAVE/databases/multispectral/.

(a) (b) (c) (d) (e) (f)

Fig. 3. Samples of ground truth, from left to right are (a) flowers, (b) thread spools, (c) fake and real beers, (d) oil painting, (e) stuffed toys, (f) fake and real strawberries.

and fake and real strawberries. To assess the completion results of all methods, we perform visual inpainting by randomly selecting positions at various ratios, spanning from 10% to 30%. Table II reports the MPSNR and MSSIM quality metrics of each method on all MSIs. The best results in the table are bolded. As can be seen from Table II, our proposed CTTNN method outperforms most of the competitors across nearly all scenarios, indicating that the recovered MSI by our model exhibits spatial and spectral structures that are closer to the original data. The non-bold outcomes of CTTNN are reflected in the MPSNR and MSSIM metrics for the oil painting and tuffed toys. Despite this, our results maintain a strong second position and exhibit a marginal difference from the top-performing result.

For visual comparison, the recovered MSI on of thread spools at a 10% sampling rate is presented in Figure 4. This illustration depicts the reconstructed MSIs at band 10, along with the corresponding error images at band 10 from various competing methods. From this depiction, the initial observation highlights that TRLRF yields a subpar visual impact, characterized by a blurry and desaturated recovered image lacking in semantic image details. In contrast, other competing techniques such as FCTN-TC and TNN struggle to recover all the elements, displaying noticeable errors. The outcomes of WSTNN and HFTNN present marginally better acceptability, while our novel CTTNN approach accurately estimates nearly all pixels. In the magnified thumbnail showcasing pseudo-color images, the proposed model distinctly delineates target contours of the mountain. Concurrently, the error images confirm that the discrepancy between the recovered outcome by CTTNN and the ground truth is minimal. Evidently, in terms of visual quality, the results attained by the proposed CTTNN model underscore the advantages of our holistic approach, which

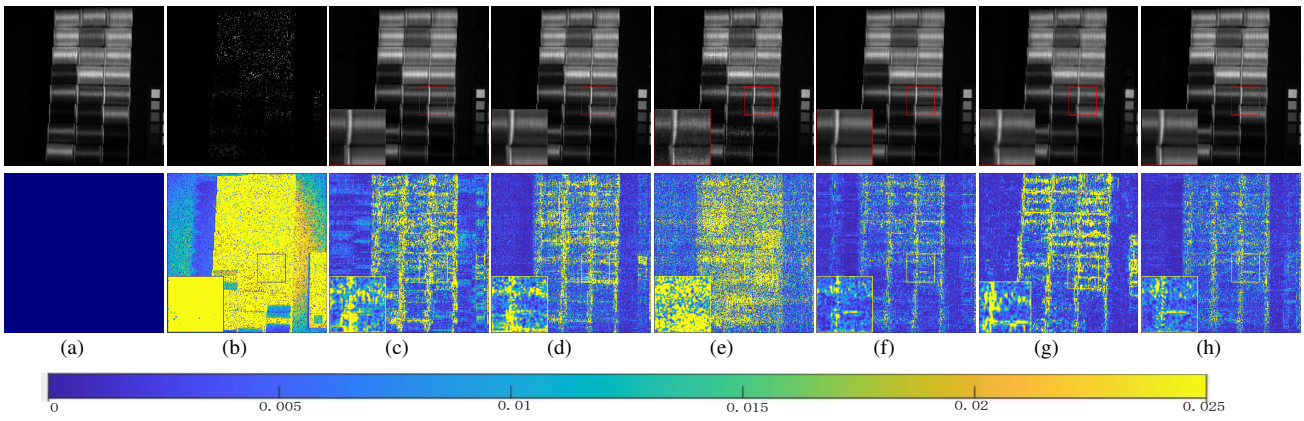

Fig. 4. Visual results of all comparative algorithms on thread spools at band 10. (a) Original image. (b) Observed data. (c)-(h) Recovered images from TRLRF, FCTN-TC, TNN, WSTNN, HFTNN and CTTNN, respectively. The second row presents the corresponding error images of the first row.

intelligently incorporates enhanced low-rank properties and the utilization of unfolding tensors.

Efficiency of execution stands as another crucial indicator for real-world applicability. In this context, Figure 5 provides a visual representation of the average execution times of all competing models across varying random missing pixel rates applied to the six recovered MSIs. Notably, the efficiency of TRLRF and TNN outperforms that of the other algorithms considerably. As computational requirements escalate, FCTN-TC, WSTNN, HFTNN, and CTTNN demonstrate comparatively diminished efficiency due to their unique data expansion strategies aimed at enhancing data properties. This outcome conforms to the reasoning that such strategies inherently introduce greater computational intricacies. However, when compared to HFTNN, CTTNN manages to sustain an acceptable level of execution efficiency. Moreover, as a counterbalancing facet, CTTNN accentuates the reinforcement of low-rank attributes and the resilience exhibited across diverse bands of MSIs.

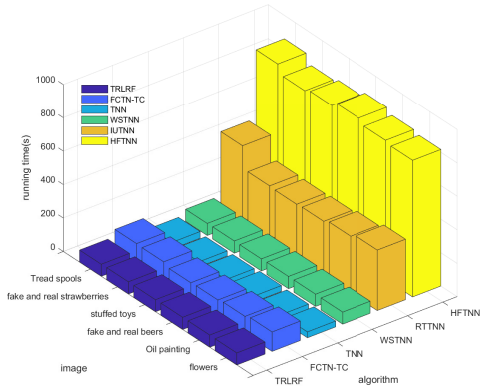

Fig. 5. The execution time of all algorithms for MSIs recovery.

V. CONCLUSION

We propose a novel tensor completion model, CTTNN, which amalgamates the enhanced low-rank property of t-SVD with the multi-dimensional tensor unfolding technique. In this model, the constituents of higher-order tensors undergo a reconstruction process into a sequence of three-way tensors. Moreover, we extend the t-SVD framework and devise the LRTC model through the incorporation of a conjoint transform-induced TNN. Subsequently, the ADMM algorithm optimizes the proposed model, yielding a systematically derived solution at each iterative step. Extensive experimental results validate that the CTTNN method surpasses other cutting-edge approaches in terms of both qualitative and quantitative measures.

***Abstract*—Multi-granularity visual classification is a challenging task derived from traditional image recognition. Previous methods commonly use the features from the final convolutional layer to perform multi-granularity visual classification. However, the features required for different granularity label classification are not consistent. The finer the granularity of the label, the more detailed the features are needed. So, the key to multi-granularity visual classification is to extract effective features for different granularity levels. Generally, the high-frequency parts of natural images usually encode detailed information, while low-frequency parts often encode global structures. Therefore, mapping the output features of convolutional layers into high-frequency and low-frequency parts may enhance feature learning with multi-granularity. In this paper, we decompose the output features from convolutional layers into high-frequency and low-frequency counterparts, and use the combinations of the high-frequency and low-frequency features from various convolutional layers to learn different granularity labels. We evaluate the proposed method on the three public available datasets, including CUB-200-2011, Stanford Cars, and FGVC-Aircraft datasets. The experimental results demonstrate the effectiveness of the proposed method.**

I. Introduction

Fine-grained visual classification (FGVC) [1]–[10] is a research field in computer vision, with the goal of identifying sub-classes with high similarity under the same super-class. Many researchers [11]–[17] are currently striving to improve the performance of FGVC models, but there is little research on the definition of fine-grain itself. In fact, the definition of fine-grain is subjective, and people at different professional levels have different definitions of fine-grain. In order to meet people's demands for different granularities, some researchers [18]–[22] have constructed a hierarchical label classification system to provide multi-granularity labels from coarse to fine granularities.

By analyzing existing multi-granularity visual classification methods [18]–[22], a common and challenging point is how to extract effective features representing different granularities to learn multi-granularity labels. Chang et al. [18] extracted features for multi-granularity labels by decomposing the final convolutional layer's features into granularity-specific parts, and each part was used for one granularity label learning. Then, they proposed fine-grained features to participate in coarse-grained label prediction, which promoted the learning of coarse-grained labels. This method disentangles the decision spaces of different granularities and improves the performance of the model. Chen et al. [19] extracted features for multi-granularity labels by constructing a feature pyramid structure using the output features at different convolutional layers. Then, they proposed upsampling deep features and combining them with shallow features to make decisions. This method uses the relationships between labels at different levels to learn features with different granularities, and has achieved better results. Meanwhile, the high-frequency parts of natural images usually encode detailed information, while low-frequency parts often encode global structures [23]–[25], as shown in Fig. 1. Therefore, mapping the output features of convolutional layers into high-frequency and low-frequency parts may enhance feature learning with multi-granularity. In this paper, we use octave convolution [26] to decompose the output features of convolutional layers into high-frequency and low-frequency features. Then, we combine cross-layer frequency features to extract effective features representing different granularities.

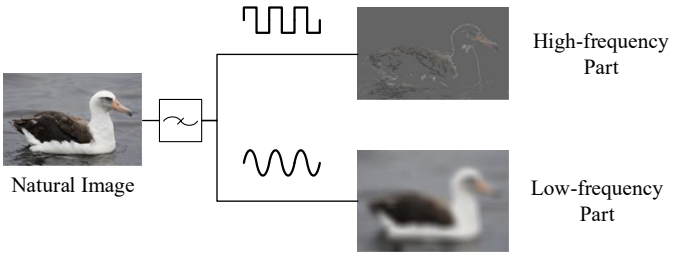

Fig. 1: Natural image information can be decomposed into high-frequency and low-frequency information.

As shown in Fig. 2, we propose a multi-frequency feature enhancement model for multi-granularity visual recognition. Specifically, we take the three-granularity labels as an example. Firstly, in order to disentangle the learning of detailed information and global structural information, we decompose the convolutional layers' features into high-frequency and low-frequency features through octave convolution [26]. Secondly, by using the relationships between labels at different levels to learn features with different granularities, we decompose the final convolutional layers' features into three feature parts, and combine the low-frequency features of shallower convolutional layers with these feature parts. Lastly, we set a gradient controller, to ensure that the gradient flow of each granularity-

specific classifier don't affect others during the reverse propagation phase. Following Chang et al. [18], we allow fine-grained features to participate in coarse-grained label learning. Through the above method, we have achieved multi-frequency feature enhancement for multi-granularity visual classification. Our contributions are as follows:

1)We decompose the features into high-frequency and low-frequency parts, to enhance the learning of detailed features and global structural features respectively.

2)We propose a new method based on combining the high-frequency and low-frequency features of different convolutional layers, to achieve multi-frequency feature enhancement for multi-granularity visual recognition.

3)We conduct extensive experiments on three publicly available datasets: CUB-200-2011 [27], Stanford Cars [28], and FGVC-Aircraft [29]. The experimental results demonstrate the effectiveness of the proposed method.

II. RELATED WORK

A. Fine-Grained Visual Classification

Fine-grained visual classification (FGVC) [1]–[10] is a highly challenging research field in computer vision, with the goal of identifying sub-classes with high similarity under the same super-class. In contrast to traditional image recognition, the difficulty of FGVC is that there are significant intra-class differences and subtle inter-class differences in images. Currently, researchers mostly use deep learning methods to solve FGVC task, and have achieved good results. Specifically, these methods can be roughly divided into three categories. The first category is based on localization-recognition methods [4]–[7], which locate distinctive feature regions and then learn fine-grained features in these regions. In the early days, researchers [4], [5] used strong supervision to locate distinctive feature regions, such as adding additional manual annotation information. In recent years, researchers [6], [7] have gradually proposed using weak supervision methods to locate distinctive feature regions, such as introducing attention mechanisms. The second category is based on network ensemble methods [8], [9], which divide fine-grained datasets into several similar subsets for classification, or directly use multiple neural networks to improve the performance of fine-grained classification. The third category is based on high-order feature encoding methods [2], [10], which improve the expression ability of CNN features through high-order synthesis. In this paper, we study a different task based on FGVC, which generates images into multi-granularity label outputs.

B. Multi-Granularity Visual Classification

Multi-granularity visual classification (MGVC) task aims to provide a sequence of labels from coarse to fine for single label images. In contrast to FGVC, MGVC not only focuses on improving model recognition performance, but also meets the demands of people with different professional levels for different granularities. Now, many researchers [18]–[20], [30], [31] have used different methods to solve MGVC tasks. For example, Chang et al. [18] decomposed the features of the final convolutional layer into several specific-granularity parts, and proposed fine-grained features to participate in coarse-grained label prediction. Chen et al. [19] constructed a feature pyramid structure using the output features of different convolutional layers, and then proposed upsampling deep features and combining them with shallow features to make decisions. Wang et al. [20] proposed a unified probability framework based on deep learning for label hierarchy transformation, to solve hierarchical classification problems by using the correlation between various categories at different levels. The above models all extracted effective features of different granularities through different methods. In this paper, we decompose the convolutional layer into multi-frequency features, and combine the frequency features of different layers to extract more effective features of different granularities.

III. METHODOLOGY

In this section, we will introduce our model for multi-granularity visual classification. As shown in Fig. 2. We divide our model into two parts, namely the multi-frequency decomposition module and the feature fusion module respectively. We process the input image with octave convolution [26] to obtain multi-frequency features. Then, we combine the high-frequency and low-frequency features of different convolutional layers to enhance the learning of multi-granularity labels.

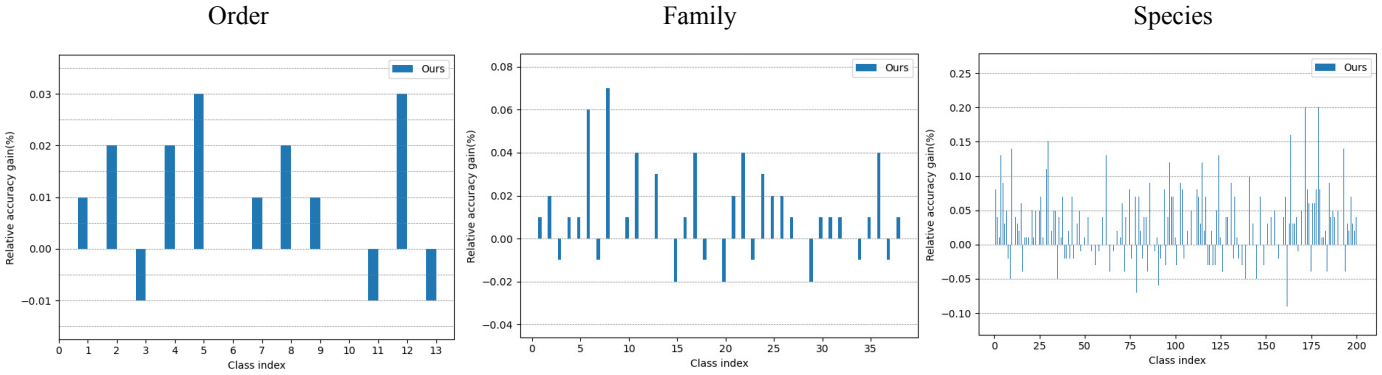

Fig. 3: Relative accuracy gain of Oct-FGoN-based, Ours compared with Oct-FGoN for each class recognition on the CUB-200-2011 dataset. X-axis represents the class index. Y-axis represents the relative accuracy gain for each class.

A. Multi-Frequency Decomposition Module

The goal of this module is using multi-frequency features to disentangle the learning of detailed information and global structural information. We decompose convolutional layers' output features into high-frequency and low-frequency features through octave convolution [26]. We replace all traditional convolutions of backbone network with octave convolutions and form our multi-frequency decomposition module.

In multi-granularity visual classification task, an image x has a multi-granularity label $\{y_1,y_2,...,y_K\}$ (K represents the number of granularities). Using ResNet50 as an example, we denote the output features of each block to $\{B_1,B_2,...,B_S,...,B_N\}$, where N is the total number of convolutional blocks. In our method, we decompose each block's output features $B_S(C_S \times W_S \times H_S)$ into high-frequency $B_{SH}(C_S/2 \times W_S \times H_S)$ and low-frequency $B_{SL}(C_S/2 \times W_S/2 \times H_S/2)$ through octave convolution [26]. We take the final convolutional layer's features and other blocks' low-frequency features as the multi-frequency features $\{B_N, B_{(N-1)L}, B_{(N-2)L}, ..., B_{(N-K+1)L}\}$. Then, we pass the multi-frequency features through the fully connected layer FC to obtain the input $\{f_H, f_{L1}, f_{L2}, ..., f_{L(K-1)}\}$ of the feature fusion module.

B. Feature Fusion Module

In this module, we use two feature fusion operations. We have the features $\{f_H, f_{L1}, f_{L2}, ..., f_{L(K-1)}\}$ output from the multi-frequency decomposition module. For the convenience of explanation, we use the three-granularity labels as an example in Fig. 2. Firstly, following Chang et al. [18], we decompose the f_H into three feature parts $\{f_{H1}, f_{H2}, f_{H3}\}$. To be more specific, we divide half of f_H into f_{H1}, and divide the other half equally into f_{H2} and f_{H3}. Because fusing cross-layer features can enhance the learning of multi-granularity labels [19], so we fuse f_{H2} with f_{L1} to denote as f_2, and fuse f_{H3} with f_{L2} to denote as f_3. We transfer the first feature regions f_{H1} to f_1, thus obtain new three feature parts $\{f_1, f_2, f_3\}$. The above feature fusion operations are set with gradient controller functions δ to stop the propagation of gradient flow, and $\oplus$ is denoted concatenation operation. The specific methods are as follows:

$$f_1 = f_{H1},$$
$$f_2 = f_{H2} \oplus \delta(f_{L1}), f_3 = f_{H3} \oplus \delta(f_{L2}). \quad (1)$$

Secondly, we have mentioned above that fine-grained features can enhance the prediction of coarse-granularity classifier. So, we fuse the fine-grain feature part into the coarse-grained feature part. To be more specific, we fuse f_1 and f_2 into f_3 to obtain F_3 that works for prediction of coarse-grained label, and fuse f_1 into f_2 to obtain F_2 that works for prediction of middle-grained label. We transfer f_1 to F_1 that works for prediction of fine-grained label. We still set gradient controller functions δ for these fusions, and $\oplus$ is denoted concatenation operation. The specific methods are as follows:

$$F_1 = f_1, F_2 = f_2 \oplus \delta(f_1),$$
$$F_3 = f_3 \oplus \delta(f_2) \oplus \delta(f_1). \quad (2)$$

Through the two feature fusion operations mentioned above, we have achieved multi-frequency features enhancement for multi-granularity visual classification task. Our optimisation objective is three independent cross-entropy loss $\sum_{k=1}^{3} L_{CE}(\hat{y_k}, y_k)$, where $\hat{y_k}$ is the label predicted by the model, and y_k is the real label. Similarly, for K granularity labels, our optimisation objective is K independent cross-entropy loss $\sum_{k=1}^{K} L_{CE}(\hat{y_k}, y_k)$.

IV. EXPERIMENTAL SETTINGS

A. Datasets and Evaluation Criterion

We validate our method on the three public available datasets. Chang et al. [18] have constructed a multi-granularity label structure for each dataset. Details are as follows. **CUB-200-2011** [27] is a bird dataset consisting of 11778 bird images from 200 categories, officially divided into 5994 training images and 5794 test images. This dataset is divided into 13 orders, 38 families, and 200 species. **FGVC Aircraft** [29] is an aircraft dataset consisting of 10000 aircraft photos from 100 categories, officially divided into 6667 training images and 3333 test images. This dataset is divided into 30 manufacturers, 70 families, and 100 models. **Stanford Cars** [28] is a vehicle dataset consisting of 16185 vehicle images from

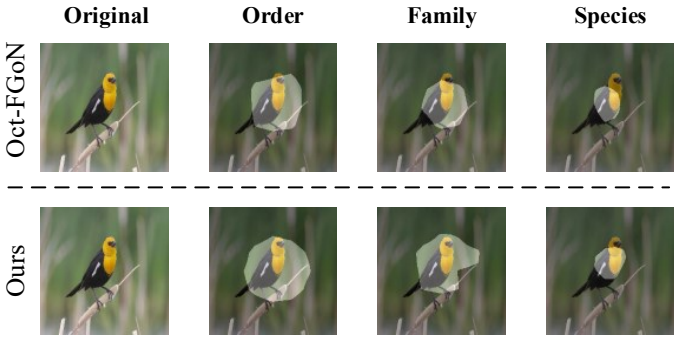

Fig. 4: Visualizations of Oct-FGoN and Ours at Order, Family, and Species granularities on CUB-200-2011 dataset.

196 categories, officially divided into 8144 training images and 8041 test images. This dataset is divided into 9 car types and 196 models.

We use the same evaluation metrics as [18]. We evaluate the network performance through accuracy, which means percentage of images whose labels correctly classified. Then calculate the average accuracy of multi-granularity labels, denoted by "avg_acc". Each experiment is run three times, and the accuracy results are shown with the mean and standard deviation.

B. Implementation Details

We use Oct-ResNet50 (replacing the traditional convolution of ResNet50 with octave convolution) [26], [32], pre-trained on ImageNet as the backbone network. On the CUB-200-2011 and FGVC-Aircraft datasets with labels of three granularities, we use the final features of residual block4 in Oct-ResNet50, and the low-frequency features of residual block3 and block2 as the multi-frequency features, denoted as f_H, f_{L1}, and f_{L2} respectively. On the Stanford Cars dataset with labels of two granularities, we use the final features of residual block4 in Oct-ResNet50, and the low-frequency features of residual block3 as the multi-frequency features, denoted as f_H and f_{L1} respectively.

For a fair comparison with other methods, we scale the input size of all images to 224×224, and use common data augmentation training methods, including horizontal flipping, random cropping, and color dithering. We set the initial learning rate as 0.001 for the pre-trained convolutional layers, and 0.1 for the newly added fully connected layers in the classifiers. We decay the learning rate with cosine annealing, and train the networks for 100 epochs per experiment. We use Momentum Optimizer with momentum value as 0.9, and weight decay value as 5×10^4.

C. Baselines

To verify the effectiveness of our method, we have conducted extensive comparative experiments with existing models: (i) **Vanilla_single**: the method uses only one network backbone (Resnet50), followed by multiple classification headers. (ii) **Vanilla_multi**: it has multiple independent backbone networks (Resnet50), each of which handles one granularity. (iii) **FGoN** [18]: it decomposes the final features into several parts, and uses fine-grained features to promote the learning of coarse-grained labels. (iv) **Oct-FGoN** [18]: replacing the convolutions in the FGoN with octave convolutions. (v) **CGVC** [19]: it constructs the features of different blocks into a feature pyramid structure, and then deep block's features participate in shallow block's feature learning. (vi) **Oct-CGVC** [19]: replacing the convolutions in the CGVC with the octave convolutions. (vii) **Ours**: decomposing the convolutional layers' features into high-frequency and low-frequency features, combining the high-frequency and low-frequency features of different convolutional layers to learn labels with different granularities.

D. Results and Analysis

Comparing with existing models, whether in coarse-grained labels or fine-grained labels, our method has achieved satisfactory results. The experimental results are shown in Table 1. From the table, it can be observed that:

Comparing to Vanilla_single and Vanilla_multi, FGoN [18] obtains better results on each granularity label. The difference from Vanilla_single is that FGoN [18] disentangles decision spaces of different granularities. And the difference from Vanilla_multi is that FGoN [18] uses fine-grained features to participate in the learning of multi-granularity labels. So, we have obtained two inspirations: (i) disentangling decision spaces of different granularities, and (ii) using fine-grained features to participate in coarse-grained label learning. They are beneficial for promoting the recognition of multi-granularity labels.

Compared to FGoN [18] and Oct-FGoN, our model has exceeded the accuracy of Oct-FGoN and FGoN [18] at each granularity. So, it is effective to combine the different convolutional layers' low-frequency features with the final convolutional layer' features. Because the relationships of the different convolutional layers' features is similar to the relationship of

the different granularity's labels. So, utilizing the relationships between different granularity labels to combine cross-layer features can enhance the learning of multi-granularity labels.

Compared to CGVC [19] and Oct-CGVC, our model has a better performance. The difference with CGVC [19] and Oct-CGVC is that we only take the low-frequency parts of the convolutional layers, and we combine these cross-layer frequency features after passing through the fully connected layer. The experimental results prove that our method is effective, because our method reduces the impact of inconsistent feature scales between different convolutional layers.

In order to more directly demonstrate the performance of our method. In Fig. 3, we compare the classification results of each class at three granularities in the CUB-200-2011 dataset with Oct-FGoN [18].

E. Visualization

In Fig. 4, we use Grad-CAM [33] to visually compare Oct-FGoN [18] with our method. Experiments show that our method has a larger receptive field in coarse-grained areas and a more accurate receptive field in fine-grained areas, which means that our method achieves disentangling the learning of detailed information and global structural information.

V. CONCLUSION

We propose a multi-frequency feature enhancement for multi-granularity visual recognition. We realize decomposing the features of convolutional layers into multi-frequency features can disentangle the learning of detailed information and global structural information. Meanwhile, the relationship of the different convolutional layers' features is similar to the relationship of the different granularity's labels, so we combine the final convolutional layer's features with low-frequency features of different convolutional layers, to obtain effective features representing different granularities. Compared with existing methods, we achieve satisfactory performance on CUB-200-2011, Stanford Cars, and FGVC-Aircraft datasets.

***Abstract*—Aspect sentiment classification (ASC) is an essential subtask of aspect-based sentiment analysis. Recently, pre-trained language models (PLMs) have gradually become the mainstream building block for the ASC task and retrieval-based methods are shown to be effective in helping PLMs better understand various downstream tasks. However, retrieval-based methods need to introduce external knowledge, and building an index of large-scale corpus leads to huge cost. To this end, we propose an effective method that utilizes training data to construct a retrieval corpus and retrieve instances most similar to current input to enhance semantic representations. In the proposed method, three kinds of retrieval metrics are applied, allowing us to quickly adapt to ASC tasks. Experimental results show that this simple retrieval augmented method can achieve significantly better performance on three benchmark ASC datasets (Twitter, Laptop, and Restaurant). Our code is available at https://github.com/rickltt/re-bert.**

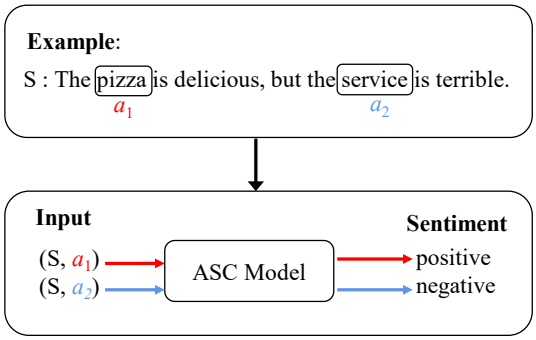

Fig. 1. An example of aspect sentiment classification process.

I. Introduction

Sentiment analysis (SA) is an important task in natural language processing (NLP) that aims to classify the sentiment polarity of a given sentence [1]. Traditional sentiment analysis studies have focused on sentence-level or document-level predictions, yet there may be multiple aspects in a given text. For example, As shown in Fig. 1, a plain sentence contains different aspects of "pizza" and "service". The polarity in "pizza" is positive, and the polarity regarding "service" is negative. In this context, the need to identify more fine-grained aspect-level perspectives and emotions, also known as aspect-based sentiment analysis (ABSA) [2], has received increasing attention over the past decade.

Aspect sentiment classification (ASC), also called aspect-level sentiment classification, is a subtask of ABSA, which aims to classify the sentiment polarity (positive, negative, or neutral) of aspects extracted from the original sentences. Fig. 1 illustrates the flow of ASC tasks, there are two aspect terms a_1 and a_2 extracted from sentence s and formed into two pairs (s,a_1) and (s,a_2), subsequently inputted into the ASC model to obtain the sentiment polarity of aspects.

The earlier work on ASC relied heavily on feature engineering [3] and subsequently ASC based on deep learning has attracted a lot of interest. After that, a variety of neural network-based models have been proposed including the CNN-based network [4, 5], memory network [6, 7], and gated network [8], and significant performance improvements have been made. In recent years, fine-tuning pre-trained language models (PLMs) such as BERT [9] and RoBERTa [10] have been reported with high performance in ASC tasks [11]. PLMs can learn generic text representations from large amounts of unlabeled corpus to enhance downstream tasks, which attracts considerable attention to improve the semantic representations of sentences for the ASC task. In natural language processing, retrieval-based methods usually work by selecting extra information related to input and concatenating it with retrieval results as a new input [12]. This way can remarkably improve the performance of models for various downstream tasks. As a result, a series of retrieval-based approaches have been applied with great success to many NLP tasks such as language modeling [13, 14], open-domain question answering [15] and machine translation [16]. However, these methods rely on a large-scale corpus and building an index requires a huge computational burden. From the perspective of the supervised learning paradigm, the most similar distribution to the test data is the training data. Moreover, the size of training data is usually much smaller than the external large-scale corpus. To this end, we present a **RE**trieval-based **BERT** (**RE-BERT**) model, which aims to utilize training data as the retrieval corpus to enhance the semantic representations for the ASC task. Specifically, as shown in Fig. 2, we first build an index

† Work was done when Tongtao Ling interned at IMSL.

of training data as a retrieval corpus. Then, for each input instance, we retrieve the top k most similar instances to the current input. Finally, we concatenate retrieval instances with the original input as a new input and feed it into the ASC model to predict the polarity of the aspect.

In our experiments, we use three different retrieval metrics to measure the similarity between instances and evaluate our approach on three ASC benchmark datasets. Compared to various state-of-the-art baselines, we find that: (1) after integrating our method, pre-trained models (i.e., BERT) for the ASC task can achieve better performance than other models that use different network architectures; (2) for different retrieval metrics, dense-vector retrieval (dense vectors encoded using pre-trained language models) outperforms spare-vector retrieval (i.e., TFIDF and BM25); (3) the results on ablation study shows that BERT-base with retrieval method can achieve similar performance with Bert-large without retrieval method, the parameter of BERT-large is nearly three times than BERT-base (340M vs. 110M). This phenomenon illustrates that even though models have hundreds of millions of parameters, a model cannot memorize all the patterns in the training data. Therefore, retrieving the relevant training data to enhance the semantic information is an effective method to enhance the inference of the model. Besides, we conduct extensive ablation studies on three widely-used datasets and perform insight analysis. The results demonstrate the effectiveness and interpretability of our proposed model.

The remainder of this paper is organized as follows. Related work is described in Section II. Our proposed method is described in Section III, including the pipeline of our model and the kinds of retrieval metrics. In Section IV, the experimental results indicate that the competitiveness with other state-of-the-art ASC models. In section V, further analysis of the ablation experiments is performed. Finally, Section VI concludes this paper.

II. Related Work

A. Aspect-based Sentiment Analysis

Aspect-based sentiment analysis aims to identify the polarity of a specific aspect term in the given sentence. Early ASC models focused on manually designed features such as dependency parse [17] and term frequency [3]. With the rapid development of deep learning, most research studies make use of neural networks to learn the word's semantic representation [5, 7, 18, 19]. Among them, Ma et al. [19] proposed a model that learns interactively representations between aspect and context by using two LSTM layers and attention mechanisms. Chen et al. [7] used bidirectional long short term memory (BiLSTM) and gated recurrent unit (GRU) network to combine multiple attention outputs. Wang et al. [18] appends the target embedding with each word embedding and gets the final representation by attention mechanisms that combine with LSTM. Li et al. [5] introduced a target-specific network to make use of the aspect information.

More recently, pre-trained language models have been achieved remarkably successful in the aspect-based sentiment analysis task. Song et al. [11] proposed to use manual auxiliary sentences to convert ABSA into a sentence-pair classification task. Xu et al. [20] proposed the Review Reading Comprehension (RRC) task and utilized the post-training method for RRC and ABSA, which can let the model acquire domain knowledge and task-aware knowledge. To address the problem of implicit sentiment in ASC (sentiments with no explicit opinion word), Li et al. [21] proposed a pre-training method for the ASC model. Xiao et al. [22] utilized inter-layer's features and position information of BERT to enhance graph convolutional network (GCN) encoding for ASC. Tian et al. [23] proposed Type-aware GCN that uses multiple layers of GCN information instead of just the last layer. Qin et al. [24] proposed a two-stage method to complete the ASC task: the first stage adds a decoder to recover the original sentence and uses a discriminator to weigh the recovered result, and the second stage removes the part and only classifies sentiment. Zhang et al. [25] design a lightweight dynamic reweighting Adapter to learn dynamic aspect-oriented semantics for aspect-based sentiment analysis. Dependency trees are widely used in GCN, but Chen et al. [26] thinks that dependency trees are not optimized and proposes an aspect-specific and language-agnostic discrete latent opinion tree model as an alternative structure for ABSA.

B. Retrieval-based Methods

Retrieval-based methods fuse recent deep learning technology and traditional retrieval technology, which has achieved remarkably successful performance in many natural language processing tasks and attracted more attention from NLP researchers [27, 28]. The parameters of pre-trained language models are very huge, but even GPT-3 [29] is unable to remember everything and it is also important to collect retrieval information from external knowledge to enhance the performance of various NLP tasks. Specifically, template retrieval is an effective intermediate step for the dialogue response generation task. On the task of machine translation, retrieved sentences are used to improve statistical machine translation and neural machine translation models. And other applications of text generation such as code generation [30], abstractive summarization [31] and knowledge-intensive generation [14].

The most important key of the retrieval-based method is the retrieval metric. There are two kinds of retrieval metrics: sparse representation and dense representation. For sparse representation, the most commonly used are bag-of-words and rule-based keyword matching (i.e., TFIDF and BM25 [32]) method. These methods have been widely applied to a general large-scale search, such as open domain question answering and machine translation. For dense representation, it requires an encoder (i.e., BERT) to transform the context into low-dimensional dense vectors and compute the similarity between two vectors. Dense representation can outperform sparse representation on different tasks, such as knowledge-grounded generation, open domain question answering and machine translation. The drawback of dense representation is the cost of time and it can not process long sequences, usually less than 512 tokens.

Considering the consequence of different retrieval metrics for retrieval-based methods, in this paper, we use TFIDF, BM25 and Dense to score the similarity and retrieve from the training data.

III. Methodology

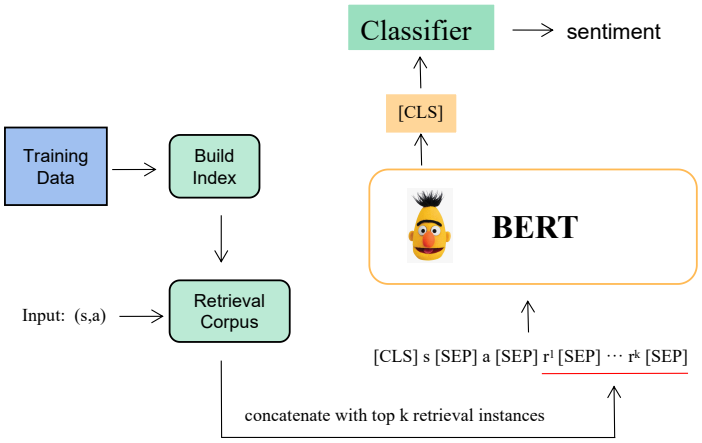

Fig. 2. The pipeline of aspect sentiment classification with retrieval from training data.

In this section, we first introduce the description of aspect sentiment classification, then we elaborate our proposed **RE-BERT** and the detail of retrieval metrics.

A. ASC Task

Given a natural language sentence s containing a set of aspect terms: $\{a_1, ..., a_n\}$, which can be wrapped into several pairs (s,a_1),...,(s,a_n) as inputs. The aspect term could be a single word or a long phrase and the goal of ASC task is to find the polarity $y \in Y$ of each aspect term, $Y = \{$ *positive*, *negative*, *neutral*$\}$. As a result, ASC is typically cast as a sentence pair classification task.

As shown in Figure 2, the ASC model mainly consists of an encoder and a classifier. We utilize pre-trained language model BERT as the base encoder to generate word vectors of sequence. For an input (s,a), we insert special tokens to construct a new input:

$$x = [CLS]\ s\ [SEP]\ a\ [SEP] \tag{1}$$

[CLS] and [SEP] are special tokens in BERT. [CLS] is a symbol in front of each sentence and [SEP] used to distinguish different sentences.

B. RE-BERT

In this paper, we aim to improve the performance of the ASC task by using retrieval results as input to generate better results. In both training and testing, for each input-label (s,a), we retrieve top k sentences $\{r^1, \cdots, r^k\}$ from training data most similar to the current input. Then, we concatenate them with the input sentence:

$$x_{concat} = [CLS]\ s\ [SEP]\ a\ [SEP]\ r^1\ [SEP] \cdots r^k\ [SEP] \tag{2}$$

After that, we input x_{concat} to the encoder BERT and obtain the contextual representation:

$$h = BERT(x_{concat}) \tag{3}$$

We leverage the representations of [CLS] $h_{[CLS]}$ as the input of the classifier, because $h_{[CLS]}$ is the aspect-aware representation of whole concatenated sentences. The classifier is a linear layer. To conduct aspect sentiment classification, a weight matrix $W \in \mathbb{R}^{D\times|Y|}$ and a bias term $b \in \mathbb{R}^{|Y|}$ are introduced to classify each aspect into a corresponding polarity, where D is the hidden size of BERT output and $|Y|$ is the number of polarities. The classification logit is defined as:

$$p = W \cdot h_{[CLS]} + b \tag{4}$$

The final predicted polarity of aspect:

$$\hat{y} = softmax(p) \tag{5}$$

The optimization loss function is a cross entropy loss between classification logits and true polarity, which is defined as:

$$\mathcal{L}(\theta) = -\sum_{i=1}^{N}\sum_{j=1}^{C} y_i^j \log(\hat{y}_i^j) + \lambda \sum_{\theta\in\Theta} \theta^2 \tag{6}$$

where y_i^j is the ground truth of polarity and $\hat{y}_i^j$ is the predicted polarity. C is the number of labels and N is the number of training instances. Θ is the parameter set corresponding to all the trainable parameters and λ is coefficient.

C. Retrieval Metrics

Given an input (s,a) and a retrieval corpus C, we aim to retrieve a set of relevant instances $z = \{(s^r, a^r)\}$ from C. How to measure the score between (s,a) and (s^r,a^r) is a considerable problem in retrieval-based methods. The widely used retrieval measurements such as BM25 and TF-IDF [32] could match keywords efficiently with an inverted index. However, these methods generate sparse-vector that is incapable to capture deep-level semantics. To alleviate the above problem, some recent works attempt to retrieve similar instances by using PLMs to generate dense-vector.

a) BM25: BM25 algorithm, usually used for search relevant score. The general formula for the BM25 algorithm is as follows:

$$Score_{bm25}(Q,d) = \sum_{i}^{n} W_i \cdot R(q_i,d) \tag{7}$$

where query $Q = \{q_1, \cdots, q_n\}$ is a tokenized sequence and we need to compute the correlation with a document $d \in D$, and D contains many documents. The correlation is calculated as:

$$R(q_i,d) = \frac{f_i \cdot (k_1+1)}{f_i + K} \tag{8}$$

$$K = k_1 \cdot (1 - b + b \cdot \frac{dl}{avgdl}) \tag{9}$$

where k_1 and b are regulating factors that usually could be set to 1.5 and 0.75 respectively. dl is the length of D and $avgdl$ is

the average length of D. fi is the frequency of occurrence of qi in Q. In addition to correlation, the other key factor is the weight W_i of q_i that is calculated to obtain final score. There are various ways to determine the correlated weight of q_i to d, the most common being IDF (Inverse Document Frequency). IDF is defined as:

$$W_i = IDF(q_i) = \log \frac{N - n(q_i) + 0.5}{n(q_i) + 0.5} \tag{10}$$

b) TF-IDF: TF-IDF (Term Frequency Inverse Document Frequency) is a weighting technique commonly used in information processing and data mining. The technique uses a statistical method to calculate the importance of a word in the overall corpus based on the number of occurrences in the text and the frequency of documents in the overall corpus. It has the advantage of filtering out common but irrelevant words while retaining the important words that affect the whole text. The correlation is calculated as:

$$Score_{tfidf}(Q, d) = \sum_{i}^{n} f_i \cdot IDF(qi) \tag{11}$$

c) Dense: How to encode text to low-dimension dense vectors is an issue that has been studied in the past decades [33]. PLMs can learn deep-level semantic representations under large amount of unlabeled corpus and encode text into low-dimensional vectors. To make use of PLMs, we try to use BERT to encode document d and query Q. Then, we compute relevant scores via inner products between d and Q. The score is calculated as:

$$Score_{dense}(Q, d) = BERT(Q) \cdot BERT(d) \tag{12}$$

IV. Experiment

In this section, we present our experimental comparison and the corresponding analysis of three widely-used ASC datasets.

A. Datasets

We conduct experiments on three ASC benchmark datasets: Restaurant, Laptop, and Twitter. Restaurant reviews and Laptop reviews are from SemEval-2014 Task 4 [34], and Twitter reviews are from the social platform Twitter [35]. These datasets are labeled with three sentiment polarities: positive, neutral, and negative. We use *Accuracy* and *Macro-F1* as metrics for all experiments. Table I shows the number of training and testing instances in each category.

TABLE I
Statistics of the benchmark datasets.

Dataset	Train			Test		
	Positive	Neutral	Negative	Positive	Neutral	Negative
Twitter	1561	3127	1560	173	346	173
Restaurant	2164	637	807	728	196	196
Laptop	994	464	870	341	169	128

B. Baseline

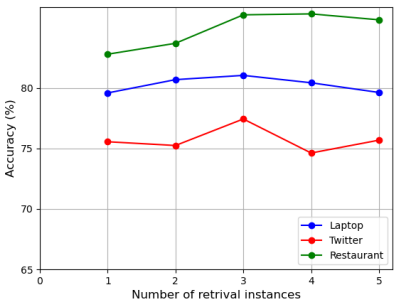
To investigate the effectiveness of the proposed method, we compare it with a range of baselines that can be categorized into three classes: non-BERT-based models, BERT-based models, and our retrieval-based models. For non-BERT-based models, we compare with (1) **ATAE-LSTM** [18], using attention-based long short-term memory network for aspect-level sentiment classification; (2) **AOA** [36], introduced an attention-over-attention neural network for aspect-level sentiment classification; (3) **MemNet** [6] considers contexts as external memories and benefits from a multi-hop architecture; (4) **ASGCN** [37], building a Graph Convolutional Network (GCN) over the dependency tree of a sentence to exploit syntactical information and word dependencies; (5) **RAM** [7] adopts multiple-attention mechanism to capture sentiment features separated by a long distance. For BERT-based models, we compare with (6) **BERT** [9], fine-tuning for text classification; (7) **BERT-PT** [20], post-training for BERT's weight using a joint post-training algorithm; (8) **BERT-SPC** [11] treats ASC task as a sentence pair classification by using BERT; (9) **AEN-BERT** [11] eschew recurrence and employs attention-based encoders for the modeling between context and target; (10) **BERT-ADA** is proposed by [38], fine-tuning BERT on the cross-domain corpus.

C. Implementation Details

The proposed model is implemented based on the Transformers toolkit[1] and PyTorch Framework. We employ BERT-BASE-UNCASED[2] as the base encoder. The maximum sentence length is set to 512 and the dropout rate is set to 0.3. Our model is trained using AdamW optimizer with the learning rate amongst [2e-5,3e-5,5e-5] and the batch size is set to 16. We set the ratio of validation to 0.1 and randomly split the original training set into a new training set and a validation set. We run all experiments three times with different seeds and report the average performance using PyTorch 1.7.0 on the Nvidia RTX 3090 GPU. The accuracy and macro-F1 score are used as the main evaluation metrics in the experimental studies.

D. Main Results

The main experimental results for three datasets are shown in Table II, where we have the following observations.



First, compared to large-scale pre-trained language models, the performance of conventional neural network models is unpromising, including the RNN-based model (ATAE-LSTM), attention-based model (AOA), GCN-based model (ASGCN) and memory network model (MemNet, RAM). On the contrary, BERT-based models have achieved effective results, indicating that the rich knowledge of PLMs captured from large-scale unlabeled data is important for downstream tasks. That is the reason why we choose BERT as base encoder to learn overall semantic representations of whole sentences.

(a) The performance of Accuracy in three datasets.

(b) The performance of Macro-F1 in three datasets.

Fig. 3. The ablation study on different numbers of retrieval instances which conducted on the test set of three datasets.

Second, compared the non-specific BERT models (i.e., BERT and BERT-PT) with task-specific BERT models (i.e., ANE-BERT), we find that task-specific models work better than non-specific models for ASC tasks. In BERT-based baselines, we can see the trend that AEN-BERT >BERT-SPC >BERT-PT >BERT, which illustrates that the information of aspect term is the core influence factor for the performance of the aspect sentiment classification model.

Finally, our retrieval-based method outperforms the most advanced baselines on three datasets, no matter in terms of Accuracy or Macro-F1 score. The results demonstrate that the effectiveness of the retrieval-based method could improve the performance of the aspect sentiment task. Meanwhile, it also indicates that our RE-BERT can better enhance sentence semantics by retrieving similar instances from the retrieval corpus. In addition, unlike the keyword matching method, Dense outperforms the other two methods (TFIDF and BM25), which is consistent with the previous assumption that PLMs can retrieve semantically deep-level sentences instead of surface lexical features. Meantime, it also indicates that our proposed RE-BERT can improve semantics by concatenating with retrieved sentences, which is better than other BERT plus-in components in previous methods.

V. ANALYSIS

In this section, we conduct several ablation studies and discuss a case study to further analyze the effectiveness of our method. For simplicity, we conduct experiments on the best performance retrieval metrics **Dense**.

A. Ablation Study

a) Ablations on the number of retrieval instances: In Figure 3, we study the influence of different retrieval instances from training data in our model. We experimented with the number of retrieval sentences in a range (i.e.,1 to 5). Specifically, the accuracy and macro-f1 of RE-BERT in the three datasets become higher as the number of retrieval sentences increases and reaches the optimal result around 3. As the number increases, performance tends to decline. This phenomenon indicates that retrieval sentences have limited semantic improvement, and too many similar sentences may cause deviations in the semantic understanding of the model. In addition, we can also find that RE-BERT always achieves

TABLE V
CASE STUDY. EXAMPLE: "EASY TO START UP AND DOES NOT OVERHEAT AS MUCH AS OTHER LAPTOPS."

Metrics	Retrieval Sentences
TFIDF	It 's fast , it 's easy easy easy to set up , easy to hook to my wireless network . The price premium is a little much , but when you start looking at the features it is worth the added cash . He loves it and it is easy to use and well the schools start teaching the kids early about computers so it was easy for him to get started .
BM25	It is easy to operate and i have already ordered more software and gadgets for my new rolls royce of laptops . Everything is so easy to use, mac software is just so much simpler than microsoft software. You can do what you want in just few seconds, even to start up your computer takes few seconds.
Dense	Easy to carry , can be taken anywhere , can be hooked up to printers , headsets . It is easy to use , fast and has great graphics for the money . The mac takes about the same amount of starting-up time as the average pc , but keeps itself cleaned up and ready to use .

a higher performance compared to the BERT-based models. All these results suggest that RE-BERT can better enhance the semantics of the whole sentence in aspect sentiment classification.

b) Ablations on the backbone of pre-trained language models: To evaluate the potential of our method, we try to use different parameter sizes of PLMs (BERT-base and BERT-large) as the encoder of **RE-BERT**. As shown in Table III, the ablation result of BERT-base with retrieval-based method rivals BERT-large without the retrieval-based method, which contains nearly three times the parameters. Compared with BERT-large without retrieval, BERT-base with retrieval has little difference of Macro-F1 on Twitter (74.91 % v.s.75.14%), Macro-F1 on Restaurant (81.03% v.s. 80.94%), Macro-F1 on Laptop (78.15% v.s. 77.35%). In addition, whether using the BERT-base or BERT-large model, the retrieval-based approach outperformed the approach without retrieval. Compared to BERT-base without retrieval, BERT-base with retrieval achieves improvements of 3.0% Macro-F1 on Twitter (72.17 % vs.75.14%), 7.7% Macro-F1 on Restaurant (73.17% vs. 80.94%) and 4.0% Macro-F1 on Laptop (73.36% vs. 77.35%).

c) Ablations on the position of concatenating: We tried to use different ways of concatenating with the original inputs and the retrieval instances. We use three types of concatenating methods: (1) **Post**, concatenating after the original input; (2) **Prefix**, concatenating before the original input; (3) **Derange**, concatenating with deranged retrieval instances. As shown in Table V, we find that **Post** and **Prefix** performed similarly, but **Derange** performed poorly. The main reason is that BERT can learn the contextual semantic representation of the whole sentence, and since the retrieval sentences have high semantic similarity with original inputs, the semantic representations learned by BERT do not differ too much, regardless of the **Post** and **Prefix** method chosen. However, the disordering may cause BERT's semantic understanding of context to be wrong, so the classification performance will be degraded.

B. Case Study

As shown in Table V, we display a case study on the Laptop dataset retrieved by three different retrieval metrics. From the example "Easy to start up and does not overheat as much as other laptops", we show the top 3 most similar sentences for each metric. We can intuitively find that the retrieved sentences show the same topic about "easy to use laptop" and the same polarity: positive. It proves that our retrieval metrics can successfully retrieve similar sentences from training data. Although we can not visually see how the neural network works with the retrieved sentences, we have shown that the

retrieved sentences have a very strong correlation with the original sentences.

VI. Conclusion

In this paper, we propose a simple and effective retrieval augmented method to fully make use of training data to enhance the semantic representations for aspect sentiment classification. Our proposed method is easily implemented with different language models and retrieval metrics on ASC task. The experimental results and analysis on three ASC benchmark datasets have shown the effectiveness and potential of the proposed method.

***Abstract*—Emotion recognition in conversations (ERC) is important for building human-like chatbots. Much research work has been devoted to the English community, however, there is still missing large-scale multimodal ERC dataset for the Chinese community. On the other hand, emotion states in the dynamic flow of conversations are typically subtle and complex. But currently most adopted emotion taxonomy for emotion recognition in conversations is based on Ekman's six basic emotion categories [1], which cannot cover the diverse set of emotions occurring in multi-turn dialogues, such as the emerging states of anxiety, puzzled and so on. In this paper, we present a Chinese multimodal conversational emotion analysis dataset (CH-MEAD), which contains $25,292$ video segments (utterances) labeled for 26 emotion categories (including *neutral*) and are collected from more than 400 Chinese TV series, movies and show. To our best knowledge, the CH-MEAD is the first large-scale Chinese multimodal conversational dataset with fine-grained emotion taxonomy, which is suitable for studying the speaker's subtle and complex emotion states in dialogues and will also promote the development of multimodal ERC in Chinese research community. Based on the CH-MEAD dataset, we propose a speaker-aware contextual multimodal fusion (SCMF) network and demonstrate its efficiency over the current SOTA models in our experiments[1].**

I. Introduction

With the popularity of conversational AI research, there has been a growing interest in the topic of multimodal emotion recognition in conversations (multimodal ERC) [2], [3]. The multimodal ERC task aims to identify the emotion of each utterance in a conversation based on the speaker's audio, visual, and textual modality information, which is crucial for building human-like chatbots [4] and has potential applications in many scenarios, such as education, health-care [5], and opinion mining in social media [6].

In the past decades, significant research work has been devoted to the multimodal ERC task. Among these, several manually annotated English multimodal emotional conversational datasets have been released, including IEMOCAP [7], MELD [8], and SEMAINE [9]. Though above public datasets have greatly promoted the research development in the field of multimodal ERC [2], [3], the vast majority of them adopt the Ekman's six basic emotion categories (joy, anger, fear, sadness, disgust, and surprise) [1], which covers a limited emotion taxonomy. Indeed, accompanied with the moving forward of conversations, some subtle and complex emotion states (i.e., curiosity, anxiety, etc.) which are not included in the Ekman's six basic emotion categories, frequently appear in dialogues. In view of this, a limited work has been devoted to building datasets with more emotion categories. [10] proposed a multimodal ERC dataset (CHEAVD) with 26 emotion categories. However, there is no textual modality in CHEAVD dataset, which is essential for multimodal emotion recognition. Moreover, the CHEAVD dataset has only $2,322$ samples, which is limited for the ERC task.

TABLE I
THE EMOTION TAXONOMY OF THE CH-MEAD DATASET, WHICH INCLUDES 8 PRIMARY EMOTIONS, 17 COMPOUND EMOTIONS, AND THE *neutral* CATEGORY.

Type	Categories
primary emotions	joy (高兴), sadness (悲伤), anger (愤怒), fear (恐惧), trust (信任), disgust (厌恶), surprise (惊讶), anticipation (期待)
compound emotions	love (爱), alarm (警觉), remorse (懊悔), contempt (蔑视), optimism (乐观), curiosity (好奇), pride (得意), guilt (内疚), envy (妒忌), disappointment (失望), pessimism (悲观), anxiety (焦虑), shy (害羞), puzzled (困惑), hesitant (犹豫), sympathetic (同情), schadenfreude (幸灾乐祸)
others	neutral (中立)

Compared with Ekman's basic emotion taxonomy, the Plutchik's wheel of emotions [11] is much more diverse and comprehensive, in which eight primary bipolar emotions are suggested, i.e., joy v.s. sadness, anger v.s. fear, trust v.s. disgust, and surprise v.s. anticipation. Also, [11] claimed that the primary emotion categories can be combined to represent the diverse set of human's subtle and complex emotions. Specifically, there are more than 20 binary compound emotions, such as love (joy + trust) and curiosity (trust + surprise) based on the primary emotions. Therefore, the Plutchik's wheel of emotions provides us a better tool for the modelling of human subtle and complex emotion states in dialogues.

[1]Our dataset will be released upon accepted.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Considering that the existing research work are most devoted to the English community, and there is still missing large-scale Chinese multimodal ERC dataset, this paper presents a Chinese multimodal conversational emotion analysis dataset (CH-MEAD) which contains audio, visual, and textual modality information, to lay foundations for the further development of multimodal ERC in the Chinese research community. We build the CH-MEAD's emotion taxonomy mainly based on the Plutchik's wheel of emotions [11] to alleviate the deficiency of the Ekman's six basic emotion categories. Specifically, We first include all eight basic emotions in our emotion taxonomy. For the compound categories in Plutchik's wheel of emotions, we filtered the ones which are rare in our daily life and cannot be clearly defined in psychology (e.g., *fatalism*) based on the votes of 5 recruited psychological professionals, and finally 12 compound emotions are kept. Considering the specificity of different cultures, we added another 5 compound emotions which are common in Eastern culture [12], i.e., shy, puzzled, hesitant, sympathetic, and schadenfreude, according to the advice of psychological professionals. The final 26 emotion categories (including *neutral*) are present in Table I. To ensure the diversity of samples in the annotated dataset, such as the variety of topics and speakers, we collected more than 400 Chinese TV series, movies and show from a large TV resource pool (> 1000) for the construction of our CH-MEAD dataset. As known, the generalization ability of model is highly correlated with the diversity of training samples. To ensure the quality of CH-MEAD dataset, we selected high quality video segments from the raw large TV resource pool by the recruited experts over two months. Then the annotation on above selected valid data are conducted by trained annotators over three months.

Based on the CH-MEAD dataset, we propose a speaker-aware contextual multimodal fusion (SCMF) network as a baseline, which first utilizes three long short-term recurrent neural networks (LSTM-RNNs) [13] to model the contextual information along the audio, visual, and textual modality respectively in a speaker-aware manner, and then performs the modality fusion based on several Transformer encoder networks [14]. Experimental results demonstrate the effectiveness of our SCMF model, and show that multimodal information is important for the emotion recognition in conversations.

II. Related Work

A. Multimodal Emotion Datasets

There has been much research work devoted to the task of multimodal emotion analysis. *The current available multimodal datasets for emotion or sentiment analysis are most non-conversational*, such as CMU-MOSI [15], CMU-MOSEI [16], MOUD [17], ICT-MMMO [18], YouTube [19], and CH-SIMS [20]. For the multimodal emotion analysis in conversations, several manually annotated datasets have been released, including the IEMOCAP [7], MELD [8]. However, all the above datasets built their emotion taxonomy based on the Ekman's six basic emotion categories, which are insufficient for the research of human dynamic and subtle emotion transition process in dialogues. [10] present a Chinese multimodal dataset with fine-grained emotion taxonomy (more than 20 emotion categories), i.e., CHEAVD, for the emotion analysis in conversations, but it only has the audio and visual modality and do not provides the textual information, which are important for the multimodal ERC task. And its emotion taxonomy are completely defined by annotators, which is lack the support of the psychological theory.

B. Emotion Taxonomy

Most existing emotion analysis datasets are constructed based on the six basic emotion categories proposed in [1] or along the affective dimensions (valence and arousal) that underpin the circumplex model of affect [21], [22]. Generally, the emotion taxonomy based on discrete categories are more intuitively interpretable than those based on the continuous affective dimensions. So this paper focused on the discrete emotion analysis.

Indeed, in the scenarios of multi-turn dialogue, the speaker's emotion expression is a dynamic process accompanied with the conversations moving forward, in which human emotion states are usually subtle and complex, such as the emerging of curiosity and anxiety, which are not included in the Ekman's six basic emotion categories but appears frequently in our daily life. Recent advances in psychology research have offered new conceptual and methodological approaches to capture the subtle human emotion expressions by studying the distribution of emotion responses to a diverse array of stimuli [23]. Studies guided by these principles have demonstrated that the emotion states of human are complex and delicate [24], [25], [26], which cannot be covered by the simple Ekman's six basic emotion categories. Plutchik's wheel of emotions [11] defines 8 primary bipolar emotions from four different dimensions and claims that the primary emotion categories can be combined to represent the diverse set of human subtle and complex emotions. Specifically, there are more than 20 compound emotion categories by combining the primary emotions. Therefore, the Plutchik's wheel of emotions offers researchers a better tool of diving deep into the human emotion analysis in conversations.

III. CH-MEAD Dataset

A. Data Collection

To ensure the diversity of samples in CH-MEAD dataset, we collected the raw data from a variety of Chinese television series, movies, and shows (a large pool of more than $1,000$ TV series/movies/shows, which are crawled from the Internet)[2]. Compared with the unimodal datasets, the requirements of multimodal datasets are relatively high. The principles for the data selection are listed as below:

[2]We consulted a legal office to verify that the academic usage and distribution of very short length videos fall under the fair use category.

1) The themes of candidate television series, movies, and show must come from real life scenarios. Fantasy novels and so forth are not accepted.
2) Mandarin is preferred and materials with regional accent are excluded. To ensure the clarity of the speaker's voice, the video segments with background music (sound) are also excluded.
3) The speaker's face and voice must appear in the frames at the same time, and there should be only the speaker appears in the pictures (no other person).

To ensure the quality of each single modality, we set individual standards for the audio, visual, and textual content respectively.

- *Audio & Textual*: The voice of the speaker must be clear, and if there's background noise, the SNR of the audio should $\geq 15db$. The textual transcription, including punctuations, must be accurate.
- *Visual*: The resolution of the video segments should $\geq$ 480p. The video pictures should be bright enough. In addition, only the video segments with camera angle $\leq 30°$ are selected.

We recruited 10 experts for the data selection. To ensure the judges are qualified, we showed them acceptable and unacceptable examples for each selection criterion and then asked them to finish a test. And only those passed the test can join the data selection process. We used the Adobe Premiere Pro[3] to crop the raw videos into utterance segments. Finally, $10,000$ video segments (from more than 400 Chinese television programs) are selected from the original video database by the qualified experts over two months.

B. Taxonomy of Emotions

As described in Section I, we build a fine-grained emotion taxonomy based on the Plutchik's wheel of emotions [11]. Specifically, we first include the primary eight emotion, i.e., joy, sadness, anger, fear, trust, disgust, surprise, and anticipation, into our emotion taxonomy. For the original compound emotion categories in Plutchik's wheel of emotions, we recruited 5 psychological professionals and asked them to vote for the ones which are common in our daily life and can be clearly identified by ordinary annotators. Finally, 12 compound emotion categories, i.e., love, alarm, remorse, contempt, optimism, curiosity, pride, guilt, envy, disappointment, pessimism, and anxiety are reserved. Considering the specificity of different cultures [12], the recruited 5 psychological professionals are asked to discuss other compound emotions which are common in Eastern culture but missing in Plutchik's wheel of emotions, and finally 5 compound emotions are included, i.e., shy, puzzled, hesitant, sympathetic, and schadenfreude. The final emotion taxonomy adopted in our dataset is shown in Table I.

C. Annotation

The data annotation in our work is performed by the recruited graduate annotators. We trained the annotators to minimize subjectivity and inconsistency as much as possible. Specifically, we first asked the professionals in psychology to label a subset of the valid data (300 utterances) collected in Section III-A to build a ground truth set. Then we show annotators the definition of each emotion category as in Table II, and half of the samples in the ground truth set are used to further illustrate different emotions and train the annotators, and the other half are used for testing. Only those who passed the test are qualified to participate in the data annotation.

Fig. 1. The online annotation interface used for building our dataset.

With reference to the number of annotators in existing multimodal ERC datasets (mostly 3-5 annotators) [7], [8], [10] and considering the cost of labeling (i.e., time and money), we assigned three annotators for each sample. The annotators were asked to label the emotion category for each utterance segment under the taxonomy defined in Table I. Except for these, the gender and age of the speaker are also required to mark. Specifically, the age is labeled as one of the child, teenagers, youth, middle-aged, and elderly. The online annotation interface present to the annotators is shown in Figure 1.

For each utterance segment, the majority annotated emotion was decided as the final label. And those without agreement (less than 2 consistent annotations) were discarded. Finally, we collected $8,787$ dialogs by three annotators over three months, which contain $25,292$ utterances totally from the $10,000$ valid video segments collected in Section III-A. The Fleiss's kappa score [27] on the final CH-MEAD dataset is 0.79, which demonstrates a substantial agreement among annotators.

Statistics & Discuss: The summary statistics of our labeled CH-MEAD dataset are present in Table III. We find that the speaker's gender distribution is very balanced, and most of the speakers are youth or middle-aged. Also, we find that about half of the dialogs collected in the CH-MEAD dataset has only 2 utterances, actually, this is because we adopted a very rigid standard for the data selection in Section III-A to ensure the quality of data. Table IV presents the number of utterance segments for each emotion category, we find that there are few examples for some emotion categories, such as fear and envy. We suspected that these emotions are rare in TV series, movies, and shows. We kept those emotion categories with few examples in our CH-MEAD dataset to provide an entrance to study the few-shot learning for the multimodal ERC task.

[3]https://www.adobe.com/products/premiere.html

TABLE II
THE DEFINITION OF EACH EMOTION PRESENT FOR THE ANNOTATORS.

Emotion	Definition
joy	Feel happy and comfortable
sadness	the feeling of being sad
anger	strong feeling of displeasure and hostility
fear	an emotion experienced in anticipation of some specific pain or danger
trust	the belief that somebody/something is good, sincere, honest, etc.
disgust	a strong feeling of dislike for somebody/something that you feel is unacceptable
surprise	an event, a piece of news, etc. that is unexpected or that happens suddenly
anticipation	a feeling of excitement about something (usually something good) that is going to happen
love	a very strong feeling of liking and caring for somebody/something
alarm	fear and worry that somebody feels when something dangerous or unpleasant might happen
remorse	the feeling of being extremely sorry for something wrong or bad that you have done
contempt	the feeling that somebody/something is without value and deserves no respect at all
optimism	a feeling that good things will happen and that something will be successful
curiosity	a strong desire to know about something
pride	a feeling of being pleased or satisfied that you get when you own something that other people admire
envy	feeling of discontent caused by sb else's good fortune or success
disappointment	a feeling of dissatisfaction that results when your expectations are not realized
pessimism	the feeling that things will turn out badly
anxiety	the state of feeling nervous or worried that something bad is going to happen
guilt	the unhappy feelings caused by knowing or thinking that you have done something wrong
schadenfreude	a feeling of pleasure at the bad things that happen to other people
shy	nervous or embarrassed about meeting and speaking to other people
puzzled	unable to understand something or the reason for something
hesitant	slow to speak or act because you feel uncertain, embarrassed or unwilling
sympathetic	kind to somebody who is hurt or sad

TABLE III
THE SUMMARY STATISTICS OF OUR LABELED CH-MEAD DATASET.

Number of dialogs	8,787
Number of utteraces	25,292
Average tokens per utterance	21.9
Number of emotions	25 + neutral
Dialog length	1: 9.7% 2: 44.2% 3: 22.0% 4: 11.5% ≥5: 12.6%
Speaker gender	male: 50.7% female: 49.3%
Speaker age	child: 1.9% teenager: 1.4% youth: 63.5% middle-aged: 30.0% elderly: 3.2%

TABLE IV
NUMBER OF UTTERANCE SEGMENTS FOR EACH EMOTION CATEGORY IN OUR LABELED CH-MEAD DATASET.

Emotion	#Num.	Emotion	#Num.
neutral (中立)	3606	joy (高兴)	2008
sadness(悲伤)	667	anger (愤怒)	2070
fear (恐惧)	153	trust (信任)	269
disgust (厌恶)	823	surprise (惊讶)	760
anticipation (期待)	1821	love (爱)	207
alarm (警觉)	228	remorse (懊悔)	217
contempt (蔑视)	1635	optimism (乐观)	582
curiosity (好奇)	2982	pride (得意)	1004
envy (妒忌)	120	disappointment (失望)	340
pessimism (悲观)	455	anxiety (焦虑)	1910
guilt (内疚)	399	schadenfreude (幸灾乐祸)	187
shy (害羞)	334	puzzled (困惑)	1594
hesitant (犹豫)	615	sympathetic (同情)	306

D. Feature Extraction

We trained three classifiers based on the utterance level audio, visual, and textual modality information respectively, and use these classifiers to extract the feature vector for each utterance from different modality information. Followings are the details:

1) Audio feature: For the input audio of each utterance, we first extract the 128-dim fbank acoustic features with the frame size of 50ms and frame shift of 12.5ms. Then the sequence of fbank acoustic features are input to a 1-layer long short-term memory recurrent neural network (LSTM-RNN), the max-pooling of the hidden states are used as the final audio feature representation for corresponding utterance, which has a dimension of 768.

2) Visual feature: Frames are extracted from the original video segments at 30Hz. The area of speaker's face for each image frame are cropped by the bounding box, which are derived by the MTCNN face detection algorithm [28]. Then

the cropped face images are all resized to 240×240 and input to the EfficientNet-B1 [29]. The max-pooling of the last feed-forward (FC) layer in EfficientNet-B1 is used as the final vector representation for corresponding utterance. The final extracted visual feature vector for each utterance has a dimension of 1280.

3) Textual feature: We fine-tune the pretrained BERT-base [30] using the text of each utterance as input, and the emotion label as the target. Specifically, the PyTorch implementation of BERT with the pretrained model file `bert-base-chinese` provided by Google was employed. The vector representation for token "[CLS]" of last Transformer layer is used as the final texutal feature representation for corresponding utterance, which has a dimension of 768.

IV. SCMF Network

Based on the CH-MEAD dataset, we propose a speaker-aware contextual multimodal fusion (SCMF) network for the emotion recognition in conversations. Figure 2 presents the overview architecture of our proposed SCMF model. Followings are the details:

For an input conversation with n utterances, its extracted audio, visual, and textual features are $[\mathbf{u}_1^a, \mathbf{u}_2^a, ..., \mathbf{u}_n^a]$, $[\mathbf{u}_1^v, \mathbf{u}_2^v, ..., \mathbf{u}_n^v]$, and $[\mathbf{u}_1^t, \mathbf{u}_2^t, ..., \mathbf{u}_n^t]$ respectively (see Section III-D). To better model the dependency among different speakers, the unimodal utterance representations are first concatenated with corresponding speaker embedding and then input to corresponding LSTM-RNN networks separately. The derived contextual unimodal representations are $[\mathbf{h}_1^a, \mathbf{h}_2^a, ..., \mathbf{h}_n^a]$, $[\mathbf{h}_1^v, \mathbf{h}_2^v, ..., \mathbf{h}_n^v]$, and $[\mathbf{h}_1^t, \mathbf{h}_2^t, ..., \mathbf{h}_n^t]$ respectively, which are the hidden states of corresponding LSTM-RNN cells.

The multimodal fusion module (MFM) in SCMF is built based on Transformer [14] encoder, which has been proved to be effective for the fusion of multimodal information [31]. As illustrated in Figure 2, a MFM network contains two unique Transformer encoders, which process the input two modality representation matrices in opposite directions. Specifically, for two different modality representation $H^A = [\mathbf{h}_1^A, \mathbf{h}_2^A, ..., \mathbf{h}_n^A]$ and $H^B = [\mathbf{h}_1^B, \mathbf{h}_2^B, ..., \mathbf{h}_n^B]$, the MFM module process them as follows,

$$\begin{aligned} \tilde{\mathbf{h}}_1^A, ..., \tilde{\mathbf{h}}_n^A &= Trans.(Q = H^A, (K, V) = H^B), \\ \tilde{\mathbf{h}}_1^B, ..., \tilde{\mathbf{h}}_n^B &= Trans.(Q = H^B, (K, V) = H^A), \\ \mathbf{u}_i^{AB} &= Concat([\tilde{\mathbf{h}}_i^A, \tilde{\mathbf{h}}_i^B]), i \in [1, n], \\ & A \in [a, v, t], B \in [a, v, t], A \neq B \end{aligned} \tag{1}$$

It's worth mentioning that the causal attention mask is applied for all Transformer encoders to ensure the subsequent utterances are unseen for current step. The final multimodal representation $\tilde{\mathbf{u}}_i$ for $i-$th utterance is the concatenation of $\mathbf{u}_i^{av}, \mathbf{u}_i^{at}, \mathbf{u}_i^{vt}$,

$$\tilde{\mathbf{u}}_i = Concat([\mathbf{u}_i^{av}, \mathbf{u}_i^{at}, \mathbf{u}_i^{vt}]), \tag{2}$$

The classification module in the SCMF model is a fully connected network with one linear hidden layer. It accepts the $\tilde{\mathbf{u}}_i$ as input and makes the final emotion prediction,

$$\begin{aligned} probs_i &= softmax(W\tilde{\mathbf{u}}_i + \mathbf{b}), \\ \hat{y}_i &= \arg\max_k(probs_i[k]). \end{aligned} \tag{3}$$

in which k is number of emotion categories.

V. Experiments

A. Baseline Models

Previous studies have shown that the utterance-level contextual modelling is essential for the emotion recognition in conversations [3], [32]. So we compare our SCMF model with current state-of-the-art models which consider the modelling of multi-turn dialogue context. The baseline models used in our experiments are as follows:

- **ICON**: [3] proposed the interactive conversational memory network (ICON), in which several gated recurrent units (GRUs) [33] are utilized to model the dialog context from self- and inter-speaker view respectively, and a memory block is also introduced to summary the global contextual information. *Different modality representations for each utterance are directly concatenated together and input to downstream networks in original ICON model.*
- **DialogueRNN**: The DialogueRNN model present in [34] treats parties in a conversation individually, and applied different GRUs for the contextual information modelling for different speakers. Also, it introduces another GRUs for the dynamic modelling of emotion states. *The audio, visual, and textual utterance representations are concatenated together and input to GRUs in DialogueRNN model.*
- **CIM**: [35] proposed the contextual inter-modal (CIM) attention model, in which the utterance-level unimodal representations are input to three different bi-directional GRUs respectively to perform the dialogue context modelling. Then an inter-modal attention module is utilized to perform the multimodal information fusion.
- **DAG-ERC**: [36] proposed the DAG-ERC model for emotion recognition in conversations, which combined the directed acyclic graph network with recurrent neural network to model the conversational context, and achieved impressive results in the ERC task. Similar with ICON and DialogueRNN, *three different modality representations for each utterance are concatenated together for downstream processing in DAG-ERC.*
- **MMGCN**: [37] proposed the MMGCN model to utilize both multimodal and long-distance contextual information based on multimodal fused graph convolutional network for the multimodal ERC task. The MMGCN model can not only make use of multimodal dependencies effectively, but also leverage speaker information to model inter-speaker and intra-speaker dependency.

To make the comparison experiments between different models more fair, **the extracted unimodal features in Section**

III-D are used as input for all baseline models and our proposed SCMF model.

B. Parameter Settings

The number of layers of LSTM-RNNs in our SCMF model are all set to 1. The dimension of the speaker embedding and hidden state of LSTM cell are set to 16 and 768 respectively. The number of layers, number of heads, dimension of hidden states for each Transformer encoder are set to 1, 16, and 768 respectively. The method of Adam [38] is adopted for optimization. The initial learning rate is 0.0001. Gradient clipping is set to 1, and the batch size is 32. Dropout with rate of 0.1 is used in the training process.

VI. RESULTS

We use the accuracy and weighted-average F1 score (denoted as Acc. and W.- F1 respectively) as the evaluation metrics in our experiments. We perform the experiments on 9-class's subset (8 primary emotion categories and the *neutral*) and 26-class's fullset respectively. The dataset are randomly split into train/dev/test set at a ratio of 3:1:1. The number of train/dev/test utterances in 9-class's subset and 26-class's fullset are $7,316/2,450/2,411$ and $15,161/5,074/5,057$ respectively.

A. Overall Performance

1) 9-class's subset: The overall evaluation results of different models on the 9-class's subset of CH-MEAD dataset are present in Table V. From Table V, we find that most models obtained better prediction scores on joy, anger, and neutral categories than other emotion categories with few samples. Compared with the baseline models which all utilized the same extracted unimodal features, we find that our proposed SCMF model achieved the best performance on both accuracy and weighted-average F1 score metrics, which obtains an improvement of 1.9% (over CIM) and 2.2% (over DAG-ERC) respectively .

2) 26-class's fullset: Table VI shows the performance of different models on the 26-class's fullset of CH-MEAD dataset. It can be found that our SCMF model outperformed other baseline models with obvious improvements, i.e., 2.3% (over CIM) on accuracy and 4.6% (over DAG-ERC) on

TABLE VI
THE OVERALL PERFORMANCE OF DIFFERENT MODELS ON THE 26-CLASS'S FULLSET OF CH-MEAD DATASET.

	Acc.	W.- F1
ICON	28.3	23.2
DialogueRNN	35.2	31.0
CIM	35.7	32.1
DAG-ERC	32.1	32.1
MMGCN	35.2	30.9
SCMF	**38.0**	**36.7**

TABLE VII
THE DETAILED F1 SCORE OF SCMF MODEL ON THE 26-CLASS'S FULLSET OF CH-MEAD DATASET.

Emotion	F1	Emotion	F1
neutral (中立)	46.2	joy (高兴)	48.3
sadness(悲伤)	19.6	anger (愤怒)	43.9
fear (恐惧)	35.3	trust (信任)	13.3
disgust (厌恶)	14.8	surprise (惊讶)	26.6
anticipation (期待)	39.6	love (爱)	41.8
alarm (警觉)	15.1	remorse (懊悔)	55.4
contempt (蔑视)	23.6	optimism (乐观)	20.9
curiosity (好奇)	58.2	pride (得意)	22.3
envy (妒忌)	32.4	disappointment (失望)	2.7
pessimism (悲观)	20.9	anxiety (焦虑)	33.4
guilt (内疚)	42.5	schadenfreude (幸灾乐祸)	8.3
shy (害羞)	35.4	puzzled (困惑)	38.5
hesitant (犹豫)	22.6	sympathetic (同情)	20.4

weighted-average F1 score metrics respectively. Table VII presents the detailed F1 score of SCMF model achieved on each emotion category, it can be found that there's a lot of room for improvement on a bunch of emotion categories, such as sympathetic, alarm, and trust, which has few samples, we believe these provide an entrance to study the few-shot learning for multimodal ERC task. Also, we find that the model's performance on different emotion categories is not proportional to the number of samples in each category, such as pride vs. remorse (F1: 24.1 vs. 62.3, #number: 1004 vs. 217), which indicates that some emotion categories are easy to distinguish, while others are difficult.

B. Ablation Studies

To inspect the effects of speaker information and fusion of different modalities in the SCMF model, we conducted several ablation studies. Specifically, we remove all speaker embeddings in the SCMF model and directly input the original extracted unimodal features of each utterance into the LSTM-RNNs to leave out the speaker information. To examine the importance of unimodal information, we use the contextualized unimodal representation output from the LSTM-RNNs, i.e., $\mathbf{h}_i^a$, $\mathbf{h}_i^v$, and $\mathbf{h}_i^t$, for the final emotion classification to evaluate the importance of audio, visual, and textual modality respectively. For the fusion of different modalities, we eliminate three unimodal features respectively and directly use the utterance encodings output from the MFM module, i.e., $\mathbf{u}_i^{av}$, $\mathbf{u}_i^{at}$, and $\mathbf{u}_i^{vt}$, for the emotion classification respectively.

TABLE VIII
THE ABLATION STUDIES FOR THE SCMF MODEL WITH CONSIDERING THE SPEAKER EMBEDDING AND FUSION OF DIFFERENT MODALITIES.

	9-class		26-class	
	Acc.	W.- F1	Acc.	W.- F1
A	33.9	25.4	18.1	9.4
V	41.1	35.4	22.5	15.5
T	48.2	47.7	33.2	31.0
A+V	46.2	42.1	25.4	20.9
A+T	49.6	48.8	34.6	33.2
V+T	52.0	51.2	36.5	35.1
A+V+T	54.9	54.2	38.0	36.7
w/o spk.	54.3	53.5	37.8	36.4

The evaluation results are present in Table VIII. We find that the performance of SCMF model slightly declined when without using speaker embeddings, which indicates the speaker identity information is useful for the multimodal emotion recognition in conversations.

For the effects of different unimodal information, we find that the textual input occupies the most important position, which owns obvious performance advantages over the audio and visual modality. And the audio inputs obtains the worst performance on both accuracy and weighted-averaged F1 score metrics. For the fusion of different two modalities, it can be found that the combination of visual and textual modalities, i.e., "V+T", outperformed the "A+V" and "A+T". Above comparison results imply the primary effects of textual information for the emotion recognition in conversations. Also, the results in Table VIII confirm the necessity of comprehensive utilization of audio, visual, and textual modality information for the speaker's emotion recognition.

VII. CONCLUSION

In this paper, we have presented a Chinese multimodal conversation emotion analysis (CH-MEAD) dataset, which contains $25,292$ video segments labeled for 26 emotion categories and collected from more than 400 Chinese TV series, movies, and shows. To our best knowledge, the CH-MEAD is the first large-scale Chinese multimodal conversation dataset with fine-grained emotion taxonomy, which allows researchers to dive deep into the modeling of speaker's subtle and complex emotional states in conversations, and provides an entrance to study the few-shot learning on the multimodal ERC task. Also, we proposed a speaker-aware contextual multimodal fusion (SCMF) network, which first models the contextual information along the audio, visual, and textual modality respectively in a speaker-aware manner, and then performs the modality fusion based on Transformer encoders. Experimental results demonstrate the effectiveness of our SCMF model and the importance of multimodal information for emotion recognition in conversations. To study the few-shot learning on the CH-MEAD dataset will be our future work.

***Abstract*—This paper studies the evolutionary dynamics and cultural transmission of color styles in painting arts. Creative cultures, such as visual arts, develop through repeated processes of knowledge transmission and modification, and characteristics of these processes can lead to macroscopic evolutionary patterns. While recent studies have found intriguing trends and dynamic patterns in the evolution of visual arts, the relationship between these trends and cultural transmission processes remains poorly understood. We first analyze the evolutionary dynamics of color distributions in oil paintings by applying a clustering method. The results reveal that some of the frequencies of the color style clusters exhibit synchronous changes that are related to creators' biases in producing paintings belonging to specific clusters. We subsequently construct models of cultural evolution to represent how these biases are transmitted between creators, based on two hypothetical transmission modes: one guided by influencer-to-descendant connections and another guided by community-to-descendant connections. Through statistical inference, we show that the influencer-guided transmission model better fits the historical data. Furthermore, highly influential creators, as inferred by the model purely from content data, remarkably align with those commonly mentioned in the literature on art history.**

I. Introduction

The recent advancement of generative AI [1]–[3] has drawn attention to the application of image processing in the field of arts, such as painting. The automatic creation technology based on machine learning enables the generation of images in diverse styles. While machine learning relies heavily on a large accumulation of image data historically created by humans, the generation of paintings in new creation styles remains a big challenge [4]. In fact, there is still limited quantitative and scientific understanding of the process in which humans develop new creation styles. If we can understand this human's creative intelligence, the knowledge can be utilized to realize automatically generating paintings in a much wider variety of styles than current systems.

Creative cultures have evolved through repeated processes of transmission and modification of creative knowledge. Cultural evolution including such cultural transmission processes has been studied based on theoretical analogies with biological evolution, and two factors, environmental and dynamical, in the evolution process are generally considered to shape evolutionary processes [5]. Environmental factors refer to various factors that generate selective pressure, and determine the direction and constraints of evolution. In the case of painting culture, these include people's preferences, the supply of painting materials, and social backgrounds such as economics and politics. On the other hand, dynamical factors refer to the effects caused by the processes of knowledge transmission, mutation, and selection, and are generally relevant for understanding the speed and regularities of evolution.

Research on the evolutionary analysis of painting art data, mainly focusing on Western art, has recently become an active field [6], thanks to the availability of large-scale digital data and the development of image analysis techniques including deep learning. Previous studies have found trends in certain time periods, in the entropy-complexity features used in physical system analysis [7] and in the features extracted by convolutional neural networks (CNNs) [8], [9]. It has also been shown that the characteristic temporal changes found in these analyses generally agree with the analysis by art experts, and the creators who represent the style of each era coincide with those widely mentioned in art history [7], [8], [10]. Another study suggested that there were significant changes in the average features of paintings, particularly during the 15th and 16th centuries, and in the late 19th century, from the analysis of color contrast, which can be associated with the popularization of oil paints and the increase in individuality in painting styles [11]. The existence of trends spanning several centuries and the presence of revolutionary periods with rapid changes have also been observed in music data, where similar evolutionary analysis has been conducted [12]–[15]. These quantitative results have revealed the relationship between the temporal changes in painting styles and social/environmental factors. However, the impact of dynamic factors due to cultural transmission on art evolution still remains poorly understood.

In this study, focusing on the fact that creators usually produce artworks in several creation styles, we investigate the impact of cultural transmission of these creative style distributions on macroscopic evolution of the painting culture. First, we analyze the color styles of oil paintings by using a clustering method and show that there are synchronous changes in the frequencies of certain color style clusters. We also confirm, through an analysis of the network of clusters obtained from creators belonging to multiple style clusters, that the creators' biased distribution of color styles had significant influence on the aforementioned synchrony.

To understand the process by which creators select the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

distribution of color styles, we construct cultural evolution models incorporating a transmission process of this distribution between creators and compare them with a random selection model. In cultural transmission, various modes of learning are generally possible, such as learning from a specific influencer, as in a master-descendant relationship, or learning from numerous creators or artworks. We here consider two extreme possibilities: *influencer-guided* transmission, where one influencer is mainly involved in the transmission, and *community-guided* transmission, where the average features from a community of creators are transmitted. We formulate the mathematical models to represent these hypothetical cases. Through statistical inference based on these models, we show that the influencer-guided transmission model better explains the historical data. Furthermore, we validate the potential of this model, which allows for the estimation of the creator's fitness (influence) from image data by unsupervised learning, by measuring the degree of match between creators with high estimated fitness and those mentioned in an influential textbook on art history.

II. Cluster Analysis of Color Style

A. Materials and method

We used image data of mostly Western art paintings obtained from a public website WikiArt.org. Some meta data are associated with the obtained image data, including the year of production, creator's name, and media (materials). For our analysis, we extracted artworks with media labeled as "oil", resulting in 32 401 artworks. We then extracted color frequency statistics from each of the images as follows. First, all images were converted to 100×100 pixels by downsampling (Fig. 1). Second, we applied color reduction to $I = 40$ representative colors, which form a set of equally spaced points in the cone-shaped HSV color space. Third, the relative frequencies $\boldsymbol{\theta}_n = (\theta_{ni})_{i=1}^{I}$ of the representative colors i for each image n were computed. The tuple $(a_n, t_n, \boldsymbol{\theta}_n)$ of creator a_n, year of production t_n, and color statistics $\boldsymbol{\theta}_n$ was used for the following analysis. The years of production in the data ranged from 1270 to 2022. The number of distinct creators was 1128.

To quantitatively study the evolution of creation styles, we analyze the temporal changes in the distribution of color statistics. To deal with the high-dimensional space of the statistics, we first apply clustering in this space to identify several concentrated regions, which we call color style clusters. Specifically, we use for clustering the discrete distribution mixture model defined as

$$P(\boldsymbol{\theta}_n) = \sum_{k=1}^{K} \pi_k P(\boldsymbol{\theta}_n | \bar{\boldsymbol{\theta}}_k),$$

where K is the number of clusters, π_k denote the probabilities of clusters (called the mixture probabilities), and $\bar{\boldsymbol{\theta}}_k$ is the mean statistics of cluster k. The k-th component discrete distribution model $P(\boldsymbol{\theta}_n | \bar{\boldsymbol{\theta}}_k)$ is defined as

$$P(\boldsymbol{\theta}_n | \bar{\boldsymbol{\theta}}_k) = \prod_{i=1}^{I} \bar{\theta}_{ki}^{L\theta_{ni}},$$

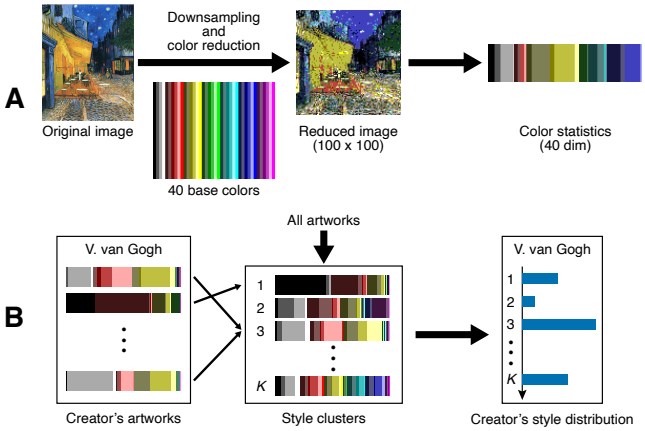

Fig. 1. Processes for analyzing color styles. A: Preprocessing for extracting color statistics. B: Color style clusters and creator's style distribution.

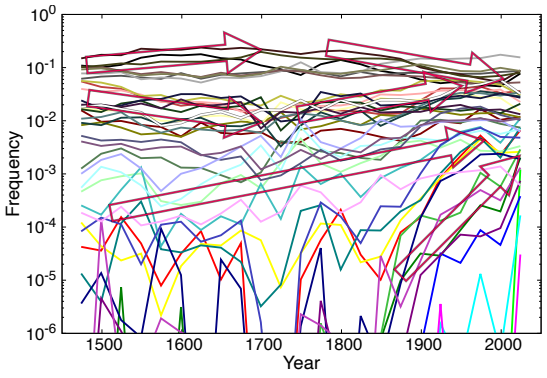

Fig. 2. Evolution of color frequencies. The plotted lines are colored in the indicating base colors (while line is shaded). Arrows indicate notable trends.

where L is an auxiliary parameter corresponding to a "sample size" to compute the probability. The clustering algorithm can be derived based on the expectation-maximization (EM) algorithm. In the E-step, the posterior probability is computed as $P(k|n) \propto \pi_k P(\boldsymbol{\theta}_n | \bar{\boldsymbol{\theta}}_k)$, where L is set as $L = 10\,t$ (t denotes the iteration time) and plays a similar role as the inverse temperature in the simulated annealing method. In the M-step, the mixture probability is updated as $\pi_k \leftarrow \sum_n P(k|n)$ and the mean statistics as $\bar{\theta}_{ki} \leftarrow \sum_n P(k|n)\theta_{ni}$. Note that we apply the clustering without using the temporal information t_n. After the convergence of the EM algorithm, we assign each artwork n to the most probable cluster $k_n = \operatorname{argmax}_k P(k|n)$, for subsequent analyses.

To get an overview of the temporal changes of the distribution of data samples, we also project the color statistics on a two-dimensional visualization space. For this purpose, we use the t-SNE method [16] with the Jensen-Shannon divergence used as the distance measure. This dimensional reduction process is conducted independently of the clustering and is used only for visualization.

B. Results

We used images whose year of production is 1450 or later because there were only a small number of images produced

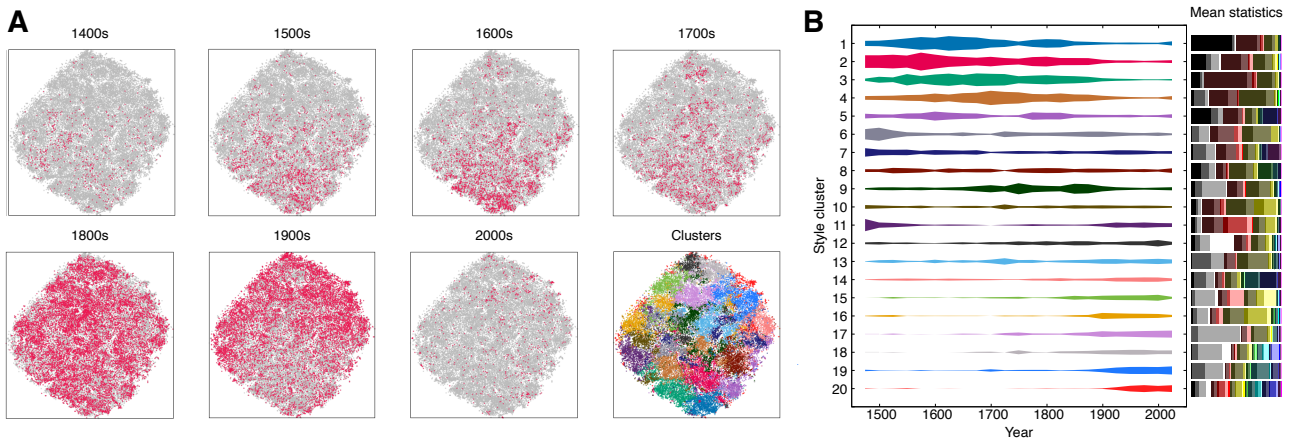

Fig. 3. A: Distribution of artworks in the visualization space. Red dots indicate artworks in each period and gray dots represent all the artworks. In the 'cluster' panel, artworks are illustrated in the colors of the clusters they belong to (cluster colors are arbitrary). B: Evolution of style cluster frequencies.

before the year. Fig. 2 shows the temporal evolution of the relative frequencies of colors, where the frequencies were calculated for each 25-years window. The most frequent colors have low brightness and low saturation, and bright and high-saturation colors are generally rare. Several trends can be observed in this figure, as indicated by arrows. First, from the 15th century to the 17th century, some of the most frequent colors increased their frequencies in the data, whereas some relatively frequent bright colors decreased their frequencies. The frequencies of these colors changed in opposite directions from the mid-18th century to the 20th century. Second, several rare bright colors had an overall gradual increase of the frequency from the 16th century to the 20th century. Last, the frequencies of vivid colors that were rarely used in early centuries increased rapidly from the mid-19th century onwards. While these general trends provide some insights, the periodwise average frequencies cannot represent variation and biases of color combinations in individual artworks. The analysis method based on style clusters solves this problem, as presented in the results below, thus providing a useful framework for studying underlying evolutionary processes.

The results of clustering and visualization of color statistics are shown in Fig. 3, where we used $K = 20$ clusters to approximate the distribution. In the visualization space, most artworks in early centuries are located in the lower half region, which represents color combinations containing mostly dark colors. Several important observations can be made in the evolution of the relative frequencies of color style clusters. First, we can observe concurrent and transient cluster structure [13], [17], that is, several clusters are active in each time period and active clusters gradually change over time. That there always exist several active clusters reflects the fact that there are usually multiple art styles and genres in any society. Second, there are two notable periods where multiple style clusters arose: from the 15th to the 16th centuries, and from the mid-19th to the mid-20th centuries. These time periods coincide with the previous result [11] showing periods with significant changes in color contrast. Third, we can observe some style clusters with synchronous rises and declines. For example, clusters 1 and 3, and clusters 17 and 18 respectively have synchronous rises in different centuries. These results indicate the presence of regularities in the evolution of color styles. In the next section, we analyze this synchrony in more detail and study its relationships with creators' behavior.

III. Synchronous Changes of Style Cluster Frequencies and Creators' Style Distributions

A. Analysis method

The relative frequencies of style clusters, as depicted in Fig. 3, can be expressed as a time-dependent mixture probability $\pi_k(t)$. The local synchrony $S_{kk'}(t)$ between the rises and declines of clusters k and k' can be formulated as

$$S_{kk'}(t) = \frac{1}{\sqrt{C_k C_{k'}}} \frac{\mathrm{d}\pi_k(t)}{\mathrm{d}t} \frac{\mathrm{d}\pi_{k'}(t)}{\mathrm{d}t},$$

where $C_k = \int \mathrm{d}t \, (\mathrm{d}\pi_k(t)/\mathrm{d}t)^2$ is a normalization constant. The (overall) synchrony can be defined as $S_{kk'} = \int \mathrm{d}t \, S_{kk'}(t)$. In the numerical analysis, the mixture probabilities are observed at discrete time steps, and the differentials and integration in these equations should be replaced with differences and summation w.r.t. time. It is noted that since the relative frequencies must sum up to unity, a rise of a cluster naturally induces a decline of another, and $S_{kk'}$ generally has a negative value if the relative frequencies of clusters k and k' fluctuate independently. Therefore, a positive value of $S_{kk'}$ indicates synchronous changes between the two clusters.

There are at least two possible factors that cause synchronous changes of cluster frequencies. First, some style clusters with similar mean color statistics, such as those located closely in the visualization space in Fig. 3, can represent separate parts of the same color style. In such a case, a change in the frequency of a color style can result in coherent changes in the frequencies of the relevant clusters. Second, the behavior of creators who usually produce artworks in several creation styles can induce the synchrony between clusters that do not necessarily represent similar color statistics. For

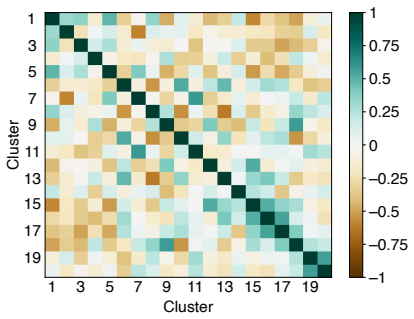

Fig. 4. Pairwise synchrony $S_{kk'}$ between clusters.

example, there are many creators who produced both portraits and landscapes, each of which are usually painted in different color combinations, and a change of artistic taste shared in a community can result in a synchronous change of color styles of both genres. To study this aspect, we calculate the *color style distribution* $\boldsymbol{\pi}_a = (\pi_{ak})_{k=1}^K$ of creator a, by counting the number of artworks by the creator belonging to cluster k and normalize the frequencies.

In both cases, some relations, feature similarity or association through creators, induce connections between clusters that lead to synchronous changes in the cluster frequencies. As in the case of association through creators, such connections can temporally change in general. These connections can be expressed as a weighted network $A(t) = \{A_{kk'}(t)\}$ of clusters, where edges $A_{kk'}(t)$ represent the degree of connection between clusters k and k' at time t. The contribution of a network on the synchrony can be quantified as $S(A) = \int \mathrm{d}t \sum_{kk'} A_{kk'}(t) S_{kk'}(t)$. To compare different networks, we impose conditions that self-connections are zero ($A_{kk}(t) = 0$) and that a normalization condition $\sum_{kk'} A_{kk'}(t) = 1$ holds.

To examine possible factors of the synchrony of style cluster frequencies, we consider the following four cluster networks. (i) Uniform network: $A_{kk'} = 1/(K-1)$ ($k \neq k'$). This is a null hypothesis. (ii) Feature similarity network: $A_{kk'} \propto \sum_i \bar{\theta}_{ki} \bar{\theta}_{k'i}$. This represents the cosine similarity between the mean statistics of the clusters. (iii) Creator-mediated association network: $A_{kk'}(t) \propto \sum_a D(t,a) \pi_{ak} \pi_{ak'}$, where $D(t,a) = 1$ if creator a is relevant at time t and 0 otherwise. This represents the co-occurrence of style clusters in the artworks produced by individual creators. (iv) Frequency-based association network: $A_{kk'}(t) \propto \pi_k(t) \pi_{k'}(t)$. This represents a hypothetical situation where creators choose the style clusters of their artworks by randomly sampling from the cluster frequencies of the time, and consequently their style distributions π_{ak} coincide with $\pi_k(t)$ of time t when creators a are active. We compare these networks in terms of the derived synchrony $S(A)$; if a network $A_{kk'}(t)$ is relevant to the macroscopic evolution of the cluster frequencies, then $S(A)$ is expected to be large.

B. Results

Fig. 4 shows the pairwise synchrony $S_{kk'}$ between style clusters, where we have used discrete time steps of 25-year width. We see some off-diagonal elements with positive values,

TABLE I
DERIVED SYNCHRONIES FOR DIFFERENT CLUSTER NETWORKS.

Network A	Derived synchrony $S(A)$
Uniform	-0.042
Feature similarity	-0.007
Creator-mediated association	0.033
Frequency-based association	-0.034

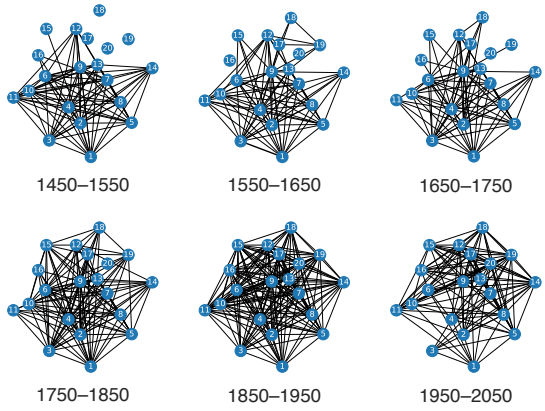

Fig. 5. Creator-mediated cluster networks in different centuries. The nodes are located similarly as the cluster centers in the visualization space in Fig. 3.

while a majority of the elements have negative values. Table I lists the derived synchronies for the four cluster networks. Only the creator-mediated association network yielded a positive synchrony, indicating that the creators' style distributions had an impact on the dynamics of style cluster frequencies and induced the synchronous changes. The result also suggests that the feature similarity of clusters also induced the synchrony. On the other hand, the small derived synchrony by the frequency-based network indicates that creators' style distributions deviated from the random selection case, in a biased and coherent (i.e. shared by many creators of the same time) way.

The creator-mediated cluster networks visualized in Fig. 5 clearly show that the association of clusters changed considerably over centuries. The connection weights between some clusters are much larger than others, and we can observe some edges between distant clusters with distinct styles also have large weights. Overall, these results show that creators' color style distributions are biased in a coherent way that cannot be simply explained by the feature similarity or random selection of style clusters, and as they vary over time these biased style distributions markedly affected the macroscopic evolution of color styles in painting arts.

IV. Cultural transmission of color style distributions

A. Cultural evolution models for creators' style distributions

The biased and coherent color style distributions of creators discussed in the previous section pose an important question: How did the creators' style distributions determine? While certain social factors such as the demand from the church or patrons are conceivable, we here focus on a simple possibility

of cultural transmission. Since complex knowledge about the art of paining is usually learned from other creators or their artworks, it is possible that the color style distribution is transmitted in this learning process.

We construct two models to examine what particular mode of cultural transmission is plausible to explain the data. In cultural phenomena, unlike in genetic evolution, the number of cultural parents is not limited to one (asexual) or two (sexual), and transmission from a varying number of cultural parents are possible. We thus consider two hypothetical situations that represent extreme cases within a broad range of possibilities. In the first *influencer-guided* transmission model, we suppose that a creator learns his/her creation style mainly from a specific influencer's artworks, as in a master-descendant relationship. In the second *community-guided* transmission model, we suppose that a creator learns the creation style from numerous creators' artworks belonging to some stylistic community. In the following, we mathematically formulate these models.

We formulate the cultural evolution models based on a stochastic description of the transmission-mutation-selection process [5]. This is a formulation similar to the models of biological evolution used in population genetics [18], except that the potential of a past creator to produce cultural offspring can in principle continue for long after his/her death. We denote by $t_a^{\rm s}$ the year that creator a started creation, which is defined as the earliest year of the creator's artworks in the data. Let $\tilde{\boldsymbol{\pi}}_a = (\tilde{\pi}_{ak})_{k=1}^K$ denote the frequency counts of style clusters in artworks of creator a. By normalizing these frequencies, we obtain the style distribution $\boldsymbol{\pi}_a$. We also denote by $\boldsymbol{\pi}_a^{<t}$ the style distribution obtained from the artworks of creator a produced before year t. Our cultural evolution models are formulated as explicit realizations of the probability distribution $P(\tilde{\boldsymbol{\pi}}_a)$ for all creators a.

B. Influencer-guided transmission model

In the influencer-guided transmission model, each learner creator selects an influencer creator among previous creators and learns the influencer's style distribution. This model can be formulated as

$$P(\tilde{\boldsymbol{\pi}}_a) = \sum_{a':t_{a'}^{\rm s}<t_a^{\rm s}} P_{\rm sel}^{t_a^{\rm s}}(a') P_{\rm dis}(\tilde{\boldsymbol{\pi}}_a|\boldsymbol{\pi}_{a'\to a}),$$

where the summation is taken over all potential creators a' with $t_{a'}^{\rm s} < t_a^{\rm s}$, $P_{\rm sel}^{t_a^{\rm s}}(a')$ is the selection probability of the influencer a' of creator a, $\boldsymbol{\pi}_{a'\to a}$ represents the style distribution transmitted from a' to a, and the last factor is given as a discrete probability distribution

$$P_{\rm dis}(\tilde{\boldsymbol{\pi}}_a|\boldsymbol{\pi}_{a'\to a}) = \prod_k [\pi_{(a'\to a)k}]^{\tilde{\pi}_{ak}}. \tag{1}$$

We incorporate two biases in the selection probability to represent potential tendencies of learner creators, which are similar to those used for modeling citation dynamics of scientific papers [19]. The first is the recency bias, which represents the creators' tendency to more likely choose a reference influencer that lived more recently. This bias can be represented by a weighting factor $\mathrm{e}^{-(t_a^{\rm s}-t_{a'}^{\rm s})/\tau_{\rm c}}$, where the time constant $\tau_{\rm c}$ represents the time scale for the bias. The second bias is the (intrinsic) fitness of an influencer, which represents a time-independent likelihood of being learned by successors due to possible factors such as prestige and visibility. To represent this bias, we introduce a fitness parameter $v_{a'}$ for each creator. We also require that a potential influencer a' must have produced at least $N_{\rm bound}$ artworks (specifically, we set $N_{\rm bound} = 7$). The selection probability can then be given as

$$P_{\rm sel}^{t_a^{\rm s}}(a') \propto \mathbb{I}(t_{a'}^{\rm s} < t_a^{\rm s})\, \mathbb{I}(N_{a'}^{<t_a^{\rm s}} \geq N_{\rm bound})\, \mathrm{e}^{-(t_a^{\rm s}-t_{a'}^{\rm s})/\tau_{\rm c}+v_{a'}}, \tag{2}$$

where $\mathbb{I}(\mathcal{C}) = 1$ if condition $\mathcal{C}$ is true and otherwise $\mathbb{I}(\mathcal{C}) = 0$, and $N_{a'}^{<t}$ denotes the number of artworks produced by creator a' before year t.

The transmitted style distribution represents the influencer's style distribution with modifications including mutations. Here, we include the influence of creators other than the influencer since it is certainly possible that a learner creator observes many others' artworks and is influenced by the average style distribution of the time. This situation can be formulated as

$$\boldsymbol{\pi}_{a'\to a} = (1-\eta-\epsilon)\boldsymbol{\pi}_{a'}^{<t_a^{\rm s}} + \eta\, \boldsymbol{\pi}^{<t_a^{\rm s}} + \epsilon\, \mathbf{1}/K,$$

where $\boldsymbol{\pi}^{<t_a^{\rm s}}$ represents the average style distribution at (just before) time $t_a^{\rm s}$, $\mathbf{1}/K = (1/K, \ldots, 1/K)$ denotes a uniform distribution, and η and ϵ are nonnegative constants. The first, second, and third terms on the right-hand side represent the transmission from the influencer, transmission from the average style distribution of the time, and random mutation, respectively. The average style distribution $\boldsymbol{\pi}^{<t}$ also incorporates the recency effect and is defined as

$$\pi_k^{<t} \propto \sum_{n:t_n<t} \mathbb{I}(t_n < t)\mathbb{I}(k_n = k)\, \mathrm{e}^{-(t-t_n)/\tau_{\rm p}}, \tag{3}$$

where the summation is taken over all artworks n produced before t, k_n denotes the cluster assigned to n, and $\tau_{\rm p}$ denotes the time constant for artworks. The parameters η and ϵ represent the strength of the second and third terms and are called the oblique transmission coefficient and the random mutation rate, respectively. It is noted that the time-decaying factors in Eqs. (2) and (3) reduce the influence of past creators and artworks as time proceeds. Additionally, the restrictions on time in these equations ensure the causal constraint that future information is not used in the definition of probability $P(\tilde{\boldsymbol{\pi}}_a)$.

C. Community-guided transmission model

In the community-guided transmission model, we consider that a learner creator first analyzes previous artworks and finds communities of creators sharing similar style distributions. The learner creator then selects a community and learns the mean style distribution of the community. This model is described as

$$P(\tilde{\boldsymbol{\pi}}_a) = \sum_{c=1}^{C} \psi_c^{<t_a^{\rm s}} P_{\rm dis}(\tilde{\boldsymbol{\pi}}_a|\boldsymbol{\pi}_{c\to a}), \tag{4}$$

where c indexes communities of creators, C is the number of communities, $\psi_c^{<t}$ represents the selection probability of

communities at time t, and $\boldsymbol{\pi}_{c\to a}$ represents the style distribution transmitted from community c to creator a. The discrete probability distribution $P_{\rm dis}(\tilde{\boldsymbol{\pi}}_a|\boldsymbol{\pi}_{c\to a})$ is the same as in Eq. (1). The creator communities are formalized as a dynamic mixture model with the following log-likelihood:

$$\mathcal{L}(t) = \sum_{\substack{a:t_a^{\rm s}<t,\\ N_a^{<t}\geq N_{\rm bound}}} \mathrm{e}^{-(t-t_a^{\rm s})/\tau_{\rm c}} \ln\Bigg[\sum_c \psi_c^{<t} P_{\rm dis}(\tilde{\boldsymbol{\pi}}_a^{<t}|\boldsymbol{\pi}_c^{<t})\Bigg], \tag{5}$$

where $\tau_{\rm c}$ is the creator time constant, $\psi_c^{<t}$ is the mixture probability, and $\boldsymbol{\pi}_c^{<t}$ is the mean style distribution of community c. Assuming that how creators analyze the community structure is time-dependent and recent creators are given more attention in this process, the time-decaying factor $\mathrm{e}^{-(t-t_a^{\rm s})/\tau_{\rm c}}$ is introduced to weigh the creators' contributions on the likelihood. We use in Eq. (4) the parameter values of $\psi_c^{<t}$ and $\boldsymbol{\pi}_c^{<t}$ that maximize Eq. (5). See Sec. IV-D for the inference method.

The transmitted style distribution in Eq. (4) is formulated similarly as in the influencer-guided transmission model: we suppose that the mean style distribution of the selected community has the dominant influence, but the mean average style distribution of the time also has some influence and there is a small chance of random mutation. This situation can be formalized as

$$\boldsymbol{\pi}_{c\to a} = (1-\eta-\epsilon)\boldsymbol{\pi}_c^{<t_a^{\rm s}} + \eta\,\boldsymbol{\pi}^{<t_a^{\rm s}} + \epsilon\,\mathbf{1}/K,$$

where η represents the oblique transmission coefficient also in this model.

D. Inference method

The main purpose of the evolution models presented in the previous sections is to compare the two hypotheses on the cultural transmission process. Both models are formulated as realizations of the same probability distribution $P(\tilde{\boldsymbol{\pi}}_a)$, and we can compare them by their total log-likelihoods normalized by the total number of artworks

$$\mathcal{L}_{\rm tot} = \Bigg(\sum_a \ln P(\tilde{\boldsymbol{\pi}}_a)\Bigg)\Bigg/\Bigg(\sum_{a,k}\tilde{\pi}_{ak}\Bigg),$$

or the exponentiated quantities $\kappa = \exp(\mathcal{L}_{\rm tot})$ called the perplexity. The perplexity can be interpreted as the effective number of style clusters to choose. The smaller this quantity is, the more predictive a model is. The log-likelihood value $\mathcal{L}_{\rm tot}$ depends on the model parameters in both evolution models. Following the maximum likelihood principle, we estimate the model parameters to maximize $\mathcal{L}_{\rm tot}$, that is, we compare the two models in their optimal conditions. Since the values of the mutation rate ϵ and artwork time constant $\tau_{\rm p}$ did not affect the likelihood so much, as they are effectively smoothing constants, we fixed them as $\epsilon = 10^{-6}$ and $\tau_{\rm p} = 20$ yrs. In the following, due to the lack of space, we briefly explain specific methods for the inference of model parameters.

In the influencer-guided model, the model parameters to be estimated are $\{v_a\}$, $\tau_{\rm c}$, and η. We use an iterative method for optimizing these parameters; when one parameter (set) is optimized the other parameters are fixed. For creators' fitness v_a, we use the expectation-maximization (EM) algorithm with the influencer variable a' treated as a latent variable for each learner creator a, which can be derived in a manner similar to the Gaussian mixture model. For parameters $\tau_{\rm c}$ and η, we use the grid search method.

In the community-guided model, the model parameters to be estimated are $\{\psi_c^{<t}, \boldsymbol{\pi}_c^{<t}\}$, $\tau_{\rm c}$, and η. We again use an iterative method for optimizing these parameters, and the parameters $\tau_{\rm c}$ and η are optimized by grid search. We use the EM algorithm for estimating $\psi_c^{<t}$ and $\boldsymbol{\pi}_c^{<t}$ with the likelihood function in Eq. (5). To ensure the temporal consistency of the community estimation, we first perform community estimated on a coarse time scale of 25-years width and use this result to initialize the parameters $\psi_c^{<t}$ and $\boldsymbol{\pi}_c^{<t}$ for individual years.

TABLE II
PERPLEXITIES AND ESTIMATED PARAMETERS OF THE EVOLUTION MODELS. RESULT FOR THE MODEL USED FOR ANALYZING CREATOR FITNESS (SEE TEXT) IS ALSO SHOWN AT THE BOTTOM.

Model	Perplexity	$\tau_{\rm c}$ (yrs)	η
Random	19.1	NA	NA
Influencer-guided (optimal)	15.6	117	0.37
Community-guided ($C = 10$)	16.4	160	0.38
Community-guided ($C = 20$)	16.2	110	0.52
Community-guided ($C = 30$)	16.1	220	0.58
Influencer-guided (for analysis)	16.2	50	0.1

E. Results

Table II shows the model comparison result. As a reference, we also compared the random model where a creator generates artworks with cluster frequencies $\tilde{\boldsymbol{\pi}}_a$ according to the temporal average style distribution $\boldsymbol{\pi}^{<t_a^{\rm s}}$: $P(\tilde{\boldsymbol{\pi}}_a) = P_{\rm dis}(\tilde{\boldsymbol{\pi}}_a|\boldsymbol{\pi}^{<t_a^{\rm s}})$. The creator time constant $\tau_{\rm c}$ was estimated in the resolution of approx. 1 year for the influencer-guided model, and 10 years for the community-guided model, due to the large computational cost of the latter model. We tested $C = 10$, 20, and 30 for the community-guided model. Compared to the random model, the influencer-guided and community-guided models both had significantly lower perplexities, indicating a clear effect of cultural transmission. We see that the number of communities C does not have much impact on the perplexity, while large values of the oblique transmission coefficient were estimated for $C = 20$ and 30, suggesting that these models overfitted the community structure. By comparison, the influencer-guided model had a smaller perplexity, which shows that influencer-guided transmission better fits our data. On the other hand, the oblique transmission coefficient was also relatively large for this model, implying that the color style distribution is learned not only from one influencer but also from others. The estimated value $\tau_{\rm c} = 117$ yrs suggests that the influence of past creators sustains for a relatively long time.

An interesting possibility of the influencer-guided model is that it can estimate the fitness (influence) of creators in an unsupervised manner. To examine the model's potential,

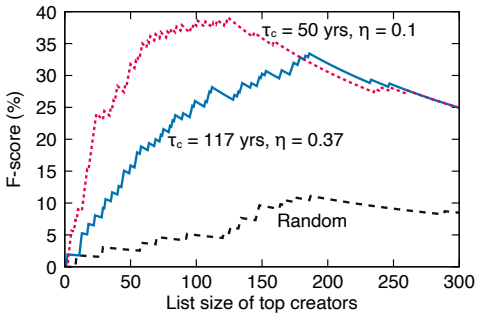

Fig. 6. Comparison of F-score measuring the accuracy of estimating influential creators in comparison with Gombrich's book [20].

we compared the list of creators with high estimated fitness with the list of creators appearing in Gombrich's classical textbook on art history [20]. Among the creators listed in [20], we removed a few who did not have major activities of painting and obtained a list of 101 creators. Using the model estimation, we made lists of varying sizes containing creators with the highest fitness, and we calculated the F-score to measure how much the results align with the Gombrich's list. We also conducted a similar calculation for a randomly sorted list of creators. The result in Fig. 6 shows that the F-score curve by the influencer-guided model with maximum likelihood parameters had significantly high values than that for the random list. While this result is already remarkable, we found that with alternative parameterization with a shorter time constant $\tau_c = 50$ yrs and a smaller oblique transmission constant $\eta = 0.1$, the F-score curve had even higher values (Fig. 6), even though the perplexity becomes higher (Table II). We discuss this mismatch between the optimized models for the likelihood measure and the accuracy of estimating "well-known" creators in the discussion section.

The 25 creators with the highest estimated fitness by the influencer-guided model with $\tau_c = 50$ and $\eta = 0.1$ are shown in Table III. We can see that the list includes creators active in various centuries. Importantly, the list contains creators with a relatively small number of artworks in the dataset, including such well-known creators as S. de Vlieger, R. Lichtenstein, and H. Hoffman. This result shows that the model predicts the fitness not merely from the number of artworks in the data, which although highly correlates with the creator's prestige. That this result was obtained purely from the image data and the meta data about the year of production for ensuring causal constraints demonstrates the potential of the present model for quantitatively and objectively analyzing painting art data and cultural evolution.

TABLE III
HIGHEST FITNESS CREATORS ESTIMATED BY THE INFLUENCER-GUIDED MODEL ($\tau_c = 50$ YRS, $\eta = 0.1$). NAMES IN BOLD FONTS INDICATE THOSE APPEARING IN GOMBRICH'S BOOK [20].

Fitness e^{v_a}	Creator a	Year t_a^s	No. of works

V. CONCLUSIONS AND DISCUSSION

We have analyzed the evolution of color styles in painting arts using statistical machine learning and evolutionary modeling methods. By analyzing the dynamics of color style clusters, we have found synchronous changes in the cluster frequencies. We also found that creators' color style distributions are biased in a coherent way and this property is a major factor of this macroscopic phenomenon. We then constructed cultural evolution models incorporating transmission and selection processes of creators' color style distributions and found that the influencer-guided transmission model better fits the data than the community-guided transmission model. We also showed that the model can estimate the creators' fitness by unsupervised learning and automatically discover important figures in the history of painting art only from the image data. All together, these results indicate that in the cultural transmission of knowledge about painting styles, not only the average color combinations but also the distribution of different sets of color combinations is transmitted from creators to creators, and this microscopic process of individual creators can lead to the macroscopic patterns in the evolution of painting style.

It should be emphasized that the present models represent a simplified description of the real evolutionary process. For example, the model can be extended to include more than one cultural parent, or dynamic changes in the parameters such as the creator time constant and the oblique transmission coefficient. The mismatch of the preferred parameterizations by the maximum likelihood estimation and the optimal accuracy of reproducing the human expert's account, found in Sec. IV-E, may be an indication of such incompleteness of the current model. It may also be possible that the present model, which "analyzes" a much larger amount of data than a human can, can find objectively correct results that humans may not find easily. Therefore, future work should study more elaborated models and examine how these models will (or will not) alter the results, and additionally, conduct a benchmark test, for

example, using synthetic data, to quantitatively measure the ability of the present model. It is also important to examine the influence of the number and values of representative colors, which were somewhat arbitrarily chosen in this study.

Our result has prospective applications for enhancing the generative AI technology. Using the evolution model with influencer-guided transmission, we can estimate the transmission paths of knowledge about creation style. In scientometrics, for example, such knowledge reference data (i.e. citation data) are used as fruitful sources for studying the dynamics of creative activities including the quantification of the scientific contribution [21], the formation of communities [22], and the nature of creativity [23], [24]. Since complete knowledge transmission paths are rarely provided in self-reports or historians' accounts especially in art fields [25], a data-driven method would provide useful complemental data for revealing the mechanisms by which new creation styles are developed. The found mechanisms can be integrated with machine learning techniques to realize "creative" generative AIs, for example, using the framework of evolutionary computation.

Finally, the present framework of applying a model integrating a probabilistic generative process and cultural evolution process can be applied to a wide domain of data. While we focused on the color style in this study, there are other important stylistic features such as spatial composition, brushstroke pattern, and painted objects. We can apply DNNs for analyzing these various features [8], [9] and with a modification of the data generation process, we can conduct a similar analysis on more general features. Other possible cultural domains of application include music [26]–[28] and literary art [29], and culinary art [30], where cultural transmission of complex knowledge is considered equally important to understand the creative aspect of human intelligence.

***Abstract*—We propose a method that links character string having a certain semantic meaning on papers in real world to the digital information in cyberspace, and call it Ultimatelink. Ultimatelink adds additional information to characters by superimposing a circular color mark on the characters without changing the shape of the characters. A URL (Universal Resource Locator) can be generated by connecting additional information of semantically organized characters which are come from captured images by digital devices. In the experiment, we investigated the behavior of Ultimatelink for the five type of Japanese characters. The target characters are multiple katakana characters, multiple kanji characters only, multiple kanji and hiragana characters, kanji with a few strokes, and kanji with many strokes. As a result of experiments, it was confirmed that information superimposition and information extraction are possible in most cases, but there are problems such as failure to extract a single character or the ability to extract color markers appropriately depending on the character shape.**

I. Introduction

In today's modern society, many people own smartphones, and the use of their cameras is not limited to photographing people and backgrounds, but has become one of the ways to connect to the Internet, for example by reading QR codes[1]. However, QR codes must be printed on paper separately from textual information, which would disrupt the layout of printed materials. In addition to QR codes, there is a technology called screen codes[2], which read information in the computer world from information on paper. Screen code is a method that prints and reads invisible microscopic patterns on paper, but because it uses special color printing technology, it is not intended to be used for printing information specified by general users using common computer devices. Therefore, it would be very convenient for us if we could easily link "textual information on paper" with "digital contents" in the computer space using common printing devices and paper without disrupting the layout of the printed matter. For example, we assume that each rendered character of "Mt.Fuji" has additional information and is printed on papers, then the printed characters are captured by digital camera. From the captured image, a URL reconstructed by the additional information extracted from each rendered characters may be assumed to a web site of explaining Mt.Fuji.

There are several methods that hide an information within characters in watermarking or information hiding research fields. For example, additional information is represented by transforming very small parts of characters to another shape[3][4] or removing a small part of characters[5][6]. However, embedded information is quite very low in those methods.

In this paper, we propose Ultimatelink to embed URL for multiple characters having a certain semantic meaning printed on papers. This method is realized by putting small color circles on the body of characters. The position of small color circles is decided by skeletonization of rendered characters and computing pseudo-stroke order which is a scanning order of skeletonized pixels.

In section 2, we describe how Ultimatelink embeds additional information to characters and extract it. In section 3, we show some experimental results, and discuss the results in section4. Finally, in section 5, we summarize the results and discuss future issues.

II. Ultimatelink

Ultimatelink is a method that links a certain semantic cohesion in the real world to accompanying/supplementary information in cyberspace. Specifically, it is a technology for superimposing and extracting binary data on characters. The process can be divided into two main categories: embedding information in a binary image and extracting information from a printed image that has been embedded and photographed by a camera such as a smartphone. Each of these processes is described below.

A. Embedding Process

The embedding process follows the flow below.

(1) Character recognition
(2) Character segmentation
(3) Prepossessing thinning (erosion)

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

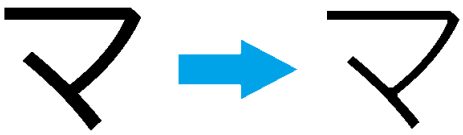

Fig. 1: Example of erosion

Fig. 2: Example of thinned image

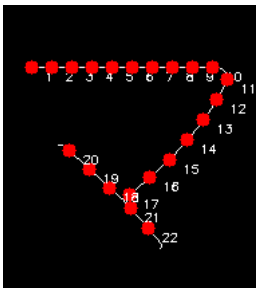

Fig. 3: Example of grid points

(4) Character image thinning
(5) Pseudo-stroke order calculation
(6) Grid points assignment
(7) Colored circles draw
(8) Final processing

Each procedure is described below in detail.

(1) Character Recognition
Images with multiple characters rendered in which you want to embed information (referred to as "original image") are prepared. We assume that the original images consist of two colors: black and white pixels which are corresponding to foreground pixels and background pixels respectively, in other words, this is equivalent to that we write characters by pencils on white color papers. The characters in the original image are recognized using an optical character recognition engine.

(2) Character Segmentation
The character string to be embedded is segmented from the original image into one character. Assuming horizontal writing, this segmentation is performed by obtaining the width and height of each character in the image. The width is obtained by extracting the consecutive rows of black pixels in the image. In this case, there are some characters, such as "リ (ri)" and "ハ (ha),"a that have an empty space within a single character. This means that these characters often have two small widths of consecutive black pixels within a character. The two small widths are able to be categorized as outliers by thresholding. Therefore, the width of those characters can be obtained by considering adjacent characters with smaller widths to be one. Similarly, the height is obtained by extracting consecutive lines of black pixels in the image. The character string can be segmented by cropping the image with a margin between the width and height obtained by this method.

(3) Prepossessing thinning (erosion)
Before performing the thinning of each segmented character image, the erosion is performed for the characters whose example is shown in Fig.1.

(4) Character image thinning
After erosion of each character, we perform thinning to it. A binary image with a line width of 1 is obtained from this process. This information is used for the position of drawing circles. Fig.2 shows an example of a thinned image.

(5) Pseudo-stroke order calculation
The pseudo-stroke order is calculated by tracing the order of foreground pixels from an image of a thinned character image. This order is based on the contour tracking method and is calculated by the following procedure.

Step1 : The first pixel found in the foreground by raster scanning is the pixel of interest.
Step2 : Find the pixel adjacent to the pixel of interest in a counterclockwise direction. The found pixel is the next pixel of interest.
Step3 : Repeat Step 2, and return to Step 1 when there are no more adjacent pixels.
Step4 : Repeat Steps 1 through 3 until all foreground pixels are found.

The pseudo-stroke order is calculated by the above procedure. The obtained pseudo-stroke order is saved for each character.

(6) Grid points assignment
A circle of radius r is drawn in pseudo-stroke order with d as the distance between circles. We call the position of circles "grid point." In some case, the circles may overlap depending on the character shape and scanning order when we draw on grid points. In such cases, the pseudo-stroke order calculated above is not used. Then the new pseudo-stroke order is searched so the the circles do not overlap. Fig.3 shows an example of drawing grid points.

(7) Colored circles draw
For the obtained grid points, circles colored according to the embedding information are drawn. The position at which the circle is drawn is randomly selected from among the grid points with a fixed random seed according to the length of the embedding information. One circle should represent two bits (four patterns), and five colors should be set in total, since colors are also needed for projection markers. In HSV color space, we fixed the value for two

Fig. 4: Colors for grid points/projection marker

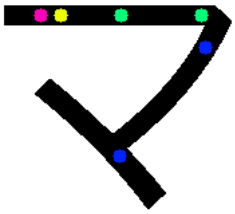

Fig. 5: Example of information embedding

axis: S = 255 and V = 255, and assign five values for one axis : H. As a result of this, five colors are generated in HSV space shown in Fig.4. The colors in Fig.4 are, from top to bottom, projection markers, embedded two bit binary information:"00," "01," "10," and "11."

(8) Final Processing
As colored circles are superimposed on rendered character images, we replace original characters with it. In addition, four projection markers are drawn to normalize the image during extraction. Fig 5 shows an example of a character image with embedded information. The character with embedded information is shown in Fig.5 and multiple colored circles are drawn on the character according to the embedded information.

B. Extraction Process

The extraction process follows the flow below.

(1) Projection markers detection
(2) Character recognition
(3) String extraction
(4) Circles detection by colors
(5) Circles detection by grid points
(6) Bit information extraction

Each procedure is described in detail below.

(1) Projection markers detection
A projective transformation is performed to transform the captured image to the same position and size as when embedding. To detect the projection markers as the basis for the transformation, mask images are created with the colors for the projection markers assigned in embedding process. We apply dilation processing to the mask images. Then circles are detected from the dilation mask image by Hough transform.

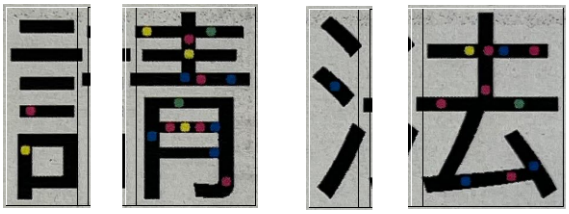

Fig. 6: Example of character segmentation failure

(2) Character Recognition
Character recognition is performed in the same way as in the embedding process.

(3) String Segmentation
We perform character string segmentation on the image after the projective transformation. The splitting of multiple characters procedure is basically the same as in the embedding process, but, in some cases, a failure to split one character into two characters by mistake may occur, as shown in Fig.6. When such a failure to split a string occurs, the string is split again according to the procedures shown below.
First, we suppose that n characters are recognized as a result of character recognition. At this time, if the length of the width of the entire character string is X, we can get the width by (X/n).

(4) Circles detection by colors
We detect colored circles from segmented images. The detection method is the same as the detection of the projection markers for each predefined color in HSV color space.

(5) Circles detection by grid points
We find grid points from the stored pseudo-stroke order information for each character. Using the same random seed determined in the embedding process, we can identify the center positions of colored circles allocated in the embedding process. Therefore, we estimate the colored circles allocated in the embedding process by finding circles with the closest distance to the identified center position from detected circles by colors in (4).

(6) Bit information extraction
The bit sequence is extracted from the estimated circles in (5) by arranging the bit sequence in specific order.

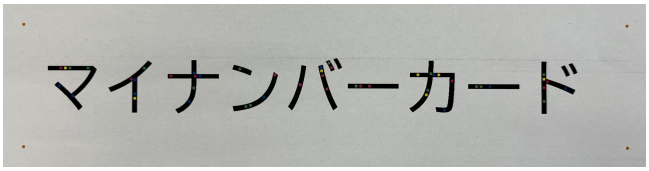
III. Experiments

In order to evaluate Ultimatelink, we conducted five experiments, which are called type A, B, C, D and E, with varying type of Japanese characters. We prepared two types of embedded information which is called type E_1 and type E_2 respectively. In the type E_1 and type E_1, the shortened URL "bit.ly/3oXpEIm" and the simple string "abcdefghijklmn" were used for the embedded information and each string consists of 14 characters which became 98 bits in ASCII code form.

TABLE I: Type of experiments

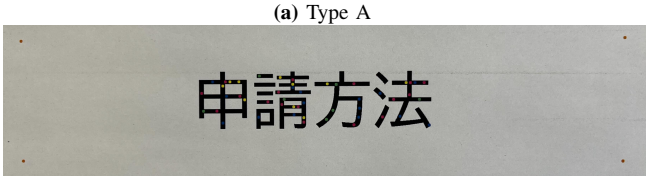
Type	Type of characters to be processed (Japanese)	Actual string	Embedded information
A	Katakana	マイナンバーカード	E_1
B	Kanji	申請方法	E_2
C	Kanji and Hiragana	お問合わせ	E_2
D	Kanji with a few strokes	一上一下	E_2
E	Kanji with many strokes	諸艶大艦	E_2

Fig. 7: Rendered target image with Gothic font (Type B)



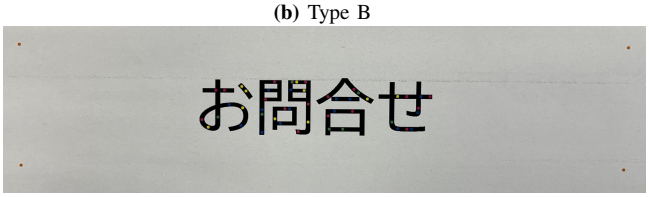
Experimental conditions are summarized in TABLE I.

We assume that A4 paper size is 2339×1654 pixels in a digital binary image, a character is rendered within 200×200 and those characters are placed around center of A4 paper. Actual string is rendered by using Gothic font, and an example of this is shown in Fig.7.

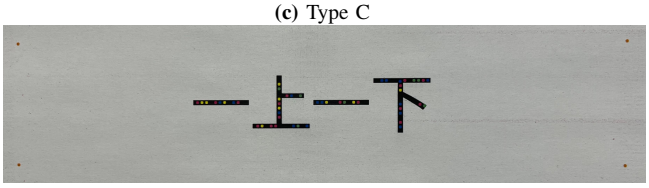


For these rendered characters, the embedding procedure of Ultimatelink is performed. Then, the characters with additional information embedded are printed out on A4 size of paper. In the extraction process, characters on papers are captured. Fig.8 shows clipped images which were captured 4032×3024 in size by digital camera.

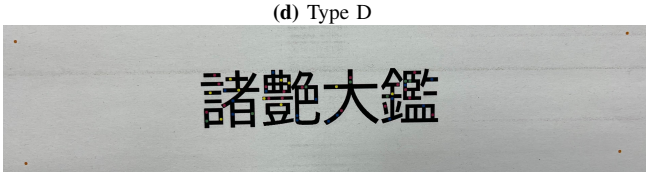
For all type of experiments, we confirmed that the embedded information was extracted correctly. Although, in type E of kanji characters with many strokes, the reproducibility was not guaranteed. In order to be successfully achieved, we needed to change parameters adequately in erosion step during the embedding process and in character recognition during the extraction process. These parameter adjustments were made manually based on try and error.



When splitting character strings in information extraction by using the method of splitting character strings in information embedding, the second character from the left and the fourth character are split incorrectly as shown in Fig.6, but the character string is split again using the number of characters during character recognition and the width of the entire character string as described in (3) of II-B in II. As a result, we confirmed that the string was correctly divided as shown in Fig 9.



(a) Type A



(b) Type B

(c) Type C

(d) Type D

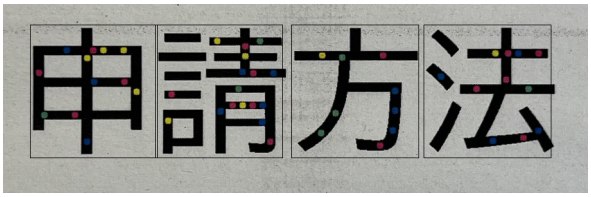
(e) Type E

Fig. 8: Clipped captured image

IV. Discussion

We confirmed that Ultimatelink was able to accurately extract information for katakana only, kanji and hiragana, and kanji only with a standard number of strokes or a small number of strokes. This is the reason why the fact that the pseudo-stroke order is preserved for each character by performing character recognition and dividing the character string into individual characters. If a pseudo-stroke order is obtained from the captured image, the thinned image of each character may change depending on the position of the drawn circle, resulting in differences in the bit sequence extracted instead of being the same as when embedding. However, by using the same pseudo-stroke order for embedding and extraction, the reference grid points can be obtained in the correct order and the information can be extracted.

In addition, the character is eroded before the character is thinned when the information is embedded. This is to prevent the circles from being too close to each other and causing failure in circle detection. The comparison of the result of drawing a circle on an image that has not undergone erosion before the thinning process and the result of drawing a circle after the erosion process is shown in Fig.10.



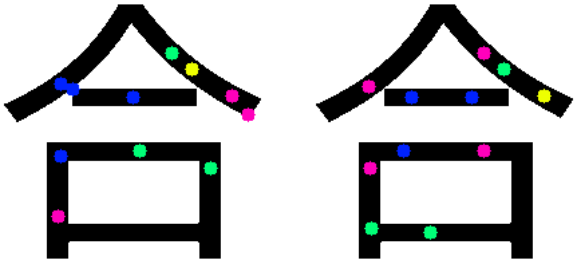


Fig. 9: Example of split success

(a) processing without erosion **(b)** eroded

Fig. 10: Comparison of circle drawing results

Fig.10(a) shows that the blue circles are too close to each other. On the other hand, Fig.10(b) shows that the distance between the circles is appropriately maintained. It is thought that this process ensures that circles are not undetected and that the information is extracted correctly.

In the case of multiple kanji characters with a large number of strokes, the results correctly extracted the information, but the reproducibility to other character images was not ensured because various parameters had to be adjusted. In the future, it will be necessary to search for parameters that can guarantee reproducibility in the case of multiple kanji characters with many strokes.

V. Conclusion

In this paper, we propose Ultimatelink for multiple characters with robust for print and scan. While the system was able to extract information without problems for katakana-only, kanji and hiragana, and kanji-only character images with a standard number of strokes and a small number of strokes, it was unable to reproduce kanji character images with a large number of strokes. Therefore, it is necessary to construct the system that is robust even when it contains kanji characters with a large number of strokes.

In addition, since this experiment was conducted on text printed on paper with a white background, it is necessary to conduct the experiment on posters and other displays with a colored background. Furthermore, since the lighting conditions in this experiment were a single lighting condition, under fluorescent light only, it is necessary to conduct the experiment under multiple lighting conditions, such as under sunlight or in a dark room.

In the method used in this experiment, images taken with a smartphone camera were imported once to a PC and processed. In consideration of future practicality, we should construct a system that can display Web pages and complete the information extraction process within a smartphone, and evaluate its practicality.

***Abstract*—We propose a system that uses depth information, which represents the distance from the sensor, instead of color information to do both measure human flow and protect privacy for low-end IoT devices. The system is designed to detect the position and number of persons from depth information. Since administrative organizations or educational institutions have been reducing their budgets, this system should be implemented at as low a cost as possible. In order to realize human flow detection system on low-end Iot devices, we use low performance depth cameras as data acquisition device controlled by single board computers, such as Raspberry Pi. As one of our goals is all data processing are performed on single board computers, we adopt computational methods for the detection as possible as simple. The proposed method is based on the background subtraction method, which prepares a reference depth image and extracts moving regions from one frame extracted from the video depth image. Furthermore, we aim to achieve high-precision people flow measurement by combining the following three elements: segmentation of moving objects using edge information, identification of human areas using floor information, and human tracking using areas where people overlap in the direction of the time axis. Experiments were also conducted and evaluated in a real space using a program that implements the presented method.**

***Index Terms*—privacy protection, depth image, human flow detection, V disparity map, low-end IoT devices**

I. Introduction

Due to the corona disaster of the past few years, we have become concerned about spatial density. If information about human flow could be automatically obtained, it would certainly help our live, not only for the problem of the Corona disaster, but also from the perspective of crowd detection during events.

All of the previous studies have attempted to measure human flow using video and image processing from existing surveillance cameras and other fixed cameras which is able to provide RGB images. Angelova et al.[1] combine a cascade classifier and a small DNN (Deep Neural Network) to accelerate processing and achieve real-time detection of the location and number of people for multiple pedestrians in suburban and urban areas taken from a vehicle. Yuhong et al.[2] for counting the number of people at the level of hundreds, called crowd measurement. CSRNet (Congested Scene Recognition Network) is a supervised deep learning model that uses density maps. Weizhe et al.[3] have used a density map that includes information on the flow of people from video images in consecutive frames and the correlation of people tracking by optical flow to more accurately estimate the number of people in a crowd of several hundred or more people and the direction of the flow of people.

However, such methods using RGB cameras, including existing surveillance cameras, simultaneously acquire information on the face and clothing that can identify a person, which raises privacy issues.

To that concern, it is one solution using depth images. In a related study, Thi Thi et al.proposed a monitoring system for elderly people using depth information[4]. In this system, one elderly person living in a room is monitored. Detection is not performed for multiple persons, which is necessary for human flow measurement.

This paper proposes a system that uses depth information to both measure human flow and protect privacy. In this system, we assume that our proposed system is utilized in administrative organizations or educational institutions. As you know, these organization have been reducing their budgets, therefore this system should be implemented at as low a cost as possible. In order to realize human flow detection system on low-end Iot devices, we use low performance depth cameras as data acquisition device controlled by single board computers, such as Raspberry Pi. As one of our goals is all data processing are performed on single board computers, we adopt computational methods for the detection as possible as simple. The proposed method is based on the background subtraction method, which prepares a reference depth image and extracts moving regions from one frame extracted from the video depth image. Furthermore, we aim to achieve highly accurate human flow measurement by combining three methods: segmentation of moving objects using edge information, identification of person areas using floor information, and person tracking using overlapping person areas in the time axis direction.Experiments were also conducted and evaluated in an

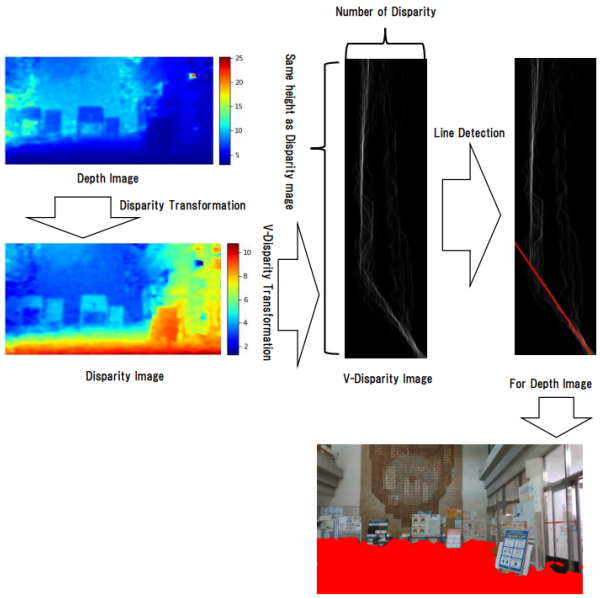

Fig. 1: Outline of floor detection from depth image

actual space using a program that implements the presented method.

II. PROPOSED SYSTEM

A. PERSON DETECTION SUMMARY

The proposed method is based on the background subtraction method of depth images. Moving objects will appear as the difference of the subtraction. To construct our method, we need two technical issues: depth images often contain noise, and a blob on binary image which is generated after the subtraction may represent overlapped persons. For the former issue, we adopt the thresholding of the size of blob and the judgment whether person is on the floor or not. For the latter issue, we use the image processing based on edge detector. The detailed method is described as follows.

1) BACKGROUND SEPARATION BY BACKGROUND DIFFERENCE METHOD: Firstly, for the depth information of the acquired F-frames, the background difference is calculated with the previously acquired background depth information, which is called a reference depth image, in order to separate the background and foreground information.

Since the depth difference image does not take into account errors in depth information by the sensor, there is a possibility that the difference between the reference depth image and frames may be generated even in areas where no person actually exists. Therefore, binarization processing is performed based on the parameter:T_1, and the area where the difference exists is designated as a tentative person area. From this region, the one with sufficient area which is selected by the parameter:T_2 is regarded as a candidate of person region. After this step, a binary image which foreground corresponds to a candidate of person region is generated.

2) EXTRACTION OF FLOOR AREA: The flow of extraction of the floor region is shown in Fig.1. It is known that flat regions such as the floor region appear as straight lines in the histogram of disparity values, called the V disparity map[5][6]. In Fig. 1, the disparity image is color-coded according to the magnitude of the value (the closer to blue, the smaller the value; the closer to red, the larger the value). Since the disparity value is the reciprocal of the depth value, the coloring is reversed compared to the original depth image.

The V disparity image is obtained by taking a histogram of the disparity values for each row. Therefore, the vertical axis equals the height of the disparity image and the horizontal axis equals the number of disparity values. Since the disparity values of flat areas such as floors and walls are constant or change step wise, they appear as straight lines in the V disparity image with a histogram taken for each row. In the V disparity image of Fig.1, the vertical lines correspond to the walls and the diagonal lines to the floor. This time, diagonal straight lines are detected by the Hough transform and mapped to the depth image to extract the floor area.

3) EDGE DETECTION FROM DEPTH INFORMATION: Within a candidate of person region, a region may contain two or more person if persons are overlapped. In order to separate those overlapped persons, we use raw depth information of a candidate of person region. There is a difference in depth between overlapping persons, which appears as a large gradient when observing the change in depth at a pixel. Therefore, we use edge detector for depth information. The contour information is detected from the depth information and subtracted from the candidate of person region This process can divide the overlapping person areas and enables us the detection of multiple persons. Because small region may not be person region, we remove those region using the area criterion T_3.

4) DETECTION BY INVERSE ORDER TRACKING CONSIDERING FLOOR AREA: If person detection by floor area is performed for each frame, it is not possible to detect persons who are not in the floor area even though they are persons. These persons may invade the floor area over time. Therefore, if the detected area is tracked and the same area exists in the floor area in a certain frame, the area is considered to be a person even if it does not exist in the floor area in the frames before and after the frame, and the frame is not deleted retroactively but remains as a person. Specifically, tracking is performed in reverse order from frame n to frame 0. If there is an object area in the floor area at frame n+1 or n-1, the same area at frame n is detected as a person even if it is not present in the floor area. The proposed method uses a measure of how much common area there is between regions called the IoU (Intersection over Union). If this IoU value is high, which means there is overlap between frames, the regions are considered to be the same moving object.

III. EXPERIMENT

A. EXPERIMENTAL ENVIRONMENT

In this experiment, a commercially available Realsense series D435i from Intel was used to acquire depth images.

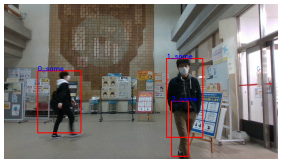
TABLE I: Evaluation Result

Scene	condition	CC	MAE	PDA
1	Canny	**0.878**	0.235	0.806
1	Sobel	0.831	**0.195**	**0.930**
2	Canny	**0.817**	0.660	**0.900**
2	Sobel	0.659	**0.280**	0.885
3	Canny	0.758	**0.11**	0.852
3	Sobel	**0.818**	1.33	**0.930**

Person detection is performed from the 200 frames of depth images obtained by capturing at three locations, which is called Scene 1, Scene 2, and Scene 3, within the our campus.

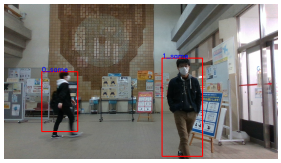
The parameters used in this experiment are then described. The threshold T_1 for binarizing the background differential depth image was set to 600 mm. The threshold values T_2 and T_3 for the micro-area area were both set to 5500, and we used the values that were good while changing the parameters. The threshold value of the Houghline transform for floor area extraction was set to the value that best covers the actual floor area by experimenting with each scene. For edge detection, we used two detectors, one is the Canny detector and the other is Sobel detector.

B. EVALUATION METHODS



We check the RGB image Visually and determine the actual number of persons in the i-th frame as Pt_i. The number of persons output by the proposed method is denoted as Po_i. Based on this number, the correlation coefficient (CC) and mean absolute error (MAE) between Pt_i and Po_i are calculated for all frames. To evaluate whether the same person is detected without duplication, or whether the detected frame is a person, the number of detected areas that correctly capture a person (hereafter Pc_i) is also visually checked to evaluate these as person detection accuracy. Pc_i/Po_i is calculated for the frame where $Po_i \neq 0$, and the average value over all frames to be processed is the person detection accuracy (PDA). The average value over all the frames to be processed is used as the human detection accuracy.

C. EXPERIMENTAL RESULTS

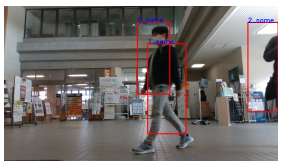


An example of the person detection results by the two edge detectors is shown in Fig. 2, respectively. To visually check the person detection results of the system, a bounding box is created by taking the bounding rectangle for each region. The same person tracked is assigned the same number.An example of how errors in large areas due to measurement errors can be suppressed is shown in Fig. 3. Fig. 4 shows an example where the same person is detected even if he/she is not in the floor area by tracking. In addition, the evaluation in each scene is shown in Table I.

D. Studies

The Canny method extracts edges in detail, resulting in more cases of duplicate detection of one person, as in Fig. 2(a), Fig. 2(c), and Fig. 2(e). On the other hand, the Sobel filter takes the edges roughly, which suppresses overlap and leads

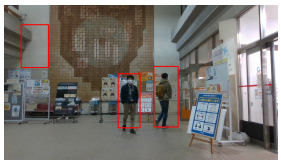
(a) Scene 1 : Canny Detector



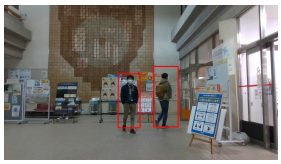
(b) Scene 1 : Sobel Detector

(c) Scene 2 : Canny Detector

(d) Scene 2 : Sobel Detector



(e) Scene 3 : Canny Detector



(f) Scene 3 : Sobel Detector

Fig. 2: Detection results in Canny Detector and Sobel Detector for each scene

(a) An example of large measurement error

(b) After taking account of floor detection

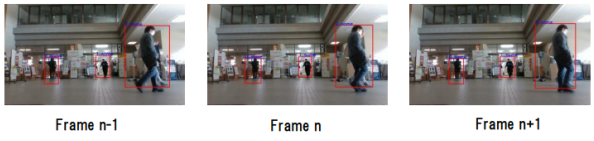


Fig. 3: Effects of floor detection to reduce measurement error

to highly accurate evaluation results. In Fig. 3(b), the miss detection region due to the large measurement error in the upper left corner of Fig. 3(a), which existed in the process up to the person segmentation by edge detection, can be removed because it is not in the floor area.

In addition, we confirmed that if only the area that exists

(a) floor detection performed in each frame

(b) floor detection performed over frame using tracking

Fig. 4: Effects of consecutive frame traking to reduce missing detection

in the floor area is considered as a person, a person who is not in the floor area may be mistakenly deleted as an error. By tracking between consecutive frames and retroactively detecting the person outside the floor area when the person enters the floor area over time, our method is able to detect the person without omissions as shown in Fig. 4(b).

The evaluation results show that the Canny method has a higher correlation coefficient in Scenes 1 and 2. This is because the number of persons is sometimes the same as the actual number of persons because of duplicate counting. For scene 1, this is confirmed by the fact that the processing with the Sobel filter has better person detection accuracy, which indicates whether the person is actually correctly present in the area being detected. The Canny method also shows better results in terms of person detection accuracy in scene 2. In Scene 2, it may be likey to occur because the background changes as the elevator door opens and closes. Canny method does not detect the elevator portion, so the person detection accuracy is better than the Sobel one. However, since the absolute mean error is better with the Sobel filter, it can be said that the number of detected frames that actually capture the person is higher with the Sobel filter.

IV. CONCLUSION.

In this paper, we conducted experiments to verify the effectiveness of a method for detecting persons in space from depth images using an algorithm that combines the background subtraction method, removal of background change regions by variance, edge detection using a Sobel filter, and determination of tracking objects using floor regions extracted from V disparity images. As a result, we were able to segment multiple overlapping persons if sufficient depth differences were generated.The problem of false detection of people due to shooting errors was improved by the presence or absence of tracking objects in the floor area.

Future issues include how to account for measurement errors in depth images and how to reject information that is detected as human motion even though it is not human motion.

***Abstract*—With the revolution of Augmented Reality (AR) Head Mounted Display (HMD), AR technology enables the provision of immersive virtual content using various interaction methods. To bridge the real and virtual world, hand-based interactions have been utilized for their simplicity and effectiveness in interacting with AR applications. Thus, assessing the Quality of Interaction (QoI) is vital for enhancing the experience of AR applications, but it has been hindered by the absence of a comprehensive database that includes human factors. In this paper, we construct an interaction dataset, Holo-QoI, which includes 49 sets of human factor metadata with associated human subjective scores. To analyze the contribution of various factors to QoI, we process HMD metadata into human factor-based features (e.g. head, gaze, and hand motion). We then design a QoI prediction framework based on a Transformer architecture to model the relationship between human factor-based features and deep features, which is used to predict the QoI score of an interaction. Through rigorous experiments, we demonstrate that our proposed model achieves an 86% accuracy using the constructed dataset.**

I. Introduction

The development of Augmented Reality (AR) technology has been driven by the desire for more immersive communication with the digital world. Using AR Head Mounted Displays (AR-HMD), AR applications have been developed in various areas such as entertainment, education, healthcare, and engineering [1]–[3]. Existing applications utilize interaction [4] through gaze movement, voice commands, controllers, and hands to bridge the gap between the virtual and real world. Among these, hand-based interactions are particularly prominent as they are intuitive, efficient, and widely used. Hand-based interactions involve complex interactions with human factors such as eye gaze and head movements. For instance, in user-friendly interactions, users tend to focus their gaze on the target, resulting in minimal movement of the eyes and head. On the contrary, in less immersive interactions, the dispersion of eye gaze and head movements leads to a decrease in user engagement and results in lower-quality interactions.

This work was supported by Institute for Information & communications Technology Promotion(IITP) grant funded by the Korea government(MSIT)(No.2020-0-00537, Development of 5G based low latency device – edge cloud interaction technology)

(a) Select (b) Move (c) Rotate

Fig. 1. Content scene example for the 3 interaction types, select, move, and rotate. The original video is recorded with each data paired with the real world. We separate the virtual parts from the full video capture, and paint the background of each data black for uniformity of further process

Therefore, high-quality hand-based interactions are necessary for an improved immersive experience in AR.

To analyze the relationship between human factors and hand-based interaction quality, there is a need for a quantitative measure to assess the interaction quality. We define this as the Quality of Interaction (QoI). To measure QoI, subjective assessment is commonly used because it can provide valuable insights into qualitative aspects such as usefulness, satisfaction, and naturalness. However, this method is time-consuming and requires a large number of participants to achieve statistically significant results [5]. It is also sensitive to various factors such as mood and prior experiences, leading to inconsistent and unreliable results. In this regard, it is crucial to have a method that can quantitatively measure the QoI and a comprehensive dataset that can provide rich data for analysis.

Recent studies have explored alternative approaches to suggest guidelines for improving the naturalness and intuitiveness of hand interactions. Kang et al. [6] present design suggestions for 3D interaction designers by analyzing the importance of the visual appearance of virtual objects for natural hand interactions. Du et al. [7] propose a new interaction method by combining Leap Motion with the HMD and assess its effectiveness through game experiments and subjective evaluation. The aforementioned methods aim to improve the quality of interaction through different approaches, but they do not provide a specific quantitative method for measuring interaction quality. Therefore, they have a limitation in terms of generalizability.

To investigate the perceptual QoI in AR HMDs during object interaction tasks, our previous research [8] utilized an AR content dataset paired with subjective scores collected from a total of 32 subjects. These subjective scores served as the ground-truth labels for supervising the QoI prediction model. To quantify the level of QoI, we extracted various features from the recorded video data and metadata obtained from the HMD. Subsequently, we trained an SVR-based model using these features to predict the QoI score of a given content. However, such an approach had limitations in both constructed dataset and predictive performance. Given the significant importance of human factors in evaluating virtual interactions [9], [10], our previous dataset had limitations in terms of both the limited quantity of data and the lack of human factor information beyond hand position data. Due to the limitations, the proposed method lacked in modeling various human factors that influence interaction quality, resulting in unsatisfying prediction performance.

In this paper, to overcome the limitations of our previous research, we analyze the contribution of various factors to QoI. We construct a large-scale QoI dataset, Holo-QoI, that includes HMD metadata sets consisting of gaze, head, hand, and object, with associated human subjective scores. Using this dataset, we overcome the limitations of our previous method. First, we design a method for processing the metadata into human factor-based features to model the influence of each human factor on interaction quality. Then, we design a Transformer-based QoI prediction framework that uses human factor-based features along with deep features to predict the QoI of the content. Experimental results show that our framework achieves a prediction accuracy of 86%, significantly outperforming the results of our previous method. Such results indicate that the applied features are appropriate and that our framework provides a more efficient way to predict QoI in AR.

II. DATASET CONSTRUCTION

To analyze the contribution of various factors to QoI, we first construct a new large-scale interaction dataset, Holo-QoI, which consists of in-device metadata paired with subjective scores for Unity AR contents. Metadata refers to the time-continuous gaze, head, hand, and virtual object 3-D position coordinates and rotation angle data obtained using the internal API of the Microsoft HoloLens 2. It is important to note that there are no existing datasets available that contain this type of data, making our dataset particularly valuable for this research.

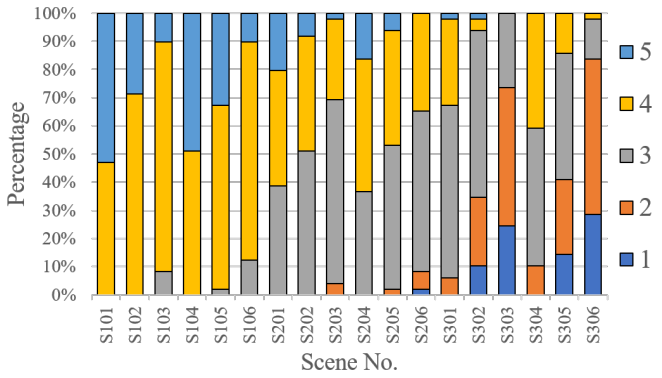

Fig. 2. Score distribution for each content scene. The bars of each column represents the score percentage of the 49 subjects.

A. Holo-QoI Dataset

To achieve our objective, we constructed 18 AR gesture interaction content scenes by varying several conditions, as summarized in Table I. Fig. 1 provides a visualization example of the representative AR gesture interaction content. Each scene is constructed and run using the Unity3D engine, with the background set to empty space to minimize visual disturbance during the assessment.

Interaction Type The interaction type condition specifies the interaction task that the subject must perform with the virtual object. The Hololens offers various built-in interaction methods, which enable users to select, move, and rotate virtual objects. In the select case, the subject is required to touch the virtual object with their bare hand. For both move and rotate cases, the subject is asked to grab the object and drag it to the target location or target pose.

Distance The distance condition specifies the distance between the subject and the virtual object in each content. Before evaluation, the arm length of each subject is measured, and the position of the virtual object is adjusted accordingly to either be closer, further or at an exact arm length.

Order The order condition determines the positioning order of the virtual objects that appear on the screen for interaction in each scene. A total of 5 objects continuously appear, and this condition decides whether the objects appear in a fixed or random order.

We aimed to obtain a dataset of HMD metadata paired with subjective scores to describe the interaction quality of content scenes, using a Microsoft Hololens 2 [11] system for the assessment. The system contains a head-mounted display with 2k 3:2 light engines, which generate holograms on see-through holographic lenses at a framerate of 30 FPS.

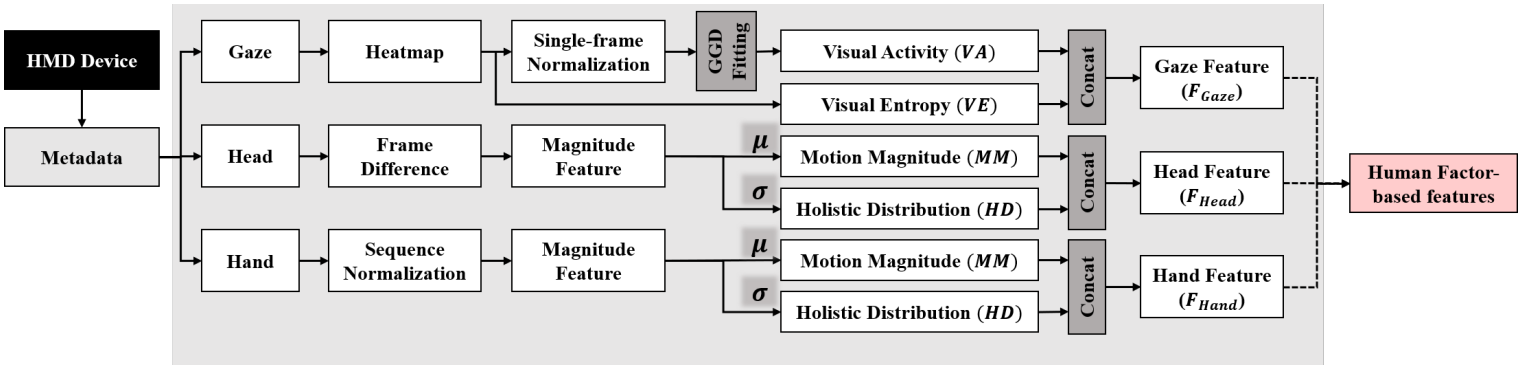

Fig. 3. Block diagram of the human factor-based feature extraction method

The metadata is obtained as a set of head, gaze, object, and hand data for each frame. The head data contains 7 dimensions, the gaze data contains 6 dimensions, the object data contains 7 dimensions, and the hand data contains 182 dimensions (7 dimensions per joint * 26 joints). The position and direction of each dimension are expressed as (x,y,z), while the rotation is expressed as (x, y, z, w). The head data captures the movement and rotation of the HMD in global coordinates, while the gaze data captures the starting point and direction of the eye gaze. Despite having two eyes, only one vector is returned because the device averages the position and direction of the eyes. The object data captures the position and rotation of the virtual object used for the interaction task. The hand data captures the movement and rotation of the dominant hand through the hand joint position and hand joint rotation.

B. Subjective Assessment

Following the subjective assessment protocol of standard IEEE P3333.1.3 [12], we design an evaluation process to measure the interaction quality of each constructed content. A total of 49 subjects participated in the evaluation, consisting of 40 males and 9 females with an age range from 24 to 35 years. All subjects were undergraduate and graduate students majoring in electronic engineering or software engineering, who were all right-handed and had little or no experience in AR interaction before.

The assessment protocol for this study was as follows: prior to beginning, the calibration settings of the HMD were adjusted, and the arm length of each subject was measured. Subjects were instructed to use their right hand to interact with each content scene. After each scene, subjects were asked to rate their interaction experience on a 5-point Likert scale, which was labeled as Very Comfortable (5), Comfortable (4), Mildly Comfortable (3), Uncomfortable (2), and Extremely Uncomfortable (1). Following each scene, subjects were given a short break to reduce visual fatigue and minimize the effects of AR sickness on subsequent scenes. This process was repeated for a total of 18 content scenes.

C. Data analysis

Table I presents the Mean Opinion Score (MOS) averaged for 49 participants for each content scene, while Fig. 2 shows the score distribution. The MOS was compared across different groupings, including interaction type (select, move, and rotate), distance (near, exact, and far), and order (fixed and random). The average MOS for each grouping was $4.269, 3.537, 2.622$ for interaction type, $3.870, 3.483, 3.074$ for distance, and $3.494, 3.458$ for order. The results indicate that the interaction type condition had the most significant impact on the score. From the results of [6], the difficulty of a hand-based interaction in AR is determined by factors such as the complexity of the movement, accomplishment time, and hand naturalness. Considering this, from the interaction types, rotate had the highest difficulty, followed by move, then select. Therefore, we derive that the QoI score is highly related to the interaction difficulty, and to improve user experience, one should consider the factors previously mentioned. The distance condition also had a minor contribution to the score, with closer objects being associated with higher scores due to their visibility from size.

III. Method

To find the relationship between the metadata and the paired scores, we process the metadata into human factor-based features. We design a QoI Predictor based on a Transformer architecture [13] to consider object and hand coordinate information along with the human factor-based features. At the output of the Transformer, this score token is then passed through an MLP (Multi-Layer Perceptron) head, resulting in the QoI prediction score of the input metadata.

A. Human Factor-based Features

Fig. 3 illustrates the human factor-based feature extraction process. In addition to hand data, which is the main interaction method, we also incorporate gaze and head data to reflect additional human features. We use appropriate feature extraction methods to extract features from these data and model the relationship between the metadata and QoI score.

Gaze For gaze (F_{Gaze}), we first process the gaze distribution of each scene per subject and convert it into a heatmap, as shown in Fig. 5. The heatmap is just an image generated from metadata, so we adopt visual activity (F_{va})[14] and visual entropy (F_{ve})[15] to extract representative features that

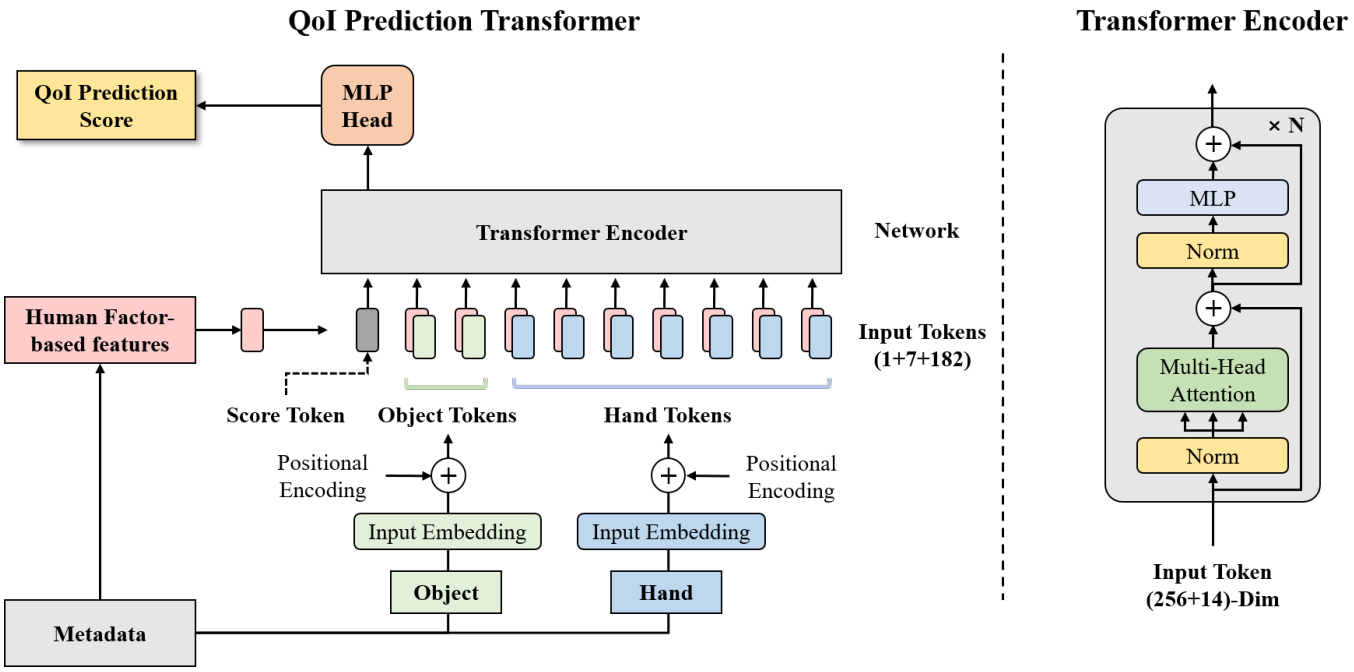

Fig. 4. Overview of the proposed QoI prediction framework

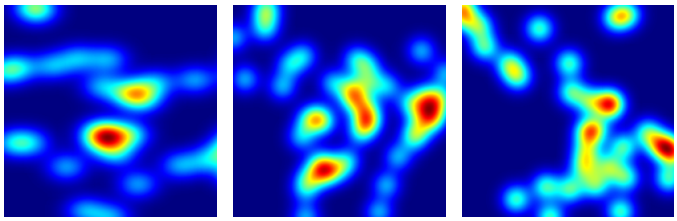
reflect human perception. These features are commonly used to evaluate the quality of virtual reality content [16]. We concatenate the two extracted features to create the gaze feature.



The visual activity is obtained by first normalizing the obtained heatmap, followed by a discrete wavelet transformation. This process quantifies gaze distribution and movement in the frequency domain. Finally, the histogram of the wavelet coefficients of each sub-band is fitted with a generalized Gaussian distribution (GGD) [17]. Let β_i be the i^{th} sub-band shape parameter of the wavelet transform histogram. Using the shape parameter, the F_{va} of the i^{th} sub-band of the heatmap is defined as:

$$F_{va} = \begin{cases} \sum_i (1 - \frac{1}{1+\exp(-2(\frac{\beta_i - C_t}{C_{tu}}))}), & \text{if } \beta_i \geq C_t \\ \sum_i (1 - \frac{1}{1+\exp(-2(\frac{\beta_i - C_t}{C_{td}}))}), & \text{otherwise} \end{cases} \quad (1)$$

where $C_t, C_{tu} C_{td}$ are normalization factors on the feature map. From experimental results of [18], normalization factors are set as $C_t = 1.1322, C_{tu} = 0.1338, C_{td} = 0.2904$.

The visual entropy score quantifies the degree of visual spread in the heatmap, where interactions with a high Mean Opinion Score (MOS) tend to show a low visual entropy score. Let (x, y) be the pixel coordinate of the heatmap H_{map}, with the center of the heatmap fixed at the coordinate $(0, 0)$. The formula for calculating the visual entropy score F_{ve} is the negative sum of the distance from each pixel (x, y) to the center, multiplied by its log value. The equation is defined as:

$$F_{ve} = -\sum_{x,y} H_{map}(x, y) \log \left(H_{map}(x, y) \right) \quad (2)$$

(a) QoI score: 5 (b) QoI score: 3 (c) QoI score: 1

Fig. 5. Heatmaps generated from different users on the same task. Each heatmap is labeled with its paired QoI score. Color represents the distribution density of gaze data(red to blue denotes high to low values).

Head and Hand For head (F_{Head}) and hand (F_{Hand}), we apply two processing techniques. First, we compute the frame difference of the head data to consider the change in the head movement. This involves subtracting the next frame's head data from the current frame's head data. Then, we normalize the hand data sequence, which smooths the hand joints' position in time to minimize noise. Specifically, we compute the magnitude feature function, which returns the mean (μ) and standard deviation (σ). We use these values to derive the motion magnitude (F_{mm}) and holistic distribution (F_{hd}) as follows:

$$F_{mm} = [\mu, \mu_h, \mu_l], \quad (3)$$

$$F_{hd} = [\sigma, \sigma_h, \sigma_l] \quad (4)$$

where $[\cdot]$ is the concatenation of the values, μ_h, σ_h is the mean and standard deviation of the top 10% data, and μ_l, σ_l is of the lower 10% data. The values are then concatenated and

TABLE II
PLCC AND SRCC PERFORMANCE COMPARISON ON HOLO-QOI DATASET

Method	PLCC(↑)	SRCC(↑)
Kim et al. [8]	0.6752	0.6914
Ours(F_{Gaze})	0.4775	0.5282
Ours(F_{Head})	0.5868	0.5936
Ours(F_{Hand})	0.8123	0.8148
Ours(F_{Gaze}, F_{Head})	0.6586	0.6698
Ours(F_{Gaze}, F_{Hand})	0.8279	0.8307
Ours(F_{Head}, F_{Hand})	0.8391	0.8447
Ours($F_{Gaze}, F_{Head}, F_{Hand}$)	**0.8598**	**0.8663**

used as the feature of each head and hand data. The motion magnitude represents the absolute difference of the head and hand position coordinates and creates a value proportional to the size of the motion. The holistic distribution is a measure of how spread out the velocity distribution is in each AR content, and it is calculated based on the size distribution of the head and hand movement.

B. QoI Predictor

Fig. 4 depicts an overview of our proposed framework. It takes in an interaction data sequence as input and predicts the score of the interaction. Our proposed framework follows a Transformer architecture to regress the sequence data to a single score. For each sequence of metadata, we apply our proposed feature extraction method to process the gaze, head, and hand data. In order to capture the relationship between the object and hand data, we utilize positional encoding to generate object and hand tokens. With a set of a score token followed by object tokens and hand tokens, we employ self-attention mechanisms and simultaneously regress the tokens. The state of the score token at the output of the Transformer encoder is then passed through an MLP head to retrieve a single value as the QoI prediction score.

C. Training

To train the Transformer encoder, we apply an L_1 regularization function to the output of the MLP head as follows;

$$\mathcal{L}_1 = |y - s| \tag{5}$$

where s is the predicted score and y is the ground truth score rated by the subject. $|x|$ denotes the absolute value of x. The encoder is trained to reduce the error between the prediction and the ground truth. For each trial, the dataset was randomly divided into $80\% : 20\%$ by scene, so that the training set would consist of 80% of the constructed dataset's data-score pairs, while the remaining 20% forms the test set.

D. Experimental results

We follow the model validation strategy of [19]–[22] and evaluate the models' predictive performance using Pearson's linear correlation coefficient (PLCC) and Spearman's rank-order correlation coefficient (SRCC) relative to the QoI score by computing the median correlation over 100 iterations.

We conducted experiments to evaluate the impact of individual features on our proposed method's prediction performance by comparing the results with our previous study [8]. Table II presents the evaluation results in terms of the PLCC and SRCC scores, with scores closer to 1 indicating better performance for each evaluation method. Our newly proposed method outperforms our previous method by a large margin. We also note that both PLCC and SRCC scores of our previous method showed an improvement in prediction by using our new dataset, due to an increase in the number of subjects participated.

E. Ablation study

To evaluate the impact of individual features on our proposed method's prediction, we compare the performance of all combinations of the extracted features. From the results shown in Table II, we observed that despite the simplicity of the features, the hand feature showed the highest correlation, followed by the head and gaze features. This is reasonable, as the overall process of AR interaction is mainly processed with the hands. However, the head and gaze features are also meaningful as auxiliary means of predicting scores, since the correlation increases when combined with the hand features. The best predictive performance was achieved when all features were used, demonstrating that the applied feature extraction methods effectively capture the relationship with QoI scores. These findings underscore the effectiveness of our analysis in establishing the metadata-QoI score relationship and our proposed method in predicting interaction quality from metadata.

IV. CONCLUSIONS

Interaction plays a vital role in AR, as better interactions lead to a more immersive user experience. Therefore, quantifying the QoI is essential for enhancing the AR experience. However, the existing dataset for this purpose has limitations in the quantity and diversity of human factor information, prompting us to develop our own large-scale AR interaction dataset. Hand-based interaction is the most commonly used method in AR, and its quality is influenced by the gaze and head movements. To model this relationship, we extract human factor-based features and design a model to estimate the interaction quality based on these features. The experimental results demonstrate that our prediction model has a strong correlation with human cognitive factors, and highlights the importance of considering gaze and head movements to enhance immersion in virtual environments through interaction in AR.

Supervised Single-channel EEG Decomposition using Detector-kernel Networks for Noise Reduction

Hiroshi Higashi
Osaka University, Japan
E-mail: higashi@comm.eng.osaka-u.ac.jp

***Abstract*—Signal decomposition techniques are ubiquitously utilized for the analysis, noise reduction, and classification of electroencephalogram (EEG) signals. Predominantly, these techniques harness the spatial features of EEG signals, thereby targeting multi-channel signals. However, decompositions employing spatial features often prove inefficient when applied to scenarios involving limited channel recording, such as with consumer-use equipment. This paper presents a novel approach for single-channel EEG signal decomposition. Rather than relying on a multitude of electrodes, we leverage training samples to cultivate a decomposition model based on convolutional neural networks. Our model hypothesizes that an observed EEG signal has essential components called kernels and comprises the time-shifted and amplitude-modulated kernels. Accordingly, the convolutional neural network-based signal decomposition model estimates these kernels and identifies their occurrence positions, thereby pinpointing time-shift and amplitude modulation. We validated our proposed decomposition method in the context of a noise reduction problem within a BCI application. Our experiment substantiated that our method effectively decomposes noise-related and non-noise-related components.**

I. Introduction

Signal decomposition is a pivotal technique in signal and data processing [1]. It is employed extensively not only for audio and speech signals [2] and images [3], but also for electroencephalogram (EEG) signal. There exists a wealth of techniques specifically designed to dissect EEG signals into various components. The application of EEG signal decomposition spans a broad range of uses, such as noise reduction [4], source separation/localization [5], and brain–computer interfaces (BCI) [6].

While EEG is predominantly measured with multiple electrodes (multi-channel) in most scenarios, signal decomposition techniques utilizing spatial features of signals, such as beamforming [7] and spatial filtering, have been thoroughly developed. For instance, independent component analysis (ICA) [8] predicates on the statistical independence among decomposed signals and estimates how these signals are spatially mixed. Apart from multi-channel measurement devices employed for research and medical purposes, there is an emergence of devices with fewer channels designed for consumer use. However, for these devices equipped with fewer channels, wherein the electrodes may be considerably distant from one another, it poses a challenge to leverage the spatial features for signal decomposition.

For measurement devices observing signals with spatially-sparse electrodes, a signal decomposition technique typically applied is single-channel signal decomposition. Classical time-frequency-based methods such as Fourier and (continuous) wavelet transforms [9] can be employed in this case. In these decomposition approaches, the decomposed signals are anchored to certain theoretical signals such as sinusoidal signals and brief waveforms, commonly referred to as mother wavelets.

Conversely, methods that tailor the decomposed signal for the target signal to be decomposed are termed data-driven or heuristic methods. When it comes to EEG decomposition, components may not always be assignable to specific frequency bands and can overlap across frequency bands. In such scenarios, data-driven methods—known for their flexibility in decomposing signals—prove to be highly effective [10]. Empirical mode decomposition (EMD) [11], a well-established data-driven decomposition method, is often applied to single-channel EEG signals.

The majority of existing data-driven decomposition techniques aim for adaptive application, meaning they rely solely on the signal-to-be-decomposed for the design of the decomposition. Given that the signal-to-be-decomposed may be relatively short, its decomposition can be significantly influenced by noise. Furthermore, the decomposition lacks consistency across multiple observed signals, making it challenging to determine whether a decomposed signal is desired or not.

In addition to the signal intended for decomposition, there are instances where other observed signals may be utilized to design the decomposition. For instance, in neuroscience studies, EEG signal samples gathered from multiple trials are typically batched and analyzed collectively. Similarly, for applications in brain–computer interfaces, training samples may exist that aid in the supervised training of classifiers. Despite the availability of an abundance of EEG samples, data-driven decomposition is typically conducted individually for each signal, with the decomposition being designed solely with the signal-to-be-decomposed.

Our research is motivated by the goal of leveraging

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

these EEG samples. We operate under the assumption that training samples are available and apply a (semi) supervised method to design short-length components, referred to as kernels. Similar to continuous wavelet transforms, we reconstruct an observed signal using a combination of time-shifted and amplitude-modified kernels. These adjustments in time-shift and amplitude are estimated by neural network modules, termed detectors. The optimization of these detectors occurs in tandem with the kernels. If the training samples originate from a specific person or task, the designed kernels and detectors could potentially be person-specific or task-specific.

To illustrate the efficacy of our proposed method, we conducted an experiment involving noise reduction for a BCI. In our experimental setup, the training samples were tagged with labels indicating whether they were free from noise events or had noise events at each sampling time index. Leveraging a supervised optimization strategy based on these labels, our method designs two modules that respectively output a noise-related signal and a non-noise-related signal.

II. Proposed noise reduction

We present a supervised signal decomposition technique leveraging an artificial neural network. This section commences by introducing the basic structure of the network. Subsequently, we elucidate a noise reduction method based on the proposed network.

A. Basic structure: A detector-kernel network

The proposed decomposition is founded on the assumption that an EEG signal can be reconstructed through a linear combination of short signals, denoted as kernels. This concept bears similarity to the Fourier transform, with kernels represented as complex sinusoidal signals, and the wavelet transform, with kernels depicted as mother wavelets. However, our proposed method distinguishes itself by designing these kernels in a supervised manner. Our proposed method employs a model comprising of detector and kernel networks. The detector network outputs coefficients for the linear combinations, while the kernel network produces the linear combinations using the detector output and a kernel.

To illustrate, let us consider a straightforward instance of a single reconstruction model that decomposes a signal into several components and reconstructs the original signal by summing the decomposed components. We posit that EEG signals can be reconstructed by N kernels, that is, an EEG signal is decomposed into N components. This model can be expressed as

$$x[i] = \sum_{n=1}^{N} \sum_{j=1}^{M_n} k_n[j] z_n[i-j], \tag{1}$$

where $x[i]$ is an observed signal with time index i, $\{k_n[j]\}_{j=1}^{M_n}$ is the nth kernel, M_n is the length of the nth kernel, and $z_n[i]$ is the magnitude of the nth kernel at time index i. Given that $z_n[i]$ represents the magnitudes, $z_n[i]$ must be a non-negative value ($z_n[i] \geq 0$). The objective of our proposed networks is to estimate the kernels k_n and their magnitudes $z_n[i]$.

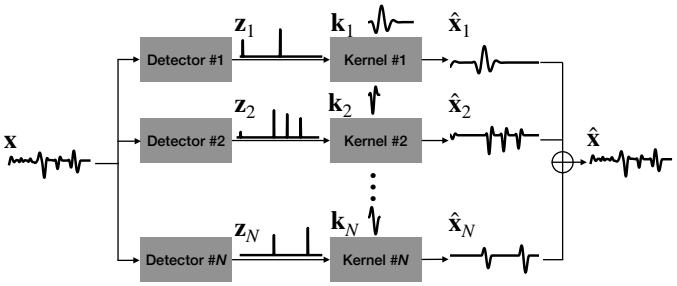

Fig. 1: Basic structure of the proposed detector-kernel network.

The proposed detector-kernel network estimates these variables in a supervised manner. The basic structure of the proposed network is depicted in Figure 1. A detector's role is to estimate $z_n[i]$. Any network that can output a non-negative signal of the same signal length as the input signal $x[i]$ may serve as a detector. For simplicity, we use a single convolutional layer in this instance. Then, the output of the nth detector is given as

$$z_n[i] = \mathrm{ReLU}\left(\sum_{j=1}^{P_n} d_n[j] x[i-j] \right), \tag{2}$$

where $x[i]$ is the observed signal and input for the detector, and $\{d[j]\}_{j=1}^{P_n}$ represents coefficients for the convolutional layer. This can be described in vector form with signal length N_t as:

$$\boldsymbol{z}_n = D_n(\boldsymbol{x}) \tag{3}$$

where $\boldsymbol{x}, \boldsymbol{z}_n \in \mathbb{R}^{N_t}$ are vector forms of the observed signal and the nth detector output defined as $\boldsymbol{x} = [x[0], x[1], \ldots, x[N_t-1]]$ and $\boldsymbol{z}_n = [z_n[0], z_n[1], \ldots, z_n[N_t-1]]$, respectively, and $D_n(\cdot)$ is an operator as described in (2). Both $\boldsymbol{x}$ and $\boldsymbol{z}_n$ have the same signal lengths. Due to the non-negative activate function, the detector output yields non-negative values. The detector output is expected to identify how time-shift and amplitude-modulate the kernel, represented by the preceding kernel network K, within the input signal $x[i]$.

The convolution with the kernels subsequently produces a decomposed signal:

$$\hat{x}_n[i] = \sum_{j=1}^{M_n} k_n[j] z_n[i-j]. \tag{4}$$

In vector form, the signal reconstruction by the N kernel network outputs can be described as:

$$\hat{\boldsymbol{x}}_n = K_n(\boldsymbol{z}_n) \tag{5}$$

where $\hat{\boldsymbol{x}}_n \in \mathbb{R}^{N_t}$ is a vector of the reconstructed signal defined as $\hat{\boldsymbol{x}} = [\hat{x}_n[0], \hat{x}_n[1], \ldots, \hat{x}_n[N_t - 1]]$ and $K_n(\cdot)$ is an operator described in (4).

The parameters to be optimized are the set of coefficients for each detector and each kernel:$\{\{d_1[i]\}_{i=1}^{P_1}, \{k_1[i]\}_{i=1}^{M_1}\}, \ldots, \{\{d_N[i]\}_{i=1}^{P_N}, \{k_N[i]\}_{i=1}^{M_N}\}$. The objective of the optimization is to minimize the discrepancy between the observed signal $x[i]$ and the reconstructed signal $\sum_{n=1}^{N} \hat{x}_n[i]$. This discrepancy is measured by

$$L = \sum_i \left\| x[i] - \sum_{n=1}^{N} \hat{x}_n[i] \right\|. \tag{6}$$

This loss function L is minimized during the training process. In this way, the detector-kernel network is trained to accurately decompose the input signal into components, each represented by a kernel.

B. Noise reduction using noisy-event occurrence periods

In this section, a method for noise reduction is described for a situation where one has a single EEG channel as input and the occurrence timings of events that might generate noise in EEG are known, but the nature of those noise components is not known. An example of this scenario could be when both an EEG channel and electrooculogram (EOG) channel are observed. The EOG signal can provide the timing of eye-related events such as blinks and saccades, which can cause noise in the EEG signal. Traditional methods for noise reduction in this situation often involve the use of multi-channel signal decomposition techniques like principal component analysis (PCA) or ICA to reduce noise components, assuming that noise components in the EEG signal are similar to the EOG signal [12]. In contrast, the method described in this section does not make such an assumption and is thus more general. The method can be used with any noise reference, as long as the timings of events that generate noise in the EEG can be detected. Other examples of noise references could include an eye tracker to detect the timings of eye blinks and saccades, or a motion capture system to reduce noise components due to body movements.

The network structure for the noise reduction is based on a signal observation model where the EEG signal, $x[i], i = 0, 1, \ldots, N_t$, contains both brain-related signals, $s_l[i]$, and noise-event-related signals, $n_l[i]$ formulated as

$$x[i] = s[i] + n[i] = \sum_{l=1}^{N_s} s_l[i] + \sum_{l=1}^{N_n} n_l[i], \tag{7}$$

where N_s is the number of the brain-related signals and N_n is the number of the brain-related signals. The purpose of noise reduction is to estimate $\{s_l[i]\}_{l=1}^{N_s}$ and $\{n_l[i]\}_{l=1}^{N_n}$.

The network consists of two detector-kernel networks: the first one is designed to extract brain-related signals and the second one to extract noise-event-related signals. Figure 2 provides a schematic representation of the network

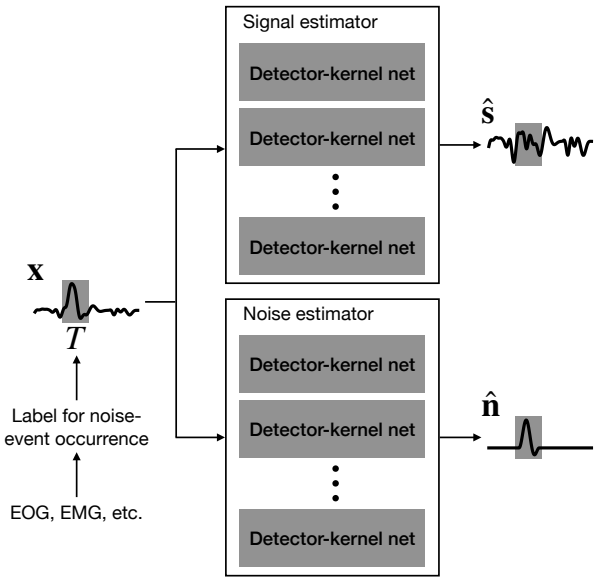

Fig. 2: Basic structure of the network for noise reduction.

structure. Here $\{D_{1,l}\}_{l=1}^{N_s}$ and $\{K_{1,l}\}_{l=1}^{N_s}$ are the detectors and kernels for the first network (signal-estimator), which is designed to extract the brain-related signals. Similarly, $\{D_{2,l}\}_{l=1}^{N_n}$ and $\{K_{2,l}\}_{l=1}^{N_n}$ are the detectors and kernels for the second network (noise-estimator), which is designed to extract the noise-related signals. The estimated noise-event-related signal $\hat{\boldsymbol{n}} \in \mathbb{R}^{N_t}$ is computed as the sum of the results of passing the input signal $\boldsymbol{x} \in \mathbb{R}^{N_t}$ through each detector-kernel pair in the second network:

$$\hat{\boldsymbol{n}} = \sum_{l=1}^{N_m} K_{2,l}(D_{2,l}(\boldsymbol{x})) = N_{\text{noise}}(\boldsymbol{x}). \tag{8}$$

where N_{noise} is the combined detector-kernel pairs for the noise-estimator. After estimating $\hat{\boldsymbol{n}}$, it is subtracted from the input signal $\boldsymbol{x}$ to obtain the signal without noise components. The result is then passed through each detector-kernel pair in the first network to estimate the brain-related signal $\hat{\boldsymbol{s}} \in \mathbb{R}^{N_t}$:

$$\hat{\boldsymbol{s}} = \sum_{l=1}^{N_s} K_{1,l}(D_{1,l}(\boldsymbol{x} - \hat{\boldsymbol{n}})) = N_{\text{signal}}(\boldsymbol{x} - \hat{\boldsymbol{n}}), \tag{9}$$

where N_{signal} is the combined detector-kernel pairs for the signal-estimator.

By minimizing loss functions, the parameters for the detector-kernels pairs are optimized. The loss function for the signal-estimator, N_{signal}, quantifies the discrepancy between the input signal and the sum of the outputs of the signal- and noise-estimators. This is calculated as

$$L_{\text{signal}} = \sum_{i=0}^{N_t - 1} |x[i] - (\hat{s}[i] + \hat{n}[i])|_2^2 = \|\boldsymbol{x} - (\hat{\boldsymbol{s}} + \hat{\boldsymbol{n}})\|, \tag{10}$$

where $\hat{s}[i]$ is the ith component of $\hat{\boldsymbol{s}}$ and $\hat{n}[k]$ is the kth component of $\hat{\boldsymbol{n}}$. On the other hand, the loss function

Algorithm 1 Learning a decomposition model for noise reduction

INPUT A set of training samples $\{\boldsymbol{x}\}$ and set of time indexes $\{T\}$ at which noise-events have occurred.
OUTPUT A signal estimator N_{signal} and noise-estimator N_{noise}
repeat
  Optimize N_{signal} by minimizing L_{signal}
  if Iterations is smaller than N_{iter} **then**
    Optimize N_{noise} by minimizing L_{noise}
  else
    Optimize N_{noise} by minimizing L'_{noise}
  end if
until Maximum iterations reach

L_{noise} for the noise-estimator, N_{noise}, evaluates the discrepancy between the input signal and the output of the noise-estimator during periods when noise events have occurred, as well as the power of the estimated signal during non-noise-event periods. With T which denotes the set of time indexes where the noise events have occurred in the epoch, the loss L_{noise} is

$$L_{\text{noise}} = \sum_{i \in T} |x[i] - \hat{n}[i]|_2^2 + \sum_{i \notin T} |\hat{n}[i]|^2. \tag{11}$$

This ensures that the noise-event-related signal is accurately estimated during noise-event-occurrence periods while giving no effect to the estimation of brain-related signals during noise-event-free periods. However, since this loss function does not take into account the output of the signal-estimator, $\hat{\boldsymbol{s}}$, a modification to L_{noise} is proposed after L_{signal} has converged or after a certain number of iterations in the optimization. The modified loss function L'_{noise} is defined as

$$L'_{\text{noise}} = \sum_{i \in T} |x[i] - (\hat{n}[i] + \hat{s}[i])|^2 + \sum_{t \notin T} |\hat{n}[i]|^2. \tag{12}$$

The pseudocode is provided in Algorithm 1 succinctly encapsulates the training process for the noise reduction model.

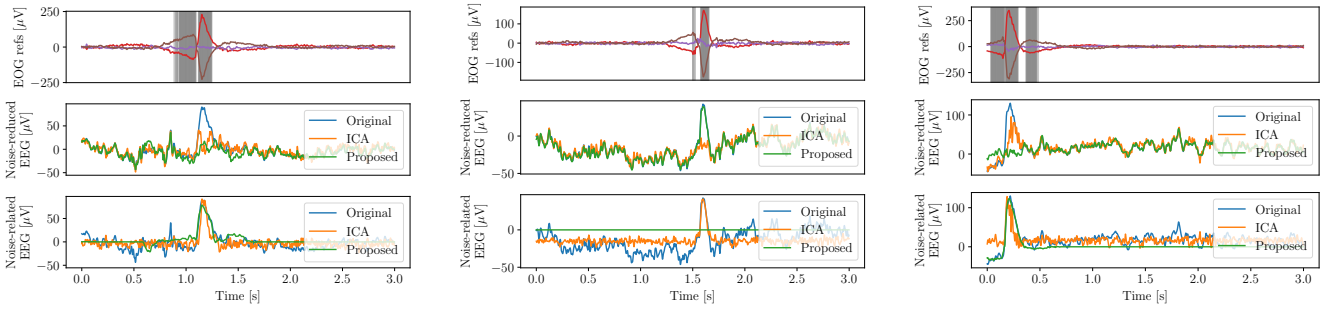
III. Experiment

A. Dataset

An open dataset for a motor-imagery-based BCI [13] used in this experiment. The dataset includes data from 15 participants, with each one performing seven different motor-imagery task. The dataset proposed the classification problem in which a signal is classified into a class out of C_1 (elbow flexion), C_2 (elbow extension), C_3 (supination), C_4 (pronation), C_5 (hand close), C_6 (hand open), and C_7 (rest). The dataset also included three EOG channels, with the electrodes placed on the left, right, and top of eyes.

As the focus of this study is on single-channel decomposition, only data from the F1 channel was used. The F1 channel is located on the frontal head area of the head, an area is often affected to noise-events such as eye blinks and saccades.

B. Classification procedures



The available samples were divided into three distinct sets: samples for signal decomposition training ($\mathcal{R}_1$), samples for classifier training ($\mathcal{R}_2$), and a testing sample set ($\mathcal{E}$). For $\mathcal{R}_1$, samples were from C_1, C_2, C_4, C_5, and C_6. The samples from C_3 and C_7 were used for the classifier training and testing sets ($\mathcal{R}_2$ and $\mathcal{E}$). These were split into training and testing samples using a leave-one-out cross validation (CV) approach.

The proposed method trained a signal decomposition model on the available samples $\mathcal{R}_1$. The signal- and noise-estimators employed 32 pairs of detector-kernel networks ($N_s = N_m = 32$). These detectors were constructed using four layers of convolutional networks, with a kernel size of 60 ms and four channels for the intermediate layers. As for the kernel networks, a kernel size was 1 s. The noise-estimators were optimized with the noise-event-free and noise-event-occurrence labels at each time index for each sample which were obtained from the EOG signals. From the three EOG channels, three bipolar EOG signals were derived. Time indexes where the EOG signals exceeded ± 50 μV were labeled as noise-event-occurrence. For the optimization of the decomposer network, we used an Adam optimizer (0.001 of learning rate, 0.5 of β_1, 0.999 of β_2, and 10^{-5} of weight decay). The optimization was carried out over 1,000 iterations with a batch size of 50. Following optimization, the signal decomposition model produced a noise-related signal and a brain-related signal for each sample. The brain-related signal was then input into a support vector machine (SVM) classifier that employs a radial basis function kernel. This SVM classifier (kernel coefficient γ ="scale", regularization parameter $C = 1$) was tasked with classifying each signal into either C_3 or C_7.

In addition to the proposed method, two alternative conditions were also evaluated for performance comparison: *Raw* and *Reject*. In the condition Raw, the signal was not subjected to any form of decomposition or noise reduction. The observed signals in $\mathcal{R}_2$ were input directly into the classifier. In the condition Reject, a simple form of noise rejection was implemented. Any samples having time indexes that were labelled as containing noise events were entirely excluded from classification.

C. Results

Figure 3 presents some examples of signal by noise reduction. The top panel exhibits the reference EOG signals, which were used to label each time index as either noise-event-free or noise-event-occurrence. The gray-shaded areas indicate time indexes labeled as noise-event-occurrence. It seems that large amplitude fluctuations in these areas on the EOG signals are caused by noisy events,

(a) (b) (c)

Fig. 3: Examples of signal samples from the sample set $\mathcal{R}_2$. The top panel shows the EOG reference signals. The middle panel shows the observed EEG signals (Original), the noise-reduced signals by ICA, and the noise-reduced signal by the proposed method. The bottom panel shows the observed EEG signals (Original), the noise-related signals by ICA, and the noise-related signal by the proposed method.

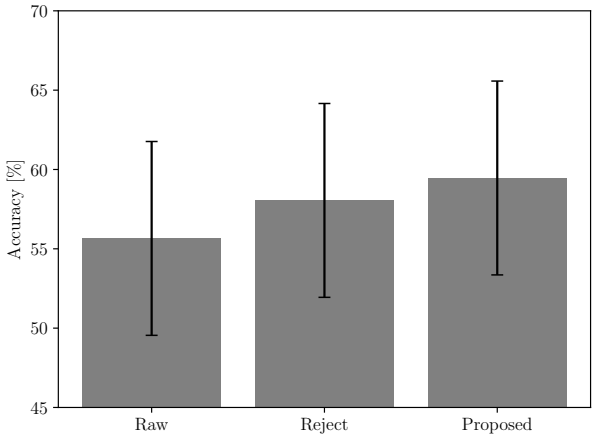


Fig. 4: Classification accuracy rates.

such as eye blinks or eye movements. The middle panel displays the original EEG signals from the F1 channel alongside their noise-reduced version. Noise reduction was performed using both the proposed method and ICA for comparison. In the ICA noise reduction, signals observed from all 64 EEG electrodes were used. Any independent components that had a correlation coefficient greater than 0.7 and less than −0.7 with any EOG signals were removed from the reconstruction for the noise-reduced signals. As can be seen in Figure 3a, both the proposed method and ICA successfully removed large fluctuations that were supposedly caused by noisy events. However, both methods often failed to completely remove these fluctuations, as demonstrated in Figure 3b for the proposed method and Figure 3c for ICA. These results show that while both methods have the potential to reduce noise-related fluctuations in the signal, neither is completely infallible.

The classification accuracy rates for each condition are presented in Figure 4. The proposed method exhibited superior accuracy rates compared to the condition Raw, indicating a significant improvement with a p-value of 0.007 given by a paired t-test. Moreover, the proposed method achieved comparable accuracy rates to those of the condition Reject, with a non-significant difference reflected by a p-value of 0.298. This highlights that the effectiveness of the proposed method in reducing noise-related components and its subsequent contribution to a robust classification.

IV. Conclusions

This paper presents a novel approach to single-channel EEG signal decomposition, grounded in the premise that a signal consist of several time-shifted and amplitude-modulated kernels. By leveraging a neural network-based model, we are able to estimate these kernels and accurately determine their time shifts and amplitude modulations. Our method was validated using a noise reduction problem in the context of BCI applications. Experimental results showed that our proposed method effectively separates noise-related and brain-related signals in a supervised manner. This presents promising prospects for the enhancement of noise reduction techniques and, consequently, for the performance and reliability of BCIs.

***Abstract*—Direct speech brain-computer interface (DS-BCI) is an ideal way for speech communication by decoding signals collected from the brain. Electroencephalogram (EEG) has gained widespread use in DS-BCI studies due to its simplicity of operation and high temporal resolution. However, as human brain exhibits considerable inter-individual variability, classification models trained on the basis of data from one subject may not generalise well to other individuals, which is a major challenge in existing EEG signal classification studies. In this paper, the cross-subject classification performance of spoken Mandarin speech with EEG signals was investigated by using an end-to-end convolutional neural network (CNN) model pre-trained on the source data and fine-tuned on the target data. The raw EEG signals were directly used as the input to the model without using extracted features. In addition, adding Gaussian noise was used as the data augmentation method in order to deal with the unbalanced dataset. The proposed method was tested on a collected EEG dataset of spoken Mandarin speech, including vowel classification and tone classification tasks. The average classification accuracies of four vowels and four tones were 63.1% and 51.7% respectively. The average accuracy of tone classification was significantly improved compared with the machine learning and subject-dependent methods. The results of this work showed the potential of the fine-tuning based CNN model in the cross-subject studies of EEG decoding.**

I. Introduction

Brain-computer interface (BCI) provides a direct access between the brain and external devices [1]. Direct speech brain-computer interfaces (DS-BCIs) are proposed as an ideal way of communication, because speech serves as a fundamental form of human communication and plays a key role in conveying thoughts and ideas. DS-BCIs decode human thoughts by reading and analysing signals from the brain [2]. They are useful for individuals with neurological disorders, such as aphasia, enabling them to effectively communicate with the world beyond their immediate limitations [3].

In the studies of DS-BCIs, speech includes three distinct modalities: overt speech, intended speech, and imagined speech [4]. Imagined speech refers to the internal dialogue or thoughts that occur in the mind of an individual without any actual form of verbal expression. Overt speech, i.e., spoken speech, refers to speech that is explicitly produced with articulation and vocalisation. While imagined speech is the most ideal form of speech BCIs, it is hard to decode due to its low signal-to-noise ratio and difficulty of temporal alignment. Therefore, this work concentrated on spoken speech, which has stronger intensity and detectable motor activities.

Many current DS-BCI studies use machine learning methods and require feature extraction [5]. In the previous studies, electroencephalogram (EEG) signals of spoken speech were analyzed using common spatial patterns and Riemannian manifolds as feature extraction methods and a linear discriminant analysis as the classifier [6], [7]. Four classes of Mandarin vowels and four classes of Mandarin tones were classified, and the average accuracies are 63.1% and 42.9% respectively. In another EEG study on Mandarin, Yang et al. classified tonal and nontonal sentences across subjects using rational asymmetry and binomial variable algorithm with 98.82% accuracy [8]. With the development of deep learning techniques, they have been applied to the studies of many EEG classification problems. For instance, some studies converted EEG signals into spectrograms as input to convolutional neural network (CNN) models [9], [10].

Extracting speech features carries the risk of losing potentially valuable information. Deep learning based models can avoid this problem by learning features directly from raw data. End-to-end neural networks have been used in different EEG classification tasks, such as motor imagery [11], attentive mental state detective [12], etc. Sereshkeh et al. employed a multilayer perceptron artificial neural network in a ternary classification task, i.e., distinguishing between 'yes', 'no' and the remaining trials, and achieved an average accuracy of 54.1 ± 9.7% [13]. By utilizing an extreme learning machine, Tan et al. classified EEG signals in BCI system and achieved a higher classification accuracy compared with support vector machines [14].

However, deep learning methods require a large amount of training data. Most current works relied on data obtained from the same subject [15]. Collecting a large dataset is difficult due to the limitation of human attention and the health status of patients. Therefore, it is necessary to explore cross-subject

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

classification methods that can improve the generality performance of classification models [16]. For instance, Cooney et al. used deep CNN and transfer learning methods to classify EEG-based imagined vowels, with the highest overall accuracy of 35.7% [17].

This work presented a deep learning method for decoding spoken Mandarin with EEG signals and investigated its cross-subject classification performance. The experimental design consists of two tasks using the collected dataset to classify four vowels and four tones of Mandarin respectively. A CNN model was pre-trained on the source data and then fine-tuned on the target data. The raw EEG data was used as input to the model. In addition, the EEG dataset was augmented by adding Gaussian noise to avoid the unbalanced dataset.

II. Methods

A. Dataset

The dataset employed in this experiment was obtained from the previous studies [6], [7], involving EEG signals of four speech modalities (i.e., listening, imagined speech, intended speech, and overt speech). The participants consisted of eleven individuals, including four female and seven male subjects (22.6 ± 3.2 years). The dataset collected EEG signals containing 70 Mandarin monosyllabic words as stimuli. It contained a total of 54 words consisting of different combinations of 4 vowels (i.e., /a/, /i/, /u/ and /ü/), 5 consonants (i.e., /b_/, /f_/, /j_/, /l_/ and /m_/) and 4 tones (i.e., Mandarin tones 1, 2, 3 and 4). It also contained 16 single vowels, which were combinations of four vowels and four tones in Mandarin. All words used in the dataset were displayed in Table I.

Scalp EEG signals were recorded using a 64-channel electrode cap manufactured by Neuroscan Inc. The stimuli and audio recordings were acquired at a sampling rate of 500 Hz. The ground channel was positioned on the forehead. The reference channels were placed at the tip of the nose, bilateral mastoids, and above and below the left eye to remove oculomotor signal interference. Data from one subject (i.e., the 6th subject) was excluded from the analysis due to the presence of numerous artifacts. After manual elimination of the less valid data, a total of 3297 trials were retained. More details of the experimental paradigm can be found in [6], [7].

TABLE I
List of Monosyllabic Stimuli

	b_	**f_**	**j_**	**l_**	**m_**	**_**
/a/	ba	fa		la	ma	a
/i/	bi		ji	li	mi	i
/u/	bu	fu		lu	mu	u
/ü/			ju	lü		ü

B. Data Preprocessing

All the EEG data were preprocessed using EEGLAB [18], which involved re-referencing and filtering. Filtering included a finite impulse response band-pass filter with cut off frequency of 0.5 $\sim$ 70 Hz and a notch filter with cut off frequency of 49 $\sim$ 51 Hz. The data were then subjected to independent component analysis and manual removal of artifacts, including those from electrocardiography, electrooculography, electromyography, etc [19].

This experiment extracted a total duration of 2500 milliseconds of spoken speech EEG data across all channels. The size of each trial was (1250, 62), corresponding to the number of samples and the number of channels. The start point and the duration of each trial were identified using a voice activity detection algorithm. To handle varying length of data, the input matrices were processed with zero-padding. The final size of each input matrix was (900, 62). All data were normalised.

The experiment was divided into two tasks, which were tone classification and vowel classification. For each trial, there were two labels that indicated its tone and vowel respectively.

C. Network Structure

The CNN architecture employed in this study was designed for EEG decoding based on EEGNet [20]. The structure of the CNN architecture was shown in Table II. The three dimensions of the size of feature map corresponded to channel, width and height respectively.

The feature extraction block of the network comprised three convolutional layers. The raw EEG data was used as input of the network. The first convolutional layer was composed of two individual layers, namely 1a and 1b. Layer 1a performed temporal convolution, while layer 1b performed spatial filtering. Subsequently, batch normalization was applied, and the results were fed into a non-linear activation function. Similar structures were employed for the second and third convolutional layers, accompanied by max pooling operations. The non-linear activation functions for the first three layers were all ReLU. The output of the network was generated using a fully connected network and a softmax function, yielding the final classification results. A dropout layer with a scale of 0.3 was used.

D. Data Augmentation

In both vowel and tone classification tasks, an imbalance in sample size between the four classes was observed, which may lead to a decrease in classification accuracy. To solve this problem, the dataset was augmented by adding Gaussian noise to the time-domain data before the pre-training process [21]. For the class with a small sample size (e.g., vowel /a/ and tone 4), trails were randomly selected and Gaussian noise with a mean of 0 and a standard deviation of 0.01 was added. This method allowed for a balanced sample size for all four classes in both tasks. The maximum difference in sample size between any two classes was not greater than 10.

E. Model Training Procedure

The training process for the pre-trained model used data from all 9 individuals except the target subject. The dataset was divided into training set and validation set. 80% of the

TABLE II

source data were used for training and the remaning 20% were used for validation. During the training process, a batch size of 16 was employed. The optimiser was Adam [22]. The loss function used to measure the difference between the predicted outputs and the true labels was the cross-entropy loss function. Learning rate for the pre-training phase was set to 0.001. The training process for the pre-trained model continued for 100 epochs. At the end of the training process, the model with the highest accuracy on the validation set was selected as the pre-trained model. This model was then used as the starting point for further fine-tuning.

For the fine-tuning stage, data of the target subject was used, allowing the model to learn and adapt to the specific features of the target subject. The data of the target subject was divided into training set, validation set, and testing set. 50% of the trials were divided into 25% for training and validation respectively, and the remaining 50% were used for testing. This split ratio was set to evaluate the performance of the model and to ensure that it generalized well to unseen data. The process did not use any data augmentation techniques. However, when splitting the target dataset, the numbers of trials for each class of data balanced in the training and validation sets, which prevented bias in the model learning process and ensured that all classes of data were fully utilised. The learning rate was set to 0.002, while keeping the other parameters consistent with the pre-training step. At the end of this process, the model with the highest accuracy on the validation set was selected as the final model.

III. RESULTS

Table III and Table IV show the confusion matrices for tone classification and vowel classification, respectively, including average accuracy and standard error of mean value for all 10 subjects as the target subject. The column labels in the confusion matrix correspond to the correct labels and the row labels correspond to the predicted labels. The highest accuracy values are marked in bold.

The average accuracy of tone classification is 51.7%. Tone 4 has the highest accuracy of 62.4%. In the previous study of tone classification task [7], i.e., the subject-dependent method using Riemannian manifold, the classification accuracies for the four classes are 37.4%, 40.5%, 48.3% and 44.7%, respectively. The average accuracy is 42.9%. The results in Table III show that the classification accuracy of tone 1 is comparable to that in the previous study. The accuracies of tone 2, tone 3 and tone 4 improve by 3.8%, 10.6%, 17.7% points respectively. The overall accuracy is 8.8% point higher than that in the previous study.

The average accuracy of vowel classification is 63.1%. Vowel /a/ has the highest accuracy of 79.2%. In the previous study [6], the average accuracy of vowel classification is 68.5%. The accuracy in this study is slightly lower than that of the subject-dependent experiment. It is noted that the classification accuracy of vowel /ü/ reaches 42.5%. It is 13.3% higher than that of the previous method, which is 29.2% [6].

The average precision, recall, and F1 scores for the two tasks are summarized in Table V. In both tasks, the three evaluation metrics yield similar results. The precision, recall, and F1 scores of the vowel classification task consistently outperform those of the tone classification task, aligning with the accuracy findings.

TABLE III
CONFUSION MATRIX OF SPOKEN TONE CLASSIFICATION

Accuracy (%)	Tone 1	Tone 2	Tone 3	Tone 4
Tone 1	37.1±3.6	31.8±4.3	14.7±4.1	16.4±4.8

/ü/	7.4±3.1	30.71±3.5	19.55±6.5	42.5±9.2

IV. DISCUSSION AND CONCLUSIONS

This work presented a cross-subject study for classifying spoken speech with EEG signals. It was tested on a Mandarin spoken speech EEG dataset, including tone classification and vowel classification tasks. A CNN network was employed, with the model pre-trained on data from non-target subjects

TABLE V
PRECISIION, RECALL AND F1 SCORE OF VOWEL CLASSIFICATION AND TONE CLASSIFICATION

	Precision (%)	**Recall** (%)	**F1 Score** (%)
Vowel	58.6	58.9	58.7
Tone	50.3	50.7	50.5

and subsequently fine-tuned using data from the target subject. The model was cross-validated with data from 10 subjects. The average accuracies of vowel classification and tone classification were 63.1% and 51.7% respectively, achieving comparable performance to the previous subject-dependent studies. The tone classification task exhibits an improvement of 8.8% point in average accuracy.

Cross-subject classification studies can be valuable in making full use of existing datasets to train models used on target subjects. The average accuracy achieved in the tone classification in this study surpassed that of the previous subject-dependent experiment. In the case of vowel classification, while the average accuracy fell slightly below the subject-dependent experiment, it still yielded comparable results. This can be attributed to the inherent challenge posed by subject-independent experiments, where data variances among different subjects introduce additional complexity. The outcomes of this study exhibit the ability of pre-trained models to extract generalizable features or patterns from the source data and effectively apply them to the target subject after fine-tuning. However, this study only focuses on spoken speech EEG signals. Future extension of this research could explore imagined speech, considering the correlation between the envelope of imagined speech and that of spoken speech [23].

Vowel /ü/ has a much lower classification accuracy than the other three classes in the previous study, because of its similar formant structure to other vowels [6]. However, this experiment showed a remarkable improvement in classification accuracy for vowel /ü/, indicating the advantage of the deep learning method over the machine learning approach in distinguishing vowels with similar formant structures.

In addition, the subject-independent study revealed improved results in the tone classification compared with the subject-dependent method, and the average accuracies of three classes demonstrated improvement, suggesting the presence of shared features from Mandarin tones across different subjects. This finding can be useful for future studies in Mandarin DC-BCIs, particularly in enhancing the adaptability of cross-user classification models by extracting appropriate features from tones.

In conclusion, the proposed method demonstrated its potential to decode spoken Mandarin speech with EEG signals across different subjects. The vowel classification obtained higher average accuracy and the accuracy of the previously challenging class was effectively improved. On the other hand, the tone classification had a better cross-subject performance.

Abstract — **Coinciding with the rapid growth of neural engineering technologies, the social demand for digital mental health is rapidly rising to date. While neuroimaging techniques, such as functional MRI or MEG, allow us to monitor neural activities in depth brain regions and sparse networks, direct application of those tools is limited in real life to assess neural well-being in real life. Literature suggests human interoceptive awareness is associated with activities and connections from the insular cortex as a part of the saliency network. Accumulating evidence suggests monitoring and modulation of these functional connectivities may reflect or improve our mental states. The neurophysiological link between signals from fMRI and EEG is isolated due to varieties of reasons; however, here we propose a novel signal processing approach to decode the time-course of functional connectivity obtained from fMRI by the concurrently recorded EEG signals (n = 28). To exploit the feasibility of this fusion network decoding, we present a novel machine learning method, "optimized forward variable selection decoder," that achieves higher decoding accuracy over classical methods. We propose a unified EEG model for brain-computer-interface applications in real life that can be applied for monitoring mental well-being in daily life.**

I. Introduction

In the last decade, the applications of machine learning (ML) approaches have attracted increasing interest in the vast majority of modalities of fields from biology to psychology, including neuroimaging studies. Previously, the forward variable selection approach was proposed in the domain of genetic data analysis. Here, we present a novel application of an optimized decoding algorithm for neuroimaging data. The decoding of neural information has dramatically increased and improved in neuroscience to date; however, the curse of its high dimensionality and non-stationarity of neurophysiological data variability yields a number of challenges.

For instance, generalization performance is one of the most important focuses of ML studies, such as ensemble learning methods. The ensemble learning methods improve their generalization ability by fusing the prediction results of basic models (e.g., the random forest is an ensemble of decision trees). However, the high dimensionality of data typically impedes the generalization performance of decoding approaches, causing estimation instability, model overfitting, local convergence, or critical estimation errors. Specifically, it has been a challenge to successfully decode with basic ML models because the decoding accuracy notably decreases in the high dimensional computations [1], [2]. Moreover, the high dimensionality is also linked to longer computational time. Therefore, it is pivotal to efficiently identify optimal sets of features for ML models that achieve successful generalization.

The recent development of the brain-computer-interface (BCI) has gained hope for solutions for mental health issues in real-life scenarios. Various BCI models have been proposed; functional connectivity (FC) is thought to reflect remotely interconnected neural activities across brain regions, and EEG correlates of FC are thought to reflect mental states [3]. However, the direct link between fMRI and electrophysiological responses is reportedly low [4], indicating potential risks to the fidelity of neural markers connecting the two distinct neural responses.

A successful integration of decoded fMRI-driven functional networks using EEG signals can have several potential benefits. It empowers us to investigate both the spatial and temporal dimensions of brain activity, reflecting remotely

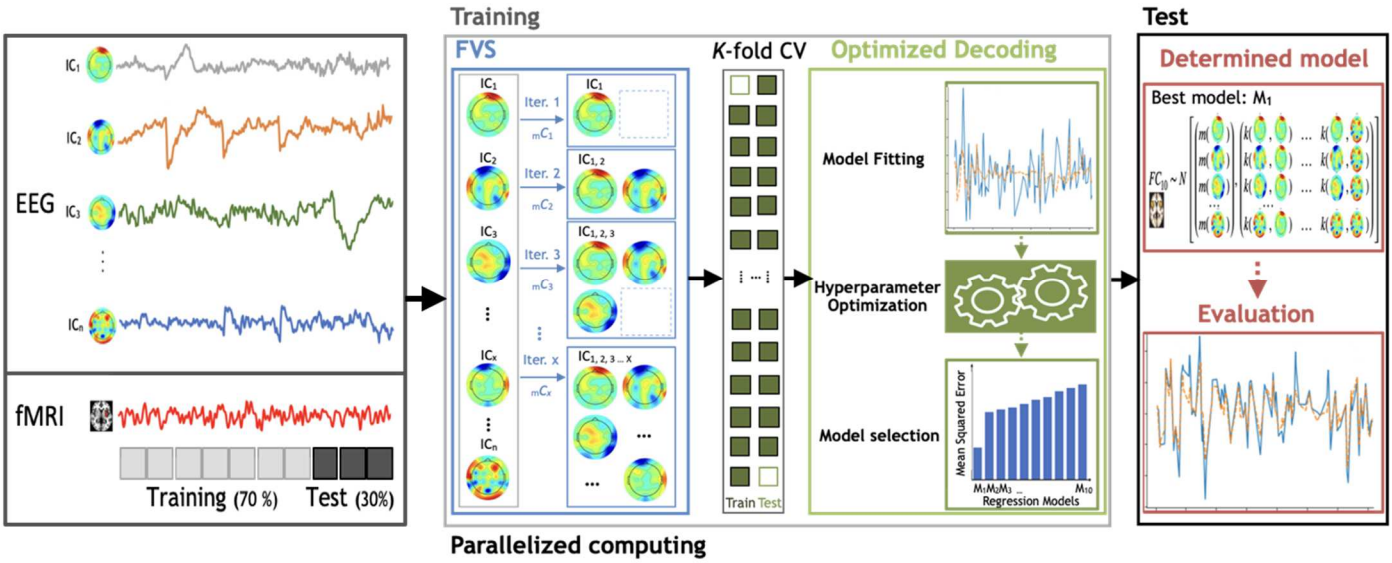

Fig. 1. Computational workflow of the optimized forward variable selection decoding toolbox (oFVSD) on the multimodal neuroimaging dataset. All features, i.e., the EEG ICAs, underwent the iterative FVS steps ('Iter.'), followed by regression-based machine learning with K-fold cross-validation ('CV'). At the decoding step, the random and grid search strategies with cross-validation were adopted to optimize the hyperparameters of model(s) at each iteration of the FVS algorithm. The training data was used to guide the refinement of decoding outcomes by minimizing the mean squared error (MSE) value, and the performance of the selected model was subsequently assessed on a separate test dataset to ensure its predictive accuracy. n: the total number of features; x: a user-defined maximum number of features. A determined computational model (a case of Gaussian process regression) is shown in the top right corner.

interconnected brain regions. However, linking the brain-to-brain activities obtained from concurrent EEG-fMRI datasets has been challenging. Yet, it can potentially connect putatively distant neural activities between indirect and direct measures of brain activities obtained from fMRI and EEGs, respectively. Here, we examined the feasibility of the enhanced forward selection decoding toolbox, which was developed in our previous study using structural MRI datasets [5] on the cross-modal neuroimaging data. Moreover, a saliency network was selected as a use case sample for this feasibility as one of the major FCs.

II. Methods and Material

We developed a novel decoding pipeline to overcome these challenges by incorporating two frameworks. Firstly, we developed an automatic ML framework that can automatically select the best model out of multiple regression models as well as classifier models with the forward variable selection (FVS) for each model [3,4]. To examine the feasibility of our approach, we examined regression models to decode the time course of FC of the saliency network obtained from functional magnetic resonance imaging (fMRI) by the concurrently recorded cortical electroencephalography (EEG) signals recorded from healthy young adults (n = 28). On ten selected regression models (see details in [5]), the FVS was followed by a hyperparameter optimization. The FVS reduces the dimension of this input, including regularization models for feature selection, as well as models that perform a random sampling of the available features to generate different subspaces of features in order to achieve a bias-variance trade-off. Note kernel models were considered to let interactions between features and nonlinear functions, therefore driving the prediction. Secondly, we employed a 'parallelized' pipeline that was coupled with the FVS algorithms to maximize the predictive performance.

A. Concurrent EEG-fMRI Data Acquisition

A 15-min eyes-open resting-state fMRI was recorded in the Siemens Skyra scanner (T2*-weighted echo-planar imaging: TR = 2,500ms; TE = 29ms; flip angle 90°; 3.0x3.0x3.5mm; slice thickness 3.5mm; FOV 192mm). The structural images of each participant were acquired using the following parameters: TR = 2,300 ms, TE = 2.98 ms, voxel size of 1.0 × 1.0 × 1.0 mm, flip angle = 9°, and FOV = 256 mm. Concurrent EEG signals were continuously recorded at 1,000 Hz with an MRI-compatible 32 channels system (BrainAmp MR plus, Brain Products).

B. fMRI Data Preprocessing

To extract the FC from the resting-state fMRI data, we performed a group independent component analysis (group-ICA) using CONN Toolbox (version 21.a; [7]). Data were

preprocessed by the default preprocessing pipeline in the CONN Toolbox, including realignment, slice timing correction, outlier detection, direct segmentation, normalization to Montreal Neurological Institute (MNI) space, and smoothing. Then, motion artifact from the blood-oxygen-level-dependent (BOLD) signal was denoised. A group-ICA was performed to separate fMRI time series into spatial source maps and loadings. The number of components was set to 20, resulting in 20 independent components (fMRI-IC). Of those fMRI-ICs, a saliency network was identified based on contributing brain regions. For each participant, we extracted the time series of each IC that represents a measure of FC in different intrinsic networks.

C. EEG Data Preprocessing

EEG data were preprocessed with the FMRIB plug-in (https://fsl.fmrib.ox.ac.uk/eeglab/fmribplugin/) for EEGLAB (https://sccn.ucsd.edu/eeglab/) followed by conventional artifact rejection procedures implement on the EEGLAB and down-sampled to 500Hz and FIR bandpass filtered at 0.01–40 Hz and artifact rejection was performed with MARA plug-in and additional visual inspections. Cleaned EEG signals underwent a logistic infomax independent component (IC) analysis, resulting in twenty-some ICs per subject (note, the number of ICs is not equal across subjects due to the variability across subjects). The time course was then convolved with a hemodynamic function and down-sampled to 0.5Hz.

D. Decoding with oFVSD.

We used the FVS algorithm [5] to identify a small number of features (EEG ICs). At each learning step, the FVS selects a feature that provides the largest increase in predictive performance and the largest reduction of MSE and then adds it to the set of 'selected' features. The FVS algorithm continued until no feature improved performance or a maximum number of selected features had been reached. At the end of FVS iterations, feature identification of selected features. Hyperparameter optimization was applied for both cases *with* and *without* the FVS. Cross-validation was applied at each forward iteration. Given the selected features, samples were randomly split into a training dataset comprising the first 70% of the samples and a test dataset with the remaining 30%. Additional fivefold cross-validation was used on the training data to select an appropriate parameter configuration for a specific model to optimize the respective hyperparameters. At this step, mean squared error (MSE) was used to determine the best-performing hyperparameters for each approach on the training dataset. Moreover, the optimization algorithm was implemented to identify the best hyperparameter values of the ML model. Depending on the number of hyperparameters of each model, either an 'exhaustive grid search' that considers all parameter combinations or the 'random search' that randomly selects a given number of values from a parameter space was considered for parameter optimization in the cross-validation step [8]. MSE and Spearman correlation coefficients between the true and predicted values were used as a criterion for decoding performance [5] so that the outcome can be comparable across nonparametric regression models.

A computer-friendly procedure was proposed for dealing with very high dimensional microbiome data [9]. This is true for neuroimaging data [5]. The number of these subsets (or comparisons) is mostly larger than the number of processors in a single computer system. Parallel computing was applied as implemented in the oFVSD. For each forward iteration, the input variables were separated randomly into a number of subsets. The computation time for each model was assessed.

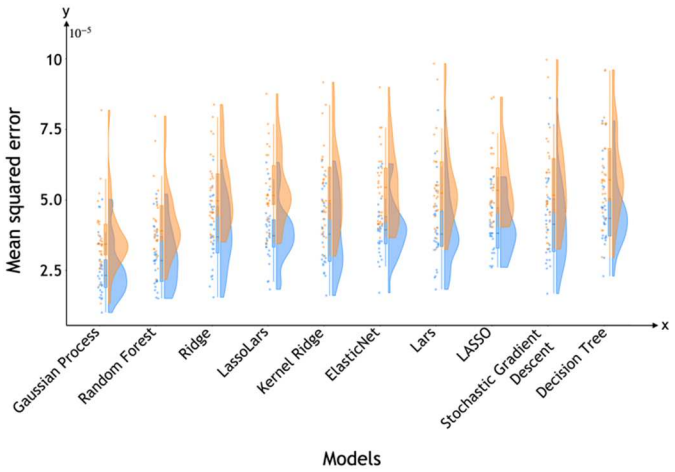

Fig. 2. Violine plots of mean squared errors of regression models *with* forward variable selection (FVS: blue color) and *without* FVS (orange color). The time-courses of the saliency network from fMRI were decoded by that of EEG ICs in a concurrent EEG-fMRI recording at resting-state. Entries are sorted in order of ascending mean squared error (MSE) values.

III. Results

A. Decoding Performance

We systematically evaluated regressor performances using the EEG and fMRI databases. As for the regression model, we predicted the time course of FC obtained from fMRI as a function of selected ICAs from the concurrently recorded EEG signals. Fig. 2 shows the MSE values for each ML model *with* and *without* the FVS algorithm to predict the time course of the

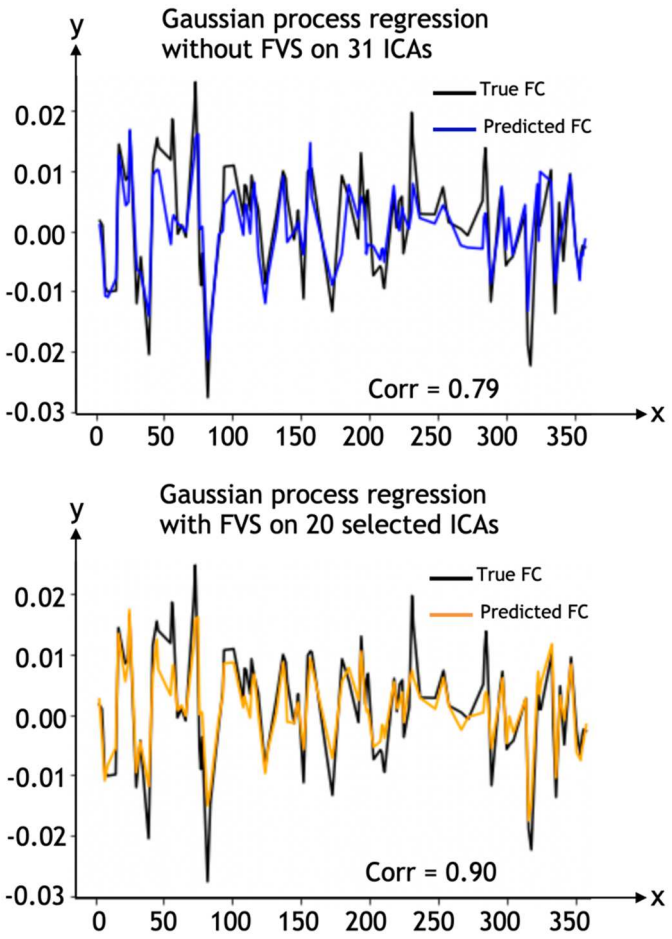

Fig. 3. Activity amplitudes of the saliency network as a function of time (in seconds) for true time-course from fMRI (in black color) and for predicted time-course decoded from EEG signals from a subject. A case of Gaussian process regression without FVS algorithm (in blue color) with all 31 EEG ICAs (overall MSE = 3.37 x 10^{-5}, Spearman ρ ('Corr') = .79, p = .058), and that with the FVS algorithm (in orange) with a subset of EEG ICAs selected with the FVS algorithm (MSE = 2.08 x 10^{-5}, Spearman ρ = .90, p < .0001).

FC from all subjects. Across all ten models, the use of the FVS algorithm strongly outperformed the conventional ML models *without* the FVS algorithm (repeated-measure ANOVA: $F_{1,28}$ = 132.517; p < .0001; η_p^2 = .826). The ML models also showed a strong effect ($F_{9,127.76}$ = 40.059; p < .001; η_p^2 = .589, corrected by Greenhouse-Geisser). Across all models, 'Gaussian Process' regression was among the best (an average MSE = 3.63 x 10^{-5}; p < .001, Bonferroni corrected) followed by 'Random Forest' (p = .002). There were little differences across models (p > .05, not significant) except that 'Decision Tree' was the worst than almost all models (not significant against 'Stochastic Gradient Descent').

Fig. 3 depicts a single case example of the time course of the saliency network activity obtained from fMRI and its predicted time course from EEG signals for both *without* and *with* FVS algorithms decoded with the Gaussian process regression. For a subject, among all model comparisons, 20 out of 31 EEG ICs were identified using the FVS-supported Gaussian process regression model.

B. Computational Cost.

Notably, it is essential to consider the computational cost (see Table 1 for the computational cost of each model and algorithm). In terms of decoding accuracy, 'Random Forest (second best)' models (MSE = 4.19) without variable selection comparatively were as good as the Gaussian Process model (MSE = 3.33, see Table 1 and Fig. 2). However, the computational costs of the Random Forest model (CPU time = 80 seconds without FVS) model were more expensive because the parameters were more complex than those of the Gaussian Process model (CPU time = 37 seconds without FVS).

Table 1 Computational time (CPU time) of the ML models to predict age. FVS: forward variable selection algorithm; Entries are sorted in order of ascending mean squared error (MSE) values.

Model	MSE (10^{-5})		CPU time (secs)	
	with FVS	without FVS	with FVS	without FVS
Gaussian Process	2.19	3.33	582	37
Random Forest	2.96	4.19	988	80
Ridge	3.80	5.34	255	5
LassoLars	3.84	5.38	376	6
KernelRidge	3.90	5.38	609	21
ElasticNet	3.97	5.45	393	22
LASSO	4.06	5.53	261	5
Lars	4.07	5.51	271	6
Stochastic Gradient Descent	4.27	5.58	777	42
DecisionTree	4.66	6.00	626	38

Additionally, the ridge regression model achieved a fairly comparable performance (MSE = 5.34) to the Random Forest (MSE = 4.19), while the computational time of ridge regression was considerably shorter (CPU time = 5 seconds without FVS) than that of Random Forest model (CPU time = 80 seconds without FVS). Conversely, the stochastic gradient descent and

decision tree models had poor performances with low values (MSE = 5.58 and MSE = 6.00, respectively).

C. Application for BCI

The decoded model can then be applied for a BCI as an estimate of the target FC time course for monitoring or neurofeedback purposes. Fig. 4 depicts a sample decoded model using the Gaussian Process. The resultant algorithm can be implemented using IC-based BCI [10]. While practicality, such as computational time, needs to be assessed for real-time BCI, this model can be surely applicable for offline assessment without using fMRI outside the laboratory setting. While we demonstrated the fusion of EEG-fMRI at the individual level in this study, future studies could elaborate on building a standardized or generalized model for practical solutions.

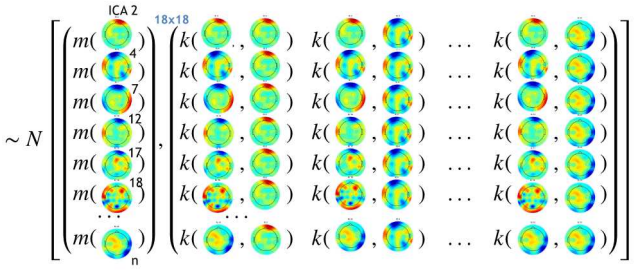

Fig. 4. A schematic sample case of decoded Gaussian Process model for a FC. Out of 32 EEG-ICs, 18 ICs were selected for this case. These model can be implemented for IC-based BCI model.

IV. Conclusions

The proposed approach presents the following advantages compared with the previous methods. Firstly, neuroscientists could benefit from the automatic selection of the most appropriate (or best-performing) model for their own data sets. In our proposed approach, 1) the benefit of feature selection was apparent; 2) Gaussian process regression appeared to perform better than the other ML models to link the EEG to fMRI FC signals; and 3) a unified BCI model has been proposed (see Fig. 1 top right panel). Further interpretation is needed to fully understand why we observed such decoding patterns and why there is a large variability in decoding performance across individuals. Although we applied parallel computational techniques for overcoming large-scale problems in the FVS algorithm, a high-performance machine is still necessary for completing our proposed method.

Our toolbox [5] can identify a minimal-size core set of features that can provide insights into the neurophysiological link between signals from fMRI and EEG. Having shared the toolbox in the Python environment, we hope our package, originally built for genetic analysis, would also be a great tool for studies on the brain-computer interface and neuroimaging.

***Abstract*—Brain-Computer Interface (BCI) provides a novel way of communicating with computers but their poor performance in terms of speed and accuracy in comparison to the other modes of communication has been the biggest obstacle in their usage for practical applications. In this work, we aim to enhance the performance of BCI by utilizing speech data collected along with the electrocorticogram (ECoG) recordings when the person is speaking. While some BCI users may have difficulty in speaking at all, many of them can speak, even though their speech may be unclear. We propose that information from this speech data can help in improving accuracy and to employ such speech context to assist the decoding process, we apply a multimodal recognition method. We use speech data contaminated by noise in our evaluation to simulate the cases where the available speech quality is low. Our experiments using data from five subjects suffering from Epilepsy show that our method of using multimodal input has a significant improvement, an absolute reduction in phrase error rate by 1.1 points from recognition using speech alone and by 51.3 points from recognition using ECoG alone.**

I. Introduction

Brain-Computer Interfaces (BCIs) allow humans to communicate with computers directly through their brains by translating their brain activity into computer-readable and implementable formats. Their application areas are rehabilitation of disabled people along with non-medical fields such as Gaming, Internet of Things (IoT), and autonomous driving [1]–[3].

BCIs are not yet widely adopted in our society because of their sub-par performance due to challenges such as the trade-off between quantity and quality of brain data that can be recorded, complex and non-stationary brain signals, and difficult feature extraction process [1]. Past studies achieved acceptable results for several tasks such as controlling a cursor or prosthesis by translating the brain activity produced while imagining motor movements [4], [5]. However, such BCIs are still limited in terms of their applicability.

Lately, the focus has been on the decoding of speech from the brain as it further extends the scope of usability. Amongst different methods of brain data acquisition, Electrocorticography (ECoG), which measures the electrical activity of the brain from sensors placed directly on the cortical surface, has been frequently used due to its high temporal and spatial resolution which is required for fast-paced continuous speech recognition [6]. However, its invasive setup restricts its usage only under strict medical requirements resulting in the availability of limited amounts of data.

Most speech-based BCI studies perform spoken speech recognition as the first step towards implementing BCIs based on imagined speech since it is easy to monitor changes in brain activity when corresponding speech data is available. Ref. [7] was the first to decode continuously spoken speech from ECoG using the Gaussian mixture model.

Recently, advancements in the field of Automatic Speech Recognition (ASR) are being employed to BCIs even though the ECoG datasets are fairly smaller in size compared to frequently used speech datasets. For example, [8] used a Bi-directional Long Short Term Memory (BLSTM) based sequence-to-sequence encoder-decoder architecture to translate brain signals into sentences. Their approach was based on multi-task learning which required training the encoder with features obtained from the simultaneously produced speech and they achieved Word Error Rate (WER) as low as 3% for a subject. Ref. [9] extended this approach by switching the encoder architecture from BLSTM to Transformer as Transformers are better at learning long-range dependencies thereby achieving improved performance. Ref. [10] proposed a novel Brain2Char architecture that employed a Connectionist Temporal Classification (CTC) Decoder along with an external language model to avoid dealing with the alignment between speech and brain and they also achieved low WER of around 10% for a much larger vocabulary.

While these studies achieved good performance, their accuracy degrades with less training data or if the electrode arrays used to measure brain activity are less dense. To mitigate this problem, they assist their model with simultaneously recorded speech data by guiding their network with speech features so that it learns to make better predictions, but the improvement in performance is still not as significant. Another limitation is that none of them consider the scenario where clean spoken speech data is not available such as where the subject has difficulty in speaking.

Taking inspiration from studies employing multimodal speech recognition [11], we propose to utilize the speech information by using it as input along with ECoG. Different from previous works where speech features were used as a target for intermediate layers, we combine information from

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

speech and ECoG features in a multimodal manner through a late fusion approach so that we can utilize the speech context efficiently. Additionally, to simulate the case when available speech quality is low, we propose to use noise-added speech in our experiments. Our aim with this approach is to show that if speech modality is available, irrespective of the quality of speech, it can be employed in BCIs to improve their performance.

II. Method

A. Dataset

Five subjects (js4, js5, js6, js7, and js8) undergoing brain monitoring through the intracranial placement of ECoG arrays for treatment of epilepsy at Juntendo University Hospital volunteered to be a part of this study. A written, informed consent approved by the Ethics Committee of Tokyo University of Agriculture and Technology, Tokyo Institute of Technology, and Juntendo University Hospital was obtained beforehand. The details about this dataset are summarised below but more information can be referred to from [9].

During the experiment, the subjects were asked to speak out loud the sentence being displayed on a screen in front of them while their corresponding speech and ECoG data were collected. All subjects were conscious during the experiments and had no trouble speaking.

The sentences used for the experiments consisted of 8 different Japanese language sentences. Each sentence is made up of three phrases. The first phrase is either 「わたしは」(I) or 「きみと」(with you), second is 「がっこうへ」(to school) or 「しょくばに」(to office) and the last one is 「いった」(went) or 「むかう」(go) .

Speaking one sentence constituted one trial, and 80 trials were recorded for each subject. The speech and ECoG data were digitized at a sampling frequency of 9,600 Hz. The number and placement of electrodes varied between subjects because it depended on their medical condition, so we adopted a subject-dependent approach by performing experiments for each subject separately.

B. Preprocessing

Simultaneously recorded speech and ECoG data for each subject were trimmed to a length equal to the maximum duration of the sentence spoken by that subject so that the model does not learn to predict the output based only on the length of the sentence.

To be inclusive of conditions where clean speech is not available or feasible, we added Signal-to-Noise Ratio (SNR) equal to -10 white noise to our raw speech data. Since it's extremely difficult to collect data from speech-disabled subjects with implanted ECoG arrays who also volunteer to participate in research, preparing such data by manually adding noise helped in simulating conditions close to the real-world scenario.

C. Network Architecture

Taking inspiration from recent works which showed end-to-end architectures can decode speech from ECoG efficiently [8]–[10], we decided on employing a similar model consisting of an encoder and a decoder with CTC and a Recurrent Neural Network (RNN) based language model for our task.

As shown in Fig. 1, our network consists of the following components:

1) **Encoder:** It contains stacked bi-directional LSTM layers which take input features $\mathbf{X}$ of dimension $[T, f]$ where T and f represent time frames and features respectively and outputs a hidden vector $\mathbf{h}$ of dimension $[T', H]$, where T' is subsampled time frames, and H is the number of projection units in the final layer of the encoder.
2) **Decoder:** Our decoder is composed of CTC block and an RNN-based language model.
   CTC: It consists of LSTM layers that take the hidden vector from the encoder as input and output probabilities over each token c_{t} in the dictionary for each time frame. The output probability for tokens in the dictionary is given as
   $$p(c_t|X) = \mathrm{Softmax}(\mathrm{LinB}(\mathbf{h}_t)), \tag{1}$$
   where LinB and $\mathrm{Softmax}$ denote the linear layer and the softmax function, respectively.
   RNN language model: To assist CTC, we use an external RNN-based model that calculates the probability of a sequence of tokens as follows:
   $$p(c_1, c_2, \ldots, c_n) = p(c_1)p(c_2|c_1)\ldots p(c_n|c_{1:n-1}) \tag{2}$$

During training, the encoder and CTC are trained to maximize the model's probability of predicting correct output by minimizing the corresponding CTC loss. RNN language model is trained separately using the text corpus.

During inference, the hidden vector from the trained encoder is fed to the decoder. For each time step t, the probabilities from the CTC block and RNN language model are fused, and the token with the maximum probability is selected. The obtained output for the current time step is then fed to the language model to predict the probabilities for the next token. Finally, when all time frames are exhausted, or <EOS> label is predicted, beam search decoding is performed to get the final predicted output.

D. Decoding Approach

To test our proposed idea of using speech features as input along with ECoG will help in making the model learn better from speech modality, we performed speech recognition experiments in the following three steps. First, we used only noisy speech features as input and employed the architecture shown in Fig. 1 while discarding the ECoG branch to perform speech recognition. Next, we used only ECoG features as input while dropping the speech branch and performed the same experiment again. Finally, using noisy speech and ECoG features

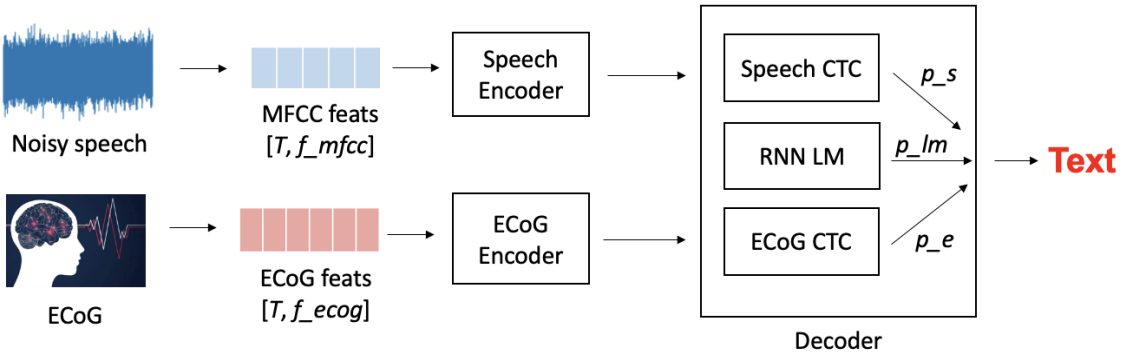

Fig. 1. Network architecture for multimodal recognition of speech and ECoG

together as input, we performed multimodal recognition and compared performance under these three scenarios.

For combining information from speech and ECoG, we used a late fusion method. We first retrieved the models trained on speech and ECoG modality individually. Then, in the decoder, we used their respective CTC scores and combined them with the language model score as follows:

$$\hat{c}_{\mathrm{t}} = \underset{c_{\mathrm{t}}}{\operatorname{argmax}} \{ w_{\mathrm{s}} \times \log p_{\mathrm{ctc}}(c_{\mathrm{t}}|X_{\mathrm{s}}) + w_{\mathrm{e}} \times \log p_{\mathrm{ctc}}(c_{\mathrm{t}}|X_{\mathrm{e}}) + w_{\mathrm{lm}} \times \log p_{\mathrm{lm}}(c_{\mathrm{t}}) \} \tag{3}$$

to get the most likely set of tokens for each frame. In (3), w_{s} and w_{e} are the weights assigned to the speech and ECoG CTC blocks, respectively, and w_{lm} is the weight for the language model. We believe that fusing information this way should prevent the model from becoming biased towards any particular modality while helping it in learning from each of these components effectively.

E. Feature Extraction from Speech

We extracted Mel Frequency Cepstral Coefficients (MFCCs) as acoustic features from speech data as they have been successfully used in many ASR as well as speech-based BCI-related studies [8]–[11]. For the calculation of MFCCs, a window of 20 msec with a frame period of 5 msec was used. We obtained MFCC features of dimension $[T, f_{\mathrm{mfcc}}]$ where T is the number of frames and f_{mfcc} is the dimension for features which was set to 13, similar to previous studies [8], [9]. The values for window length and frame period were set so that the output dimension of MFCC features across the time axis coincides with that of ECoG features.

F. Feature Extraction from ECoG

Our feature extraction process from ECoG has been inspired by past studies [8], [9] as they achieved state-of-the-art results in decoding speech from neural signals.

We began with removing channels that showed obvious signs of contamination by noise resulting in 54 channels for subjects js4, js5, js6 and js8 and 53 channels for subject js7. Next, a lowpass filter at 200 Hz followed by downsampling at 400 Hz was performed. A notch filter was applied at 50 Hz and 100 Hz to attenuate power line noise. To extract brain activity in the high gamma range (70–150 Hz), which is shown to be associated with speech [8], we used eight bandpass filters with centers between 70 and 150 Hz and averaged them across bands. ECoG data was further downsampled at 200 Hz and normalized using the z-score method to avoid bias due to the presence of any outliers.

The resultant ECoG features had dimension $[T, f_{\mathrm{ecog}}]$ where T is the number of time frames which is the same as that obtained for MFCC features and f_{ecog} is equal to the number of channels or electrodes used for that subject.

G. Implementation

We performed our experiments using ESPnet [12], an end-to-end speech processing toolkit. Our speech recognition model consisted of an encoder with four BLSTM layers; each layer had 320 units followed by a projection layer with 320 units. The subsampling factor for the encoder was set to 1/8 to reduce computational complexity. The CTC block consisted of one LSTM layer with 300 units. For the RNN language model, we trained a phrase-level model using one BLSTM layer with 1,000 units.

Since the focus of our work was to test how speech and ECoG features impact the recognition performance, we kept the language model weight constant at 0.5 across all types of input while the remaining 0.5 came from the weights for speech and/or ECoG CTC blocks. For recognition using only noisy speech as input, $w_{\mathrm{s}} = 0.5$ and $w_{\mathrm{e}} = 0.0$, for ECoG only input, $w_{\mathrm{e}} = 0.5$, and $w_{\mathrm{s}} = 0.0$, and lastly, for the case of multimodal features, w_{lm} was kept fixed at 0.5, while we tried different combinations for w_{s} and w_{e}.

H. Evaluation

As discussed in Section II-A, we performed speaker-dependent experiments, which restricted us from pooling data across subjects resulting in around five minutes of data per subject. To mitigate the effects of data insufficiency, we performed a five-fold cross-validation where for each fold, we split our data (80 trials) into the train (56 trials), validation (eight trials) and test set (16 trials).

TABLE I
AVERAGE PER(%) FOR SPEECH RECOGNITION USING DIFFERENT INPUT FEATURES

Features	PER(%)
Speech	6.7
ECoG	56.9
Multimodal	**5.6**

We evaluated the performance of our model in terms of Phrase Error Rate (PER), which is given as

$$\text{PER} = \frac{S + I + D}{N}, \tag{4}$$

where S, I, and D are, respectively, the minimum number of substitutions, insertions, and deletions required to convert the predicted output into ground truth, and N is the total number of phrases in the actual output. Since this is an error rate, a lower PER is desirable.

III. RESULTS

The average PERs obtained across five subjects for speech recognition using different features as input (Speech, ECoG, and Multimodal) have been presented in Table I. Here, the results presented for multimodal features are when using the following combination of weights, $w_{\text{lm}} = 0.5$, $w_{\text{s}} = 0.3$ and $w_{\text{e}} = 0.2$.

As can be verified from Table I, recognizing speech using multimodal features has the lowest PER. Our late fusion method significantly reduced PER by 51.3 points from the case of using only ECoG features and by 1.1 points from the case of using only speech features. This proves that through proper utilization of information from speech, we can majorly enhance the accuracy of BCI systems. In particular, PER obtained using multimodal features was even lower than that obtained for using only speech features, which has been the goal of this research, i.e., to make the performance of speech recognition from ECoG comparable to that of ASR systems to make it possible to employ them for different applications.

We also tested our method for different combinations of Speech and ECoG CTC weights while keeping the language model weight fixed at 0.5, and the results have been presented in Fig. 2. When $w_{\text{e}} = 0.0$, w_{s} becomes 0.5, which correponds to the case of using only speech as input, whereas when $w_{\text{e}} = 0.5$, w_{s} becomes 0.0 corresponding to the case of using only ECoG features as input. For all subjects, multimodal features have the lowest PER and, therefore, better performance than using only speech or only ECoG features for different combinations of speech and ECoG CTC weights, thereby proving the effectiveness of our method.

IV. DISCUSSION

Our proposed method was able to achieve competing PERs for all subjects even with less training data and a lesser number of electrodes as compared to previous studies [8], [10]. Usually, it is difficult to directly compare these error rates because of the large gap in the experiment conditions,

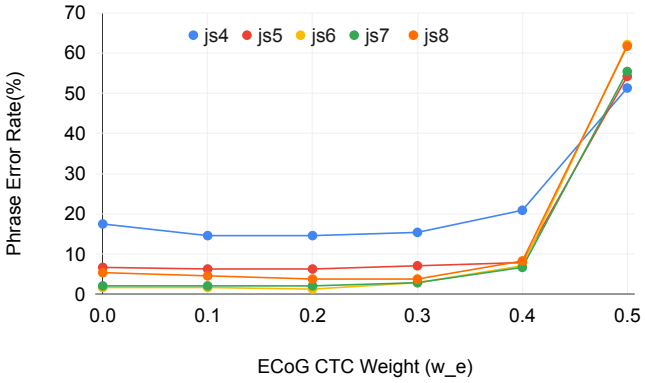

Fig. 2. PER(%) for different fusion weights for speech and ECoG

TABLE II
COMPARISON OF PER(%) FOR SPOKEN SPEECH RECOGNITION

Method	js4	js5	js6	js7	js8	Avg.
Komeiji [9]	18.7	35.8	33.1	30.9	41.9	32.1
Ours	**14.6**	**6.3**	**1.3**	**2.1**	**3.8**	**5.6**

such as vocabulary size, variability across subjects as well as the implementation architecture. However, just to evaluate the improvement in performance using our proposed approach, we compared our results with Komeiji et al. [9] since they have also used the same dataset and evaluation metric as ours. As presented in Table II, our method of using speech along with ECoG as input exceeds their performance where they used speech features to train the encoder by a large margin across all five subjects showing a promising application of our approach in future.

V. CONCLUSION

In this paper, we proposed multimodal recognition of ECoG for improved BCI communication. To our knowledge, we are the first to employ speech features as input and use noise-added speech data in our experiments. We achieved an average PER of 5.6% across subjects which outperforms the previous state-of-the-art results.

Currently, our method requires spoken speech data from subjects to perform multimodal recognition. However, we should also cater to scenarios where it is not available such as when the subject has completely lost their ability to speak or for decoding imaginary speech from ECoG. We would like to extend our method so that it does not rely on the necessity of having spoken speech data from the same subject during inference. We would also like to evaluate our method with non-invasive brain data acquisition techniques such as EEG or fMRI where we can explore a bigger dataset with many subjects and a larger vocabulary size in the future.

***Abstract*—In this paper, we present a lightweight method for real-time semantic segmentation models by leveraging the power of pre-trained vision-language models. Our approach incorporates the CLIP text encoder, which provides rich semantic embeddings for text labels, and effectively distills its rich textual knowledge to the segmentation model. The proposed framework integrates the image and text embeddings, enabling visual and textual information alignment. Besides, we introduce learnable prompt embeddings to capture class-specific information and enhance the semantic understanding of the model. To ensure efficient learning, we devise a two-stage training procedure that allows the segmentation backbone to learn from fixed text embeddings in the first stage and optimize the prompt embeddings in the second stage. Extensive experiments and ablation studies demonstrate the effectiveness of our method in significantly improving the performance of the real-time semantic segmentation model.**

I. Introduction

Semantic segmentation is one of important computer vision tasks that aims to assign semantic labels to every pixel in an image, effectively dividing it into meaningful parts. The primary purpose is to enable machines to understand the content of an image at a granular level, allowing them to distinguish between different objects, regions, or parts in the image. Numerous real-world applications, such as autonomous driving and augmented reality, require high efficiency in inference speed, as fast interaction and response are often essential. Therefore, developing real-time semantic segmentation models has become a critical topic of interest in recent research.

Several models [1]–[5] have been proposed to meet the demand of low-latency algorithms for real-time semantic segmentation. Despite these advances, there are still challenges that existing methods cannot fully resolve, especially the trade-off between the inference speed and the accuracy of the model. In addition, designing more sophisticated architectures to further improve the feature representation of the models while keeping low latency at the same time is challenging to strike a balance.

To this end, we propose to leverage the power of pre-trained vision-language models [6], [7] to enhance the real-time semantic segmentation models. Specifically, our designed framework and training procedure aims to transfer the rich textual knowledge from the Contrastive Language-Image Pre-training (CLIP) [6] text encoder to the real-time semantic segmentation model STDC-Seg [4]. The complete framework is shown in Fig. 1. First, we integrate the image and text embeddings, facilitating the alignment of information from both visual and textual domains. By calculating the cosine similarity between these embeddings, we generate a score map that captures the semantic similarity between different image regions and text labels. The score map is then concatenated with the image feature maps, enabling the fusion of visual and textual information. To further enhance the semantic understanding of the model, we introduce class-specific learnable prompt embeddings, which are added to the label token embeddings. This augmented input is subsequently passed through the CLIP text encoder, resulting in enriched embeddings for each class with enhanced semantic meanings. By incorporating learnable prompts, the model gains the flexibility to optimize the prompt embeddings and capture class-specific discriminative information effectively.

Moreover, to ensure efficient learning, we devise a two-stage training procedure. In the first stage, we allow the segmentation backbone to learn from fixed text embeddings, enabling it to align image features with the text embeddings of the label from the CLIP text encoder. The purpose of this stage is to distill the backbone with the rich textual knowledge from the CLIP model into its feature representation. In the second stage, we focus on optimizing the learnable prompt embeddings while keeping the backbone fixed. This allows the model to refine the prompt embeddings to capture class-specific information, further enhancing the segmentation performance.

By integrating these components and training stages, our proposed framework significantly improves the performance of the real-time semantic segmentation model STDC-Seg. It is important to note that our method incurs only negligible additional latency during inference, making it a lightweight and practical solution for real-world applications.

Our main contributions are summarized as follows:

- We propose a method to enhance the real-time semantic segmentation model STDC-Seg by effectively transferring the CLIP textual knowledge. This results in significant

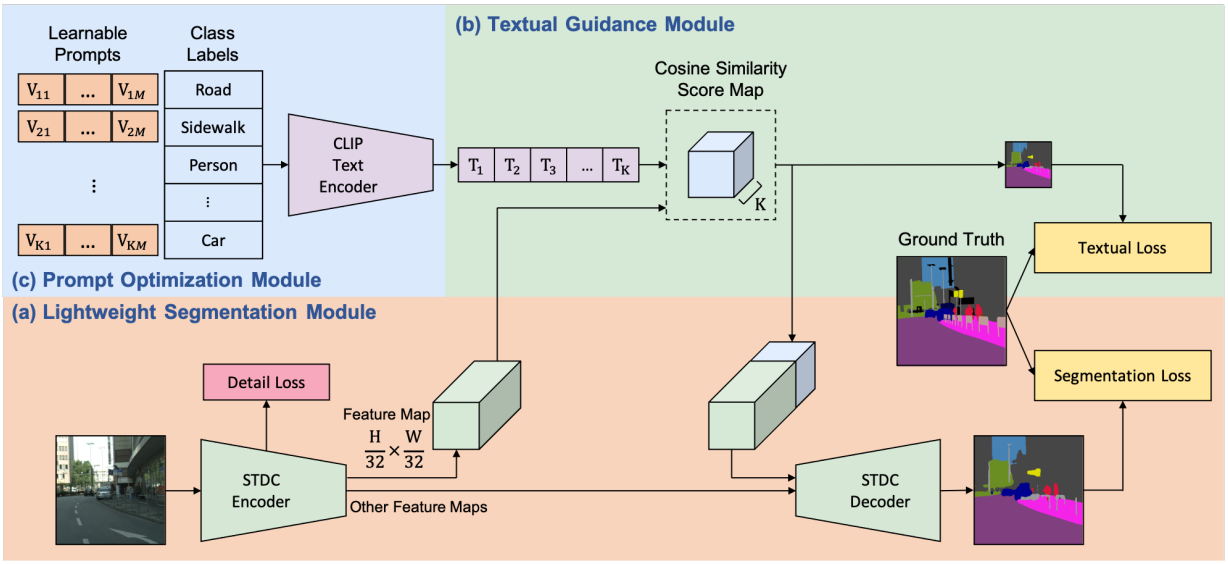

Fig. 1. Block Diagram and Information Flow of the Proposed Framework. (a) Lightweight Segmentation Module; (b) Textual Guidance Module; (c) Prompt Optimization Module.

performance improvements with minimal additional latency during inference.

- We introduce a two-stage training procedure that effectively trains both the lightweight segmentation backbone and class-specific learnable prompts, leading to enhanced performance in real-time semantic segmentation tasks.
- We conduct extensive experiments on two standard datasets for semantic segmentation, including ablation studies, to validate the effectiveness of our method and provide valuable insights.

II. Related Work

A. Real-Time Semantic Segmentation

Real-time semantic segmentation is an active research area that aims to enable efficient and accurate segmentation of images in real-time scenarios. BiSeNetV1 [1] proposed a compact and efficient dual-path network architecture to deal with spatial information and global context. DFANet [2] utilized multi-scale feature propagation and feature aggregation to balance computation and accuracy. BiSeNetV2 [3] further improved the performance of BiSeNetV1 with a refined architecture design. STDC-Seg [4] employed spatio-temporal decomposition and context aggregation mechanisms to enhance accuracy and efficiency simultaneously, and the proposed STDC backbone is proved to be more efficient and robust than previous methods in their experiments. Recently, PP-LiteSeg [5] redesigned the decoder of STDC-Seg, resulting in improvements in both speed and accuracy. This study focuses on STDC-Seg as the baseline method since it proposed the STDC backbone with state-of-the-art performance.

B. Pre-Trained Vision-Language Model

Vision-language pre-training [6]–[9] has become a hot research topic in recent years, as it enables models to learn joint representations of images and natural language. CLIP [6] and Align [7] are two of the most well-known methods, especially CLIP, which has gained much attention since its release. CLIP leverages a vision-language contrastive training process to learn a shared embedding space for images and texts, enabling zero-shot inference on various downstream tasks. CLIP's success is attributed to its ability to learn from diverse data sources and utilize contrastive learning, which encourages the model to learn discriminative representations for positive and negative pairs. In this study, we utilize the pre-trained CLIP text encoder as the textual knowledge source in our framework.

C. Prompt Tuning

Prompt tuning [10]–[12] is a method used to fine-tune pre-trained language models to improve the performance of language models on downstream tasks by adapting the model to the specific task at hand. Many methods have been proposed in recent years, including hand-craft-based prompt template generation [10] and automated prompt template generation [11] with sequence-to-sequence large language models like T5 [13]. Besides, there are also prompt tuning methods that directly optimize the prompt in the embedding space [12] instead of generating a prompt template in the text space. Especially in vision-language prompt tuning, CoOp [14] introduced learnable contexts to CLIP text encoders to improve performance on few-shot image classification. CLIP-Adapter [15] proposed to train the lightweight feature adapters attached to CLIP using a small amount of labeled data. These advancements in the prompt tuning for vision-language models have led to significant improvements in the ability of models to understand and generate natural language descriptions of visual content. In our study, since we understand that the prompt tuning method of CoOp best fits the real-time scenario, we employ it as part of our framework.

D. Semantic Segmentation with Pre-Trained Vision-Language Model

Pre-trained vision-language models have revolutionized the field of semantic segmentation, with several methods exploring their potential to enhance performance. Language-Driven Semantic Segmentation [16] combined the CLIP text encoder with a Vision Transformer-based [17] segmentation model and aligned the output feature maps of the decoder with text embeddings, allowing the segmentation model to achieve zero-shot semantic segmentation [18] capabilities. DenseCLIP [19] aligned image features from the output of the image encoder with text embeddings. It also utilized unified context optimization methods as in CoOp, and incorporated an additional Transformer [20] for visual context-aware prompt tuning, resulting in state-of-the-art performance across various semantic segmentation datasets.

Despite their impressive results, both methods do not acquire real-time capabilities due to their design. In our study, we specifically address the task of real-time semantic segmentation. We leverage the textual knowledge provided by the CLIP text encoder to enhance the accuracy of STDC-Seg while minimizing the impact on inference speed. By incorporating this textual knowledge, we aim to strike a balance between accuracy and inference speed in real-time semantic segmentation tasks.

III. Methodology

A. Model Architectures

This section presents a comprehensive description of our proposed framework for real-time semantic segmentation. Our framework consists of three main modules: the Lightweight Segmentation Module (LSM), Textual Guidance Module (TGM), and Prompt Optimization Module (POM). We aim to integrate these modules to enhance the performance of STDC-Seg, a real-time semantic segmentation model. This chapter will delve into each module, providing a comprehensive explanation, followed by our designed training procedure.

1) Lightweight Segmentation Module (LSM): Our Lightweight Segmentation Module (LSM) follows an encoder-decoder structure for semantic segmentation. Specifically, the encoder is responsible for extracting image features at different levels, ranging from shallow to deep layers. This results in a set of feature maps at various stages. On the other hand, the decoder integrates these feature maps to produce the final segmentation output, as shown in Fig. 1(a).

The typical decoding process starts by handling the high-level features, which are upsampled and combined with the low-level features using pixel-wise addition. This process is repeated from deep to shallow features, ensuring that the integrated features contain the necessary information for pixel-wise classification, which is essential for accurate segmentation. Let X represent the input image, and Y represent the ground-truth semantic mask. We aim to have the predicted mask $Y' = D(E(X))$ closely approximate Y, where E and D represent the encoder and the decoder, respectively. In this paper, we employ STDC-Seg as our LSM.

2) Textual Guidance Module (TGM): Inspired by DenseCLIP [19], the Textual Guidance Module (TGM) is designed to enhance the power of the STDC backbone in the LSM by leveraging textual knowledge from the CLIP text encoder. This module takes two inputs: the feature map from the last stage of the STDC backbone and the text embeddings of the label from the CLIP text encoder, as shown in Fig. 1(b).

Let $F^{(1)}, F^{(2)}, F^{(3)}, F^{(4)} = E(X)$ represent the output feature maps of the STDC backbone from stage one to stage four, with $F^{(4)} \in \mathbb{R}^{\frac{H}{32} \times \frac{W}{32} \times d}$, where H and W are the height and width of the input image, and d is the channel dimension. Additionally, let $L_1, L_2, ..., L_K$ denote the label texts corresponding to K classes (e.g., road, person, car). We pass each label text through the CLIP text encoder to obtain their respective embeddings: $T_1, T_2, ..., T_K \in \mathbb{R}^d$.

To transfer the textual knowledge from the CLIP text encoder to the STDC backbone, we compute the cosine similarity between each pixel of $F^{(4)}$ and the text embeddings $T_1, T_2, ..., T_K$. This results in a score map $S \in \mathbb{R}^{\frac{H}{32} \times \frac{W}{32} \times K}$, which is computed as follows:

$$S_{i,j,k} = \frac{F^{(4)}_{i,j} \cdot T_k}{\|F^{(4)}_{i,j}\| \|T_k\|}, i = 1...\frac{H}{32}, j = 1...\frac{W}{32}, k = 1...K \quad (1)$$

The score map generated by the TGM can be treated as a predicted semantic map at a lower resolution. We can then supervise it by comparing it with the ground-truth semantic map as an auxiliary task. By computing the cosine similarity, we align the image features with the corresponding label text embeddings provided by the CLIP text encoder. This alignment allows the STDC backbone to incorporate the textual knowledge from the CLIP text encoder, thereby enhancing the representation power.

3) Prompt Optimization Module (POM): Inspired by CoOp [14], the Prompt Optimization Module (POM) aims at handling the class-specific learnable prompt embeddings, $V_{ij} \in \mathbb{R}^{d_t}$, $i = 1, 2, ...K$, $j = 1, 2, ..., M$, where K represents the number of classes, M represents the number of learnable embeddings for each class, and d_t is the dimension of the CLIP token embeddings. Additionally, we have $E_{ik} \in \mathbb{R}^{d_t}$, $i = 1, 2, ..., K$, $k = 1, 2, ..., l$, which represents the token embeddings of the class label text, where l denotes the sequence length of the token embeddings. The purpose of having learnable prompt embeddings is to have trainable text embeddings provided by the CLIP text encoder, thereby enhancing the discriminative qualities of the text embeddings associated with each class label, as shown in Fig. 1(c).

To obtain the trainable text embeddings, we concatenate $V_{i1}, V_{i2}, ..., V_{iM}$, and $E_{i1}, E_{i2}, ..., E_{il}$ for each class i, and feed this concatenated input to the CLIP text encoder, resulting in the output text embedding $T_i \in \mathbb{R}^d$, which can be expressed as:

$$T_i = POM([V_{i1}\ V_{i2}\ ...\ V_{iM}\ E_{i1}\ E_{i2}\ ...\ E_{il}]) \quad (2)$$

Throughout the training procedure, the parameters of the CLIP text encoder remain fixed. As a result, the trainable text embeddings T_i are always in the CLIP pre-trained domain, providing valuable textual knowledge. We rely on this property to enhance the performance of our model.

B. Two-Stage Training Procedure

In our framework, we design a two-stage training procedure to effectively transmit textual knowledge from the CLIP text encoder to the lightweight STDC backbone. In the following sections, we will first describe the loss functions employed during training and then delve into the separate training processes for each stage.

1) Loss Functions: The primary task of semantic segmentation is carried out by the LSM, which is responsible for generating the predicted semantic mask. To optimize this task, we employ the cross-entropy loss with Online Hard Example Mining (OHEM) [21], a commonly used technique in existing methods. The cross-entropy loss (CE) is calculated as follows:

$$CE(x, y) = \frac{1}{N} \sum_{n=1}^{N} -\log \left(\frac{\exp(x_{n,y_n})}{\sum_{k=1}^{K} \exp(x_{n,y_k})} \right) \quad (3)$$

Here, x represents the logit output by the model, y denotes the ground-truth class, and N is the total number of the pixels. OHEM enhances the optimization process by emphasizing those challenging examples contributing significantly to the loss.

In our framework, we refer to the loss of the primary task as L_{seg}. Additionally, as mentioned earlier, the TGM generates a score map that can be considered a low-resolution semantic mask, suitable for training as an auxiliary task using the same loss function as the main task. In our implementation, the low-resolution semantic mask is first bilinearly upsampled to match the size of the ground-truth semantic mask. Then, we compute the textual loss, denoted as L_{text}, between them using cross-entropy. The textual loss helps the method to leverage the rich semantic information provided by the pre-trained CLIP model. The alignment with the textual space of the CLIP model enforces a good regularization and enables us to learn an efficient segmentation model. Furthermore, following the approach of STDC-Seg, we also incorporate the detail loss, denoted as L_{detail}, into our training process. Finally, the total loss, denoted as L, is calculated as follows:

$$L = \lambda_1 * L_{seg} + \lambda_2 * L_{text} + \lambda_3 * L_{detail} \quad (4)$$

Here, we set λ_1, λ_2, and λ_3 all to 1.

2) First Training Stage: In the first stage, as depicted in Fig. 2, we do not use learnable prompts. Instead, we only input the label text's token embeddings into the CLIP text encoder, keeping the text embeddings fixed. This stage allows the STDC backbone to learn and align with the text embeddings provided by the CLIP text encoder. This alignment enables the STDC backbone to leverage textual knowledge as additional information for semantic segmentation.

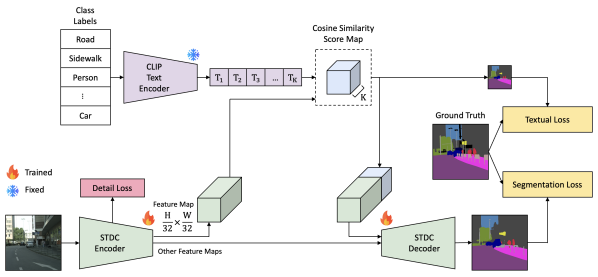

Fig. 2. The Setups of our First Training Stage.

3) Second Training Stage: In the second stage, as depicted in Fig. 3, we introduce the utilization of learnable prompt embeddings in the POM while keeping the parameters of the STDC backbone fixed. This choice is based on the understanding that in the first stage, the STDC backbone already assimilated textual knowledge from the CLIP text encoder, allowing it to adapt to changing text embeddings. Consequently, the POM focuses on optimizing the prompts to provide precise descriptions for each class label, thereby augmenting the discriminative characteristics of the optimized text embeddings for the STDC backbone.

Our framework achieves significant improvements after the two training stages compared to the original model. The LSM can simultaneously handle semantic segmentation tasks with visual and textual knowledge. The POM provides optimized text embeddings with discriminative information. The TGM connects these two modules and integrates the two embedding spaces, successfully transmitting textual knowledge from the CLIP text encoder to the STDC backbone.

C. Inference

After completing the two-stage training procedure, we can achieve real-time inference speed with minimal additional time compared to the original STDC-Seg model during the inference phase. This achievement is accomplished by retaining only the final trained text embeddings and discarding the learnable prompt embeddings and the CLIP text encoder, as illustrated in Fig. 4. By adopting this approach, the computational cost is limited to calculating cosine similarity in the TGM and including a few additional channels to the encoded feature maps. Consequently, the overall increase in Floating Point Operations (FLOPs) is negligible, enabling efficient real-time inference while preserving the accuracy and performance gains of our training methodology.

IV. Experiments

A. Experimental Settings

1) Datasets: To evaluate the performance of our proposed methods, we conduct experiments on two real-time semantic segmentation datasets, including the Cityscapes [22] dataset and the CamVid [23] dataset. The Cityscapes dataset is a large-scale dataset for urban scene understanding with pixel-level annotations of 30 different classes, where 19 of them are generally used for semantic segmentation tasks. There are

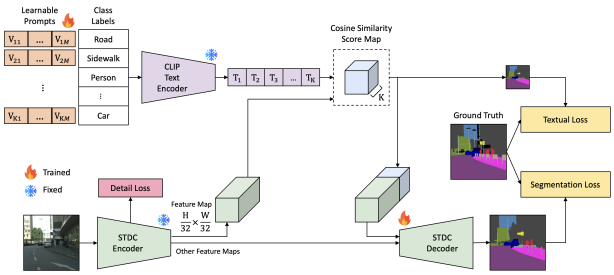

Fig. 3. The Setups of our Second Training Stage.

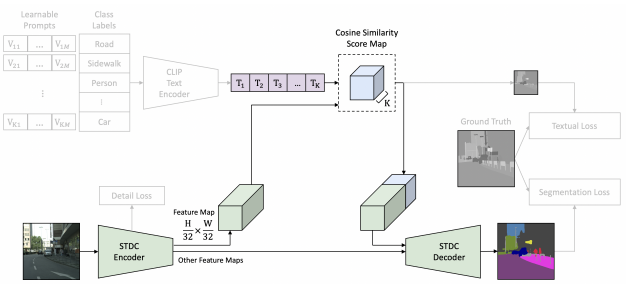

Fig. 4. The Colored Area Indicates the Inference Process of our Framework.

5,000 finely annotated images with 2048 x 1024 pixels in size, split into three subsets: training, validation, and testing, with 2,975, 500, and 1,525 images, respectively. Besides, the CamVid dataset, collected from vehicle-mounted cameras, has 11 semantic classes. It comprises 701 finely annotated images with 960 x 720 pixels in size, also split into three subsets: training, validation, and testing, with 367, 101, and 233 images, respectively. We train our models with a training set and evaluate them on a validation set of each dataset separately.

2) Implementation Details: In our experiments, we utilize stochastic gradient descent (SGD) [24] as our optimizer with a momentum of 0.9 and weight decay of 0.0005. For the Cityscapes dataset, the initial learning rate is set to 0.005 for the backbone and learnable prompts and 0.05 for other parameters. The batch size is set to 24, and we employ the "poly" learning rate policy, where the initial rate is multiplied by $(1 - \frac{\text{current_iteration}}{\text{max_iterations}})^{\gamma}$ with a total of 160,000 iterations and γ equals 0.9. Additionally, we use a linear warm-up strategy for the first 1,000 steps.

For the CamVid dataset, the initial learning rate is set to 0.01 for the backbone and learnable prompts and 0.1 for other parameters. The batch size is set to 16, and we also use the "poly" learning rate policy with the same parameters as before but with a total of 10,000 iterations. The warm-up strategy is applied for the first 200 steps.

We apply data augmentation techniques in both datasets, including color jittering, random horizontal flip, random crop, and random resize, to enhance the training data. For the Cityscapes dataset, we train the model using a scale range of [0.125, 1.5] stepping by 0.125, and the cropped resolution is set to 1024 x 512. On the other hand, for the CamVid dataset, the scale range is [0.5, 2.5] stepping by 0.25, and the cropped resolution is set to 960 $\times$ 720.

During training and evaluating performance, we use the mmsegmentation [25] library version 0.30.0 along with PyTorch [26] 1.12.1. The training is performed on a system equipped with two NVIDIA GTX 3090 GPUs, utilizing CUDA 11.3 and cuDNN 8.2. For testing the inference speed, we conduct experiments on a different setup. We modify the code provided by STDC-Seg [4] and use PyTorch 1.2.0, CUDA 10.0, and cuDNN 7.5. Additionally, we employ TensorRT 5.1.5.0 to optimize the inference process as STDC-Seg did. These experiments are carried out on an NVIDIA GTX 1080Ti GPU to benchmark the inference speed of our method.

B. Main Results

In our evaluation, we compare the performance of our proposed methods with the baseline STDC-Seg model on both the Cityscapes dataset and the CamVid dataset. By doing so, we aim to demonstrate the effectiveness of our approach in improving the performance of STDC-Seg using textual knowledge.

1) Results on Cityscapes: In Table I, we present our proposed method's segmentation accuracy and inference speed on the Cityscapes validation set. Notably, compared to the baseline STDC-Seg50 model, which achieves a validation mean Intersection over Union (mIoU) of 72.2, our proposed methods incorporating textual knowledge through a two-stage training procedure can enhance the performance to 72.9. This improvement comes with only a slight sacrifice in inference speed.

2) Results on CamVid: Table II presents the comparison results of our method and STDC-Seg on the CamVid dataset. We train the STDC-Seg model on the training set and evaluate its performance on the validation set. By applying our two-stage training procedure with text knowledge guidance, we are able to increase the mIoU of STDC-Seg from 75.3 to 78.0. This significant performance improvement further demonstrates the effectiveness of our method in enhancing segmentation accuracy by leveraging textual knowledge.

3) Qualitative Results: Here, we present qualitative results on the Cityscapes validation set, as depicted in Fig. 5. Specifically, our method achieves more precise segmentation of poles (colored in gray) compared to STDC-Seg. Poles are challenging to segment accurately due to their thin shape, which can often be overlooked by the model. However, our results demonstrate that the transfer of textual knowledge significantly enhances performance. In (a), (b), and (c), the segment masks of the poles exhibit significantly improved accuracy, addressing the issue of missing or incomplete segmentation in STDC-Seg. Furthermore, we observe improvements in segmenting fences (colored in Tuscan) as well. Fences are challenging to segment as they frequently overlap with other objects, such as buildings or walls. Our method demonstrates better results, suggesting that the transmitted textual knowledge aids in discriminating the fence from other objects. In (c) and (d), we can observe

TABLE I
QUANTITATIVE COMPARISONS OF THE BASELINE AND THE TWO STAGES OF OUR MODELS ON THE CITYSCAPES VALIDATION SET.

Model	#Params ↓	FLOPs ↓	mIoU (%) ↑	Inference Speed (FPS) ↑
STDC1-Seg50 (baseline)	8.57M	16.95G	72.2	250.4
Ours (stage 1)	8.60M	16.96G	72.7	245.3
Ours (stage 2)	8.60M	16.96G	**72.9**	245.3

TABLE II
QUANTITATIVE COMPARISONS OF THE BASELINE AND THE TWO STAGES OF OUR MODELS ON THE CAMVID VALIDATION SET

Model	#Params ↓	FLOPs ↓	mIoU (%) ↑	Inference Speed (FPS) ↑
STDC1-Seg (baseline)	8.57M	22.42G	75.3	197.6
Ours (stage 1)	8.59M	22.43G	76.6	196.8
Ours (stage 2)	8.59M	22.43G	**78.0**	196.8

substantial improvements in fence segmentation compared to STDC-Seg.

These qualitative results highlight the effectiveness of our approach in enhancing the segmentation of challenging objects such as poles and fences. By leveraging the textual knowledge transmitted to the model, we address the limitations of the base STDC-Seg method and achieve more accurate and detailed segmentations.

C. Ablation Studies

1) Effectiveness of Two-Stage Training Procedure: In the early stages of our experiments, we encountered challenges in directly transfer textual knowledge from the CLIP text encoder to the STDC backbone with learnable prompts. Training the learnable prompts and the STDC backbone at the same time results in worse performance than our two-stage settings. We believe this is because the STDC backbone lacks textual knowledge before our training since it is not pre-trained with a vision-language training procedure. Consequently, when trained simultaneously with learnable prompts, the text embeddings from the CLIP text encoder constantly change, making it difficult for the STDC backbone to keep up and leading to unstable performance.

To address this issue, we adopt a two-stage training procedure. In the first stage, we fix the text embeddings and allow the STDC backbone to align itself with the textual knowledge. In the second stage, we fix the STDC backbone and adjust the learnable prompts to optimize the "prompt sentence" from the embedding space.

As shown in Table III, on the Cityscapes dataset, training the model without the two-stage procedure yield an mIoU of 72.7, whereas, with the two-stage training, the mIoU is improved to

TABLE III
ACCURACY COMPARISON BETWEEN TRAINING PROCEDURES WITHOUT AND WITH MULTIPLE STAGES (CITYSCAPES VALIDATION SET).

Procedure	mIoU (%) ↑
end-to-end 1 stage	72.7
2 stages (1^{st} stage)	72.7
2 stages (2^{nd} stage)	**72.9**

TABLE IV
ACCURACY COMPARISON BETWEEN TRAINING PROCEDURES WITHOUT AND WITH MULTIPLE STAGES (CAMVID VALIDATION SET).

Procedure	mIoU (%) ↑
end-to-end 1 stage	76.4
2 stages (1^{st} stage)	76.6
2 stages (2^{nd} stage)	**78.0**

TABLE V
COMPARISONS OF THE EFFECTS OF DIFFERENT NUMBERS OF LEARNABLE PROMPT EMBEDDINGS ON THE CAMVID VALIDATION SET.

M	mIoU (%) ↑
8	76.3
11	**76.4**
14	75.3
17	76.0

TABLE VI
COMPARISONS OF THE EFFECTS OF WEIGHT DECAY IN LEARNABLE PROMPT EMBEDDINGS ON THE CAMVID VALIDATION SET.

Weight decay (M=8)	mIoU (%) ↑
0.0005	75.9
No weight decay	**76.3**

72.9. Similarly, as shown in Table IV, on the CamVid dataset, training without the two-stage procedure results in an mIoU of 76.4, while training with the two-stage procedure achieves an mIoU of 78.0. These results indicate a significant improvement in adopting of the two-stage training procedure.

Based on these findings, we strongly suggest that the two-stage training procedure is crucial for effectively transmitting textual knowledge from the CLIP text encoder to the STDC backbone. It allows for better alignment and optimization, ultimately improving the segmentation performance on both the Cityscapes and CamVid datasets.

2) Number of Learnable Prompt Embeddings: During the second stage of training, we conduct experiments to determine the optimal number of learnable prompt embeddings, denoted as M. We explore different values of M, specifically $M = 8,\ 11,\ 14,$ and 17, and analyze their impact on performance. As shown in Table V, we observe that the performance gain reaches a saturation point around $M = 11$. This suggests that increasing the number of embeddings beyond a certain threshold does not yield significant improvements in performance.

We conjecture that there is a limitation to the number of embeddings because excessively long prompts may contain unrelated or extraneous information for the task of classifying between labels in segmentation. Therefore, there is a balance to be struck between having enough prompt embeddings to capture relevant information and avoiding an excessive number that includes noise or irrelevant details.

3) Regularization of Prompt Embedding Space: We make an interesting observation regarding the regularization of the learnable prompt embeddings and their impact on performance. Specifically, in the CamVid dataset, we notice that applying an L2 weight decay regularization of 0.0005 to the prompt embeddings results in a significant drop in performance, with the mIoU decreasing from 76.3 to 75.9, as shown in Table VI. This trend is consistent across most of our experiments.

We believe the reason behind this phenomenon lies within the embedding space. If we imagine the embeddings space of all tokens as a normal distribution, with the centers representing frequently occurring words and the outer regions containing less frequent words, applying L2 weight decay regularization to the learnable prompt embeddings tends to push these embeddings towards the zero vector, which corresponds to the center of the distribution. Consequently, the prompts would predominantly consist of frequent words.

However, we argue that a powerful prompt should incorporate specific words that help the model distinguish between different labels. Relying solely on frequent words may not provide the necessary discriminative power. From a higher-level perspective, let's consider the well-known prompt "A photo of a [CLASS]." In this example, words like "a" and "of" are likely close to the distribution's center, representing frequent words. On the other hand, the word "photo" is more specific and likely to be further away from the center. Restricting the prompt embeddings to only frequent words might hinder the ability of the prompts to convey specific meanings.

Based on these observations, we suggest that: to equip the learnable prompts with the ability to capture the specific meanings from the embedding space, one has better not to apply L2 weight decay regularization on them. By doing so, we provide the prompts with the opportunity to reach beyond frequent words and incorporate more specific and contextually relevant terms, ultimately improving the performance of the segmentation model.

V. CONCLUSION

In conclusion, this research has contributed to the field of real-time semantic segmentation by leveraging the pre-trained vision-language model CLIP. The proposed framework enhances the STDC-Seg model by effectively incorporating textual knowledge from the CLIP text encoder. This integration enables the fusion of visual and textual information, leading to substantial performance improvements while maintaining minimal additional latency during inference. To further improve the model's semantic understanding and capture class-specific details, learnable prompt embeddings are introduced. The two-stage training procedure effectively trains both the lightweight

segmentation backbone and the learnable prompts, optimizing the model's performance in real-time semantic segmentation tasks.

***Abstract*—The intricate workings of the human brain, which utilizes acquired information from the environment to anticipate future challenges, still lack comprehensive understanding. To understand the mechanism, this study investigated the effects on electroencephalographic (EEG) signals of the process of anticipation of difficulty in auditory tasks. We designed a similarity problem in which human participants were first presented with two tones, followed by a questioning tone, and were asked to answer which of the first two tones was similar to the questioning tone. We analyzed EEG signals recorded during the presentation of the second of the first two tones, a period during which we assumed the participants were anticipating the upcoming problem. By manipulating the similarity of the first two tones in terms of two attributes (position and frequency), we eliminated other effects on the EEG signals caused by the tone difference and attributes, and extracted the brain activity related to the anticipation of the task difficulty. We found event-related potentials (P2, P3, and N4) and frequency bands (theta, alpha, and beta) in the prefrontal regions, alpha band in the EEG signals were significantly correlated with task difficulty. These results demonstrated the reliability of EEG to evaluate the anticipation of difficulty.**

I. Introduction

The human brain has the remarkable ability to anticipate and make anticipations about future events [1]. This capacity allows us to prepare and adapt our behavior based on our anticipations [2] and greatly impacts decision-making [3]. These anticipations can be related to various aspects, including the difficulty of future tasks or events. For example, if we are familiar with a particular task or activity, such as solving a complex math problem or playing a challenging musical piece, our brain can draw upon past experiences and knowledge to anticipate the level of difficulty we might encounter. When it comes to anticipating the difficulty of future events, our brain relies on a combination of past experiences, knowledge, and contextual cues. Through a process called mental simulation, our brain generates internal representations of possible future scenarios and evaluates their anticipatory difficulty based on existing information [4]. This anticipation allows us to allocate appropriate cognitive resources and prepare ourselves mentally and physically [5]. Understanding how anticipations are formed and modulated is a complex and intriguing area of research. Additionally, understanding the neural mechanisms and responses involved in anticipation could lead to numerous engineering applications. For instance, techniques that predict individual anticipatory responses to future events could aid in the development of alert systems for autonomous driving, or stress monitoring systems for mental health assessments.

Previous studies have primarily relied on behavioral measures to investigate these anticipations, such as reaction times and self-reported ratings [6]. However, these measures provide limited insight into the underlying neural processes that give rise to anticipations. Advancements in neuroimaging techniques, specifically electroencephalography (EEG), have revolutionized our ability to measure the electrical activity in the brain with remarkable precision at the millisecond level. This unprecedented level of temporal resolution offers a distinctive and unparalleled opportunity to delve into the realm of perception-based anticipations and explore the underlying neural processes. By analyzing the patterns of neural activity associated with anticipations processing, EEG can reveal neural markers of perceived anticipation. For instance, Simonet et al. used EEG to investigate the neural marks underlying movement anticipation and found an enhanced alpha band in response to movement anticipation [7]. Additionally, Kverage et al. employed EEG and examined oscillatory activity in the low-frequency bands in vision anticipation, revealing that low-frequency bands reflected vision anticipation [8]. Vanhollebeke et al. found that the anticipatory phase of stress and challenges is also associated with the alpha band [9]. These findings underscore the significance of oscillatory activity in mediating the integration of anticipation.

This research aims to investigate brain activities related to the anticipation for the difficulty of an upcoming auditory task. We designed an experiment where human participants were required to listen to two tones, followed by a questioning tone. They were then prompted to determine which of the first two tones was more similar to the question tone. The difficulty level of the question was manipulated by controlling the similarity of the initial two tones: if the tones were similar, the question was considered difficult, whereas if they were dissimilar, the question was relatively easy. Our hypothesis

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

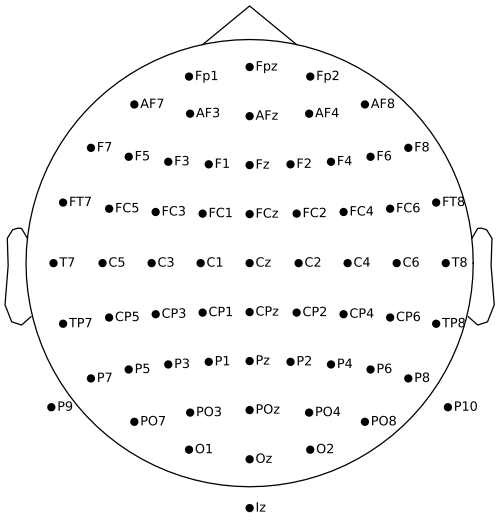

Fig. 1. The layout of the channels

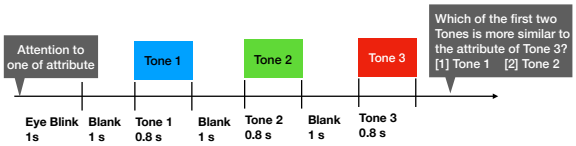

Fig. 2. The procedure of a single trial

posited that participants would anticipate the difficulty level of the upcoming problem while the first two tones were being presented.

To explore perception anticipation in auditory tasks, this research utilizes EEG to analyze event-related potentials and oscillatory activity. By capitalizing on the temporal precision of EEG, the study aims to uncover neural markers associated with anticipation in the face of partial information about upcoming problems i.e., the presentation period for the first two tones. Since EEG signals can be influenced by factors other than the anticipation of difficulty—such as the differences between the two tones—we employed two tone attributes, frequency and position. The participants evaluated the similarity between the tones in terms of either of these attributes. We then designed a normalized feature by combining the observed signals of the attributes to mitigate the impact of these other factors. By deciphering the neural makers underlying auditory perception and anticipation, we can advance our understanding of human cognition and develop innovative solutions that enhance safety, user experience, and mental well-being in various domains.

II. Experiments and Methods

A. Participants

All 26 participants (13 female; age range 22–28) had normal hearing and reported no psychological or neurological disorders. All studies were approved by the Committee for Human Research at Graduate School of Informatics, in Kyoto University. All participants signed a written informed consent prior to participating in their respective studies and received monetary reimbursement afterward.

B. Experimental environment

The participants were seated comfortably in front of an LCD screen (24-inch) on a chair in a dark room. On a table between the participants and the display, a keyboard was provided to input actions by pressing its keys. Auditory stimuli were sent using Psychopy3. The pure tones for the stimuli are spatial sounds that were generated based on the head-related transfer function [10] and presented through in-ear headphones (Etymotic ER3). The volume for stimulus sounds was tuned for each participant such that the sound did not make them uncomfortable and was kept constant during the experiment.

EEG signals were recorded using an ActiveTwo system (BioSemi) from 64 active scalp electrodes and digitized at 512 Hz. The 64 electrodes were positioned to cover the head as shown in Figure 1 according to the extended International 10/10 system. Additional signals were measured in the extra active electrodes placed on the left and right earlobes, on the left and right temples, and upper and lower sides of the left eye.

C. Task

The procedure of a trial is illustrated in Figure 2. At the beginning of each trial, the participants were provided with clear instructions regarding the specific attribute of the tones they needed to focus on. We utilized two attributes of the tones: their frequency and location. By integrating these attributes, we designed normalized EEG features to isolate brain activity specifically associated with anticipating difficulty (refer to Section II-G for details). Following the instructions, participants were given a 1.0-s duration to blink and relax their eyes. This brief period aimed to minimize blinking during the EEG recording phase. Then three sound stimuli (Tone 1, Tone 2, and Tone 3), which were pure tones with various positions and frequencies, were presented in sequence. Each sound stimulus lasted 0.8 s with a 1.0 s interval period. At the end of the trial, the participants were prompted to indicate which of Tone 1 and Tone 2 was more similar in the instructed attribute to Tone 3 and they answered within 3 s by the keyboard.

The experiment had two parts: the behavior and the EEG experiments. To account for variations in individual sensitivity to tone frequency and position, as well as the potential differences in perceived difficulty among participants for the same tones, we conducted a preliminary behavioral experiment prior to the

EEG study. This preliminary experiment aimed to fine-tune the difficulty level of the task for each participant, ensuring a tailored and optimized experience based on their specific abilities and perceptions. This difficulty level was subsequently tested in the EEG experiment.

In the behavior experiment, five similarity levels for each frequency/position attribute (see Section II-D) were tested. Each participant performed 10 trials for each similarity level of the attributes, 100 trials in total. Out of the five similarity levels for each attribute, the two similarity levels were assigned as the high and low difficulty levels for each participant based on the task performance in the behavior experiment. This assignment for the similarity level was performed such that the accuracy closer to 50% was assigned to the high difficulty level, and closer to 100% was assigned to the low difficulty level. In case there were two or more with 100% accuracy, the highest similarity level among them was assigned as the low difficulty level. For a special case where the participants performed the task perfectly for all similarity levels, the highest similarity level was assigned as the high difficulty level.

EEG signals were then recorded using these two difficulty levels. Two attributes were randomly selected out of the candidates (see Section II-D) to achieve the high and low difficulty levels, and then these two values for the attributes were randomly combined. Each participant performed 48 trials for each difficulty level of the attributes, for a total of 192 trials.

D. Auditory stimuli with similarity level

We manipulated the difficulty of the task by controlling the similarity between Tone 1 and Tone 2. To extract the neural activity related to the difficulty anticipation, we used two attributes, frequency and position, for controlling the similarity. This section describes the definition of the similarity levels for the attributes. Each attribute has five similarity levels. Level 1 represents the highest similarity and Level 5 is the lowest.

The first attribute is frequency, which defines the pitch of a tone [11]. In our experimental setting, 880 Hz (high A) was the lowest frequency. Based on the principle of equal temperament [12], we defined 24 frequencies:

$$\phi_n = 880 \times (\sqrt[24]{2})^n, \ (n = 0, 1, ..., 23). \tag{1}$$

The frequencies for Tone 1 and Tone 2, f_1 and f_2, were randomly selected out of these 24 candidates. Then the similarity level for f_1 and f_2 was calculated as

$$D_f = \left| \log_2 \left(\frac{f_1}{f_2} / 880 \right) * 24 \right|. \tag{2}$$

In order to set the frequency for Tone 3 (f_3), the higher and lower frequencies in f_1 and f_2, were randomly selected from $\{\max(f_1, f_2)/(\sqrt[96]{2})^n, \min(f_1, f_2) \cdot (\sqrt[96]{2})^n\}$. Table I shows some examples of the combinations of the tone frequencies and their similarity levels in the frequency attribute.

The second attribute was position, which defines the arrival direction of the tones. As shown in Figure 3, a semicircle surrounding a participant's head was defined, and 36 positions were set at $5°$ intervals from $-90°$ to $90°$ as:

$$\psi_n = -90 + 5n, (n = 0, ..., 35). \tag{3}$$

The positions for Tone 1 and Tone 2, p_1 and p_2, were randomly selected out of these 36 candidates. Then the similarity level for p_1 and p_2 was calculated as

$$D_p = |p_1 - p_2| / 30°. \tag{4}$$

In order to set the position for Tone 3 (p_3), the more rightward and leftward positions in p_1 and p_2, p_r and p_l, were randomly selected from $\{\max(p_1, p_2) - 5, \min(p_1, p_2) + 5\}$. Table II shows some examples of trials about the position attribute.

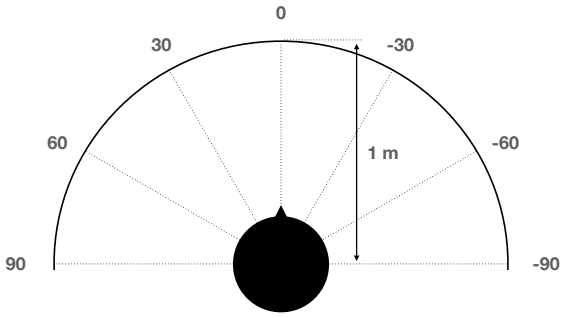

Fig. 3. The definition of the position attribute for the tones. The position attribute represents the arrival direction of the tone that is defined with the semicircle surrounding a head.

TABLE I

EXAMPLES OF TRIALS ABOUT FREQUENCY ATTRIBUTE

A: 880 Hz; $A^{\#}$: 932.328 Hz; B: 987.767 Hz				
Trial Number	Tone 1	Tone 2	Question Tone	Similarity Level
1	A	B	$A \times (\sqrt[96]{2})^n$	4
2	A	B	$B/(\sqrt[96]{2})^n$	4
3	A	$A^{\#}$	$A^{\#}/(\sqrt[96]{2})^n$	2
4	$A^{\#}$	A	$A \times (\sqrt[96]{2})^n$	2

E. Data Preprocessing

The EEG signals were preprocessed and analyzed by using Python 3.9.7 and an open-source Python package MNE 1.2 [13]. We reconstructed the equivalent sources from scalp EEG recordings with average reference [14] and the data were band-pass filtered from 0.2 Hz to 40 Hz. Continuous data was segmented into epochs ranging from -0.2 s to 0.8 s at the onset of tone stimulus. An automatic routine was applied to exclude data epochs contaminated by eye movements and muscle artifacts [15]. Then we used spherical spline interpolation to repair bad channels [16].

The trials had conditions that are presented with three letters:

TABLE II

EXAMPLES OF TRIALS ABOUT POSITION ATTRIBUTE

Trial Number	Tone 1	Tone 2	Question Tone	Similarity Level
1	$60°$	$-30°$	$-25°$	3
2	$-30°$	$60°$	$55°$	3
3	$60°$	$30°$	$55°$	1
4	$30°$	$50°$	$25°$	1

TABLE III

DESCRIPTION OF LABELS IN DIFFERENT EXPERIMENTAL CONDITIONS

	Frequency attention	Position attention
High difficulty level	FHH	PHH
	FHL	PHL
Low difficulty level	FLH	PLH
	FLL	PLL

- The first letter: The attribute on which the participant evaluated the similarity. "F" represented the attribute of frequency and "P" represented the attribute of position.

- The second letter: The difficulty level for the frequency attribute. "H" represented the high difficulty level and "L" represented the low difficulty level.

- The third letter: The difficulty level for the attribute on which the participant did not evaluate the similarity. "H" represented the high difficulty level and "L" represented the low difficulty level. For example, the label "FHH" represents a trial condition in which the target is frequency, the frequency similarity is at the high difficulty level, and the position similarity is at the high difficulty level.

F. EEG features

In order to find the neural effects of the anticipation of the difficulty level, we extracted some EEG features described in this section. Here, an EEG signal of participant p for trial k at channel c was represented as $\text{EEG}_k[p, c, n_{(t_{\text{start}}, t_{\text{end}})}]$, where $n_{(t_{\text{start}}, t_{\text{end}})}$ are all points from t_{start} to t_{end}.

1) Event-related potential (ERP): ERPs are small voltages generated in response to a specific stimulus. They reflect the summed activity of postsynaptic potentials generated when a large number of similarly oriented cortical pyramidal neurons discharge synchronously while processing information [17].

We obtained the ERPs of the participant p for the trial k at the channel c by normalizing to the baseline of 200 ms pre-stimulus activity (baseline correction) as:

$$\begin{aligned}&\text{ERP}_k[p, c, n_{(-0.2,0.8)}] = \\ &\text{EEG}_k[p, c, n_{(-0.2,0.8)}] - \overline{\text{EEG}_k[p, c, n_{(-0.2,0)}]}.\end{aligned} \tag{5}$$

where the bar in the equations represented the average of the time series $n_{(t_{\text{start}}, t_{\text{end}})}$ of EEG signals from t_{start} to t_{end}.

2) Time-frequency representation (TFR): TFR visualizes the frequency content of brain activity as it varies over time. It can provide insight into the brain's dynamic activity.

We used the Wavelet transform [18] with 300 ms of sliding window, 50 ms of sliding step, and 2 Hz of spectral smoothing. Then, we obtained the TFR of the participant p for the trial k at the channel c by normalizing to the baseline of 200 ms pre-stimulus activity (baseline correction) as:

$$\begin{aligned}&\text{TFR}_k[p, c, n_{(-0.2,0.8)}] = \\ &Wavelet(\text{EEG}_k[p, c, n_{(-0.2,0.8)}]) - \\ &\overline{Wavelet(\text{EEG}_k[p, c, n_{(-0.2,0)}])}.\end{aligned} \tag{6}$$

where the bar in the equations represented the average of the time series $n_{(t_{\text{start}}, t_{\text{end}})}$ of TFR from t_{start} to t_{end}.

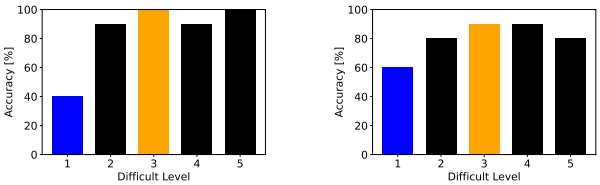
G. EEG analysis

Let $X_k[p, c]$ be an EEG feature, which is one of the features of the participant p for the trial k at the channel c defined in Section II-F and y_k is the label for trial k.

$Original$ EEG features were obtained by averaging the EEG signals with the same label of difficulty level as:

$$o_{\text{H}}[p, c, n] = \overline{X_{k|(y_k \in \{\text{FHH,FHL,PHH,PHL}\})}[p, c, n]}, \tag{7}$$

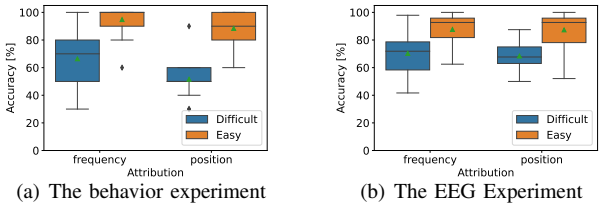
$$o_{\text{L}}[p, c, n] = \overline{X_{k|(y_k \in \{\text{FLH,FLL,PLH,PLL}\})}[p, c, n]}, \tag{8}$$



where the bars in the equation represent the average of the EEG features for all trials k that satisfied condition y_k.

The original EEG features, which are typically averaged based on the same label, might not exclusively capture the anticipation of difficulty. They could also be influenced by other responses, such as the perceived differences between Tone 1 and Tone 2 [19], [20]. Therefore, we proposed EEG features by combining the two attributes. To isolate the brain activities associated with difficulty anticipation under trial conditions d, a subtraction can be performed by subtracting the EEG feature of the trial conditions that the participant did not evaluate from the EEG feature of the trial conditions that the participant evaluated.

We defined the proposed EEG feature (the normalized feature) as follows. Initially, we calculated features that captured the difference between the attended and unattended trials of a specific attribute, while maintaining the difficulty level of this attribute constant. For instance, we computed the difference between trials where the participant was asked to assess the similarity of tones based on frequency, and trials focused on position. Four variations of this feature were formulated, as dictated by:



$$\begin{aligned}&s_{\text{FH}}[p, c, n] = \\ &\overline{X_{k|(y_k \in \{\text{FHH,FHL}\})}[p, c, n]} - \overline{X_{k|(y_k \in \{\text{PHH,PLH}\})}[p, c, n]},\end{aligned} \tag{9}$$

$$\begin{aligned}&s_{\text{FL}}[p, c, n] = \\ &\overline{X_{k|(y_k \in \{\text{FLH,FLL}\})}[p, c, n]} - \overline{X_{k|(y_k \in \{\text{PHL,PLL}\})}[p, c, n]},\end{aligned} \tag{10}$$

(a) Frequency selection (b) Position selection

Fig. 4. An example of the accuracy of one of the participants for the five difficulty levels, as well as for the high and low difficulty levels. The blue and orange boxes represent the distributions of accuracy for high and low difficulty levels, respectively.

(a) The behavior experiment (b) The EEG Experiment

Fig. 5. The task performance (accuracy) in behavior and EEG experiments. The blue and orange boxes represent the distributions for middle 50% range of accuracy for high and low difficulty levels, respectively. The green triangles indicate mean values and the black horizontal lines indicate median values, while black dots are outliers.

$$s_{\mathrm{PH}}[p,c,n] = \overline{X_{k|(y_k\in\{\mathrm{PHH,PHL}\})}[p,c,n]} - \overline{X_{k|(y_k\in\{\mathrm{FLL,FLH}\})}[p,c,n]}, \tag{11}$$

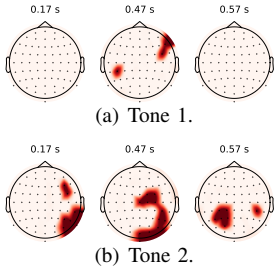
$$s_{\mathrm{PL}}[p,c,n] = \overline{X_{k|(y_k\in\{\mathrm{PLH,PLL}\})}[p,c,n]} - \overline{X_{k|(y_k\in\{\mathrm{FHL,FLH}\})}[p,c,n]}, \tag{12}$$

where the bars in the equation represent the average of the EEG features for all trials k that satisfied condition y_k.

Next, to derive EEG features that are independent of the focused tone attribute, we averaged the previously mentioned features across the same difficulty level. The normalized feature was ultimately defined as follows.

$$s_{\mathrm{H}}[p,c,n] = (s_{\mathrm{FH}}[p,c,n] + s_{\mathrm{PH}}[p,c,n])/2, \tag{13}$$

$$s_{\mathrm{L}}[p,c,n] = (s_{\mathrm{FL}}[p,c,n] + s_{\mathrm{PL}}[p,c,n])/2. \tag{14}$$



III. Result

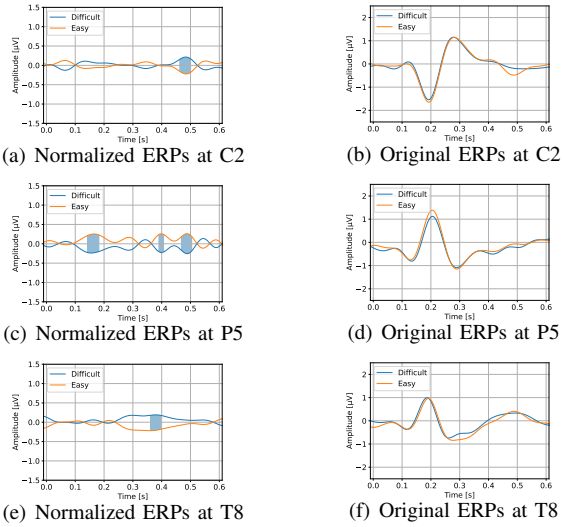
A. Behavior

The participants completed the behavior experiment with the five similarity levels to determine their own high and low difficulty levels for the EEG experiment. The difficulty levels were selected based on the task performance for the five similarity levels in the behavior experiment. An example of the accuracy of one of the participants for the five similarity levels, as well as the selection of high and low difficulty levels, is shown in Figure 4. Furthermore, the accuracy for the two difficulty levels are shown in Figure 5. The task performance between the high and low difficulty levels showed significant differences ($p < 0.01$) for the frequency and position attributes in both the behavior and EEG experiments.

B. EEG

1) Event-related potential (ERP): Figure 6 illustrated topographic maps of Normalized ERPs highlighting regions with significant differences between the two difficulty levels. Specifically, the differences are observed at 0.17 s, 0.47 s, and 0.57 s. These topographic maps provide a visual representation of the neural activity variations associated with different levels of difficulty during the specified time intervals. In the period for Tone 2, significant differences were found in the right central vertex, right parieto-occipital, and left parieto-occipital regions, while there were almost no differences in Tone 1. Because of this result, all results below are only for Tone 2. We selected channels, C2, P5, and T8, as the representatives for the areas with the significant differences, respectively.

(a) Tone 1.



(b) Tone 2.

Fig. 6. Topographic maps of the significant differences in the normalized between the two difficulty levels of the sound stimulus at 0.14 s, 0.23 s and 0.32 s. The red parts indicate significant differences ($p < 0.05$).

The ERP results of these channels are depicted in Figure 7. The significant difference in the ERPs in the right central vertex region can be attributed to the variation to N4, as shown in Figure 7(a) and 7(b). Additionally, in the left parieto-occipital region, the ERPs can be attributed to the variation to P2, N4, and P3, as shown in Figure 7(c) and 7(d). Moreover, in the right temporal region, the ERPs can be attributed to the variation to P3, as shown in Figure 7(e) and 7(f).

2) Time-frequency representation (TFR): Figure 8 illustrates topographical maps showing areas with significant differences in Tone 2 between the two difficulty levels in the time-frequency representation at 0.07 s, 0.50 s, 0.58 s, and 0.64 s. In the theta (4–7 Hz), alpha (8–11 Hz), and beta (12–20 Hz) bands, significant differences were all found in the prefrontal and occipital regions at 0.07 s, while at 0.50 s, 0.58 s, and 0.64 s in the alpha and beta bands, significant differences were found in the left central vertex and occipital regions. The gamma band showed significant differences in the right and left parieto-occipital regions. Because of these results, we selected channels, Fz, C3, and Pz, as the representatives for the prefrontal, left central vertex, and occipital areas, respectively. The TFR results of these channels are depicted in Figure 9.

(b) P-values at C3

(c) P-values at Pz

Fig. 9. The normalized TFR in Tone 2. The parts of red indicate significant differences ($p < 0.05$).

can be attributed to the variation to the theta, alpha, and beta bands at 50–100 ms, as shown in Figure 9(a). Additionally, in the left central vertex region, the TFR can be attributed to the variation in alpha band and beta1 band (12–16 Hz) at 80–280 ms and 380–700 ms, as shown in Figure 9(b). Moreover, in the occipital region, the TFR can be attributed to the variation to alpha band and gamma band (25–35 Hz) at 500–700 ms, as shown in Figure 9(c).

IV. Discussions

In this study, we investigated EEG features that are involved in anticipation of the difficulty of upcoming auditory tasks. By manipulating sound similarity, the participants anticipated how much difficult the upcoming task would be. The behavior experiment revealed significant differences in task performance between high and low difficulty levels. This suggests that the chosen level of difficulty was appropriate. In the EEG experiment, the analysis of ERPs revealed significant differences in several brain regions. The right central vertex region showed notable variations primarily in the N4 component. In contrast, the left parieto-occipital region displayed variations in the P2, N4, and P3 components, while the right temporal region exhibited variations specifically in the P3 component. Furthermore, the analysis of TFR uncovered additional significant differences across various brain regions. During the earlier time interval, the prefrontal and occipital regions demonstrated significant variations across multiple frequency bands. Moving to later time intervals, the left central vertex and occipital regions displayed significant differences, particularly in the alpha and beta bands. Additionally, the right and left parieto-occipital regions exhibited distinctive variations specifically in the gamma band.

In the prefrontal area, according to earlier studies, synchronization of low and medium frequency bands was involved in attention transformer [21]. In the present study, there were significant differences in the low and medium frequency bands (5–20 Hz) at the beginning of the event (50–100 ms). This indicates that the participants assigned more attention to the task of the high difficult level than that of the low difficult level. Furthermore, previous studies have indicated that the evocation of N4 components occurs when there is semantic

inconsistency [22]. In the present study, since similarity was used as a basis for judging the level of difficulty, participants can clearly perceive this inconsistency when the task was easy, so N4 was clearly evoked. In contrast, the N4 was not evoked when the task was difficult. We also found a P3 variation in the left parieto-occipital region, which, according to earlier studies, was usually associated with self-perception, that is, metacognition [23]. This suggests that after perceiving information the participants usually compared the perceived environmental information with their self-competence, to anticipate the difficulty of the problem. In addition, following time-frequency analysis, significant differences were observed in the alpha band between 400–700 ms in both the left central vertex region and the parieto-occipital region. However, the nature of these differences varied: in the left central vertex region, alpha band synchronization was observed, whereas, in the parieto-occipital region, desynchronization was observed in both the alpha and gamma bands. We believe these were important neural markers to prepare resources in response to upcoming problems of varying difficulty.

In summary, this study explores the neural mechanisms involved in anticipation during auditory tasks. The findings highlight the role of attention and predictive behavior in responding to environmental information. The results also reveal distinct patterns of neural activity associated with different levels of task difficulty, as measured by ERPs and TFR. These patterns suggest the involvement of specific brain regions and frequency bands, indicating variations in cognitive processing. The study enhances our understanding of how the brain adapts to different levels of cognitive demand and opens possibilities for applications in cognitive load monitoring and adaptive task design. Further research can expand upon these findings to investigate the specific cognitive processes associated with task difficulty levels.

Event-Related Potential in Rapid Serial Visual Presentation-based Partial Face Cognition Depends on Visible Face Components

***Abstract*—Under the SARS-CoV-2 pandemic situation, wearing masks became a must-do action in our daily life. Although some parts of the face are covered, humans can still recognize people's faces precisely. In this study, we aimed to identify how the visibility of different parts of the face affects face recognition using an electroencephalogram (EEG). We also investigated how physical response affects the cognition mechanism. In the experiment, we performed a face cognition task using a rapid serial visual presentation (RSVP) stimulus. The experiment consisted of two cognition tasks, images displayed at 1000 msec with a button press when the target is shown and images displayed at 200 msec without any physical responses. Six faces under seven visibility conditions (full-face shown, eyes covered, nose covered, mouth covered, eyes and nose covered, eyes and mouth covered, and nose and mouth covered) were presented as the stimulus to identify the effect of each part being visible or not visible. As a result, we observed two components of P300 event-related potential (ERP) evoked, P3a and P3b, that related to partial face cognition. For both physical response tasks, we found that the P300 peak value was significantly lower, and the P3a and P3b latency were significantly delayed when the eyes were not visible. These results suggest that the eye could be the most crucial feature in face cognition, and there is a possibility of substituting the no physical response task with the physical response task.**

I. Introduction

During the SARS-CoV-2 pandemic, wearing masks has become a health precaution that everyone needs to follow. By wearing masks, part of the face became hidden, but people could still recognize faces regardless of the small visible face area. Previous studies claimed that holistic face processing enhances the identification judgment [1]–[3]. Covering part of the face decreases the ability to recognize faces [1], [4], [5] However, whether holistic face processing applies to partial face cognition and how people can recognize masked faces are still in question. To clarify the question on the partial face mechanism, we utilized the rapid serial visual presentation (RSVP) paradigm, which is a widely-used stimulus for visual perception study [6].

RSVP is a temporal sequence of target and non-target images with the probability of the target image being considerably smaller than the non-target image. Generally, the rate of presentation is expeditious. The electroencephalogram (EEG) response was focused on in this study due to its high temporal resolution [7], [8]. During the RSVP task, a time-lock response related to the perceived target image called event-related potential (ERP), is induced with the particular pattern [9], [10]. The pattern of ERP response consists of many components, such as P300 which is related to the target recognition found at 250-700 msec after the stimulus invoked [6], [11]. Each component was typically named according to its polarity and latency after the stimulus onset.

Among many ERP components, N170 and vertex positive potentials (VPP) are considered as a face responsive ERP [12]–[14]. For target and non-target face cognition, the relevance of N200 and P300 potentials outweighs that of the N170 and VPP components [13], [14]. In partial face cognition, some studies claimed that lacking the eye component results in N170 latency extension, but the N170 amplitude remained unchanged [15]–[19]. In contrast, other studies reported that a face with eyes invisible affected both N170 amplitude and latency [20], [21]. With these arguments, how the face feature affects the ERP response needs to be clarified.

Based on the aforementioned studies, ERP components were utilized as a biomarker for partial face and whole face cognition to study how each component of the face features plays a role in face cognition. We hypothesized that people could recognize an uncovered face easier and more precisely than a partially covered face due to the holistic face processing and more components of the face are provided in the whole face cognition. Additionally, many studies in the EEG-based RSVP paradigm usually utilized button press tasks [6] which can cause mental fatigue and the results can be affected by decreasing attention during the task [22]. Therefore, we also investigated how ERP changes during 'button press' and 'no button press' tasks in order to minimize workload during ERP tasks in future studies.

II. Materials and Methods

A. Dataset

The data recorded from 18 young and healthy participants (average age: 26.05 ± 2.61 years; minimum age: 22; maximum age: 31) during the partial face cognition task in our previous study [23] was used. The experiment consists of two tasks; button press and no-button press task. Both tasks have the same flow of experiment, starting with the instruction and the target face presentation, followed by 500 msec of fixation presentation, and the presentation of the face images. The

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

stimulus presentation time was set to 1,000 msec for the button press task and 200 msec for the non-button press task with an inter-stimulus interval (ISI) of 500 msec. Each task consists of seven blocks, showing seven face image conditions; full face, face with eyes covered, face with nose covered, face with mouth covered, face with eyes and nose covered, face with eyes and mouth covered, and face with nose and mouth covered, respectively. Six Asian face images were used in each block; one target face image and five non-target face images. Each face was presented 20 times per block, resulting in 120 trials in total. The EEG data was recorded together with the eye movements using a 72-channel Refa amplifier (electrode alignment: 10-10 international system; reference: average of all EEG input channels; ground: left wrist). (see [23] for details)

B. Data Analysis

The acquired signals were pre-processed in the same manner as done in Chanpornpakdi and Tanaka [23] using MNE package 1.3.0 [24] in Python 3.5.8. The data were first re-referenced with the average of earlobe electrodes (M1 and M2). To obtain as less-contaminated EEG data as possible, they were filtered with a 1–30 Hz bandpass filter and submitted to extended Infomax independent component analysis (ICA). The clean EEG data were segmented from -100 msec to 1000 msec from the target onset, resulting in 120 epochs. The epoched data were grouped into 12 electrodes based on the brain regions; frontal, parietal, occipital, and temporal regions, and averaged among the electrodes in the same group. (see [23] for details)

To acquire the ERP, we concatenated the preprocessed EEG epochs of each participant in each condition together and took the average of the concatenated data, called the grand average, across the participant and a topographic map of the grand average was plotted. The grand average ERP was calculated on 20 trials per participant across 18 participants, making the total number of trials 360. In the statistical test, the maximum amplitude and latency of the corresponding amplitude of the two ERP components, N170 (negative peak at 100–200 msec) and P300 (positive peak at 300–400 msec for early P300, or P3a, and 400–600 msec for later P300, or P3b), were extracted from each participant. An upper-tailed dependent t-test was applied for each amplitude and a lower-tailed dependent t-test was used for each latency of the ERP components (N170, P3a, and P3b with peaks of 18 participants for each component as the dependent variable) to test our hypothesis that the amplitude of ERPs during full-face cognition is larger than the amplitude of ERPs during partial face cognition. The ERP peaks evoked and latencies in the full-face condition were compared with those evoked in each partial face condition (six conditions: covered eyes, covered nose, covered mouth, covered eyes and nose, covered eyes and mouth, and covering nose and mouth).

Furthermore, we also applied a two-way repeated measures analysis of variance (ANOVA) test to the amplitude of the ERP peaks; N170, P3a, and P3b, to test our hypotheses that: 1) all the face condition groups have equal mean ERP peaks, 2) all the physical task condition groups have equal mean ERP peaks, and 3) the factors are independent, or the interaction effect of the face cognition and task conditions does not exist. The two factors in our ANOVA test were seven face cognition conditions (full-face and six partial face conditions) and two button press conditions (button press and no button press condition) and Greenhouse–Geisser correction was used in multiple comparisons. The dependent variable was the same as that used in the t-test and the sample size was 18. After identifying the factors (button, face condition, and the interaction of both factors) that have significantly different in ERP among themself, we performed pairwise t-tests to explore the relationships that showed significant differences using Benjamini/Hochberg (non-negative) correction.

III. Results

In this study, we compared the ERP elicited during full-face and partial face cognition in button press and no button press tasks. Figure 1 shows the examples of the grand average ERP and topographic map of the full-face, partial face with eyes visible, and partial face with eyes invisible conditions during the button press task and no button press task, respectively. The face conditions shown were the full-face, face with nose covered, and face with eyes and nose covered image cognition condition. The face image with nose covered stimulus presentation was to show as an example of a part of the face covered and the P3b of this condition was found to be the largest among all the conditions. The face with the nose and eyes covered was shown as an example of the ERP when the two parts of the face were covered and how the ERP was elicited differently when the eyes were covered in addition to the nose.

A. Amplitud of Evoked ERP

Four ERP components were observed: N170, P200, N250, and P300. We have highlighted the two essential ERP components for face cognition in Figure 1; N170 (a characteristic ERP for face cognition) in gray and P300 (an attention ERP for target and nontarget cognition) in yellow and blue color. N170, P200, and N250 of the perceived target were observed with larger amplitudes in the frontal and central electrodes that became smaller as the position moved toward the posterior region, regardless of the type of image condition. The other component observed was the P300 component, which contained two subcomponents: early P300 (P3a) observed at a latency of approximately 300 msec, predominant at the frontal region of the brain, and later P300 (P3b) observed at a later latency around 400–600 msec, noticeably at the parietal region of the brain. We could also see that the N170 of the target and non-target face images were almost at the same level whereas the P300 component of the target image has a larger amplitude than that of the nontarget image. Moreover, both tasks shared a common result: there were drops in the P300 peaks evoked when the eye component of the target was invisible.

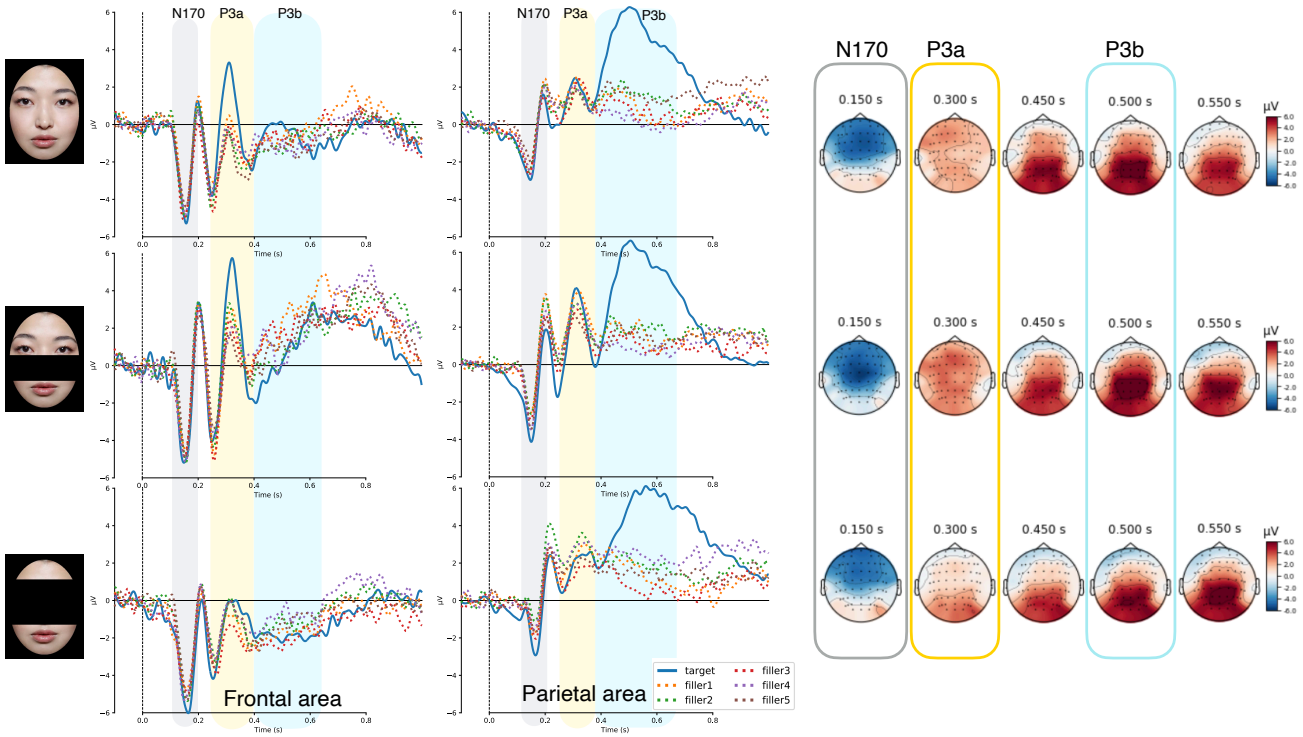
To test our hypothesis, we have performed the upper-tailed dependent t-test on the amplitude of N170, P3a, and P3b. The results were plotted and shown in Figure 2. Figure 2 shows the peak of N170 in the frontal region, P3a in the frontal region,

and P3b in the parietal region in each face condition during the button press and no button press tasks. When comparing the ERP peaks evoked in each condition, peaks of N170 in the frontal electrode region from both the button press and no button press tasks were at a similar level, and there was no significant difference observed between the peaks evoked in full-face and partial face cognition. However, we found a significantly larger peak in N170 in the comparison of the full-face cognition condition and face with eyes and nose covered cognition in the button press condition ($p < 0.05, d = 0.449$).

For P300, the peaks of both P3a and P3b subcomponents dropped when the eye component was invisible during both button press tasks when compared to the full-face cognition condition. However, the significant differences of P3a amplitude in the frontal area between the full-face and partial face cognition were found only when the eyes and mouth were covered ($p < 0.05, d = 0.423$) in the button press task and when the eyes and nose were covered ($p < 0.05, d = 0.478$) in the no button press task. Furthermore, the peak of P3b in the parietal region during full-face cognition was significantly larger than the partial face condition when the eyes ($p < 0.001, d = 0.882$), and eyes and mouth were covered ($p < 0.01, d = 0.648$) in the button press task and when the eyes and nose ($p < 0.01, d = 0.647$), and eyes and mouth were covered ($p < 0.001, d = 1.015$) in the no button press task.

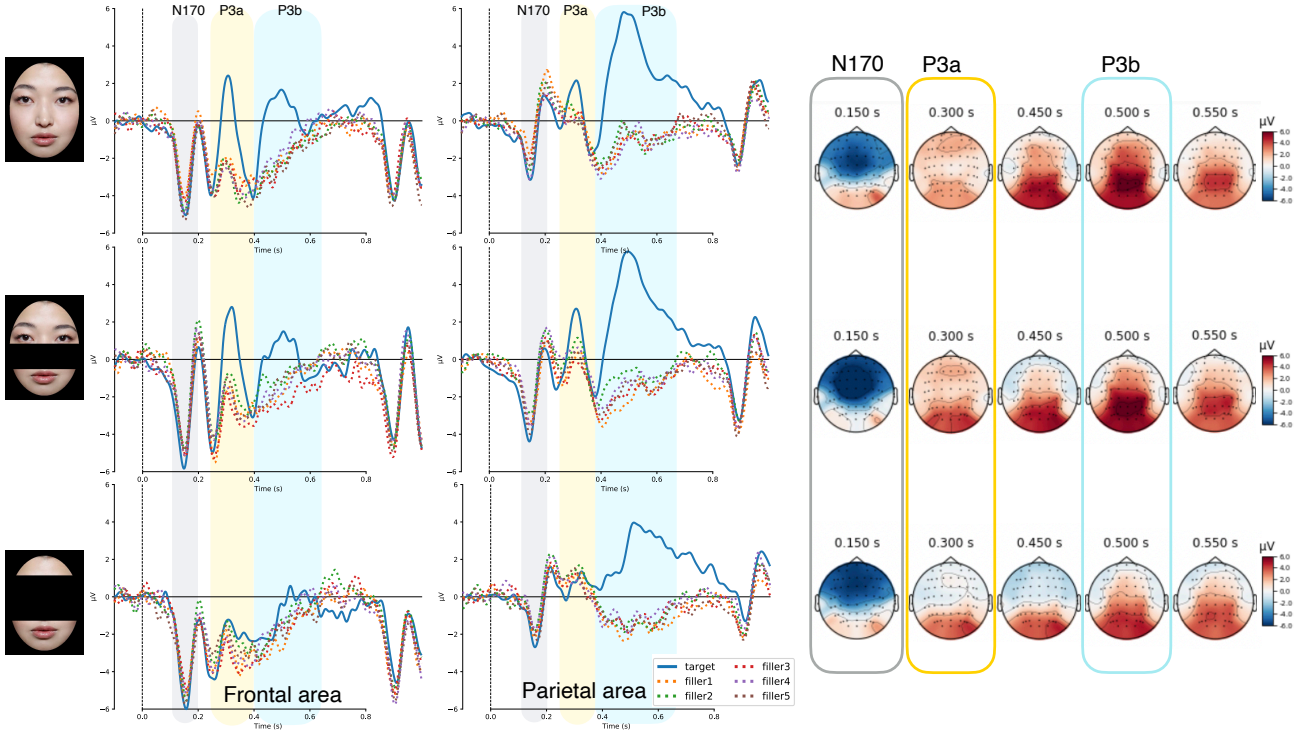
B. Latency of Evoked ERP

Figure 1 also shows the topographic map around 0.150 sec, 0.300 sec, 0.450 sec, 0.500 sec, and 0.550 sec that represents the N170, P3a, and P3b, respectively. The N170 peak, in which either the nose or mouth was covered, has slightly larger peaks in the central area in both button press tasks. We could also clearly see from the topographic map in Figure 1 that there are some delays in the latencies of the ERPs.



We have performed the lower-tailed dependent t-test to observe the delay of elicited ERPs caused when removing parts of the face during the cognition task. As a result, we found that there were significant delays in N170 elicited when the eyes and nose were covered ($p < 0.01, d = -0.644$) around 0.010 sec and when the eyes and mouth were covered ($p < 0.05, d = -0.557$) around 0.011 sec in the button press task. However, we did not observe any significant delay of N170 elicited between the full-face and partial face cognition in no button press task. Similarly, we also found that the P3a elicited in both the button press task was significantly delayed when the eyes, eyes and nose, and eyes and mouth were covered. In the button press task, when the eyes ($p < 0.05, d = -0.475$), eyes and nose ($p < 0.05, d = -0.549$), and eyes and mouth were covered ($p < 0.05, d = -.478$), P3a got extended by 0.015 sec, 0.024 sec and 0.021 sec, respectively. In the no button press task, when the eyes ($p < 0.05, d = -0.517$), eyes and nose ($p < 0.05, d = -0.570$), and eyes and mouth were covered ($p < 0.005, d = -0.699$), P3a got extended by 0.017 sec, 0.020 sec and 0.026 sec, respectively.

For the latency of the evoked P3b, we found that P3b got extended in all the conditions except when the nose and mouth were covered in the button press task. When the eyes ($p < 0.001, d = -1.368$), nose ($p < 0.05, d = -0.420$), mouth ($p < 0.05, d = -.519$), eyes and nose ($p < 0.001, d = -1.106$), and eyes and mouth were covered ($p < 0.001, d = -1.099$), the P3b subcomponent was delayed by 0.062 sec, 0.019 sec, 0.020 sec, 0.055 sec, and 0.046 sec, respectively. Contradictory, we only found a significant delay in P3b latency only when the eyes ($p < 0.001, d = -1.021$), eyes and nose ($p < 0.001, d = -0.977$), and eyes and mouth ($p < 0.05, d = -0.463$) were covered in the no button press task. The delays were around 0.041 sec, 0.045 sec, and 0.027 sec, respectively.



C. Interaction of Face Conditions with Physical Response

The results of the two-way repeated-measures ANOVA test for the amplitude of N170, P3a, and P3b peaks around the frontal and parietal regions are presented in Tables I, II, and III, respectively. From Table I, when comparing the full and partial face cognition conditions, the amplitude of the N170 component associated with partial face cognition has similar peaks in both the button press and no button press conditions, $F(1, 17) = 0.692, p = 0.010.417, {\eta_p}^2 = 0.003$. However, we could not observe the significant differences in conditions, $F(6, 102) = 0.779, p = 0.552, {\eta_p}^2 = 0.725$, and the interaction of button press tasks face cognition conditions in the elicited N170, $F(6, 102) = 0.218, p = 0.945, {\eta_p}^2 = 0.765$.

From Tables II and III, we found that the button press task significantly affected both P3a, $F(1, 17) = 11.082, p < 0.01, {\eta_p}^2 = 0.028$, and P3b, $F(1, 17) = 9.708, p < 0.01, {\eta_p}^2 = 0.042$. In addition, the face cognition condition had a significant main effect on P3a, $F(6, 102) = 5.893, p < 0.001, {\eta_p}^2 = 0.062$, and P3b, $F(6, 102) = 9.305, p < 0.001, {\eta_p}^2 = 0.075$. Pairwise t-tests revealed that the P3a peak evoked in partial face cognition was significantly different when: covered eyes were compared with covered nose ($p < 0.05, d = -0.592$); covered eyes and mouth were compared with covered nose ($p < 0.05, d = -0.601$); covered eyes and nose compared with mouth ($p < 0.05, d = -0.467$), mouth ($p < 0.01, d = -0.751$), nose and mouth ($p < 0.05, d = -0.677$); and covered mouth were compared with covered nose ($p < 0.05, d = -0.338$). The P3b peaks evoked in partial face cognition were also significantly different from each other when comparing covered eyes with covered eyes and mouth ($p < 0.01, d = 0.464$), full-face ($p < 0.05, d = -0.256$), mouth ($p < 0.001, d = -0.503$), and nose ($p < 0.05, d = -0.330$). The comparison of the P3b peak between covered eyes and mouth and covered eyes and nose ($p < 0.05, d = -0.400$), full-face ($p < 0.005, d = -0.759$), mouth ($p < 0.001, d = -0.997$), nose ($p < 0.005, d = -0.817$), and nose and mouth ($p < 0.005, d = -0.702$) were also significantly different. In addition, the P3b peak evoked when the eyes and nose were covered was significantly different from the peak evoked when the mouth was covered ($p < 0.005, d = -0.610$), and the P3b peak elicited during

full-face cognition when compared with partial face cognition with the mouth covered was also significantly different ($p < 0.05, d = -0.275$). We found no significant interaction between face cognition condition and button press condition for neither P3a, $F(6, 102) = 1.551, p = 0.206, {\eta_p}^2 = 0.014$ (Table II), nor P3b, $F(6, 102) = 2.632, p = 0.067, {\eta_p}^2 = 0.01$ (Table III). However, pairwise t-tests revealed that some of the face cognition condition results varied significantly between the button conditions.

IV. DISCUSSION

A. Evoked ERP Components

As mentioned in the introduction, the N170 and VPP are typical face-characteristic ERPs associated with face cognition. The observations relating to N170 and P300 match the finding that these ERP components are characteristic of face stimuli,

whereas the amplitude of the P300 depends on the target and non-target conditions of the face stimulus [13], [14]. In addition, we found significant differences between the N170 peaks of the full-face and partial face cognition conditions only in the button press task. This result emphasizes that the N170 component is the face characteristic ERP component and is sensitive to facial features only either when performing behavior response or participants had enough time to perceive the face image.

We also found a positive peak at approximately 200 msec, with a greater amplitude around the frontal region. This positive peak latency is consistent with the VPP and P200 latencies [25]–[27]. Hence, there are two options that this peak could belong to. However, N170 and VPP have been reported to be face-sensitive responses from the same neuron generator in the occipito-temporal region [15], [25]. On the other hand, P200 reflects the feedback of the visual cortex, which is necessary for perception, and the response is more sensitive to configural face processing or spacing processing rather than featural face processing [28]. On this account, the observed peak is more likely to be P200, and the subsequent negative peak found around 250 msec could be named N250. N250 indicates the categorization process for individual faces [26].

Regarding the P300 component, the P3a subcomponent is related to focal attention and represents the response to a new event or stimulus that causes an attention shift, whereas P3b is related to the memory stage and represents the response to cognition [29]–[31]. These findings indicate that the early P3a subcomponent found in this experiment might reflect the attention to the facial image, and the later P3b subcomponent reflects the response when the participant recalls the face from their short-term memory storage.

B. ERP Amplitude and Latency

From our experiment, we obtained that covering the eye component significantly dropped the ERP components for both N170 and P300, where P3a indicated the attention process and P3b indicated the identification process perception. We found that the amplitude and latency of N170 peaks of the partial face cognition conditions when the eyes component was covered only was significantly decreased and delayed when compared to the full face cognition condition in the button press task. While the latencies of maximum N170 peaks got extended when the eyes and nose, and eyes and mouth were covered, the amplitude of N170 was significantly dropped only when the eyes and nose were covered. This result implies that the eyes are the most important. Apart from the eyes which are the structural information, having a nose would provide the configural information of the distance between eyes and nose and make the performance of face cognition better which is in line with the mentioned study [32]. Therefore, when the eyes and nose were covered, we could observe both declinations in amplitude and latency. However, this result was obtained only in the button press task, which means that the N170 component is the face characteristic ERP component and is sensitive to facial features only either when performing behavior response or when there was enough time for the participant to perceive the face image.

When we investigated the partial face cognition studies that found the delay and decrease in amplitude of N170, we found the common factor that could be the cause of such response changes in N170. The two factors were stimulus presentation time and the condition of behavior response. Eimer [16] and Eimer [33] performed the experiment with a stimulus presented at only 100 msec but the participant was asked to press the button. The studies showed that the N170 peak was delayed when using a face with no eyes images compared with the intact face [16] and the N170 peak was lower and delayed in the experiment using the face with no internal features and a face lacking external features when compared to the intact face [33]. Other studies showed that presenting the stimulus images at 250 msec and 500 msec showed the delay in N170 latencies regardless of having behavior response or not [15], [17], [19]. Furthermore, when the stimulus was presented randomly in the range from 500 msec to 1000 msec and the participant was asked to provide the behavior response, N170 peak latency was extended and the amplitude also became lower for the face with Gaussian noise when compared to the full-face [20], [21].

From these studies, stimulus presentation time and the condition of behavior response might be the factors that affect N170. Our assumption is that a missing eye component face image only delays the N170 latency if either the stimulus was presented more than 250 msec or the stimulus was presented at a duration lower than 250 msec but the participants were asked to perform a physical response. Furthermore, we assumed that if the stimulus was presented longer than 500 msec in the physical response task, both the amplitude and latency of N170 will be smaller and longer. This assumption could explain why the significant diminish observed in N170 peak, and latency delay only in the button press task in which we presented the stimulus for 1000 ms and asked the participant to provide button press feedback. Certainly, other factors may cause the N170 response to be prolonged and diminished such as the type of stimulus, the duration of the inter-stimulus interval, etc. which are left to be clarified.

C. Limitation and Future Work

In our experimental design, the presentation time changed drastically between the physical response tasks. This can cause a better perception of the button press task due to a longer time to expose to the stimulus and process the presented information of the image. Furthermore, we could not find the difference in the N170 peak which could be a hint for the partial face cognition in the no button press task due to the short duration of stimulus presentation. To overcome such problems, we should reconsider the better presentation time that diminishes any inconsistency in our experiment in order to investigate the effect of workload in button press task precisely. It was suggested that 500 msec could be the most suitable for the RSVP face cognition task [6].

In the data pre-processing methods, we have only a small number of trials for each type of face image: therefore we only corrected the eye movement using ICA without rejecting any epochs. Applying ICA has a risk of losing some ERP components. To prevent that, we only removed the eye movement artifacts referencing to the eye movement data we recorded along with the EEG. However, there might be some other artifacts caused by the movements and sweat of the participants left in the processed data. Ideally, we should increase the number of trials to at least 100 trials [34] per face image to obtain clean ERPs. However, this study contained two tasks. Each task contained seven blocks; consisting of 6 images presented 20 times per image. As a result, A total of 120 images were presented in each block, 840 images per task, and 1,680 images in the whole experiment. The time taken to present all these images including the fixation of 500 msec in between each stimulus was around 21 minutes in the button press task and 10 minutes in the no button press task. In addition to the experimental duration, the EEG headset and training tasks needed to be arranged prior to the experiment. Therefore, we could only perform 20 trials for each image as Cohen and Polich [35] suggested that the average of 20 trials can yield a stable ERP with high reliability while Rietdijk, Franken, and Thurik [36] suggested that it could be as low as 14 trials, and Jensen and MacDonald [37] suggested 13 trials is the minimum trials needed to achieve high power (> 0.8) for 16 participants in a within-participants experiment. Others argued on the appropriate trial for averaging ERP and cannot come up with a conclusion. Certainly, a greater number of trials could give more stability and reliability to the ERP obtained. However, the number of trials itself cannot be considered alone. There are many factors such as sample size and fatigue caused during the experiment can also affect the quality of EEG.

In the future, we plan to perform another experiment on no button press task with a larger trial number. We will also introduce the eye-tracker to confirm our EEG results with the eye gaze.

***Abstract*—Speech interactions and digital assistants rely on effective wake word detection models to identify predefined words. In this study, we address the need for an efficient wake word detection model and propose a "three-way residual separable convolution network" (3W-ResSC) inspired by human multi-perspective learning. Our 3W-ResSC model combines three information: residual learning (ResNet), point-wise pattern, and depth-wise patterns from a CNN mixer (Mi). In addition, to conclude and emphasize information, our independent multi-view attention (iMVA) is proposed based attention mechanism (At). Based on ResNet, Mi, and At, we propose three different combinations for our model; ResNet+Mi, ResNet+At, and ResNet+Mi+At. By leveraging the strengths of these three combinations, our combinations are investigated to find the outstanding performance and pattern. To evaluate our model, we conduct experiments on multiple datasets, including Gowajee, HeyFireFox, HeySnips, and GSCv2. The results demonstrate that our 3W-ResSC outperforms baseline models in terms of equal error rate (EER), Matthews correlation coefficient (MCC), and false rejection rate (FRR) in multi-class classification. Additionally, we introduce a wake word detection framework specifically designed for streaming processing. This framework leverages an independent speech window, resembling a buffer-like streaming production process. Overall, our proposed 3W-ResSC model and wake word detection framework offer significant advancements in wake word detection, showcasing improved performance and efficiency, which discuss in various datasets and training sizes. These findings contribute to the development of more effective wake word detection and speech processing when using ResNet, Mi, and At in deep learning.**

I. Introduction

Speech interactions and digital assistants built into smartphones and voice command devices require a wake word detection system to anticipate the detection of predefined words [1]. For this, a lightweight model with small memory footprint, small computational cost, and low latency is needed [2] to quickly activate the device as soon as the wake word appears in streaming audio.

In recent work, a deeper model requires high computational resources [3]–[5] for training and inference based on a number of parameters and model complexity, such as Wav2KWS [6] and Keyword Transformer [7], which are not appropriate to deploy on mobile devices with limited processing unit and memory. For smaller model, the recurrent neural network (RNN), is sequential in nature and perform well with sequential frame information. However, it prevents the parallel chunk-streaming process on GPUs from being clogged by previous frames. Therefore, most current systems apply a convolutional neural network (CNN) for a frame-by-frame processing, which does not required previous frames. A CNN kernel is repeatedly applied by sliding through time or frequency and covers a small and fixed frame length. Each kernel can capture local patterns, which can expand the receptive field by stacking CNN layers. The expanded receptive field of the higher layers can "see" longer frame lengths compared to the lower layers, which capture more global patterns. These are why CNN is better utilized resource than RNN and deeper models on devices. However, when learning with highly concentrated deep details, the CNN model falls short. Highly CNN layers lose some information and may experience vanishing gradient problems [4], [8]. By adding function and skipping connections, ResNet [9] solves this problem. Res8 [8] model presents the dilated CNN pattern with ResNet to achieved high accuracy. Though, the Res8 performance depends on a sufficient amount of speech data, which may not be enough when the dataset size is small or complex data is present.

As previously mentioned, we proposed a method to improve the efficiency of Res8 [8] for wake word model. Our "three-way residual separable convolution network (3W-ResSC)" is proposed, inspired by the concept of human multi-perspective learning [10]; that is, "the human brain flexibly adapts to support the information-processing needs of different perspectives and can mix to extend performance," as the same way that Jääskeläinen [10] described. Responding to our inspired concept, we implemented a learning method for deep learning with three kinds of information like multi-perspective learning: The first information is the original input with residual learning (ResNet). For the second and third, point- and depth-wise patterns are mixed (Mi) based on 2D separable dilated CNN inspired by [11]. This process involves dividing a single convolution with dilation factor into two or more convolutions to produce the same output, enabling a more informative view for learning with a minimal computational requirements. Also, to conclude the human multi-perspective learning, our independent multi-view attention (iMVA) is proposed based on attention mechanism (At) that inspired by traditional MVA [12]. Our iMVA captures and learns three side-view components including channel, global, and local attention, specifically to emphasize and conclude the learning information. There-

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

fore, our 3W-ResSC have three-way combinations to adding information like a human multi-perspective learning such a ResNet+Mi, ResNet+At, and ResNet+Mi+At. Furthermore, our wake word model is proposed for streaming processing with our wake word detection framework, which scope information for learning in an independent speech window as a buffer-like streaming production process. Besides, to prove the overall performance of our wake word model, we experiment with four datasets: Gowajee [13] for wake word data with one sequence and a low training size, HeyFireFox [14] for data with three sequences and a medium training size, HeySnips [15] for data with two sequences with a large training size, and Google Speech Command V2 (GSCv2) [16] for data with many keywords and a large training size. Furthermore, to provide further performance on varying training sizes, we specifically sampled HeySnips into HeySnipsV.Small and HeySnipsV.Medium to represent a small and medium training sizes.

Our main contributions of this paper are as follows: (i) 3W-ResSC wake word model was proposed. 3W-ResSC block and 3W-ResSC learning block (3W-ResSC-LB) were redesigned its internal network from Res8 which were imitated from human multi-perspective learning. (ii) The evaluation of overall and various training size performance objectives was proposed. (iii) Streaming inference for wake word detection framework was proposed.

II. Our Wake Word Detection Framework Based on Streaming Inference Support

Our wake word detection framework, a frame-level based system with simulated streaming inference, is shown in Fig. 1. The framework consists of three parts: (i) speech alignment for training, (ii) feature extraction, and (iii) wake word model.

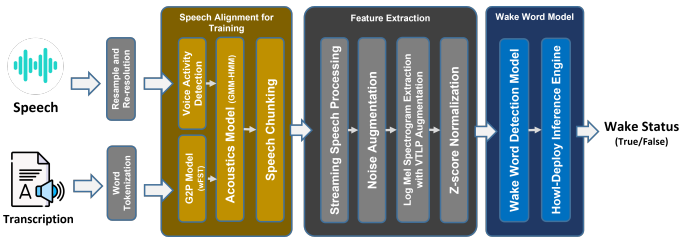

Fig. 1: A proposed wake word detection framework based on streaming inference support. Note that the transcription input is not required in the inference process.

A. Speech Alignment for Training

In general, wake word detection requires speech alignment for the training process to scope information before being chunked. This can provide word- or phoneme-based alignment. Phoneme-based alignment [17] involves intricate phonetic segmentation and matching, introducing computational complexity. In contrast, word-based alignment [17] offers computational efficiency by working with complete words. So, we focus on word-based alignment and aligned information is chunked to frame-based. Speech alignment requires two data inputs: speech and transcription. The speech data is resampled to 16 kHz for normal quality, and transcription is tokenized to word level for aligned speech preparation. We build our wake word detection framework on top of the speech alignment name's Montreal forced aligner (MFA)[1] [18]. The MFA, a traditional method that is processed in the same way as Kaldi frameworks, is chosen for its popularity with good performance and free license. It is used for tasks such as voice activity detection from energy-based to filter silence windows, grapheme-to-phoneme (G2P) model from weighted finite-state transducer (wFST) to extract phonetic of word, and acoustics model from Gaussian mixer model with hidden Markov model (GMM-HMM) to extract probability of sequential speech. The MFA version 2.0 is chosen for this experiment. Finally, the MFA is adapted to our framework, the speech is aligned and chunked for the feature extraction process.

B. Feature Extraction

As is commonly done in streaming speech processing, we chunked the speech before extracting features by frame-based length. The window size of 500 frames is set. The speech window uses noise augmentation by mixing the Microsoft scalable noisy speech dataset (MS-SNSD) [19] with original speech window. Then, the feature extraction from speech window is performed by using log Mel spectrogram (LMS), the parameters is 40 Mel filterbanks, 512 fast Fourier transform (FFT) size with 257 Fourier bins, and 200 hop length. All of these made the feature robust and streaming support. Besides, to learn more perspectives, the vocal tract length perturbation (VTLP) [20], [21] is applied to simulated new vocal track information in speech and increase the informative number of speakers. Finally, the feature is normalized by z-score to improved generalization, which is called Z-LMS. In summary, the previously mentioned feature dimension is define as "(batch, channel, time, number of Mel bin)".

C. Wake Word Model

Our 3W-ResSC, based on a non-sequential lightweight model, is performed by applying ResNet, mixer (Mi), and attention (At) to separable dilated CNN for learning. After that, our model is evaluated by the Howl-deploy inference engine[2] [14] to simulate streaming inference process use cases. This engine simulates the streaming inference process based on the PyAudio stream library. For the inference process, we use original speech data as input for PyAudio streaming pipeline, while the aligned speech data is not used, as if it were the actual streaming production process. The speech input is repeated play based on window length that is close to speech input from device. Then, the window is forwarded to feature extraction and wake word model process, respectively, to detect the wake word. In this paper, we set a 500 frames for window length and 16 window buffer size for the streaming process.

III. Our 3W-ResSC Model

We propose a model to improve Res8 performance by capturing more information based on human multi-perspective learning like three information. The first information captures overall information from original speech, like ResNet. Second and third information capture depth- and point- wise patterns to mix information using the CNN mixer concept (Mi). The original CNN mixer was initially proposed for image processing and harnesses the advantages of depth-wise features from the RGB channel, as well as point-wise features for each image layer. In our work, unlike the original CNN mixer, we do not utilized the RGB color channel. Instead, we extract the depth-wise features from the Mel bins [8], as explained in II-B subsection. Then, to conclude on a specific component from three information of ResNet and mixer, our independent multi-view attention (iMVA) is proposed based attention mechanism (At), that inspired by traditional MVA [12]. The traditional MVA is designed for the noise erasure task that is not for wake word detection, which is different from our task challenges. In our work, we adapt the concept of MVA to wake word detection task, specifically by scoping input into window levels that allow us to avoid the future context requirement. Thus, the attention mechanism of our iMVA is specifically focused on independent learning at the window level. Building upon these concepts, our 3W-ResSC is proposed with three combinations including ResNet+Mi, ResNet+At, ResNet+Mi+At.

First and foremost, we introduce the ResNet+Mi based 3W-ResSC block in Fig. 2 (purple rectangle). Dilated CNN [11], [22] with ResNet [9] is the main process in our model which use the convolution operation [22] to extract hidden feature and learning. Assume the input feature to a our model is $x_t = \{x_1, ..., x_T\} \in R^T$. The key operation of our model is the mapping feature of dilated convolution and is expressed as

$$F(x_{m,n}) = (x_{m,n} *_l k_{m,n}) = \sum_{j=-\inf}^{\inf} \sum_{i=-\inf}^{\inf} x_{i,j} \cdot k_{m-l_i,n-l_j} \tag{1}$$

where m, n indicates the 2D-position of $M \times N$ matrix, $x_{m,n}$ is the 2D Z-LMS feature input at m and n, $k_{m,n}$ is the kernel function at m and n, and $*_l$ is the dilated convolution [11] where l is a positive integer value called the dilation factor that apply the $k_{m,n}$ over the $x_{m,n}$ input. Further, to reduce loss of output information and overfitting problem, the ResNet concept is introduced to easier learn the residual by adding previous information to output information as $F(x^{in}_{m,n}) + x^{out}_{m,n}$, where $x^{in}_{m,n}$ denotes the feature input that refers to the $x_{m,n}$ above, $F(x^{in}_{m,n})$ is the feature output from convolution network, and $x^{out}_{m,n}$ is the input from ResNet's skip-connection (depicted by the green line), as refer to a sequence in Figure 2. This ResNet is the first information in our model.

To extend the mixed information (Mi) for the second and third information, in mathematically, commutative is fundamental property of convolution $(x_n * k_n = k_n * x_n)$, then

$$F(x^{in}_{m,n}) = (k_{m,n} *_l x^{in}_{m,n}) = \sum_{j=-\inf}^{\inf} \sum_{i=-\inf}^{\inf} k_{l_i,l_j} \cdot x^{in}_{m-i,n-j} \tag{2}$$

and, $k_{m,n}$ is separated to $M \times 1$ and $1 \times N$ as expressed in (3).

$$k_{m,n} = k^{depth}_m \cdot k^{point}_n \tag{3}$$

where k^{depth}_m indicates the kernel at m in a depth-wise pattern and k^{point}_n indicates the kernel at n in a point-wise pattern. Therefore, the 2D dilated convolution of (2) is modified to perform twice the dilated convolution by (3) in depth-wise and point-wise kernels same as separable convolution concept [23]:

$$(k_{m,n} *_l x^{in}_{m,n}) = \sum_{j=-\inf}^{\inf} k^{point}_{l_j} \sum_{i=-\inf}^{\inf} k^{depth}_{l_i} \cdot x^{in}_{m-i,n-j} \tag{4}$$

From (4), a convolution consists of two computed kernels. A depth-wise kernel (a spatial convolution performed independently over each channel of an input) is followed by a point-wise kernel (1x1 convolution), projecting the channel's output by the depth-wise convolution onto a new channel space.

Thus, to capture a point-wise pattern, a point-wise kernel is used instead of the normal kernel of (1) as expressed in (5).

$$f(x^{in}_{m,n}) = (x^{in}_{m,n} *_l k^{point}_{m,n}) = \sum_{j=-\inf}^{\inf} \sum_{i=-\inf}^{\inf} x^{in}_{i,j} \cdot k^{point}_{m-l_a,n-l_j} \tag{5}$$

In the same way, we used depth-wise kernel instead of the normal kernel of (1) as expressed in (6).

$$F(x^{in}_{m,n}) = (x^{in}_{m,n} *_l k^{depth}_{m,n}) = \sum_{j=-\inf}^{\inf} \sum_{i=-\inf}^{\inf} x^{in}_{i,j} \cdot k^{depth}_{m-l_a,n-l_j} \tag{6}$$

The output information is then embedded by adding functions with three information to improve Res8 performance, can be defined as

$$s_{m,n} = F(x^{in}_{m,n}) + f(x^{in}_{m,n}) + x^{out}_{m,n}. \tag{7}$$

$F(x^{in}_{m,n})$ is used to highlight the important prosody information of the Z-LMS feature (depth-wise CNN), then $x^{out}_{m,n}$ from ResNet skip-connection is used for reconstruction to reduce the lossy information, and $f(x^{in}_{m,n})$ deeply extracts the convolution output into point-wise information from the same $F(x^{in}_{m,n})$ input. All of which is a ResNet+Mi combination, as shown in the 3W-ResSC block (purple rectangle) of Fig. 2. In addition, we employ the Swish activation function [24] instead of ReLU to retain more informative negative values, coupled with the GELU activation function [25] for nonlinear transformations within the point-wise pattern. The depth-wise CNN involves significant computational complexity. Swish activation aids in the smoother flow of gradients during backpropagation, potentially resulting in faster convergence and enhanced training

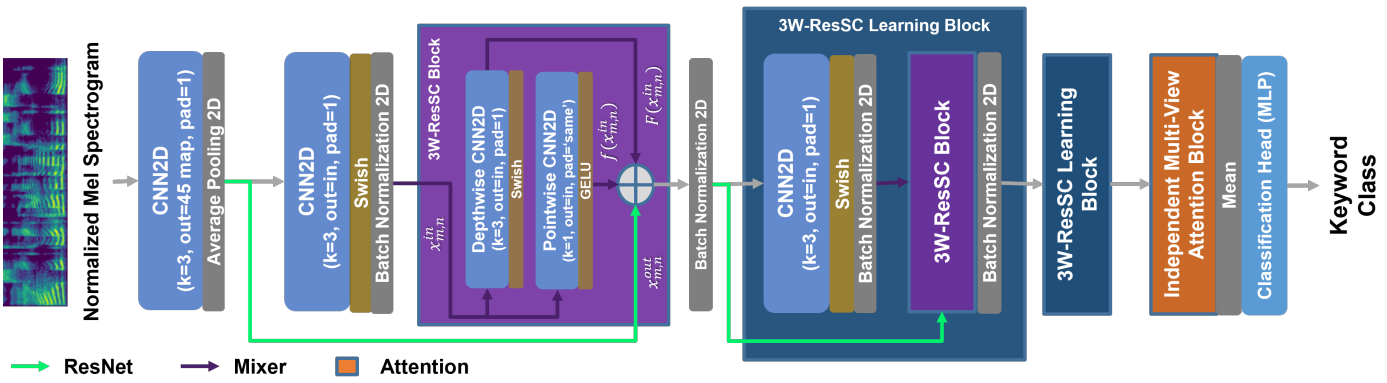

Fig. 2: Our proposed 3W-ResSC wake word model.

stability. Meanwhile, the use of GELU in the point-wise CNN has gained popularity due to its effectiveness in handling a broad range of activation values.

In addition, to emphasize and summarize the three information, attention (At) is applied in the final layer before the classification head to increase capturing and concluding capabilities. MVA based on attention mechanism is used to specifically capture the three side-view components [12] such as channel, global, and local attentions. Channel attention emphasizes representations from compressed time with channels. Global and local attention implemented through dual paths, efficiently reflect the long sequential features. However, in our work, we utilize iMVA instead of MVA due to the limitation of wake word detection in terms of streaming window forwarding, which is a crucial for proper real-world application in wake word detection area. In the real-world application, the speech window consistently forwarded to the wake word model at all times, leading to uncertainty about when the speech will end. As a result, long sequential features cannot be effectively utilized in this task. Therefore, our iMVA is proposed specifically for wake word detection tasks ensuring proper functionality, our iMVA employ the feature input in terms of window level instead of a long sequential feature. It supports streaming by learning the independent speech windows. Regardless, for efficient global and local attentions, overlapped chunking is adopted at the window level. Overlapped chunking involves chunking the window to a sequential sub-window, that can provide information relate to the long sequential feature of the original MVA, but in our iMVA is the sequential sub-window feature instead. The details of iMVA implementation setting refer to the original MVA [12]. As a result, our iMVA does not require future context for learning and prediction, as shown in Figure 3.

In our work, our 3W-ResSC has three-way combinations including ResNet+Mi, ResNet+At, and ResNet+Mi+At. ResNet+Mi incorperates three kinds of information like a human multi-perspective learning. Also, the added At is used for the informative conclusion and emphasis. ResNet+At and ResNet+Mi+At are proposed to investigate the impact of informative conclusion and emphasis effects on the perfor-

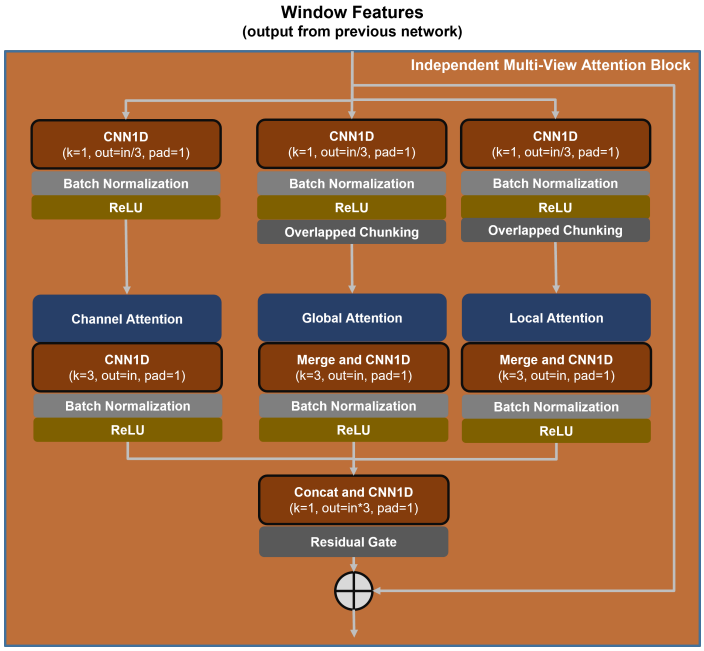

Fig. 3: A proposed independent multi-view attention (iMVA) block. Note that the input is window features from the previous output 3W-ResSC learning block.

mance of our model. Above mentioned are three combinations of "3W-ResSC" wake word model, the full combination (ResNet+Mi+At) as shown in Fig. 2. Besides, for the model parameter and computation (multiply-accumulate operations: MAC), Table I is reported. ResNet+Mi is the best with 56K parameters and 8M MACs. ResNet+At has 161K parameters and 20M MACs. ResNet+Mi+At has 161K parameters and 20M MACs. Although the addition of At in combination necessitates a larger model size and increase computation, which can be a double-edged sword. We refer the definition provided in [26] to establish the criteria for a streaming and effective wake word detection task. According to the baseline for streaming wake word detection of [26], the model should have fewer than 250K parameters and less than 101M MACs. Therefore, all of our 3W-ResSC meets the streaming wake

word detection task requirement, especially in ResNet+Mi. Our model is configured with the following hyper-parameters: 300 max epochs with saving, 0.001 learning rate, 0.98 learning rate decay, and Adam optimizer.

TABLE I: A number of parameters and model complexity of our wake word detection framework and baselines.

Model	Parameters	MACs
Res8 (ResNet) [8], [14]	109.84K	14.91M
MobileNetV2 [14], [27]	2,226.47K	9.21M
ConvMixer [28], [29]	119.20K	22.73M
Streaming Transformer [2]	58.59K	37.17M
3W-ResSC (ResNet+Mi)	56.43K	8.02M
3W-ResSC (ResNet+At)	161.80K	20.96M
3W-ResSC (ResNet+Mi+At)	161.84K	20.97M

IV. Experiments

The experiments were conducted on a desktop computer running Windows 10 OS, equipped with an Intel Core i7-11370H processor, 32 GB of RAM, and an NVIDIA GeForce RTX 3070 GPU with 8 GB of memory. Inference was simulated using our streaming framework, limited to multi-thread CPU without GPU utilization. For dataset experiments, we have the overall performance and training size performance objectives. The overall performance objective is used for our model and all baselines while the training size performance objective is used to investigate our combination model. In evaluation metrics, we use the EER and MCC for balanced performance evaluation. Also, FRR is used for multi-class classification. For model compression, all models in our study are dynamic quantized with Pytorch precision 16-bit.

A. Datasets

Four datasets were experimented to prove the model's performance for the waked keyword and dataset size challenges [30]. HeyFireFox and HeySnips were used to prove the more than one sequence wake keyword challenge, the prediction result will be true if all the sequential prediction result is an exact pattern. GSCv2 was used to prove the multiple wake keyword challenge similar to a multi-class classification. Additionally, Gowajee, a Thai language dataset, focuses on the one wake keyword with performance when using a small data size with a new accent, due to the limited resources on speech processing tasks.

HeyFireFox contains three sub-wake keywords: "Hey", "Fire", and "Fox". The dataset is split into two sets; the positive set contains only the denoted sequence in one file, and the negative sets are the rest. HeySnips and Gowajee are split like HeyFirefox, with the sequences "Hey Snips" and "Gowajee", respectively. For GSCv2, each file contains only one keyword. We select positive set as ten classes like a multi-classification including "yes", "no", "up", "down", "left", "right", "on", "off", "stop", and "go". The other classes are changed to "unknown", like a negative set. Besides, for the dataset size challenges, we set 3 criteria to define the training dataset size including small, medium, and large. In the positive set, the small size is less than 350 train utterances, the medium is between 350 to 3000, and the large is more than 3000. For the negative set, the small size is less than 10000, medium is between 10000 to 20000, and large is more than 20000. However, for the training process, the MFA is used for speech alignment. HeyFireFox, HeySnips, and GSCv2 datasets are in English. The nature of English transcription contains white space for word boundaries which easier to tokenize. In contrast, Thai transcription does not have. Therefore, in this experiment, the Attacut model [31] is used for tokenized Thai transcription, a state-of-the-art in Thai tokenization model that performs well with high speed. Furthermore, four datasets were resampled to a 16 kHz sampling rate and 16-bit PCM resolution. Subsequently, they were partitioned into train, dev, and test sets, following the methodology outlined in the original dataset paper [13]–[16].

In addition, each dataset contains varying uncontrolled factors such as recording system, speaker culture, and wake keyword challenge, that may not directly compare performance with each other datasets. Based on this issue, our models are experimented with two objectives. First is the overall performance based on various datasets which shows the model is robust in any dataset environment. Second is the training size performance based on different training sizes on the same dataset which shows each of our combination models is proper in differ model training limitation. For the second objective, we create HeySnipsV.Small and HeySnipsV.Medium from HeySnips dataset to experiment on this objective. HeySnipsV.Small experiments for small training size limitation that refers the sampling training size to match that of the Gowajee dataset in train and dev sets. HeySnipsV.Medium experiments for medium training size limitation that refers the sampling training size to match that of the HeyFireFox in train and dev sets. Also, the original HeySnips experiments for non training size limitation which has large training size. We conclude the statistical report based on positive and negative sets as shown in Table II.

TABLE II: Statistical dataset based on positive and negative sets.

Dataset	Positive set				Negative set			
	Train	Dev	Test	Size	Train	Dev	Test	Size
Gowajee [13]	336	104	17	small	14,518	1,640	979	medium
HeyFireFox [14]	502	76	54	medium	26,132	2,531	2,504	large
HeySnipsV.Small	336	104	1,121	small	14,518	1,640	6,730	medium
HeySnipsV.Medium	502	76	1,121	medium	26,132	2,531	6,730	large
HeySnips [15]	7,636	1,180	1,121	large	45,474	6,854	6,730	large
GSCv2 [16]	30,769	3,703	4,074	large	54,074	6,278	6,931	large

B. Evaluation Metrics

For evaluation performance of the overall performance and training size performance objectives, the experiments aim to evaluate two metric types; balanced and multi-class metric types. To measure balanced performances, the Matthews correlation coefficient (MCC) and equal error rate (EER) are used.

MCC is a reliable statistical rate that produces a high when the prediction obtains good results in all four categories of confusion matrix [32], as described in (8).

$$MCC = \frac{(TP \times TN) - (FP \times FN)}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TN + FN)}} \quad (8)$$

where TP represents the true positive value, FP represents the false positive value, TN represents the true negative value, and FN represents the false negative value.

For false errors, the EER reports the same rate as false rejection (FRR) and false acceptance (FAR), well-known in bio-matrices verification tasks. EER uses the inference threshold between 0.00 and 1.00 with a step of 0.05 to fine-tune the best threshold. However, for multi-class performances, the challenge is to avoid many rejection cases [33] in wake word detection. Therefore, only FRR is focused on to report the performance.

C. Results and Discussions

First, we evaluate the model's performance for the overall performance objective (see section IV-A). Table III shows the performance based on various datasets. Our 3W-ResSC (ResNet+Mi) shows the best performance of 0.72% EER and 73.52% MCC based on Gowajee. For HeyFireFox, the best EER of 4.60% on our 3W-ResSC (ResNet+Mi+At) and MCC of 73.67% on our 3W-ResSC (ResNet+At). For HeySnips, our 3W-ResSC (ResNet+At) achieves the best performance at 2.98% EER and 95.62% MCC. In addition, for multi-class classification based on GSCv2 in Table IV, ResNet+Mi achieved the best dev FNR of 1.99% and test FNR of 1.71%, demonstrating its suitability for multi-class classification.

However, in each combination, our 3W-ResSC results still differ, that is proper in different cases. Referring to Table II with previously mentioned results, ResNet+Mi is proper when the positive training size is small and the negative training size is medium, while ResNet+At performs better when the training size is large. ResNet+Mi+At is suitable for medium to large training sizes. Yet, each dataset contains the uncontrolled environment such as recording system, speaker culture, and wake keyword challenge. Based on this, HeySnipsV.Small and HeySnipsV.Medium are experimented for the same dataset in different training sizes, to address the second objective. Table V shows the training size performance based on HeySnips dataset. ResNet+Mi achieved the best performance of 5.04% EER and 91.65% MCC in small training sizes (HeySnipsV.Small). ResNet+Mi+At achieved the best performance of 4.21% EER and 93.72% MCC in medium training sizes (HeySnipsV.Medium). ResNet+At acheived the best performance of 2.98% EER and 95.62% MCC in large training sizes (HeySnips). As these training size result patterns illustrated in Figure 4 for EER and Figure 5 for MCC, ResNet+Mi is suitable for small, ResNet+Mi+At is suitable for medium, and ResNet+At is suitable for large training size. Besides, if the training size is increased, the combination of our 3W-ResSC can extend performance. ResNet+At is the best for extend performance when using large training sizes. Additionally, for multi-class classification based on GSCv2 in Table IV, ResNet+Mi achieved the best dev FNR of 1.99% and test FNR of 1.71%, demonstrating its suitability for multi-class classification.

In summary, our study involved experiments with three combinations of human multi-perspective learning concepts, namely ResNet+Mi, ResNet+At, and ResNet+Mi+At, where Mi stands for Mixer and At stands for attention. The results of our study showed that each combination performed best under different circumstances: (1) ResNet+Mi performed best with small training data and showed better performance in terms of multi-class classification on the GSCv2 dataset. (2) ResNet+At performed best with large training data and words with higher wake sequences. (3) ResNet+Mi+At performed best with medium training data and words with higher wake sequences. Furthermore, our study found that adding the At combination to each ResNet combination resulted in a noise-robust model, which is a evident when comparing the results of Res8, ResNet+Mi (without At), ResNet+At, and ResNet+Mi+At (with At).

V. Conclusions

In this paper, our 3W-ResSC wake word model is proposed to improve the Res8 model, which is imitated from the human multi-perspective learning concept like a three information. First information is ResNet. Second and third information are depth- and point- wise from CNN mixer (Mi) concept. In addition, for informative conclusion and emphasis, our iMVA based on attention mechanism (At) is proposed. Thus, from previously mentioned ResNet, Mi, and At, our 3W-ResSC has three-way combinations including ResNet+Mi, ResNet+At, ResNet+Mi+At. Our experiments on Gowajee, HeyFireFox, HeySnips, and GSCv2 showed that our 3W-ResSC significantly outperforms the baselines, which is related to our combinations. ResNet+Mi performs best with small training size and show better performance in multi-class classification task. ResNet+At perform best with large training sizes and ResNet+Mi+At perform best with medium training sizes. All of these make our proposed combination useful for training with limitations. Additionally, to support inference real-world application, our wake word detection framework is proposed to guide the training and inferencing in our model. We believe that this study of our 3W-ResSC with combinations is an effective tool for wake word detection, and may perhaps be used in future audio-focused machine learning work.

***Abstract*—This paper describes an end-to-end singing transcription method that directly estimates a musical score (a sequence of sung notes with metrical positions) from a music audio signal. The monotonicity of audio-to-score mapping naturally calls for the use of connectionist temporal classification (CTC). Inspired by the success of character-level automatic speech recognition, previous studies on CTC-based music transcription represent a musical score as a sequence of various kinds of symbols (*e.g.*, note pitches and values and barlines) defined in some music notation. Such a naive notation-respecting representation, however, does not fit the non-overlapping monotonic audio-to-symbol alignment and the positions of barlines and the durations of beats tend to be incoherent in the estimated score. To solve this problem, we propose a tatum-level singing transcription method that jointly estimates the pitch (including rest), onset flag, and metrical position at each tatum. Our approach enables the tatums to be monotonically aligned with regularly-spanned intervals of the music signal and the estimated notes are located on the estimated metrical positions that are encouraged to be periodic. Experimental results clearly showed that our proposed model reached comparable accuracy on score-level singing transcription with only unaligned training data, and the proposed tatum-level representation significantly improved the stability of the metrical structures in the estimated scores.**

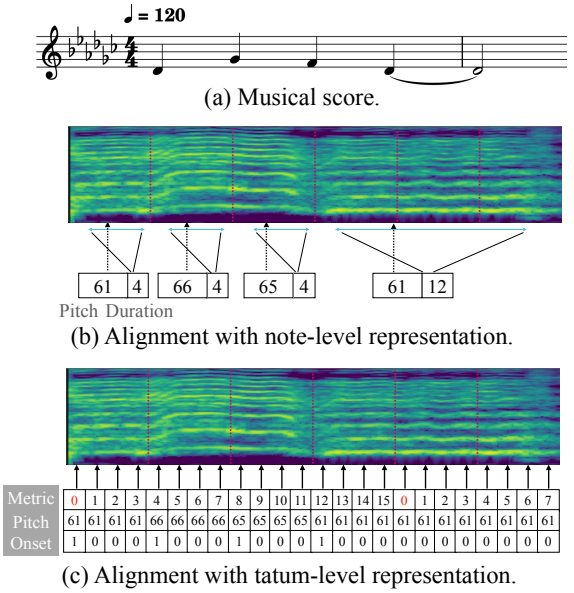

Fig. 1. Comparison of (b) conventional and (c) proposed methods of CTC-based audio-to-score transcription.

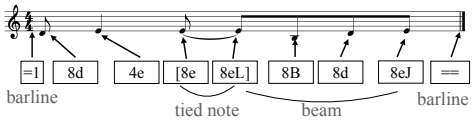
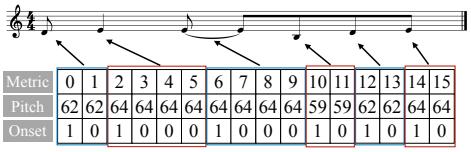
I. Introduction



Automatic singing transcription (AST) is one of the most fundamental music analysis tasks in the field of music information retrieval (MIR). Its ultimate goal is to estimate a *musical score* of the vocal part (described in the MusicXML format) from a music audio signal. The estimated scores can be used for melody-based music search (*e.g.*, query-by-humming [1], [2]), score-guided singing voice separation [3], [4], and interpretable emotion recognition [5].

Most studies on AST have attempted to estimate a *piano roll* of the vocal part (described in the MIDI format) [6]–[10], where each sung note is represented by a semitone-level pitch and onset and offset times in seconds. The basic strategy is to estimate a continuous contour of fundamental frequencies (F0s) in Hz (*a.k.a.*, melody extraction) with a deep neural network (DNN) and then segment it to a series of sung and rest notes (discontinuous step function) with a note tracking method [7], [8]. Note that the piano roll differs from the musical score in the time units of the note onsets and offsets. The onsets and offsets are represented in frames or seconds in the piano roll representation, whereas they are represented in quantized units such as beats or fractions of beats in the score representation. To obtain a musical score from a piano roll, rhythm transcription methods [11] are required for quantizing the onset and offset times of notes onto a grid represented in musical metrics such as beats or tatums.



Only a few studies have tackled audio-to-score transcription [12], [13], which typically involve audio-to-MIDI transcription and MIDI-to-audio transcription. Such a cascading approach, however, suffers from several problems. Since F0 annotations aligned with music audio signals are limited both in size and variation, the accuracy of supervised F0 estimation is hard to improve. The complicated dynamics of the F0 contour (*e.g.*, vibrato and glissando) make it hard to perform frequency and temporal quantization without referring to the audio data [12]. This calls for the end-to-end (*i.e.*, audio-to-score) approach to AST that can make effective use of non-aligned pairs of musical scores and audio signals.

Considering the monotonicity of audio-to-score alignment, connectionist temporal classification (CTC) [14] has been used for audio-to-score automatic music transcription (AMT) [15],

(b) The proposed tatum-level representation.

Fig. 2. Comparison of score representations.

[16] (Fig. 1). In the analogy with CTC-based automatic speech recognition (ASR) that converts a speech signal to a sequence of characters [17], one may try to convert a music signal to a sequence of various kinds of symbols (*e.g.*, note pitches, note values, and barlines) defined in some music notation (*e.g.*, Lilypond [18] and Kern [19], Fig. 2 (a)). It is, however, unclear how such instantaneous and temporal symbols are monotonically aligned with the audio signal in a non-overlapping manner (Fig. 1 (b)). Note that the basic CTC is intended for instantaneous symbols (*e.g.*, phonemes and note pitches) that can be estimated in local regions. To estimate temporal symbols (*e.g.*, note values and barlines), acoustic features should be aggregated from a nonlocal region. The mixture of these modes harms the stability of CTC-based training, leading to incoherent metrical structure in the estimated score. Indeed, previous CTC-based methods were tested only on synthetic data and evaluations on real audio data have not been reported in the literature.

To solve this problem, we propose a CTC-based AST method that converts a music audio signal to a tatum-level score representation with a metrical structure. The tatum is a minimum time unit on a score, which is assumed to be the sixteenth note length in this study. Representing a musical score as a sequence of tatums, each having a pitch (MIDI note number or 128 (rest)), an onset flag ($\in [0, 1]$), and a metrical position ($\in [0, 15]$) (Fig. 2 (b)), we can achieve stable monotonic audio-to-tatum alignment (Fig. 1 (c)). Specifically, a convolutional recurrent neural network (CRNN) that predicts the probabilities of pitches, onset flag, and metrical positions from a music signal at the frame level is trained such that the CTC loss is minimized. At run-time, the most likely tatum-level sequence is estimated with a Viterbi algorithm that explicitly considers the durations of sung notes and the metrical structure.

II. Related Work

Conventional AST approaches combine frame-level F0 estimation and note tracking, where the piano-roll representation is a transcription target [20], [21]. Recently, deep learning techniques have been used for F0 extraction tasks, remarkably improving the estimation accuracy [6]–[8]. A hidden semi-Markov model (HSMM) [12] was employed to quantize F0 contours into sequences of musical notes. Attempts to directly transcribe the musical signals into note events have also be made [9], using deep neural networks to overcome the error accumulation problem in cascading methods. To improve the accuracy of piano-roll transcription, the CTC loss was used as an auxiliary loss function in addition to the standard frame-wise cross-entropy loss [10].

In the context of AST that aims to estimate musical scores, rhythm transcription methods have been explored to quantize piano-roll representations into musical scores [11], [22], [23]. A hybrid DNN-HSMM model [13], for example, was proposed to avoid depending on the preprocessing step of F0 estimation, in the same way as the DNN-HMM approach to ASR. In these studies, representations of rhythmic information for music transcription have been studied. In general, it is possible to represent rhythmic information either at the tatum level using metrical positions or at the note level using note values. Studies using HMMs have shown that the tatum-level representation generally performs better than the note-level representation because certain logical structures of musical rhythms cannot be represented in the latter [23].

Several recent studies have attempted end-to-end AMT to address the error accumulation issue in cascading methods. Inspired by the success of end-to-end ASR with either the attention mechanisms or CTC, studies on end-to-end AMT have employed both attention mechanism [24] and CTC [15], [16] to directly transcribe audio signals into musical scores. To facilitate sequence-to-sequence learning in these methods, it is necessary to represent a musical score as a sequence of symbols. Previous CTC-based end-to-end AMT methods [15], [16] used a *note-level* score representation, where quantized durations of notes were directly estimated as output symbols. However, these methods have been shown to work only on synthetic audio signals made from MIDI-like data. Besides, an encoder-decoder model with an attention mechanism and a *tatum-level* score representation was also employed [24]. This study proposed a regularized training method that encourages the attention matrix to have monotonic and regular structures, aligning the tatums with the frames in a beat-synchronous manner. However, this approach often failed to find correct alignments because the attention matrix does not necessarily be monotonic in early epochs of non-regularized training.

III. Proposed Method

This section describes the proposed CTC-based end-to-end AST method that considers metrical structure.

A. Problem Specification

Given a music audio signal as input, the goal is to estimate a musical score of sung notes. Let $\mathbf{X} \triangleq \{\mathbf{x}_t\}_{t=1}^{T}$ be a frame-level sequence of acoustic features obtained by stacking the mel-spectrogram of the music signal and that of the singing voice separated with a source separation method called Open-Unmix [25], where T is the number of frames. The input to our system is $\mathbf{X}$.

In this paper, the music signal is assumed to have a time signature of 4/4, and the duration of the sixteenth note is regarded

as the minimum time unit called a tatum, *i.e.*, each measure includes 16 metrical positions (tatums). Let $\mathbf{Y} \triangleq \{y_n\}_{n=1}^N$ be a tatum-level score representation, where N is the number of tatums and $y_n \triangleq (b_n, p_n, o_n)$ is a triplet of a metrical position $b_n \in [0, 15]$ (relative position in the measure), a semitone-level pitch $p_n \in [0, 128]$ represented by a MIDI note number ($p_n = 128$ indicates the rest), and an onset flag $o_n \in \{0, 1\}$. To reconstruct a musical score from $\mathbf{Y}$, we first determine the positions of barlines from $\mathbf{B} \triangleq \{b_n\}_{n=1}^N$ under the assumption of the time signature and then the note pitches and values are determined from $\mathbf{P} \triangleq \{p_n\}_{n=1}^N$ and $\mathbf{O} \triangleq \{o_n\}_{n=1}^N$.

B. End-to-End Training

In the training phase, given paired data of the input $\mathbf{X}$ and the ground-truth output $\mathbf{Y} \triangleq (\mathbf{B}, \mathbf{P}, \mathbf{O})$, we train a DNN with the CTC loss in a supervised manner. The input length is assumed to be longer than the output length ($T > N$), which always holds in AST.

1) Single-Label CTC: We first explain the standard CTC. Suppose we aim to estimate only $\mathbf{B}$ from $\mathbf{X}$ ($\mathbf{P}$ and $\mathbf{O}$ are not considered here). Let K be the number of kinds of original output symbols (metrical positions) (*i.e.*, $K = 16$). The special blank symbol "*" working as a wild card is introduced.

A DNN is trained such that the posterior probability of the *tatum-level* sequence $\mathbf{B}$ given as the ground-truth data, denoted by $p(\mathbf{B}|\mathbf{X})$, is maximized. Let $\boldsymbol{\pi} \triangleq \{\pi_t\}_{t=1}^T$ be a *frame-level* sequence such that $\mathbf{B} = \mathcal{M}(\boldsymbol{\pi})$, where $\pi_t \in [0, K-1] \cup \{*\}$ represents the output symbol at frame t, and $\mathcal{M}(\boldsymbol{\pi})$ is a reduction operator that annexes repeated symbols and removes all blank symbols from $\boldsymbol{\pi}$. If $\mathbf{B} = \{1, 2, 3\}$, for example, $\{1, 1, 1, *, *, 2, *, *, 3, *\}$ is a possible example of $\boldsymbol{\pi}$. The DNN is used for inferring metrical positions in frames as follows:

$$(\boldsymbol{\phi}^{\mathrm{B}}, \boldsymbol{\phi}^{*}) = \mathrm{DNN}(\mathbf{X}), \tag{1}$$

where $\boldsymbol{\phi}^{\mathrm{B}} \triangleq \{\phi_{tk}^{\mathrm{B}}\}_{t=1,k=1}^{T,K-1}$, $\boldsymbol{\phi}^{*} \triangleq \{\phi_t^{*}\}_{t=1}^{T}$, ϕ_{tk}^{B} is the posterior probability of metrical position k when $\pi_t \neq *$, and ϕ_t^{*} is that of $\pi_t = *$ at frame t.

$p(\mathbf{B}|\mathbf{X})$ is obtained by accumulating the posterior probabilities over all possible $\boldsymbol{\pi}$'s (frame-to-tatum alignments) that can be reduced to $\mathbf{B}$ as follows (Fig. 3 (a)):

$$p(\mathbf{B}|\mathbf{X}) = \sum_{\boldsymbol{\pi} \in \mathcal{M}^{-1}(\mathbf{B})} p(\boldsymbol{\pi}|\mathbf{X}), \tag{2}$$

where $\mathcal{M}^{-1}(\mathbf{B})$ is an expansion operator that maps $\mathbf{B}$ to a frame-level sequence and $p(\boldsymbol{\pi}|\mathbf{X})$ is the posterior probability of a sequence $\boldsymbol{\pi}$. Assuming the conditional independence over frames, $p(\boldsymbol{\pi}|\mathbf{X})$ is given by

$$p(\boldsymbol{\pi}|\mathbf{X}) = \prod_{t=1}^{T} p(\pi_t|\mathbf{X}), \tag{3}$$

where $p(\pi_t|\mathbf{X})$ is the local posterior probability given by

$$p(\pi_t|\mathbf{X}) = \begin{cases} (1 - \phi_t^{*})\phi_{t\pi_t}^{\mathrm{B}} & \text{if} \quad \pi_t \neq *, \\ \phi_t^{*} & \text{otherwise.} \end{cases} \tag{4}$$

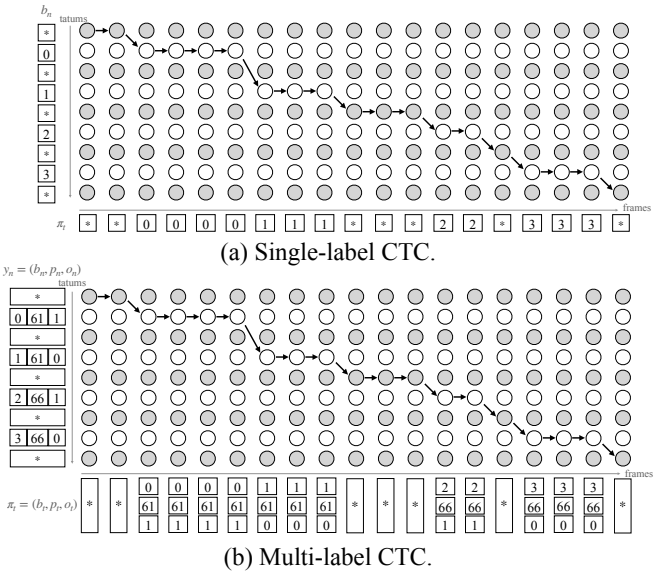

Fig. 3. Possible alignment paths in CTC.

2) Multi-Label CTC: In our study on joint pitch, onset, and metrical estimation, we use the multi-label CTC (MCTC) loss [26]. Let I be the size of the pitch vocabulary ($I = 129$).

A DNN is trained such that the posterior probability $p(\mathbf{Y}|\mathbf{X})$ of the *tatum-level* sequence $\mathbf{Y}$ given as the ground-truth data is maximized. Let $\boldsymbol{\pi} \triangleq \{\pi_t\}_{t=1}^T$ be a *frame-level* sequence (alignment path) such that $\mathbf{Y} = \mathcal{M}(\boldsymbol{\pi})$, where $\pi_t \triangleq (b_t, p_t, o_t) \in \{(k, i, \{0, 1\})\}_{k=1,i=1}^{K-1,I-1} \cup \{*\}$ denotes the output symbol (triplet or $*$) at frame t, and $\mathcal{M}(\boldsymbol{\pi})$ is a reduction operator. The DNN is used for jointly inferring metrical positions, note pitches, and onset flags at the frame level as follows:

$$(\boldsymbol{\phi}^{\mathrm{B}}, \boldsymbol{\phi}^{\mathrm{P}}, \boldsymbol{\phi}^{\mathrm{O}}, \boldsymbol{\phi}^{*}) = \mathrm{DNN}(\mathbf{X}), \tag{5}$$

where $\boldsymbol{\phi}^{\mathrm{P}} \triangleq \{\phi_{ti}^{\mathrm{P}}\}_{t=1,i=1}^{T,I-1}$, $\boldsymbol{\phi}^{\mathrm{O}} \triangleq \{\phi_t^{\mathrm{O}}\}_{t=1}^{T}$, ϕ_{ti}^{P} is the posterior probability of pitch i when $\pi_t \neq *$, and ϕ_t^{O} is that of the onset presence at frame t.

In the same ways as Eq. (2), $p(\mathbf{Y}|\mathbf{X})$ can be computed with dynamic programming (DP) as follows:

$$p(\mathbf{Y}|\mathbf{X}) = \sum_{\boldsymbol{\pi} \in \mathcal{M}^{-1}(\mathbf{Y})} p(\boldsymbol{\pi}|\mathbf{X}), \tag{6}$$

where $\mathcal{M}^{-1}(\mathbf{Y})$ is an expansion operator. Assuming the conditional independence over frames and labels, the posterior probability $p(\boldsymbol{\pi}|\mathbf{X})$ can be computed in the same ways as Eq. (3), where $p(\pi_t|\mathbf{X})$ is given by

$$p(\pi_t|\mathbf{X}) = \begin{cases} (1 - \phi_t^{*})\phi_{tb_t}^{\mathrm{B}}\phi_{tp_t}^{\mathrm{P}}(\phi_t^{\mathrm{O}})^{o_t}(1 - \phi_t^{\mathrm{O}})^{1-o_t} & \text{if} \quad \pi_t \neq *, \\ \phi_t^{*} & \text{otherwise.} \end{cases} \tag{7}$$

C. Network Architecture

The DNN used in this study is based on an encoder-decoder architecture (Fig. 4). Since wide-band harmonic structures and long-term temporal structures are considered to be useful clues for pitch estimation and metrical analysis, respectively, two

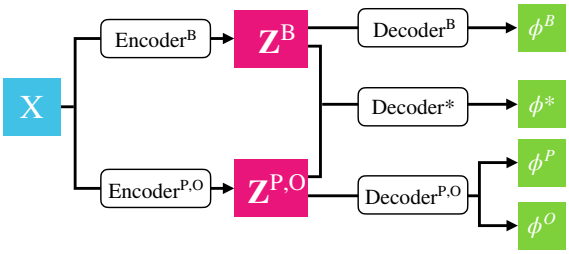

Fig. 4. Network architecture.

separate encoders are used to extract latent metrical features $\mathbf{Z}^{\mathrm{B}}$ and latent pitch features $\mathbf{Z}^{\mathrm{P,O}}$ as follows:

$$\mathbf{Z}^{\mathrm{B}} = \mathrm{Encoder}^{\mathrm{B}}(\mathbf{X}), \tag{8}$$

$$\mathbf{Z}^{\mathrm{P,O}} = \mathrm{Encoder}^{\mathrm{P,O}}(\mathbf{X}). \tag{9}$$

To estimate the pitch and onset presence at each frame, it is sufficient to focus on the local region of the singing voice around the frame. To estimate the metrical position, in contrast, it is necessary to collect long-term periodic information over multiple measures from the background music.

We then compute the posterior probabilities of the metrical positions, pitches, onset presence, and blank symbol, denoted by $\boldsymbol{\phi}^{\mathrm{B}}$, $\boldsymbol{\phi}^{\mathrm{P}}$, $\boldsymbol{\phi}^{\mathrm{O}}$, and $\boldsymbol{\phi}^{*}$, as follows:

$$\boldsymbol{\phi}^{\mathrm{B}} = \mathrm{Decoder}^{\mathrm{B}}(\mathbf{Z}^{\mathrm{B}}), \tag{10}$$

$$(\boldsymbol{\phi}^{\mathrm{P}}, \boldsymbol{\phi}^{\mathrm{O}}) = \mathrm{Decoder}^{\mathrm{P,O}}(\mathbf{Z}^{\mathrm{P,O}}), \tag{11}$$

$$\boldsymbol{\phi}^{*} = \mathrm{Decoder}^{*}(\mathbf{Z}^{\mathrm{B}}, \mathbf{Z}^{\mathrm{P,O}}). \tag{12}$$

Since the blank symbol tends to be selected at frames with small confidence about the pitch, onset, or metrical estimation, all the latent features are considered.

D. Decoding

After the CTC-based training, one can estimate the frame- and tatum-level sequences $\hat{\boldsymbol{\pi}}$ and $\hat{\mathbf{Y}}$ as follows:

$$\hat{\boldsymbol{\pi}} = \arg\max_{\boldsymbol{\pi}} p(\boldsymbol{\pi}|\mathbf{X}), \tag{13}$$

$$\hat{\mathbf{Y}} = \mathcal{M}(\hat{\boldsymbol{\pi}}). \tag{14}$$

According to this method, however, the estimated metrical positions may not have a monotonically increasing order.

To impose the constraint of monotonically increasing metrical positions, we propose a refined decoding method based on an HSMM. Generally in music performances including singing, the durations of beats or tatums keep stable because of the regularity of metrical structure in music. To utilize this temporal stability, we introduce the durations of tatums $\mathbf{D} \triangleq \{\mathbf{d}_n\}_{n=1}^{N}$ measured in frames. Consider the frame-level input features and tatum-level output features described in Section. III-A, namely, input spectrograms $\mathbf{X} \triangleq \{\mathbf{x}_t\}_{t=1}^{T}$, and output metrical positions $\mathbf{B} \triangleq \{b_n\}_{n=1}^{N}$, pitches $\mathbf{P} \triangleq \{p_n\}_{n=1}^{N}$ and onset flags $\mathbf{O} \triangleq \{o_n\}_{n=1}^{N}$. We formulate the generative process of $\mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D}$ and $\mathbf{X}$ as an HSMM, which only allows the metrical positions to make periodic progress, that is,

$$b_n = \begin{cases} b_{n-1} + 1 & b_{n-1} < 15, \\ 0 & b_{n-1} = 15, \end{cases} \tag{15}$$

and encourages the durations of metrical positions to be stable by assuming

$$p(d_n|d_{n-1}) \propto \exp\left(-\lambda \left| \frac{d_n}{d_{n-1}} - 1 \right| \right). \tag{16}$$

With the HSMM, one can efficiently decode the sequence of metrical positions, pitch values and onset flags with the Viterbi algorithm (see details in Appendix A).

IV. Evaluation

This section reports experiments conducted for evaluating the effectiveness of the proposed method.

A. Experimental Conditions

1) Dataset: We made a dataset consisting of 343 Japanese popular (JPOP) songs with the corresponding musical scores in the MusicXML format transcribed by experts and real audio recordings extracted from the original CDs. It was randomly split into a training set of 308 songs and a test set of 35 songs. Although this JPOP dataset is useful for evaluating the practical performance, it cannot be released due to copyright issues. We thus also used the publicly available RWC Popular Music dataset [27] for evaluation. In detail, we randomly selected 12 songs with the signature of 4/4 to form a test dataset (Nos. 7, 8, 13, 18, 20, 47, 63, 79, 80, 84, 90, and 100). The vocal scores of these songs were transcribed by experts in the MusicXML format as well.

Note that most common datasets (*e.g.*, MIR-ST500 [28]) consist of singing voices with annotations in the MIDI format, where the onset and offset times of each note are given in seconds. These datasets have thus been used for audio-to-MIDI AST, but are hard-to-use for audio-to-score AST (ours) due to the lack of ground-truth musical scores.

To reduce the computational cost, all the audio recordings were resampled at 22050 Hz and cut into segments of 8 seconds. To find the corresponding segments of scores, we synthesized waveforms from the scores and aligned them with the original signals with dynamic time warping (DTW). These alignment results were then used to segment the ground truth scores. The spectrogram of a music signal was obtained with short-time Fourier transform (STFT) with a window of 2048 samples and a hop length of 256 samples (11.61 ms). The mel spectrogram was then obtained with 128 mel filter banks.

2) Network Configuration: The CRNN used for evaluation was configured as follows. $\mathrm{Encoder}^{\mathrm{B}}$ and $\mathrm{Encoder}^{\mathrm{P,O}}$ were implemented with CNNs of the same structure. Each CNN had five layers and the numbers of channels for these layers were 64, 32, 32, 32, and 32, respectively. The kernel sizes for the hidden layers were 5, 5, 3, 3, and 3, respectively. Following the CNN, a fully-connected layer was used for reducing the hidden dimension to 256 at each frame. $\mathrm{Decoder}^{\mathrm{B}}$, $\mathrm{Decoder}^{\mathrm{P,O}}$ and $\mathrm{Decoder}^{*}$ were implemented with RNNs. Each RNN had two layers of BLSTMs, and the number of channels in the hidden layers was all 256. The CRNN was trained by an Adam optimizer with a learning rate of 1×10^{-4} for 20 epochs with the training set.

TABLE I
COMPARISON OF EDIT-DISTANCE-BASED ERROR RATES (%) OF DIFFERENT METHODS.

Test Dataset	Method	Pitch Error	Miss Rate	Extra Rate	Onset Error	Offset Error	Mean Error
JPOP-test	VOCANO [9] + quantization [22]	9.0	47.8	14.2	47.4	31.2	29.9
	Note-level CTC (baseline)	**6.9**	24.6	**7.5**	37.3	27.3	**20.7**
	Tatum-level CTC (proposed)	8.8	**23.4**	14.1	**35.1**	**26.4**	21.6
RWC-test	VOCANO [9] + quantization [22]	12.7	16.5	15.6	40.6	29.5	23.0
	Note-level CTC (baseline)	**9.1**	**12.1**	**11.7**	35.5	**24.0**	**18.5**
	Tatum-level CTC (proposed)	9.4	13.3	18.9	**32.3**	26.9	20.2

TABLE II
COMPARISON OF BEAT AND DOWNBEAT F SCORES (%) FOR DIFFERENT METHODS.

Test Dataset	Method	Beat			Downbeat		
		Precision	Recall	F score	Precision	Recall	F score
JPOP-test	VOCANO [9] + quantization [22]	53.3	42.8	45.7	15.3	15.7	14.8
	Note-level CTC (baseline)	50.7	28.0	34.6	13.0	6.9	8.6
	Tatum-level CTC (proposed)	**80.5**	**73.6**	**75.2**	**67.9**	**68.8**	**67.3**
RWC-test	VOCANO [9] + quantization [22]	39.5	39.3	39.0	24.7	25.2	24.6
	Note-level CTC (baseline)	41.0	26.7	31.5	15.4	8.1	10.37
	Tatum-level CTC (proposed)	**77.0**	**82.0**	**79.3**	**66.5**	**70.2**	**68.0**

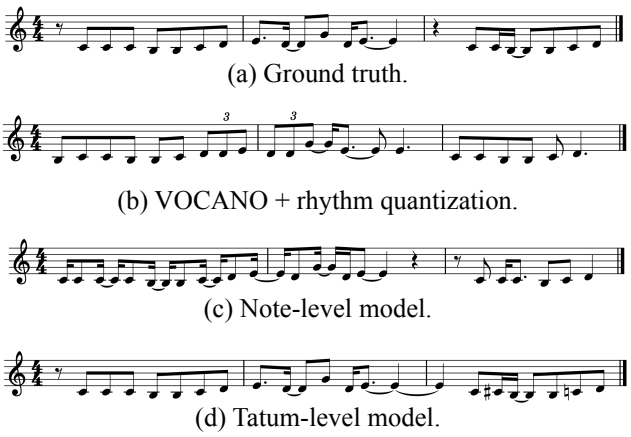
The HSMM used in the decoding phase was configured as follows. The hyperparameter λ in the transition model was set to 100, the minimum and maximum pitch values were $p_{min} = 43$, $p_{max} = 79$, and the minimum and maximum tatum durations were $d_{min} = 6$, $d_{max} = 30$, corresponding to tempos from 215 bpm to 43 bpm.

B. Compared Methods

To evaluate the efficiency of the proposed method, we compared it with VOCANO [9], a singing transcription system which combined pitch extraction and note segmentation. The original training data used for VOCANO have no overlap with the test data in our experiments. Since VOCANO was designed for estimating a pitch contour from singing voice, we processed the frame-based result obtained by VOCANO with a rhythm quantization method based on an HMM [22].

For comparison, we configured a baseline model based on a note-level score representation that estimates the note value of each note instead of the metrical position. This model was similar to ones used in the literature [15], [16] and was almost the same as the proposed method, except that each output symbol was given by $y_n \triangleq (d_n, p_n, o_n)$, where p_n and o_n are the same as ones described in Section III-A and $d_n \in [1, 16]$ represents the note duration. Note that only the duration within a measure was considered, and notes longer than a measure were split into different symbols. For example, a note with the pitch value of 64 and a duration of 18 tatums was represented as $(16, 64, 1), (2, 64, 0)$. The note-level baseline model was trained with the same procedure and the same dataset as the proposed CTC-based method and decoded with the greedy algorithm as Eqs. 13,14.

C. Evaluation Measures



We evaluated the estimated results with edit-distance-based metrics [29] in a way similar to the word error rate used for ASR. These metrics were computed by performing alignment between the estimated notes and ground-truth notes with DP and then identifying five exclusive types of errors: pitch errors, missing notes, extra notes, onset time errors, and offset time errors. The onset time and offset time errors are defined in terms of score times in units of tatums, but they do not take into account metrical positions. To evaluate the metrical structure of estimated scores, we additionally calculated the precision, recall, and F-score by inspecting the beat and downbeat positions of the correctly aligned notes.

D. Experimental Results

Tables I and II show the evaluation results. The multi-step combination of VOCANO and rhythm quantization had a low overall accuracy in terms of both the edit-distance-based metrics and the beat and downbeat F scores. This shows the difficulty of quantizing the estimated frame-level F0 contours. The CTC-based method with the note-level representation and its variant with the tatum-level representation had similar mean error rates in Table I, and the latter had higher beat and downbeat F scores (Table II). This shows the effectiveness of the end-to-end approach to AST based on CTC with the tatum-level representation.

Fig. 5 shows examples of musical scores estimated for the same piece of music from the JPOP-test dataset. As shown in Fig. 5(b), the score estimated by VOCANO contained extra notes and missing notes as well as a number of rhythmic errors. The score estimated by the baseline model with the note-level representation had mostly correct pitches and note values, but suffered from severe misalignment of metrical positions. Since the note-level representation does not consider beat and downbeat positions, rhythmic errors were accumulated when estimated notes were concatenated together. Compared with the baseline model, the proposed tatum-level model significantly reduced errors in metrical positions while keeping errors in pitches and note values at the same level.

Fig. 6 shows the histograms of the durations of the estimated notes obtained by the note-level model and the tatum-level model on the JPOP-test dataset. We found that the CTC-based

(a) Ground truth.

(b) VOCANO + rhythm quantization.

(c) Note-level model.

(d) Tatum-level model.

Fig. 5. Examples of estimated scores.

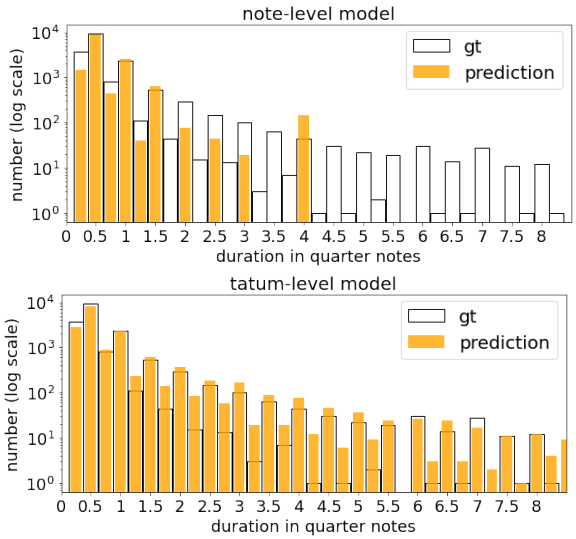


Fig. 6. Histograms of the note values estimated by the note-level (above) and tatum-level (below) CTCs, where "gt" stands for the ground truth data.

model with the note-level representation failed to correctly predict note values longer than a half note. Although the method was designed for dealing with note values longer than a whole note, the model failed to learn this property. With the proposed tatum-level representation, the histogram of the estimated note values was similar to that of the ground truth data. The proposed representation increased the rate of correctly estimating note values and contributed to correctly predicting metrical positions.

V. Conclusion

In this paper, we proposed an end-to-end AST method based on the CTC-based training with a tatum-level score representation consisting of positions of the tatums within measures, note pitches, and onset flags. The experimental results showed that the proposed method achieved better accuracy on the estimation of metrical positions of notes, and a mean edit-distance-based error rate similar to the CTC-based baseline method with a note-level score representation. We also found that the cascade of F0 extraction and rhythm quantization yielded a significantly worse result.

There are several issues left for future work. First, we assumed that the minimum time unit of a score is the sixteenth note, and we thus need to extend the model for fine-grained time units. Second, the proposed method can only transcribe songs with the time signature of 4/4, and other common meters should be properly dealt with. Additionally, popular music can have multiple meters within a song, and such variable meters should also be considered. Finally, in the decoding with the HSMM, a note-level musical language model is expected to be effective to improve the result, as in the case for ASR.

Appendix

A. HSMM-Based Decoding

1) Formulation of the HSMM: To impose the constraint of monotonically increasing metrical positions, we propose a refined decoding method based on an HSMM. Generally in music performances including singing, the durations of beats or tatums keep stable because of the regularity of metrical structure in music. To utilize this temporal stability, we introduce the durations of tatums $\mathbf{D} \triangleq \{\mathbf{d}_n\}_{n=1}^N$ measured in frames in the proposed HSMM. Consider the frame-level input features and tatum-level output features described in Section. III-A, namely, input spectrograms $\mathbf{X} \triangleq \{\mathbf{x}_t\}_{t=1}^T$, and output metrical positions $\mathbf{B} \triangleq \{b_n\}_{n=1}^N$, pitches $\mathbf{P} \triangleq \{p_n\}_{n=1}^N$ and onset flags $\mathbf{O} \triangleq \{o_n\}_{n=1}^N$. We formulate the generative process of $\mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D}$ and $\mathbf{X}$ as

$$p(\mathbf{X}, \mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D}) = p(\mathbf{X}|\mathbf{B}, \mathbf{P}, \mathbf{O}) p(\mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D}). \quad (17)$$

In Eq. 17, $p(\mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D})$ represents the language model of the hidden variables. We assume the distributions of pitches $\mathbf{P}$ and onsets $\mathbf{O}$ to be uniform, and formulate the transition probabilities as

$$p(\mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D}) = p(b_1, p_1, o_1, d_1) \times \prod_{n=2}^{N} p(b_n, p_n, o_n, d_n | b_{n-1}, p_{n-1}, o_{n-1}, d_{n-1}). \quad (18)$$

We assume the initial distribution of $\mathbf{B}$ and $\mathbf{D}$ is uniform, namely

$$p(b_1, p_1, o_1, d_1) = \frac{1}{K_b} \frac{1}{K_o} \frac{1}{p_{max} - p_{min} + 2} \frac{1}{d_{max} - d_{min} + 1}, \quad (19)$$

where $K_b = 16, K_o = 2$ are the number of distinct metrical positions and onset flags, p_{min} and p_{max} are assumed minimum and maximum pitch values other than the rest, and d_{min}

TABLE III
AN EXAMPLE OF THE FRAME-LEVEL VARIABLES.

Metrical Position $\bar{b}_t$	15	15	15	15	0	0	0	0	0	1	1	1	1	...
Tatum Duration $\bar{d}_t$	4	4	4	4	5	5	5	5	5	4	4	4	4	...
Tatum Counter $\bar{c}_t$	3	2	1	0	4	3	2	1	0	3	2	1	0	...
Pitch $\bar{p}_t$	62	62	62	62	62	62	62	62	62	59	59	59	59	...
Onset $\bar{o}_t$	1	1	1	1	0	0	0	0	0	1	1	1	1	...

and d_{max} are assumed minimum and maximum lengths of a tatum. The transition probabilities of b_n, d_n from b_{n-1}, d_{n-1} are determined by

$$\begin{aligned} &p(b_n, p_n, o_n, d_n | b_{n-1}, p_{n-1}, o_{n-1}, d_{n-1}) \\ &= \frac{1}{K_o} \frac{1}{p_{max} - p_{min} + 2} \delta_{16}(b_n, b_{n-1} + 1) p(d_n | d_{n-1}), \end{aligned} \quad (20)$$

where δ_{16} is the Kronecker's function modulo 16, that is

$$\delta_{16}(x, y) = \begin{cases} 1 & \text{if } x \equiv y \pmod{16}, \\ 0 & \text{if } x \not\equiv y \pmod{16}. \end{cases} \quad (21)$$

As suggested in [30], the transition probabilities of d_n from d_{n-1} are given by

$$p(d_n | d_{n-1}) \propto \exp\left(-\lambda \left| \frac{d_n}{d_{n-1}} - 1 \right| \right). \quad (22)$$

2) Frame-Level Formulation of the HSMM: The probabilistic model proposed in Section. A1 contains temporally asynchronous variables, $\mathbf{X}$ on the frame level and $\mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D}$ on the tatum level. To formulate the model in a synchronous way, we introduce the frame-synchronized versions of metrical positions $\bar{\mathbf{B}} \triangleq \{\bar{b}_t\}_{t=1}^T$, pitches $\bar{\mathbf{P}} \triangleq \{\bar{p}_t\}_{t=1}^T$, onset flags $\bar{\mathbf{O}} \triangleq \{\bar{o}_t\}_{t=1}^T$, and tatum durations $\bar{\mathbf{D}} \triangleq \{\bar{d}_t\}_{t=1}^T$. These variables can be constructed from the corresponding frame-level variables with $\bar{b}_t = b_n$, $\bar{p}_t = p_n$, $\bar{o}_t = o_n$ and $\bar{d}_t = d_n$ when $u(n-1) + 1 \le t \le u(n)$, where

$$u(n) \triangleq \begin{cases} 0 & n = 0, \\ \sum_{j=1}^n d_j & n > 0, \end{cases} \quad (23)$$

is the index of the last frame for each tatum. In addition, a tatum counter $\bar{\mathbf{C}} \triangleq \{\bar{c}_t\}_{t=1}^T$ is used to represent the position of the current frame within the tatum, counting down from $d_n - 1$ to 0. Table III shows an example of the frame-level variables.

With the tatum-level variables the HSMM can be rewritten as

$$\begin{aligned} p(\mathbf{X}, \mathbf{B}, \mathbf{P}, \mathbf{O}, \mathbf{D}) &= p(\mathbf{X}, \bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}}, \bar{\mathbf{D}}, \bar{\mathbf{C}}) \\ &= p(\mathbf{X} | \bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}}) p(\bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}}, \bar{\mathbf{D}}, \bar{\mathbf{C}}). \end{aligned} \quad (24)$$

In Eq. 17, $p(\bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}}, \bar{\mathbf{D}}, \bar{\mathbf{C}})$ represents the language model of the frame-level hidden variables. It is similar to Eq. 18, except that the transition probabilities become

$$\begin{aligned} &p(\bar{b}_t, \bar{p}_t, \bar{o}_t, \bar{d}_t, \bar{c}_t | \bar{b}_{t-1}, \bar{p}_{t-1}, \bar{o}_{t-1}, \bar{d}_{t-1}, \bar{c}_{t-1}) \\ &= \begin{cases} \delta(\bar{b}_t, \bar{b}_{t-1}) \delta(\bar{p}_t, \bar{p}_{t-1}) \delta(\bar{o}_t, \bar{o}_{t-1}) \delta(\bar{d}_t, \bar{d}_{t-1}) \delta(\bar{c}_t, \bar{c}_{t-1} - 1), \\ \bar{c}_{t-1} > 0, \\ \frac{1}{K_o} \frac{1}{p_{max} - p_{min} + 2} \delta_{16}(\bar{b}_t, \bar{b}_{t-1} + 1) p(\bar{d}_t | \bar{d}_{t-1}) \delta(\bar{c}_t, \bar{d}_t - 1), \\ \bar{c}_{t-1} = 0. \end{cases} \end{aligned} \quad (25)$$

In Eq. 24, $p(\mathbf{X} | \bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}})$ represents the emission probabilities of the observed spectrograms given the metrical positions, pitch values and onset flags. We assume the conditional independence of $\mathbf{X}$ given $\bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}}$, and we have

$$p(\mathbf{X} | \bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}}) = \prod_{t=1}^T p(\mathbf{x}_t | \bar{b}_t, \bar{p}_t, \bar{o}_t), \quad (26)$$

According to Bayes' theorem, the emission probability of a frame can be written as

$$\begin{aligned} p(\mathbf{x}_t | \bar{b}_t, \bar{p}_t, \bar{o}_t) &= \frac{p(\bar{b}_t, \bar{p}_t, \bar{o}_t | \mathbf{x}_t) p(\mathbf{x}_t)}{p(\bar{b}_t, \bar{p}_t, \bar{o}_t)} \\ &\propto \frac{p(\bar{b}_t, \bar{p}_t, \bar{o}_t | \mathbf{x}_t)}{p(\bar{b}_t, \bar{p}_t, \bar{o}_t)}. \end{aligned} \quad (27)$$

We assume that $p(\bar{b}_t, \bar{p}_t, \bar{o}_t)$ is a uniform distribution and that $p(\bar{b}_t, \bar{p}_t, \bar{o}_t | \mathbf{x}_t)$ can be estimated with a DNN trained in an end-to-end manner as described in Section III-B. Under the assumption of conditional independence of $\bar{b}_t, \bar{p}_t, \bar{o}_t$ given $\mathbf{x}_t$, we put that

$$\begin{aligned} p(\bar{b}_t, \bar{p}_t, \bar{o}_t | \mathbf{x}_t) &= p(\bar{b}_t, | \mathbf{x}_t) p(\bar{p}_t, | \mathbf{x}_t) p(\bar{o}_t, | \mathbf{x}_t), \\ &= \phi^{\mathrm{B}}_{t\bar{b}_t} \phi^{\mathrm{P}}_{t\bar{p}_t} (\phi^{\mathrm{O}}_t)^{\bar{o}_t} (1 - \phi^{\mathrm{O}}_t)^{1-\bar{o}_t}, \quad (28) \\ p(b_n | \mathbf{x}_t) &= \phi^{\mathrm{B}}_{t\bar{b}_t}, \quad (29) \\ p(p_n | \mathbf{x}_t) &= \phi^{\mathrm{P}}_{t\bar{p}_t}, \quad (30) \\ p(o_n | \mathbf{x}_t) &= (\phi^{\mathrm{O}}_t)^{\bar{o}_t} (1 - \phi^{\mathrm{O}}_t)^{1-\bar{o}_t}. \quad (31) \end{aligned}$$

It is notable that only the outputs $\phi^{\mathrm{B}}, \phi^{\mathrm{P}}$ and ϕ^{O} are used here since they can be interpreted as the posterior probabilities when the neural network judges a frame to be non-blank.

3) Viterbi Decoding: With the probabilistic model described above, we can estimate the optimal metrical positions $\mathbf{B}^*$, pitch values $\mathbf{P}^*$ and onset flags $\mathbf{O}^*$ by first estimating

$$\bar{\mathbf{B}}^*, \bar{\mathbf{P}}^*, \bar{\mathbf{O}}^*, \bar{\mathbf{D}}^*, \bar{\mathbf{C}}^* = \operatorname{argmax} p(\mathbf{X}, \bar{\mathbf{B}}, \bar{\mathbf{P}}, \bar{\mathbf{O}}, \bar{\mathbf{D}}, \bar{\mathbf{C}}), \quad (32)$$

and then obtain $\mathbf{B}^*, \mathbf{P}^*, \mathbf{O}^*$ from $\bar{\mathbf{B}}^*, \bar{\mathbf{P}}^*, \bar{\mathbf{O}}^*$. Eq. 32 can be solved efficiently with the Viterbi algorithm.

***Abstract*—We present a self-trainable method, Mask2Hand, which learns to solve the challenging task of predicting 3D hand pose and shape from a 2D binary mask of hand silhouette/shadow without additional manually-annotated data. Given the intrinsic camera parameters and the parametric hand model in the camera space, we adopt the differentiable rendering technique to project 3D estimations onto the 2D binary silhouette space. By applying a tailored combination of losses between the rendered silhouette and the input binary mask, we are able to integrate the self-guidance mechanism into our end-to-end optimization process for constraining global mesh registration and hand pose estimation. The experiments show that our method, which takes a single binary mask as the input, can achieve comparable prediction accuracy on both unaligned and aligned settings as state-of-the-art methods that require RGB or depth inputs.**

I. Introduction

More than hundreds of years ago the historic art form of hand shadow puppetry had already been documented in many ancient countries. Since then, making hand shadow puppets has been a low-cost household entertainment activity that parents can play with their children. As far as human perception is concerned, it is interesting that humans can recognize the animals and characters portrayed by the hands and fingers from merely their projected shadows. It is also remarkable that people are able to develop and create different ways of making hand shadow puppets, which may involve the generative capability of imagining some target shape and adjusting the hands and fingers to match the imaginary shape with the shadow. Inspired by the discriminative and generative nature in the visual process of doing hand shadow puppets, we aim to explore the possibility of learning to estimate the 3D hand pose and shape from an input hand silhouette, through a similar trial-and-error manner of learning to do hand shadow puppets.

Our main goal in this endeavor is to train a renderer-equipped deep network that takes a binary mask of a hand's silhouette as the input and predicts the corresponding 3D hand shape that produces a silhouette very similar to the input. (Fig. 1 shows several example results obtained using our model.) To build such a model, we employ MANO [1] as the 3D hand-shape renderer in our deep network. We propose a new network, called Mask2Hand, which consists of an encoder, a MANO layer, a differentiable render, and the refinement module. Fig. 2 shows an overview of the proposed Mask2Hand network. Our network takes a binary mask as the input and uses the encoder to generate the required parameters for the MANO layer to render the hand mesh. The encoder learns to predict the pose-related principal components of MANO and the 3D global transformation of the hand from only a single input binary mask. Based on the principal components and global transformation, the MANO layer reconstructs the 3D hand mesh and the hand joint positions. We then use a differentiable renderer to generate the 2D projected silhouette from the hand mesh. Finally, the refinement module compares the projected silhouette with the input binary mask to refine the entire network. Three groups of loss functions are tailored for training the aforementioned modules, including the pose loss, silhouette loss, and mesh loss. The loss functions and the operations involved in the modules are all differentiable—we are able to train the entire network from end to end. Our code can be found at GitHub by searching Mask2Hand.

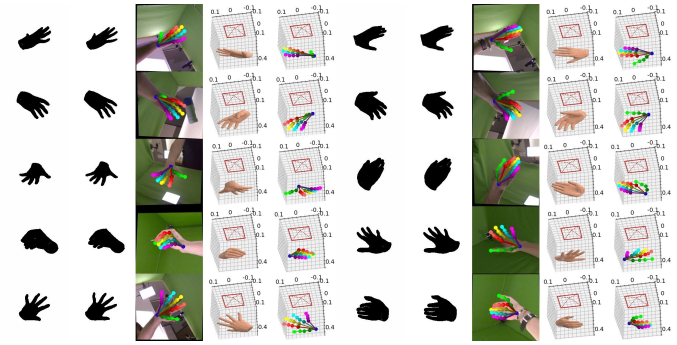

Fig. 1. The proposed method, Mask2Hand, learns to solve the challenging task of predicting the 3D hand pose and shape from a 2D binary mask of hand silhouette. Each row in the left or right half of the figure illustrates an example result of performing our method on real data. The first column shows the input of 2D binary mask. The second column shows the rendered mask using the predicted hand shape. The third column shows the predicted 2D skeleton depicted in the image space. Note that the color images are simply for visualization; our method does not use any RGB data. The last two columns show the predicted mesh and 3D skeleton.

As this work aims at addressing a rather new and challenging task of predicting the 3D hand pose from a single 2D binary mask, it is quite encouraging that the proposed Mask2Hand network can achieve comparable prediction accuracy on 3D hand pose and shape estimation as state-of-the-art methods, although we only need a single binary input

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

image while theirs require an RGB image or a depth map. Note that our model can be trained under supervision with manually annotated joint positions or in a fully self-supervised manner without human annotations. Furthermore, since our method learns to predict the global transformation of the hand, its evaluation performance under the unaligned setting of hand pose estimation does not degrade as much as other methods do. Such a property is particularly favorable as, in real applications, it is not allowed to align the prediction with the unknown ground truth.

In addition to the motivation of hand shadow puppets, there are some other advantages and real-world applications of working on binary silhouettes. First, in contrast to RGB input, binary images can be obtained with relatively inexpensive sensors, such as low-resolution range sensors and low-resolution infrared sensors. They are especially useful when the lighting condition is poor and not much color information is available. Second, a line of research [2]–[4] in the hardware domain explores the usage of ambient light as a ubiquitous sensing medium. Light sensors, such as photodiodes or solar cells, measure and track the shadow blockage that a user's hands cause with low cost and ultra-low power consumption, which have the potential to be widely used in IoT devices for shadow-based hand pose estimation systems. Finally, binary input is more robust to adversarial attacks of imperceptible pixel perturbation. From the literature on adversarial machine learning [5], we know that invisible image manipulation can seriously spoil the functionality of DNNs. However, this common type of attack is not directly applicable to the binary setting since small perturbation in pixel values is impossible with binary images. Also, pixel inversion in binary silhouettes can be easily identified and addressed.

II. Related Work

One of the research endeavors inspiring us is *Shadow Theatre* [6], which aims to reproduce computationally the shadow puppet theatre—an ancient shadow-oriented form of performance art—just like how we are motivated by hand shadow puppetry. Won and Lee [6] develop an algorithm to incorporate several features and heuristic rules that are related to shadow generation using human bodies. The proposed method optimizes the poses of human bodies to match the given 2D target shapes. The underlying nonlinear high-dimensional optimization is solved using the proposed heuristic strategies so that a plausible solution can be found with reasonable computing resources. Nevertheless, the computation still requires tens to hundreds of minutes to complete on GPU.

A. 3D Hand Pose and Shape Estimation

Various methods have been proposed to address the problem of 3D hand pose and shape estimation. Generally, the techniques that are used to solve 3D human pose estimation can also be applied to 3D hand pose estimation. Based on the input format, we consider the following four categories of methods on 3D hand pose and shape estimation: RGB-based, depth-based, event-camera-based, and silhouette-based methods. Among them, silhouette-based methods are most closely related to this work, where we seek to generate the 3D hand pose and mesh from merely a single binary-valued image of hand silhouette.

Despite the discrepancy in their input type, many of the methods take 2D joint detection as the basis. Such an approach is promising, and many existing deep-learning-based techniques can be employed. The following is a brief review of recent methods in the four categories.

a) RGB-based Methods.: Lin *et al*. propose a method called Mesh Transformer (METRO) [7] that explores non-local relationships between vertices and joints to reconstruct a 3D human pose from a single RGB image without using parametric mesh models. This method can also be extended to hand mesh reconstruction. Chen *et al*. [8] propose Camera-space Mesh Recovery (CMR) that generates 3D meshes from a single RGB image by extracting 2D cues including joint landmarks and silhouette. Chen *et al*. [9] present a self-supervised 3D hand reconstruction network called S^2HAND that estimates 3D poses from 2D detected keypoints. Liu *et al*. [10] propose a semi-supervised 3D hand-object pose estimation method leveraging spatial-temporal consistency in videos to obtain pseudo-labels for self-training. Li *et al*. [11] propose a hand pose estimation method by using multi-task learning to categorize joints into groups so that different features can be learned to recover the 3D joint locations in a group-wise manner.

b) Depth-based Methods.: Xiong *et al*. [12] propose the Anchor-to-Joint Regression Network (A2J) that exploits informative anchor points to enhance the generalization ability of 3D pose estimation. Fang *et al*. [13] present a dense-prediction-based 3D hand pose estimation method called JGR-P2O that uses a pixel-to-offset prediction network and a joint graph reasoning module to enable end-to-end training and improve computational efficiency.

c) Silhouette-based Methods.: Silhouette-based methods have not yet been widely applied to hand/body pose estimation. The task to be solved is more challenging than those in other settings of RGB-based and depth-based methods. The difficulty comes from the lack of information in the input data, where the shading, color, and depth of the 3D objects are absent in the binary-valued images. Lee *et al*. present the Silhouette-Net [14] method that generates 3D hand poses based on binary-valued silhouettes and can achieve a performance similar to or better than depth-based methods if multiview silhouettes are provided. However, their method requires the guidance of depth maps during the training stage. In contrast, our method does not require additional depth information during training, and it only needs a single-view 2D binary mask of the hand as the input. Despite the challenging setting, estimating the 3D hand pose and mesh from limited binary information in the input is our major goal in this work.

B. 3D Hand Models

Several hand mesh models have been proposed, such as MANO [1], Sphere-Meshes [15], and Convex Parts [16]. With

the help of these models, hand shape generation and pose estimation can be processed via parametric methods. Typically, a hand model like MANO is designed to parameterize a triangle mesh into pose, shape, and rotation parameters. MANO has been widely used by hand pose estimation methods [17]–[26] to train their deep networks; the deep networks learn to predict the hand shape in the target image by regressing to the principal components of the MANO model. As shown in Fig. 2, our method also uses the MANO model to construct the target hand shape. By learning to optimize the parameters of MANO meshes, our method achieves the goal of generating the 3D hand mesh from a binary-valued silhouette image.

III. Our Approach

To predict the hand pose and shape from a binary mask, we propose a two-phase end-to-end trainable network, *Mask2Hand*, that aims to reconstruct 3D hand meshes in the camera space. Fig. 2 illustrates the overall pipeline of our method. In what follows, we detail each module of the pipeline and describe how we formulate the loss functions.

A. Model Architecture

The core modules of our model include an encoder for estimating the MANO parameters, a MANO layer that reconstructs the 3D hand mesh, a differentiable renderer for optimizing the hand pose, and a RefineNet improving the accuracy.

a) Encoder.: Given a hand silhouette image presented as a binary mask, the encoder first uses a ResNet18 [27] backbone to extract features from the input. Then, these features are fed into four different estimators to encode 3D information into the PCA space of MANO [1] and predict the extrinsic camera parameters. More specifically, the output of the encoder consists of the first six or forty-five hand-pose-related principal components $\theta \in \mathbb{R}^6$ or $\mathbb{R}^{45}$ of MANO, shape parameters $\beta \in \mathbb{R}^{10}$, 3D rotation $R \in \mathbb{R}^3$ in axis-angle representation, and 3D translation $T \in \mathbb{R}^3$.

b) MANO Layer.: The 3D hand shape is represented by a triangle mesh that contains a vertex set $V \in \mathbb{R}^{778\times 3}$ and fixed faces F indicating the connection between them. In our network, the hand mesh and joints $J \in \mathbb{R}^{21\times 3}$ are reconstructed using MANO [1]. Being a low-dimensional parametric hand model, MANO can generate the required hand mesh from parameters including the hand-pose-related principal components θ, shape $\beta \in \mathbb{R}^{10}$, rotation R, and translation T.

c) Differentiable Renderer.: Given intrinsic camera parameters and hand meshes in the camera space, we use the differentiable rendering technique [28] to project 3D estimations into the 2D image space. By applying various losses between the rendered mask of the hand silhouette and the input binary image, we can integrate self-supervision into our end-to-end optimization process for constraining global mesh registration. Here we use the PyTorch3D [29] implementation of the differentiable renderer. The loss functions will be detailed later in the subsequent sections.

d) RefineNet.: In the previous stage, we only consider several pose-related principal components of MANO for parametrizing hands in a low-dimensional space. The lower degree of freedom may have an expressiveness problem in that the finer details of hand gestures cannot be ideally reconstructed. Therefore, we incorporate a small convolutional neural network, called the RefineNet module [1], into our model to deal with this issue. The network takes the concatenation of the input image and the projected silhouette as input, and it produces residual coordinate values that serve as the point-wise offsets to the previously constructed mesh. The final output of our model is the summation of the originally reconstructed hand mesh and the offset predicted by the RefineNet. The refined joints are then estimated by MANO's joint regressor given the refined mesh as its input.

B. Loss Functions

The complete objective function that we design for training our Mask2Hand model comprises three main loss terms:

$$\mathcal{L} = \mathcal{L}_{\text{pose}} + \mathcal{L}_{\text{silhouette}} + \mathcal{L}_{\text{mesh}} \,, \tag{1}$$

where we have the pose loss $\mathcal{L}_{\text{pose}}$ on the predicted joints, the silhouette loss $\mathcal{L}_{\text{silhouette}}$ on the 2D projected silhouette of the hand, and the mesh loss $\mathcal{L}_{\text{mesh}}$ on the reconstructed 3D mesh.

1) Pose Loss.: The pose loss in Eq. (1) further consists of two loss functions that use the unaligned and aligned joint positions to evaluate the preliminary and refined joint predictions by the squared L2-norm error:

$$\mathcal{L}_{\text{pose}} = \lambda_{\text{J}}\mathcal{L}_{\text{J}} + \lambda_{\text{alignJ}}\mathcal{L}_{\text{alignJ}} \,, \tag{2}$$

where we have $\mathcal{L}_{\text{J}}$ for the unaligned joint evaluation and $\mathcal{L}_{\text{alignJ}}$ for the aligned joint evaluation, with λ_{J} and λ_{alignJ} as the weight factors. The 3D positions of the K joints are represented as a K by 3 matrix, *i.e.*, $J \in \mathbb{R}^{K\times 3}$. The loss function $\mathcal{L}_{\text{J}}$ of the unaligned joint evaluation is computed as

$$\mathcal{L}_{\text{J}} = \frac{1}{K}\sum_{i=1}^{K}\left\|J_i - \widehat{J}_i\right\|_2^2 + \frac{1}{K}\sum_{i=1}^{K}\left\|J_i - \widehat{J}_i^{\text{ref}}\right\|_2^2 , \tag{3}$$

J_i is the ground-truth 3D position of joint i, $\widehat{J}_i$ is the preliminarily reconstructed position of joint i, and $\widehat{J}_i^{\text{ref}}$ is the final prediction after refinement.

For the aligned joint loss, the predicted joints are aligned with the ground truth using orthogonal Procrustes Analysis (PA) [31], and then the L2 loss is applied to the aligned and the ground-truth joints:

$$\begin{gathered}\mathcal{L}_{\text{alignJ}} = \frac{1}{K}\sum_{i=1}^{K}\left\|J_i - \widetilde{J}_i\right\|_2^2 + \frac{1}{K}\sum_{i=1}^{K}\left\|J_i - \widetilde{J}_i^{\text{ref}}\right\|_2^2 , \\ \text{where } \widetilde{J} = \text{PA}(J, \widehat{J}) \text{ and } \widetilde{J}^{\text{ref}} = \text{PA}(J, \widehat{J}^{\text{ref}}) \,.\end{gathered} \tag{4}$$

The procedure of alignment $\text{PA}(J, \widehat{J})$ can be described as follows.

[1]Our RefineNet module is different from the dense prediction network proposed in [30] despite the same name.

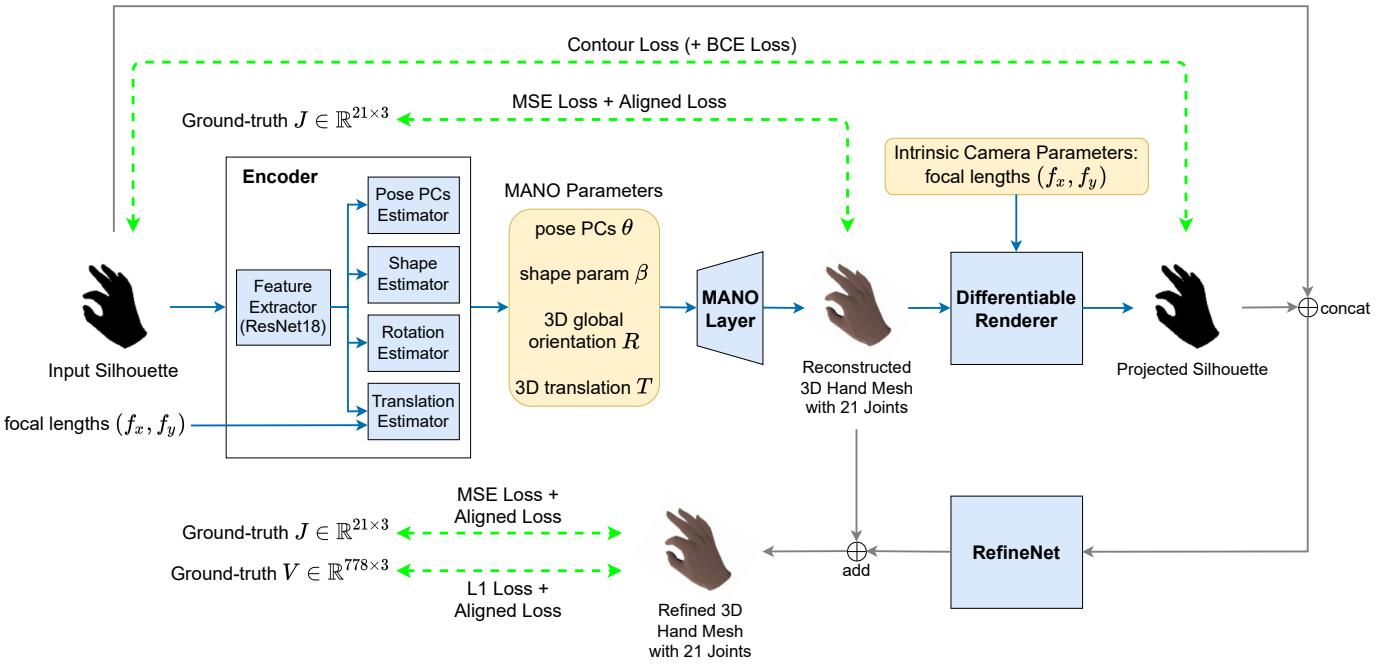

Fig. 2. The Mask2Hand network comprises the Encoder, MANO Layer, Differentiable Renderer, and RefineNet. The Encoder takes a binary mask as the input and generates the required parameters for the MANO Layer; the parameters include the shape, the six or forty-five pose-related principal components of MANO, the 3D global orientation, and translation of the hand. Based on these parameters, the MANO Layer reconstructs the 3D hand mesh (represented by 778 vertices) with the 21 positions of the hand joints. The Differentiable Renderer generates the 2D projected silhouette of the hand mesh, and the RefineNet can compare the projection with the input binary mask to refine the entire model. We design different loss functions for different modules in our model. The green dashed lines indicate what losses are applied to the associated modules. Please refer to the text for the detailed formulations of the loss functions.

1) Translate the joints so that their mean lies at the origin:

$$J \leftarrow J - \frac{1}{K}\sum_{i=1}^{K} J_i\,, \quad \widehat{J} \leftarrow \widehat{J} - \frac{1}{K}\sum_{i=1}^{K} \widehat{J}_i\,.$$

2) Divide the joints set by its Frobenius norm to remove the uniform scaling component:

$$J \leftarrow J/\|J\|_F\,, \quad \widehat{J} \leftarrow \widehat{J}/\|\widehat{J}\|_F\,.$$

3) Solve the orthogonal Procrustes problem: given matrices J and $\widehat{J}$, find an orthogonal matrix $Q \in \mathbb{R}^{3\times3}$ that maps J most closely to $\widehat{J}$, *i.e.*, $\min_Q \|JQ - \widehat{J}\|_F$ subject to $Q^\top Q = I_{3\times3}$. The solution consists of $Q = UV^\top$ and $s = \sum_i \sigma_i$, where $U\Sigma V^\top$ is the singular value decomposition of $J^\top \widehat{J}$ and σ_i's are the singular values.
4) $\widetilde{J} = \left(\widehat{J}Q^\top \times s\right) \times \|J\|_F + \left(\sum_{i=1}^{K} J_i\right)/K$, where the Procrustes output is scaled by the norm and shifted by the mean that we derive from J in the first two steps.

2) Silhouette Loss.: For the module of differentiable rendering, the ideal result is that the 2D projected hand silhouette matches the input binary mask exactly. Hence, our silhouette loss is based on the binary cross-entropy (BCE) and the contour loss:

$$\mathcal{L}_{\text{silhouette}} = \lambda_{\text{bce}}\text{BCE}(S, B) + \lambda_{\text{contour}}\text{ContourLoss}(S, B)\,, \tag{5}$$

where S is the rendered silhouette and B is the input binary mask. Our contour loss is a differentiable estimation of Chamfer distance between two contours, calculated as a pixel-wise multiplication between the contour of rendered silhouette and the pre-computed distance field of the ground-truth silhouette's contour. The detailed steps for computing the Chamfer distance are summarized as follows:

1) Compute the distance transform [32] for the contour ∂B of the ground-truth binary mask B in the dataset to get the distance field $\Psi_{\partial B}$.
2) Apply differentiable binarization to the rendered silhouette image S. In our case, we convert a pixel value $x \in [0, 1]$ in S to an approximately binary value as $\frac{1}{1+e^{-100\,(x-0.5)}} \simeq \{0, 1\}$.
3) Zero out the pixel values that are greater than the threshold 0.5 to deal with the noise near the wrist caused by PyTorch3D differentiable rendering. The result of Steps 2 & 3 is a clean and nearly binarized silhouette $\overline{S}$.
4) Apply Laplacian operator to $\overline{S}$ to get $\Delta\overline{S}$. The contour $\partial\overline{S}$ is then obtained by $\partial\overline{S} = \tanh(\max\{\Delta\overline{S}, 0\})$, which maps the values on the contour to near 1 and all the rest to 0.
5) Do element-wise product between the resulting contour $\partial\overline{S}$ and the distance field $\Psi_{\partial B}$ to retrieve the corresponding distance values and then take the sum to get $\text{ContourLoss}(S, B)$.

All of the aforementioned computations are differentiable. Therefore, we can readily include the silhouette loss in our method, and end-to-end train the network.

3) Mesh Loss.: We employ the mesh loss to measure the error in predicting the 3D vertices of the hand mesh. Like the pose loss, the mesh loss is also evaluated on both the unaligned and aligned predictions:

$$\mathcal{L}_{\text{mesh}} = \lambda_{\text{V}}\mathcal{L}_{\text{V}} + \lambda_{\text{alignV}}\mathcal{L}_{\text{alignV}} \,. \tag{6}$$

The unaligned vertex loss $\mathcal{L}_{\text{V}}$ consists of the L1 losses for the predictions from the preliminary and refined meshes:

$$\mathcal{L}_{\text{V}} = \frac{1}{M}\sum_{i=1}^{M}\left\|V_i - \widehat{V}_i\right\|_1 + \frac{1}{M}\sum_{i=1}^{M}\left\|V_i - \widehat{V}_i^{\text{ref}}\right\|_1 , \tag{7}$$

where $V \in \mathbb{R}^{M\times 3}$ is the ground-truth 3D vertices of the hand mesh, $\widehat{V}$ is the preliminarily reconstructed mesh, and $\widehat{V}^{\text{ref}}$ is the final prediction of vertices after refinement.
For the aligned vertex loss $\mathcal{L}_{\text{alignV}}$, the predicted vertices are aligned with the ground truth using orthogonal Procrustes analysis as described in the aligned pose loss Eq. (4), and then the L1 loss is applied to the aligned and the ground-truth mesh as

$$\mathcal{L}_{\text{alignV}} = \frac{1}{M}\sum_{i=1}^{M}\left\|V_i - \widetilde{V}_i\right\|_1 + \frac{1}{M}\sum_{i=1}^{M}\left\|V_i - \widetilde{V}_i^{\text{ref}}\right\|_1 , \tag{8}$$
$$\text{where } \widetilde{V} = \text{PA}(V, \widehat{V}) \text{ and } \widetilde{V}^{\text{ref}} = \text{PA}(V, \widehat{V}^{\text{ref}}) \,.$$

IV. Experiments

Since the problem formulation of the task that we aim to address is different from those commonly adopted in prior work, we have not found state-of-the-art methods that take exactly the same input setting and could therefore be considered for direct comparison with our approach. Note that the work of Lee *et al.* [14] is only posted on arXiv as a preprint without available code. Therefore, we do not include their method in the following comparisons. Moreover, their method requires depth maps during training, which is more restrictive than ours. In our experiments, we first compare our method with the state-of-the-art depth-based model A2J [12] on a synthetic dataset and show that transferring our task for an existing model to solve is probably not as straightforward as it may seem. Further, we use the real data in FreiHAND to compare our method with the three state-of-the-art RGB-based methods: I2L-MeshNet [22], MeshTransformer [7], and CMR (ResNet18) [8]. The results show that our method performs particularly well under the unaligned evaluation setting of 3D hand pose estimation, which is more practical for real applications.

A. Datasets

We conduct experiments on the following two datasets.

a) Synthetic Dataset.: This dataset contains 20,000 training and 2,000 test binary images synthesized using MANO [1], [33]. For each sample in the dataset, its hand-pose principal components $\theta \in \mathbb{R}^6$ are randomly sampled from the uniform distribution between $[-2.0, 2.0)$, and each rotation angle of its 3D global orientation R is randomly sampled from the uniform distribution $[-\pi, \pi)$. We use MANO to generate the corresponding hand shapes from the sampled parameters. The ground-truth 3D coordinates of the 21 hand joints can thus be automatically derived from the MANO rendered hand shapes.

b) FreiHAND [34].: It is a common real-world RGB dataset with 32,560 training samples and 3,960 test samples. We binarize the segmentation masks available in the training set and use them as the input to our model. However, since its original evaluation set does not provide segmentation masks, we resort to splitting its original training set into a random partition of 26,000 training, 3,280 validation, and 3,280 test images to achieve a reasonably fair evaluation of our method.

For quantitative evaluation, we report the standard metrics used by the FreiHAND dataset on the predictions of 3D joints and meshes:

- **MPJPE**: the *mean per joint position error*, which measures the Euclidean distance (in cm) between the ground-truth joints and the predicted joints.
- **MPVPE**: the *mean per-vertex position error*, which measures the Euclidean distance (in cm) between the ground-truth vertices and the predicted vertices of a mesh.
- **AUC of PCK**: the *area under the curve* of the *percentage of correct keypoints*, which is plotted using 100 equally-spaced thresholds between 0 cm to 5 cm.
- **AUC of PCV**: the *area under the curve* of the percentage of correct vertices.
- **PA-MPJPE** or **PA-MPVPE**: It first applies Procrustes alignment between the ground truth and the prediction, and then calculates MPJPE or MPVPE. This metric aims to measure reconstruction error that neglects the effect of global rotation, translation, and scaling.
- **mIoU** and **Dice coefficient**: In addition to the preceding metrics used by the FreiHAND dataset for the evaluation of joint and mesh predictions, we also use the *mean intersection over union* and the *Dice coefficient* to evaluate the similarity between the input binary mask and the mask projected from the predicted hand mesh.

TABLE I
Comparison with the depth-based model A2J [12] on the synthetic dataset. (PA means Procrustes Aligned)

Method	Input	MPJPE ↓	AUC$_J$ ↑	PA-MPJPE	PA-AUC$_J$
A2J [12]	Mean depth + 5-view aug.	7.73 cm	0.35	1.93 cm	0.62
Ours	Binary (0, 255) + 5-view aug.	**0.87 cm**	**0.83**	**0.53 cm**	**0.89**

B. Comparison with State-of-the-Art Depth-based Methods

To demonstrate that state-of-the-art depth-based models cannot be easily transferred to the task with binary input, we

Ours (45 PCs)		0.68	0.86	0.69	0.86

compare our model with A2J [12] on the synthetic dataset. The input image of our model is binarized to $\{0, 255\}$ while that of A2J is binarized to 0 (as the background) and the mean depth of joints to treat the depth-based model fairly. This way, in spite of the fact that the input image is binary-valued, we still provide sufficient statistics of depth information to A2J. As shown in Table I, for the unaligned setting, our model achieves MPJPE of 0.87 cm, and A2J reaches MPJPE of 7.73 cm. The results indicate that A2J fails to learn to localize 3D hand joints accurately when the input is binary, even if the reference mean depth is given. In contrast, our method has the promising ability to recover the positions of the joints in the camera space. In terms of MPJPE after Procrustes alignment, our approach also outperforms A2J by a large margin, as presented in Table I. Some other depth-based models are not quantitatively compared with ours for the following reasons. V2V-PoseNet [35] takes a 3D voxelized depth map as its input, which is expected to fail for silhouette-based input since the voxelization process cannot work for binary images. Hand PointNet [36] converts a depth map into a 3D point cloud and then uses it as the model's input. Likewise, the conversion procedure cannot function properly for silhouettes, making it inadequate for the task of binary input.

C. Comparison with State-of-the-Art RGB-based Methods

For the comparison with state-of-the-art RGB-based methods, we select the leading models from the FreiHAND competition leaderboard at CodaLab [2], including CMR [8] and MeshTransformer [7]. To make a fair comparison with our method, we use the officially released code to re-train their models on the FreiHAND dataset randomly partitioned by us, as mentioned in Section IV-A, under the settings of both binary and RGB input. The former is for performance observation, while the latter is primarily for convincing proof that these models are not trained imperfectly. As presented in Table II, CMR achieves MPJPE and MPVPE of 4.31 cm with silhouette-based input, while MeshTransformer fails to localize 3D hand joints and mesh in the camera space. Our model reaches MPJPE of 3.56 cm and MPVPE of 3.57 cm, which outperforms the previous two methods by a large margin and is even comparable to the result of CMR with RGB input. The superior performance of our model in the unaligned case indicates that it has a better ability to reconstruct 3D hand mesh in the camera space, which is more practical in real applications. In terms of mIoU and Dice coefficient, our model achieves similar results as CMR.

TABLE IV
ABLATION STUDY. (MEANING OF ⋇ IN THE FIRST COLUMN: THE ALIGNED LOSS IS ONLY APPLIED TO THE REFINED JOINTS AND VERTICES. (A FOR ALIGNED LOSS, B FOR BCE LOSS, C FOR CONTOUR LOSS, R FOR REFINE NET, M FOR MESH LOSS.)

A	B	C	R	M	MPJPE (cm)↓	MPVPE (cm)↓	PA-MPJPE (cm)↓	PA-MPVPE (cm)↓	mIoU↑
✓		✓	✓	✓	3.55	3.56	0.78	0.79	0.87
✓		✓	✓		3.67	3.84	0.86	1.18	0.76
✓		✓			3.73	3.73	0.94	0.94	0.83
✓			✓	✓	3.60	3.61	0.80	0.81	0.87
		✓	✓	✓	3.83	3.91	1.36	1.56	0.86
⋇			✓	✓	3.66	3.67	0.79	0.80	0.86
✓	✓	✓	✓	✓	3.56	3.57	0.78	0.79	0.87
✓	✓	✓			3.72	3.73	0.90	0.93	0.83
	✓	✓	✓	✓	3.66	3.67	1.04	1.06	0.88

When the predicted joints and vertices are aligned with the ground truth by Procrustes analysis, our approach reaches PA-MPJPE of 0.68 cm and PA-MPVPE of 0.69 cm. These experimental results are significantly better than CMR's performance under the setting of binary input and are comparable to CMR's results with RGB input. Furthermore, unlike MeshTransformer, which totally fails in the unaligned case, our method performs stably well in both cases. Such a balanced behavior is preferable in our task since localization and detail recovery are vitally important for projecting a silhouette similar to the input one.

D. Implementation Details

Our encoder's backbone is based on ResNet18 [27]. PyTorch3D's implementation [29] is employed for our differentiable renderer. We use the Adam optimizer to train our network with a batch size of 32. The initial learning rate is set to 10^{-4}, and we use the ReduceOnPlateau scheduler to adjust the learning rate. The whole network is trained for 150 epochs, and the checkpoint with the lowest validation loss is selected for our final usage. For the FreiHAND dataset, we apply data augmentation of random rotation between $[-\pi, \pi)$ and scaling between $[\,0.9, 1.1)$ in the 2D image space. For the synthetic dataset, we randomly sample only one of the five views for each training data at every epoch to perform data

augmentation. We set $\lambda_{\mathrm{J}} = 2 \times 10^{-3}$, $\lambda_{\mathrm{alignJ}} = 2 \times 10^{-2}$, $\lambda_{\mathrm{contour}} = 10^{-4}$, $\lambda_{\mathrm{V}} = 0.1$, and $\lambda_{\mathrm{alignV}} = 1$ to balance each loss term. λ_{bce} is set to 0 for our final model and 0.5 for the ablation study.

E. Ablation Study

We evaluate different configurations of our method to analyze the effectiveness of each component and examine the effects of the loss functions.

1) Effects of Shape Parameters.: In our ablation study, we use six pose PCs and set β to the mean shape, *i.e.*, $\beta = \mathbf{0}$. By comparing the first row of Table IV and the penultimate row of Tables II & III, we can observe that regressing shape parameters in the first stage of our model helps reduce the burden of refinement and achieve better performance in the aligned case.

2) Effectiveness of Each Component.: As shown in Table IV, we explore the evaluation results on the FreiHAND dataset with the exclusion of different components. Our base model consists of Encoder, MANO Layer, and Differentiable Renderer. After incorporating the RefineNet module into our network with pose loss only, we observe that both MPJPE and PA-MPJPE decrease while MPVPE and PA-MPVPE undesirably increase. This result is in line with our expectation since the pose loss cannot impose strong enough constraints on the deformation of the preliminarily constructed hand mesh. Based on the observation, we further apply the mesh loss to the output of the RefineNet, which helps to strengthen the functionality of refinement and improve all evaluation metrics significantly.

To reveal the effects of other losses, we exclude them one at a time from our entire network. First, we remove the contour loss between the input binary image and the projected silhouette. The evaluation result shows that the model's performance on both hand pose and shape estimation degrades, especially the unaligned ones, demonstrating the effectiveness of the contour loss for achieving more accurate global mesh registration. Second, we eliminate the aligned losses of both joints and vertices. Our experimental result shows that MPJPE, MPVPE, PA-MPJPE, and PA-MPVPE increase by 0.28, 0.35, 0.58, and 0.77, respectively. Such a significant deterioration in performance indicates that the aligned losses not only play crucial roles in the reconstruction of fine-grained gestures but also help to improve mesh recovery in the camera space. Finally, we remove all losses inserted before RefineNet. The result shown in the sixth row of Table IV suggests that adding the pose loss and contour loss before the refinement stage can help our model improve the ability to localize the 3D hand mesh in the camera space.

3) Effects of Adding the BCE Loss.: We also do some experiments to see whether adding the binary cross-entropy loss between the input binary mask and the projected silhouette has any positive effect. As listed in Table IV, directly incorporating the BCE loss into our entire architecture contributes nothing to the final performance. To understand the root cause of this counterintuitive phenomenon, we take away the RefineNet module and the aligned loss one at a time with the presence of BCE loss. The experimental results show that the BCE loss can enhance our model's performance by a large margin when the aligned losses are absent. This implies that the BCE loss does not have much effect when the model learns the shape estimation task to a certain degree guided by the stronger training objectives, *i.e.*, the aligned losses of joints and vertices.

V. Conclusion

This paper introduces the Mask2Hand network that learns to predict the 3D hand pose and shape from a 2D binary mask without relying on any RGB or depth information. Despite the more challenging input setting of our task in comparison with prior work on hand pose and shape estimation, we show that the proposed method can achieve comparable performance as state-of-the-art RGB-based and depth-based methods. With the parametric hand model and the differentiable rendering technique, we integrate the self-supervised mechanism into our end-to-end training process without the need for human annotations. We propose several loss functions to model different aspects of 3D hand pose and shape estimation. Since our method explicitly learns to predict the global transformation of the hand, its better performance in the unaligned setting is thus promising for real applications.

***Abstract*—Reversible image processing methods have been actively researched by using data hiding techniques. In these methods, additional information for reversibility should be embedded into the processed image. Their main targets for image processing are luminance and saturation. In this paper, we focus on tone control that specifically enhances blue or red tone with reversibility. Through our simulations, we prove that our method can effectively enhance color tones and the data embedding process does not severely affect the quality of output images.**

I. Introduction

With the development of the Internet and social networking services, we widely use image processing applications. In general image processing, however, it is difficult to restore the original image after processing. The processing history or original image itself should be stored separately, when we desire to reconstruct the original image. Recently, reversible image processing methods based on reversible data hiding (RDH) have been paid attention. In particular, reversibility is strongly required in medical, satellite and military images. Particularly, many contrast enhancement methods with reversibility have been proposed [1]–[4]. Wu et al. proposed a histogram shifting (HS) based RDH method for grayscale images to achieve reversible contrast enhancement [1]. In this method, additional information is embedded into the image histogram to ensure the reversibility. Further, Wu et al. introduced pairs of adjacent pixels and applied an HS-based RDH method to the two-dimensional histogram. The method allows for reversible contrast enhancement while preserving the overall average luminance [4]. However, these methods are the techniques for grayscale images. When we apply them to color images with three color components, the hue may be distorted. Therefore, Wu et al. proposed another method that enhances the contrast of color images by referring to the HSV color space [5]. The method could enhance the contrast without the severe distortion of the hue and saturation. Nevertheless, the method does not completely restore the original image due to the rounding errors in most cases.

Here, a processed image is defined as an image that has no information for the reversibility. In contrast, an output image represents an image containing the additional information for the reversibility in this paper. Sugimoto et al. ensured the reversibility by embedding the additional information into the processed images to correct the rounding errors [6], [7]. While most previous methods have only discussed on reversible contrast enhancement, the method [7] enables not only contrast enhancement but also multiple functions with the reversibility. Moreover, these functions are independently executed from each other. The method uses the prediction-error expansion with HS (PEE-HS) method [8] in order to embed the additional information. Although the method allows multiple processing for saturation and luminance, the hue control is not considered.

In this paper, we propose a reversible tone control method that effectively enhances blue or red tone. The proposed method further mitigates visual distortion; the additional information is embedded into the B component of RGB images in enhancing red tone, and vice versa. Simulation results show the effectiveness of our color tone enhancement and also evaluate the effects of the data embedding process on the output image quality.

II. Preparation

A. Previous method [7]

Sugimoto et al. proposed a reversible image processing method that enables multiple functions for the luminance and saturation [7]. This method has five functions for the luminance component: contrast enhancement, sharpening/smoothing, and increasing/decreasing. Additionally, we can also improve the saturation. These functions can be applied independently from each other, and multiple functions can be combined together.

The HSV color space is used in the previous method. This space consists of the hue (H), saturation (S), and luminance (V). The color space conversion from RGB to HSV is given by

$$\begin{cases} H = \begin{cases} 60 \times \frac{G-B}{Max-Min} & \text{if } \textit{Max = R} \\ 60 \times (\frac{B-R}{Max-Min} + 2) & \text{if } \textit{Max = G} \\ 60 \times (\frac{R-G}{Max-Min} + 4) & \text{if } \textit{Max = B} \\ \text{undefined} & \text{if } \textit{Max = 0}, \end{cases} \\ S = Max - Min, \\ V = Max, \end{cases} \tag{1}$$

where Max and Min represent the maximum and minimum values in the RGB components of each pixel, respectively.

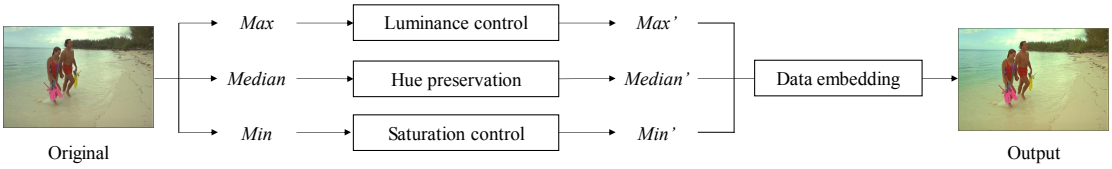

Fig. 1 Block diagram of previous method.

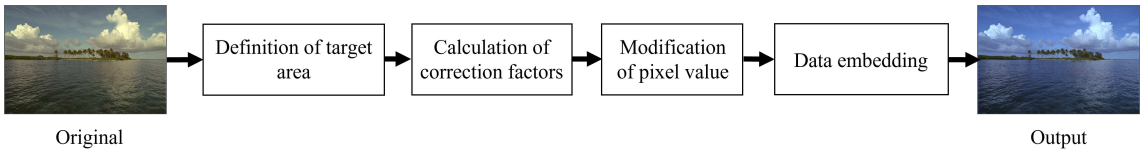

Fig. 2 Block diagram of tone control process.

Note that the median value is called $Median$. Figure 1 shows the block diagram of the previous method. The previous method indirectly controls HSV components by controlling Max, $Median$, and Min that are originally the R, G, or B value.

1) Luminance control: The luminance component is defined as an 8-bit grayscale image composed of the Max values of each pixel. The contrast is enhanced by applying the histogram equalization based RDH method [1] to the luminance component. The sharpening and smoothing functions are conducted by applying the specific spatial filter to the luminance component. Further, the luminance can be increased or decreased by raising or reducing Max. As can be seen in Eq. (1), however, Max affects not only the luminance component but also the saturation component. Therefore, the saturation is regularly distorted by changing Max simultaneously. In the previous method, Min should be adjusted to preserve the saturation before and after the process.

2) Saturation control: Based on Eq. (1), the saturation can be improved by increasing Max or decreasing Min. In the previous method, the saturation improvement is executed by decreasing Min in order to prevent from interfering with the luminance control. The intensity of improvement can be controlled by the decreasing amount of Min.

3) Hue preservation: Hue can be preserved by maintaining C_H. C_H is defined by

$$C_H = \frac{Median - Min}{Max - Min} \simeq \frac{Median' - Min'}{Max' - Min'}, \qquad (2)$$

where Max' and Min' refer to Max and Min after the processes in II-A1 and II-A2, respectively. $Median$ should be adjusted so as to preserve C_H without significant change.

4) Data embedding: Each of the above processes requires additional information to ensure the reversibility. For example, in section II-A2, Min is excluded from the process and stored as a part of additional information when Min should have a negative value after the process. The additional information is embedded by using the PEE-HS method [8].

The previous method achieved a full reversible image processing for the luminance and saturation without affecting the hue component. Thus, the hue control was not considered in the method. In the next section, we propose a reversible image processing method that controls blue or red tone.

B. $\mathrm{YD_bD_r}$ color space

The $\mathrm{YD_bD_r}$ color space consists of the luminance (Y), blue chrominance ($\mathrm{D_b}$), and red chrominance ($\mathrm{D_r}$). This space is used in JPEG2000 [11], which is one of the international standards on image coding. The color space conversion from RGB to $\mathrm{YD_bD_r}$ is given by

$$\begin{cases} Y = \lfloor \frac{R+2G+B}{4} \rfloor, \\ D_b = B - G, \\ D_r = R - G. \end{cases} \qquad (3)$$

The conversion between RGB and $\mathrm{YD_bD_r}$ can be conducted reversibly. Since $\mathrm{D_b}$ and $\mathrm{D_r}$ are obtained as integer values without causing rounding errors, we can flexibly control blue and red tones with the smaller amount of additional information.

III. Proposed Method

In this section, we propose a reversible image processing method that arbitrarily controls blue or red tone of color images. We describe the procedures of the tone control and restoration processes, respectively.

A. Tone control process

Figure 2 shows the block diagram of the tone control process in the proposed method. The RGB color space is first converted to the $\mathrm{YD_bD_r}$ color space, and then a target area is defined within the D_b-D_r plane. Here, the target area refers to an area, where the average color becomes an achromatic color after the tone control process. It should be noted that the $\mathrm{YD_bD_r}$ color space is used as a reference space, while the actual processing is performed in the RGB color space. The correction factors bring the average color of the target area

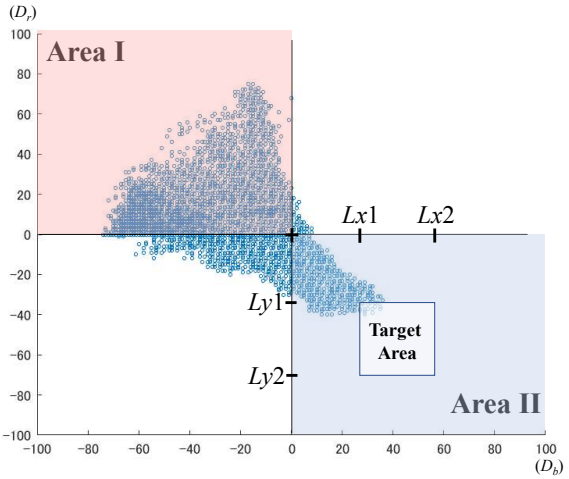

Fig. 3 Scatter plot of pixels in D_b-D_r plane.

to an achromatic color; they are calculated and multiplied by all pixels in the image. The RGB components of each pixel are represented as decimals, so they are rounded to integer values. Finally, the additional information required for the reversibility is embedded into the processed image using the PEE-HS method [8]. Detailed descriptions of each process are given below.

1) Definition of target area: The conversion from the RGB color space to the $\mathrm{YD_bD_r}$ color space is performed using Eq. (3). Figure 3 shows the scatter plot of pixels in the D_b-D_r plane. From this figure, the target area is determined from either area I or II. In defining the target area in area I, we enhance the blue tone. In contrast, we can enhance the red tone by defining the target area in area II. Additionally, the proposed method can control the enhancement intensity by adjusting the size and position of the target area using parameters *Lx*1, *Lx*2, *Ly*1, and *Ly*2. *Lx*1 and *Lx*2 ($|Lx1|<|Lx2|$) are located along the x-axis, while *Ly*1 and *Ly*2 ($|Ly1|<|Ly2|$) are located along the y-axis. Each value represents the distance from the origin. Therefore, these four parameters form a rectangular target area.

2) Calculation of correction factors: The averages of R, G, B, and Y of the pixels in the target area are represented as R_{ave}, G_{ave}, B_{ave}, and Y_{ave}, respectively. Correction factors are then calculated to ensure that R_{ave}, G_{ave}, and B_{ave} are analogous to each other. This leads to make the average color achromatic. R_{ave}, G_{ave}, and B_{ave} are rounded to integer values and stored as additional information. The correction factors for RGB components are obtained by

$$\begin{cases} K_r = (\frac{Y_{ave}}{R_{ave}}), \\ K_g = (\frac{Y_{ave}}{G_{ave}}), \\ K_b = (\frac{Y_{ave}}{B_{ave}}). \end{cases} \tag{4}$$

Here, K_r, K_g, and K_b are factors for the R, G, and B components, respectively. Since these factors are obtained as decimals, each pixel value should be rounded after multiplying by these factors. These rounding errors prevent the reversible restoration. For the reversibility, the locations of pixels affected by rounding should be stored as additional information called a location map. The location map is preliminarily compressed using JBIG2 [12]. However, K_g constantly exist in the range of 0.98 to 0.99 regardless of the enhancement intensity. This indicates that the effect by K_g on the multiplication process is significantly small. In order to reduce the amount of additional information, we define $K_g = 1.0$ in any case.

3) Modification of pixel value: The proposed method may cause overflows in the target component to be enhanced when the pixel value is multiplied by the correction factor. Thus, it is necessary to preprocess on the component to be enhanced. We first explore the maximum value P_{max} in the target component, which remains less than 255 after multiplication by the correction factors. All pixels, which exceeds P_{max}, are then replaced with P_{max}. The replaced pixels and their variations are stored in additional information. After preprocessing, the R and B components are multiplied by the correction factors so that the processed image with a red or blue tone enhancement is obtained.

4) Data embedding: For the perfect reversibility, additional information is embedded into the processed image using the PEE-HS method [8]. Based on Eq. (3), the G component more strongly affects the Y component than the other components. Namely, variations in the G component lead to severer visual distortion. In the data embedding process, the G component is thus excluded from the target. The additional information is embedded into the B component in enhancing red tone, and vice versa. The component data used to embed the additional information is stored in the least significant bit (LSB) of the top-left pixel of the G component. The LSB is replaced to 0 in embedding into the B component, and replaced to 1 in embedding into the R component.

The additional information consists of the followings: R_{ave}, G_{ave}, B_{ave}, the data to revert the preprocessing, and the original LSB of the top-left pixel of the G component. The proposed method can restore the original image using the additional information.

B. Restoration process

Figure 4 shows the block diagram of the restoration process in the proposed method. We describe each step in detail.

1) Data extraction: First, the component used to embed the additional information is identified by referring to the LSB of the top-left pixel of the G component. We extract the additional information, and the processed image excluding the additional information is reconstructed. The LSB of the top-left pixel of the G component is restored with the extracted data.

2) Calculation of correction factor: By assigning R_{ave}, G_{ave}, and B_{ave} to Eq. (3), the average luminance Y_{ave} of the target area is obtained. Correction factors K_r and K_b are then calculated by Eq. (4).

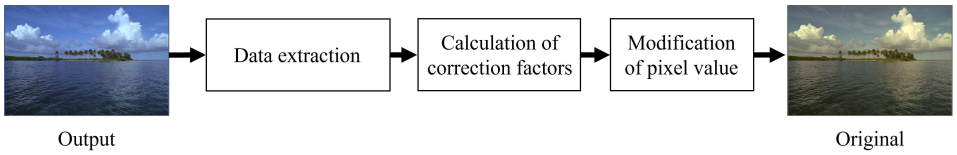

Fig. 4 Block diagram of restoration process.

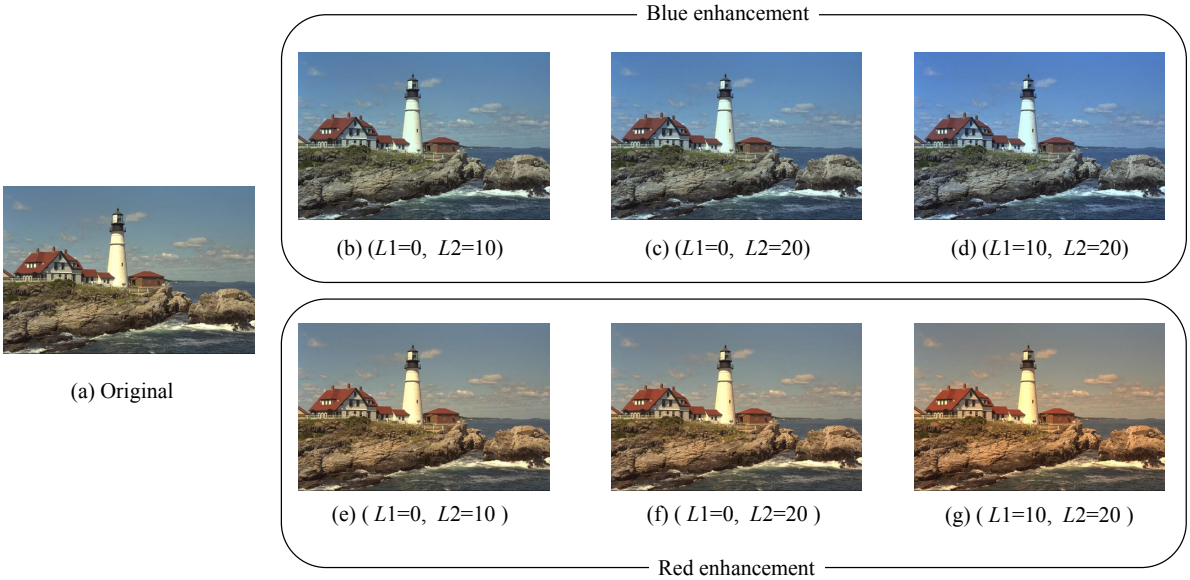

Fig. 5 Output images (kodim21).

3) Modification of pixel value: The R and B components of the processed image are divided by their respective correction factors so that the pixel values before correction are restored. By referring to the location map, the pixels affected by rounding are reverted to their originals. The pixels with P_{max} of the enhanced component are also reverted to the originals, and the original image is reconstructed.

IV. Simulations

In this section, we evaluate the image quality of output images through comparing scatter plots of pixels in the D_b-D_r plane between before and after the tone enhancement process.

A. Simulation conditions

We used five images with 512 × 768 pixels from the Kodak Lossless True Color Image Suite [13]. In this simulation, we defined each parameter as $|Lx1| = |Ly1|$ and $|Lx2| = |Ly2|$ to make the target area square, and denoted them as $L1$ and $L2$, respectively. The intensity of enhancement can be controlled by adjusting the size and position of the target area. We evaluated the output images obtained with parameters ($L1$, $L2$) = (0, 10), (0, 20), and (10, 20), respectively.

B. Evaluation of color tones for output images

Figure 5 shows the output images of kodim21 generated by the proposed method. The upper and lower images show the results of enhancing the blue or red tone, respectively. As the dimension of target area or the distance between the target area and origin is larger, the intensity of the enhancement strengthens. As can be seen from Figure 5, it is clear that ($L1$, $L2$) = (10, 20) is most effective for tone enhancement.

Figure 6 shows the scatter plots of pixels in the D_b-D_r plane for each image corresponding to Figure 5. The blue tone enhancement leads to the increment of D_b values and the decrement of D_r values, so the global distribution is shifted to the lower right direction. In contrast, in the red tone enhancement, the global distribution is shifted to the upper left direction. By increasing $L1$ or/and $L2$, the averages of D_b and D_r in the target area become farther from the origin. This provides the stronger enhancement for the target color tone.

Figure 7 shows the output images with ($L1$, $L2$) = (10, 20). In these output images, the enhancement of blue or red tone was effectively achieved. In each image, additional information was completely embedded, and thus the reversibility is guaranteed.

Table I shows the average correction factors calculated

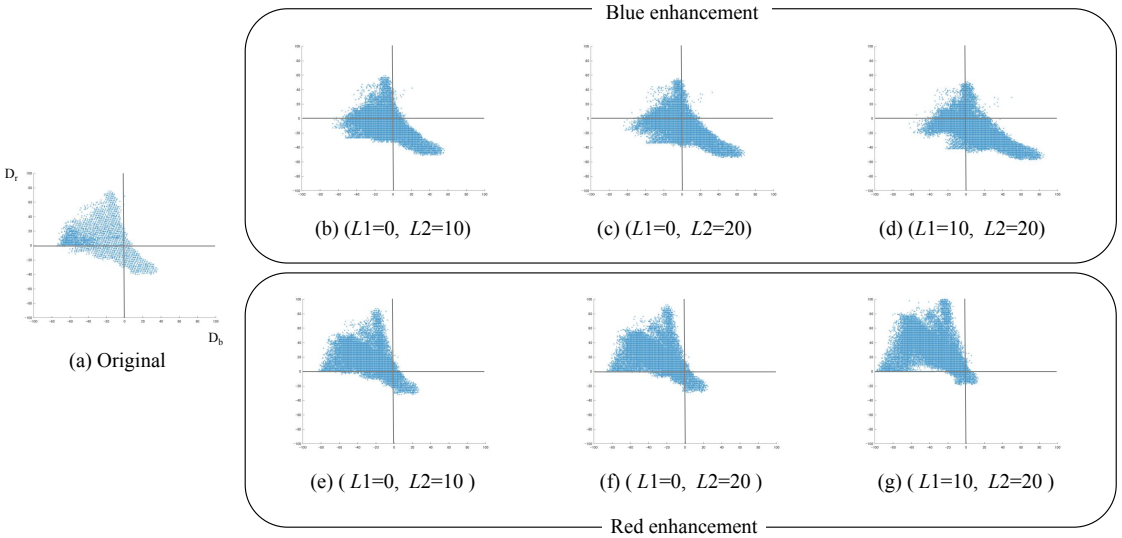

Fig. 6 Scatter plots of pixels in output images in D_b-D_r plane (kodim21).

Fig. 7 Output images in ($L1$, $L2$) = (10, 20).

for all the test images. It is obvious that the correction factor becomes larger/smaller by the increment of $L1$ than the increment of $L2$. This is because few numbers of pixels are distributed in the area far from the origin.

C. Effect of data embedding process on output image quality

We need to embed additional information into the processed image to ensure the reversibility. Generally, a data embedding process causes distortion in the marked image, i.e., output image. In this section, we examine the effect of the data embedding process on the output image quality. Table II shows the average values of PSNR and SSIM between the images before and after data embedding, i.e., the processed and output images. The quality of output images decreases with the increasing intensity of enhancement. As the correction factor becomes larger, the amount of additional information should increase. Nevertheless, the PSNR and SSIM values are relatively high, and it is difficult to visually recognize the artifacts in the output images.

V. Conclusions

We proposed a reversible tone control method that enhances blue or red tone in this paper. Since most previous methods aimed to only control the contrast enhancement, so the proposed method is a challenging approach. Through our

TABLE I Correction factors using tone control process.

	Blue enhancement		Red enhancement	
	K_b	K_r	K_b	K_r
($L1$, $L2$) = (0, 10)	1.1022	0.9289	0.9596	1.0632
($L1$, $L2$) = (0, 20)	1.1509	0.9075	0.9411	1.1126
($L1$, $L2$) = (10, 20)	1.3326	0.8277	0.8945	1.1715

TABLE II Quality assessment of output images.

	PSNR[dB]		SSIM	
	Blue enhancement	Red enhancement	Blue enhancement	Red enhancement
($L1$, $L2$) = (0, 10)	51.25	50.43	0.9968	0.9773
($L1$, $L2$) = (0, 20)	49.24	49.23	0.9930	0.9672
($L1$, $L2$) = (10, 20)	47.01	45.73	0.9974	0.9405

simulations, we confirmed that blue and red tones can be flexibly and reversibly controlled by using our method. In our future work, we will specifically investigate the effectiveness of the proposed method by using different image datasets and evaluation indices.

***Abstract*—Misinformation has become a major challenge in the era of increasing digital information, requiring the development of effective detection methods. We have investigated a novel approach to Out-Of-Context detection (OOCD) that uses synthetic data generation. We created a dataset specifically designed for OOCD and developed an efficient detector for accurate classification. Our experimental findings validate the use of synthetic data generation and demonstrate its efficacy in addressing the data limitations associated with OOCD. The dataset and detector should serve as valuable resources for future research and the development of robust misinformation detection systems.**

I. Introduction

The widespread dissemination of misinformation online, whether in news articles or brief tweets, represents a serious threat to information security and undermines public confidence in online information. The spread of rumors and misinformation can negatively affect people in many ways, such as by being influenced by misleading information, by being victimized by hate speech, by being aggrieved by racism, and by suffering psychological distress [1], [2]. Those who generate online misinformation often utilize multimodal misinformation, such as images and texts, to maximize the effect [3].

Since misinformation is usually accompanied by images to capture the readers' attention and add more credibility, a term has emerged to describe the occurrence of an image or text being taken out of its original context or when an image or text is manipulated so as to create misunderstandings and misrepresentations: "multimodal misinformation". One common form of multimodal misinformation is Out-of-context (OOC) which refers to separating authentic images and texts from their original context to change (or eliminate) the intended meaning, which can deceive the audience by making the information appear more credible. Despite its prevalence, the use of out-of-context images and texts remains one of the easiest and most effective ways to create realistically appearing misinformation [4], [5].

Unlike the deepfake generation, the generation of OOC does not require extensive technical knowledge or experience. Moreover, this type of manipulation is harder to detect since neither the image nor the text is distorted. Furthermore, misleading content can be produced in numerous ways [6], [7]. Existing deepfake detection methods are not helpful since the out-of-context relationship between the image and text is at the semantic level rather than at the signal level [8]. As a result, verifying such content relies heavily on manual fact-checking, which can be costly, time-consuming, and error-prone [9]. Therefore, there is a pressing need to develop machine learning-based algorithms as an alternative solution for automatically detecting OOC.

Several recent studies on detecting inconsistencies between images and texts have demonstrated promising performance on benchmark datasets. Existing methods have taken various approaches, such as relying on entities, context, or social media responses/reactions to posts, to identify such misinformation [10]. Notwithstanding the advancements made in this field, OOCD still has limitations, including a lack of relevance to real-world situations due to random mismatches in the training and testing datasets, the need for interpretable explanations to verify accuracy and understand the reasoning, the need for scalability to handle the increasing volume of misinformation in real-time, the dependence on specific languages (e.g., English) limiting applicability to other languages, the scarcity of labeled multimodal datasets, and the challenge of detecting and adapting to adversarial attacks based on misinformation. These limitations highlight the need for research and development of more robust and comprehensive methods for OOCD [11], [12].

In the work reported here, we addressed the challenge of OOCD. **First**, to address the data limitations, we devised a novel training and evaluation method that uses synthetic data generation to enhance the accuracy of OOCD models. Generating synthetic data, which does not require human labeling effort, expands the diversity and complexity of the training data, enabling the detector to better identify and classify instances of information that deviate from their surrounding context. Furthermore, we can address the problem of explainability by generating a synthetic multimodal dataset that aids in understanding the reasoning behind the detection. **Second**, we created a novel dataset for OOCD tasks. This dataset should be a valuable resource for future research and benchmarking. **Finally**, we developed a detector that leverages state-of-the-art machine learning algorithms and techniques to accurately identify OOC multimodal information. This work offers several benefits to the image-text OOCD field by improving the reliability and credibility of image-text data analysis.

II. Related Work

A. Available Datasets

Gathering large-scale labeled multimodal misinformation datasets is difficult due to their scarcity and the substantial manual effort required. Some examples of datasets that have been created for detecting multimodal misinformation include the MultimodAI Information Manipulation (MAIM) dataset [13] and the Multimodal Entity Image Repurposing (MEIR) dataset [14]. The MAIM dataset includes over 239K image-caption pairs with randomly mismatched falsified media. The MEIR dataset introduces swaps over named entities for people, organizations, and locations. It is based on the assumption that, for each image caption (package), there is an unmanipulated related package (geographically near and semantically similar) in the reference set. This enables the integrity of a query package to be verified by retrieving a related package and comparing the two.

Another such dataset is the TamperedNews dataset [15] in which named entities specific to people, locations, and events are randomly swapped with other named entities within the article body. These text manipulations can lead to strong linguistic biases. Zellers *et al.* [16] replaced image captions with synthetic ones that matched the images, which remained relevant to the article's content. The usefulness of image analysis on this task is rather limited, whereas analyzing the captions and the article body results in the best detection performance. The recently developed COSMOS dataset [17] contains 200K images and 450K captions, where each image is associated with two captions from two sources. The randomly chosen text is used to generate mismatched image-caption pairs. Most of the data in COSMOS is not labeled, although a small subset has been manually annotated as in- or out-of-context.

Another recently developed dataset is the Visual News dataset [18], which contains more than one million publicly available news images paired with both captions and news article text collected on a diverse set of topics from news sources in English (The Guardian, the BBC, USA TODAY, and the Washington Post). It was leveraged to create the Visual News Captioner, which generates captions by attending to individual word tokens, named entities in the input news article text, and localized visual features. It was used to create the NewsCLIPpings [12] dataset, a large-scale dataset designed for automatic retrieval of image-text pairs [18]. It contains 988K image-caption pairs for news media mismatch detection. Several strategies can be used to automatically retrieve suitable images for the given captions, including caption-image similarity, caption-caption similarity, person match, and scene match, to identify cases in which there are inconsistent entities or inconsistent semantic context. Finally, the Twitter-COMMs [19] dataset consists of multimodal tweets covering such topics as COVID-19, climate change, and military vehicles. It was created using the Twitter API v2 [1]. Hard negatives are created by retrieving the image of the sample tweet with the most textual similarity with a given caption (using the "Semantics / CLIP Text-Text split" method of Luo *et al.* [12]), and random negatives are created by selecting an image for a given caption at random to resolve the class imbalance of data collected from Twitter.

Several studies have focused on human-made fake news detection, resulting in the development of such datasets as FakeNewsNet [20] and Fakeddit [21]. Another study focused on creating a videos and captions dataset, i.e., a video-based dataset [2], that contains 4,000 real-world Facebook news posts with captions randomly taken from other posts to generate mismatched samples. It was developed for detecting semantic inconsistency between videos and captions in social media posts. The datasets relevant to the work reported here are summarized in Table I. The key differences, such as the image-text mismatch procedure used in each dataset, are highlighted.

B. Image Captioning

Generating a high-quality description of an image using natural language is the goal of image captioning. This is a challenging task for both humans and machines [22], [23]. However, recent advancements in large-scale vision-language models (VLMs) and large-language models (LLMs) have made it possible for models to generate captions that are increasingly difficult to distinguish from those generated by humans. Some models, such as OFA [24], Flamingo [25], and BLIP-2 [26], have demonstrated impressive performance in image captioning tasks. In certain evaluations, several approaches have been rated as good as or better than human users.

Researchers have explored various approaches, such as "Plug-and-play VQA" (visual question answering) [27], and "PromptCap" (Prompt-guided image Captioning) [28], to generating natural language prompts in conjunction with a generative pre-trained transformer (GPT) to achieve state-of-the-art (SOTA) performance in visual question-answering. Mokady *et al.* [29] utilized continuous embedding as a prompt for the GPT-2 model [30] to achieve strong single-viewpoint image captioning performance. Zeng *et al.* [31] used a CLIP-based model [32] to extract key tags from an image and then used the GPT-3 model [33] with a specialized prompt to generate an appropriate image caption.

C. Text-to-Image Generation

Deep generative models have achieved tremendous success in text-to-image (T2I) generation tasks and have recently attracted intensive attention. Existing T2I generation models can be categorized as GAN-based, VAE-based, and diffusion-based. Although GAN-based [34] and VAE-based models [35] synthesize images with promising quality and diversity, they still cannot match user descriptions well.

Diffusion-based models [36] have demonstrated unprecedentedly high-quality and controllable image generation and have been broadly applied to T2I generation tasks. They were first introduced into T2I generation with classifier-free guidance. The introduction of the DALL-E deep learning

model [37] made it possible to perform zero-shot T2I generation with arbitrary text input. It quickly inspired several follow-up models, including Glide [38], a text-guided diffusion model supporting both image generation and editing. It implements the text generation feature in the transformer blocks used in the denoising process. The CogView model [39] is a transformer with a vector quantized-variational autoencoder [40] tokenizer similar to that in DALL-E [37], and it supports Chinese text input. The Imagen model [41] has a T2I structure that does not use latent images and instead directly diffuses pixels using a pyramid structure. The Stable Diffusion model [42] is a large-scale implementation of the latent diffusion model (LDM) [43] that achieves T2I generation. These models use pre-trained large-scale text encoders to provide more controllable guidance signals. They either introduce super-resolution models or encode images into the low-dimensional latent space to achieve a trade-off between efficiency and high resolution.

D. Multimodal Misinformation Detection

Studies on MMD have focused on OOC image-text pairs or cross-modal named entity inconsistencies. Aneja *et al.* [17] proposed using a self-supervised approach to establish whether two captions accompanying an image are consistent. However, the unlabeled dataset they collected does not support veracity detection training and evaluation. Furthermore, the assumptions made about the availability of such a dataset may affect the model's feasibility in a generic test setting, and its disproportionate reliance on text mode may lead to an increased decision-level bias.

Luo *et al.* [12] leveraged the expressiveness of a large pre-trained contrastive model, CLIP [32], to classify mismatches on the basis of retrieval; in addition, they evaluated two VLMs, CLIP and VisualBERT [44], on the proposed dataset and achieved classification accuracies of 60.23% and 54.81%, respectively. They showed that both machine and human detection are limited, indicating that the task is challenging. Abdelnabi *et al.* [10] collected evidence for both visual and textual components for use in performing cycle consistency checks. However, relying on such external information for validity checks makes the entire approach very expensive, complex, memory intensive, and challenging to deploy in a generic test setting. Furthermore, in this use case setting, the primary objective was to verify the content of a news item quickly. Therefore, sufficient reliable information related to the news topic may not be available yet on the web.

Huang *et al.* [11] used two VLMs, CLIP and VinVL [45], for the multimedia inconsistency detection task. They encoded each image and its corresponding caption separately and then compared their embeddings; dissimilar embeddings suggested an out-of-context text-image pair. They evaluated their method on several large-scale datasets. However, their method does not address the potential biases in the VLMs used, which may have affected the accuracy of the OOCD. In addition, their method relies on the availability of textual information associated with the image, which may not always be available. The self-supervised distilled learner (SSDL) method devised by Mu *et al.* [46] uses two strategies to estimate the cross-modal consistency status in terms of a binary class label (Pristine or Falsified). However, the effectiveness of the SSDL approach relies heavily on the quality and accuracy of the annotated data used during the training phase. Errors and biases in the annotations can severely degrade the model's ability to learn and generalize effectively. Moreover, the SSDL approach fails to address potential biases or provide strategies for mitigating them. Furthermore, the training and fine-tuning of the self-supervised models are computationally intensive and take a considerable amount of time.

The method devised by Zhang *et al.* [47] detects OOC multimodal misinformation by using an interpretable neural-symbolic model. However, it does not address other types of misinformation and lacks empirical evaluation and comparison to other approaches. The model shows theoretical promise, but without thorough experimental validation, its effectiveness and superiority over other methods are uncertain. It is also subject to challenges like scalability, efficiency, and generalization across domains and languages, raising concerns about its practical viability. Table II summarizes existing methods for detecting multimodal misinformation.

III. PROPOSED APPROACH

Our proposed approach has distinctive features. Unlike existing approaches, it achieves remarkable results without relying on external sources or additional data to enhance and augment the learning process of the classifier. Furthermore, it eliminates the need to conduct Internet-based searches to validate the accuracy of the classifier's decision or to establish the connection between an image and the corresponding caption. These features will allow us to advance our approach further as the underlying models evolve.

A. Problem Statement

Detecting OOC is a challenging problem that not only stems from multimodal semantic mismatches but also from the lack

TABLE II
SUMMARY OF EXISTING MULTIMODAL MISINFORMATION DETECTION METHODS.

Work	Year	Models	Dataset	Method Description
Aneja *et al.* [17]	2021	spaCy NER, Mask-RCNN, Object Encoder, Universal Sentence Encoder, SBERT	COSMOS	Uses a self-supervised approach to establish whether two captions accompanying an image are consistent.
Luo *et al.* [12]	2021	CLIP, VisualBERT	VisualNews	Classifies mismatches on the basis of retrieval (CLIP and VisualBERT were evaluated on proposed dataset).
Abdelnabi *et al.* [10]	2022	ResNet152, sentence transformer, BERT + LSTM ,spaCy NER, CLIP	NewsCLIPpings	Collects evidence for both visual and textual components for use in cycle consistency checks.
Huang *et al.* [11]	2022	CLIP, VinVL	NewsCLIPpings & private datasets (DARPA)	Encodes an image and its corresponding caption separately and then compares their embeddings for multimedia inconsistency detection task.
Mu *et al.* [46]	2023	CLIP, SimCLRV2 , ResNet50	NewsCLIPpings	Uses two networks, Student Classifier (semi-supervised learning) and Teacher Network (self-supervised learning), for SSDL.
Zhang *et al.* [47]	2023	MLPs and SAFE, VisualBERT, CLIP, VINVL, FaceNet+BERT	NewsCLIPpings	Uses a hybrid model that combines a neural network and symbolic reasoning and captures context and semantics of content by using textual and visual information.

of mature problem definitions and datasets for evaluation. Deep neural networks require large amounts of data, and manual annotation is labor-intensive. Furthermore, the limited evaluation of real-world misinformation and the absence of comparisons with synthetic multimodal misinformation make it difficult to assess progress in the field. One of the main reasons for the spread of misinformation is the increasing use of generative AI to create multimodal misinformation. However, few methods exist to detect misinformation because annotated datasets are scarce. Our proposed approach is aimed at detecting OOC by using synthetic misinformation generated from the original dataset. This maximizes the utilization of limited annotated data by generating additional samples. We estimate the level of consistency between the multimodal data using the generated synthetic data, enabling us to assess the overall consistency within the original data. This estimation is performed as a binary classification (match or mismatch).

B. Data Preparation

Our approach involves the creation of synthetic data versions using the original image, caption, and label from the original dataset[12]. This process consists of two key steps. Firstly, Starting with the original image I, we utilize an image captioning model to generate a corresponding caption C'. Subsequently, employing a text-to-image T2I model, we generate an image I' based on the basis of the original caption C. As a result, our augmented dataset comprises the original images accompanied by their corresponding captions and the generated images and generated captions. The dataset preparation process is outlined in Figure 1.

1) Caption Generation: The process of generating a caption for the original image is performed using a pre-trained image captioning model to generate multiple captions on the basis of a given image. The captions produced are condensed into a single (summary) caption to create the output. Formally, given an image $I \in \mathbb{N}^{H \times W \times C}$, we aim to make a sequence of m tokens $x_1 ... x_m$ describing the image in some vocabulary V and produce a probability distribution $P(x_m \in V | I, x_1 ... x_{m-1})$, which is the probability of the next token in the sentence, given both the image and all the previous tokens.

We used the BLIP-2 [26] model and fine-tuned it specifically for the image captioning task. BLIP-2 is a vision-language pre-training framework designed to utilize large amounts of noisy

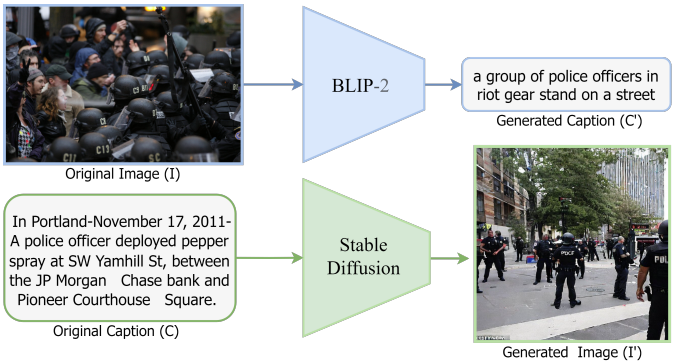

Fig. 1. Representation of steps involved in dataset preparation.

web data for effective pre-training. The model uses synthetic image-caption pairs from a seed captioning model and a filter to eliminate low-quality synthetic captions, resulting in a large dataset. BLIP-2 has shown remarkable transfer performance in many vision-language tasks, and it excels in zero-shot and fine-tuning scenarios for image captioning because the BLIP-2 model is trained on massive image and language datasets (the MS-COCO datasets [22]).

2) Image Generation: Our work uses an LDM [43] loaded with Stable Diffusion v1.4 weights to generate synthetic images. The Stable Diffusion model was trained on a subset of the LAION5B dataset [48] and generated (512×512) pixel images, which are then resized to the native image size of each dataset. To provide conditioning from text prompts, a frozen CLIP ViT-L/14 text encoder is used in conjunction with Stable Diffusion [41], [43]. Although LDMs can generate images from several different conditionings (image, text, semantic map), we only generated images using text prompts (captions). This enables zero-shot learning; it requires only a text prompt describing the contents of the image without any real images.

To generate images through text prompts, we require a prompt (caption) that describes the desired image's contents to guide the diffusion process. The prompt is first projected into an intermediate representation via CLIP's text encoder and then mapped to the intermediate layers of the LDM's denoising UNet using cross-attention [43]. This guidance helps the LDM diffuse a latent representation of an image starting

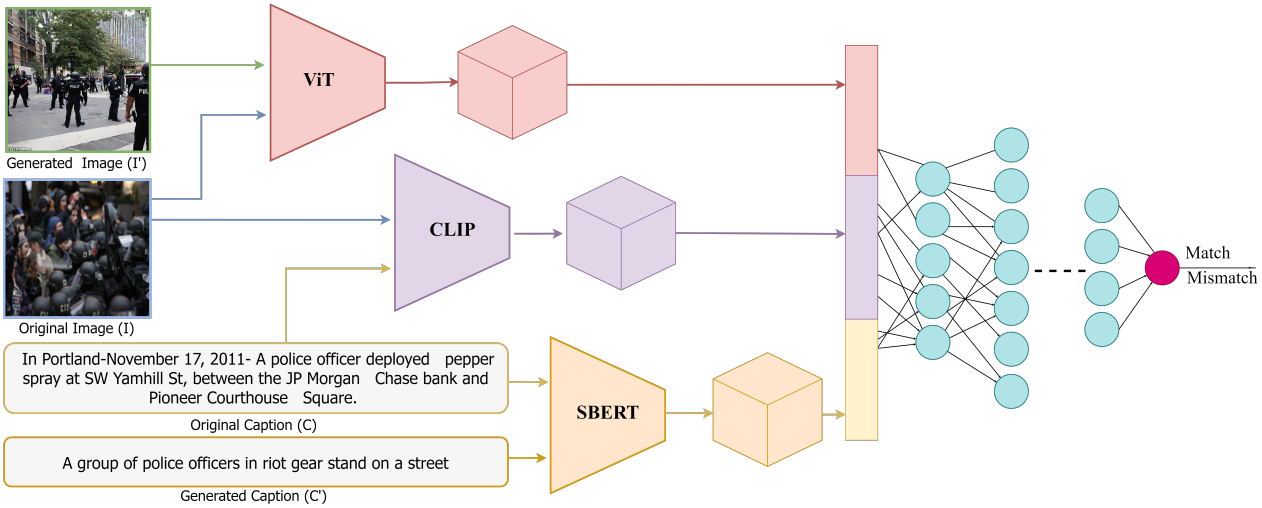

Fig. 2. Overview of our proposed approach.

from Gaussian noise. The resulting latent representation is then decoded back into the pixel domain to produce the final image.

Three primary hyperparameters control the generation process. One is the number of steps the denoising diffusion implicit model (DDIM) takes in the denoising process. More steps generally result in more realistic and coherent images, while fewer steps result in more disjointed and surreal images [36]. We generated synthetic images using 500 DDIM steps. The second hyperparameter is the unconditional guidance scale (UGC), which controls the scale between the precision of the generated image matching, the provided prompt, and generation diversity. This is accomplished by scaling between the jointly trained conditional and unconditional diffusion models [49]. A lower UGC value means less guidance and more diversity, while a higher value means more guidance and less diversity. The third hyperparameter is the Seed, which is the starting point for diffusion, generating the initial Gaussian.

C. Out-Of-Context Detection Model

Our proposed multimodal model, which effectively detects OOC by leveraging synthetic misinformation, is illustrated in Figure 2. Deep features are extracted from our dataset (I, C, I', C') and used by the classifier to more effectively train the model and to enhance its ability to discern patterns of consistency between pristine and falsified examples. These features are extracted from the original image I and caption C by using a pre-trained multimodal CLIP model [32]. Additionally, features are extracted from the original caption C and the generated caption C' by using Sentence-BERT [50]. A vision transformer (ViT) [51] is used to extract features from the original image I and the generated image I'. All of these features are concatenated and input into the classifier.

The output of the classification process yields one of two scenarios depending on the contextual relationship between the original image I and its corresponding caption C. In the first scenario, if the original image and caption (I, C) are within the same context, the generated image I' derived from the original caption will inherently share the context of the original caption C and align with the original image I. Similarly, the generated caption C' will be in the same context as the original image I, which is consistent with the original caption C. As a result, there is a high similarity between the original image and the generated image (I, I'), and between the original caption and the generated caption (C, C').

If the original image and caption (I, C) are out of context, the original image and the generated image $I, I')$ and also the original caption and the generated caption (C, C') will have low similarity scores, as follows:

$$((I, C, y) = \begin{cases} If \quad y = Match \\ High_{Similarity}((I, C), (C, C^{'}), (I, I^{'})) \\ \\ Otherwise \quad y = Mismatch \\ Low_{Similarity}((I, C), (C, C^{'}), (I, I^{'})) \end{cases}$$

where y denotes the label of the pair of the original image and caption (match or mismatch). $High_{Similarity}$ is defined as the highest similarity score among all pairs, indicating a high correlation between the image and caption. Conversely, $Low_{Similarity}$ is defined as the minimum similarity score among all pairs, indicating a low correlation between the image and caption.

IV. Experimental and Results

In this section, we describe our experimental setting and then present and analyze the results.

A. Dataset

We used the NewsCLIPpings [12] dataset, which consists of pristine and falsified OOC images. It was constructed on the basis of the VisualNews [18] corpus, which includes news articles from four major news outlets: the BBC, The Guardian, the Washington Post, and USA Today. The NewsCLIPpings dataset was constructed using various methods for automatically retrieving convincing images for a given caption, capturing cases with inconsistent entities or semantic context (such as text-text similarity or image-image similarity), etc. We use the Merged/Balanced dataset, which contains data representative of all retrieval methods and contains 85K balanced pristine and falsified examples, 71,072 training examples, 7,024 validation examples, and 7,264 test examples, divided into a 10:1:1 ratio. To initiate our generation-assisted detection approach, we used the original image-caption pairs as prompts to generate synthetic image-caption pairs, as illustrated in Figure 1.

B. Experimental Settings

We conducted two evaluation experiments to assess the merits of our proposed approach comprehensively. To establish the effectiveness and efficacy of our approach, we compared the results with those of previous studies. This comparative analysis serves as a robust validation of our proposed approach.

1) Experiment using Cosine Similarity: In the first experiment, we used CLIP (ViT-B/32) [32], a powerful model, to extract embedded features from the original image-caption pairs. This process yielded a 512-dimensional vector, represented as $(I_{embdCLIP}, C_{embdCLIP})$, for each pair. To quantify the similarity between the original image and caption (I, C), we used the cosine similarity metric to calculate $CLIP_{similarity}$. To evaluate the similarity between the original caption and the generated caption $(C, C^{'})$, we used Sentence-BERT [50] (all-mpnet-base-v2) for embedding both captions and obtained a 768-dimensional vector $(C_{embdSBERT}, C^{'}_{embdSBERT})$ for each pair. We then measured the similarity between their embeddings by using the cosine similarity metric, resulting in $SBERT_{similarity}$.

Furthermore, we used a vision transformer (ViT_L_16) [51] to extract the embeddings from both the original image and the generated image $(I, I^{'})$; this embedding yielded a 1,024 item vector, represented as $(I_{embdViT}, I^{'}_{embdViT})$, for each image. Using cosine similarity, we compared the embeddings of $(I, I^{'})$ to obtain $ViT_{similarity}$, thereby quantifying their similarity. Next, the three similarity values were fed into machine learning classifiers to distinguish patterns between the (I, C) pairs with coherent context and those with incoherent context. Table III presents the experimental results in comparison with those for four other classifiers.

2) Experiment using Feature Extraction: In the second experiment, we used feature extraction techniques to analyze the effectiveness of different feature map combinations. The feature maps were obtained from three models (see Figure 2), namely CLIP, Sentence-BERT, and Vision Transformer, as represented by $(I_{embdCLIP}, C_{embdCLIP})$, $(C_{embdSBERT}, C^{'}_{embdSBERT})$, and $(I_{embdViT}, I^{'}_{embdViT})$, respectively.

To analyze the feature maps, we followed a two-step approach. We first flattened each pair of feature maps and separately fed them into machine learning classifiers and a transformer designed for tabular data analysis. Next, we consolidated all the feature maps and fed them into both the machine learning classifiers and the transformer. To optimize the classification process, we utilized dimensionality reduction techniques on the combined set of concatenated features. This enabled us to reduce the complexity of the data while retaining important information. To thoroughly investigate the potential of different feature map combinations, we systematically evaluated multiple combinations. The results of these evaluations are summarized in Table IV.

TABLE III
DETECTION PERFORMANCE (IN %) BASED ON SIMILARITY SCORES

Model	Similarity					
	CLIP+SBERT		CLIP + ViT		CLIP+SBERT+ViT	
	ACC	AUC	ACC	AUC	ACC	AUC
SVM	66	72	65	72	67	73
Random Forest	62	71	62	67	67	72

Transformer	66	72	65	72	67	73

TABLE IV
DETECTION ACCURACY (IN %) BASED ON FEATURE MAPS

Model	Features		
	CLIP	CLIP+SBERT	CLIP+SBERT+ViT
SVM	50	50	54
Random Forest	49	50	52
XGBoost	52	53	55
MLP	53	55	56
Transformer	**56**	**60**	**62**

C. Discussion

OOCD presents substantial complexities due to the unaltered nature of the image and its accompanying caption. These two elements exist in separate contexts, often featuring the same names of individuals and places but with different temporal attributes, such as dates. This disparity between the image and its caption poses a considerable challenge in detecting the asymmetry, necessitating further efforts to develop robust models in the future. Despite these complexities, the results obtained with our proposed approach are highly encouraging, motivating the continued advancement of this approach.

Our proposed approach resulted in the highest accuracy among the approaches compared, surpassing other research in this field, as shown in Table V. This table compares our best experimental accuracy with those of previous studies using the same dataset without leveraging additional information to enhance the classification process. Further development of this approach is expected to yield even better results as future research introduces more powerful models capable of

accurately measuring the similarity between images or captions and providing improved image captioning.

The efficiency of our approach makes it potentially suitable for real-time operation, delivering prompt responses. This efficiency arises from the parallel implementation of the models used. Furthermore, alongside the OOCD model, we built a dataset of generated images from real captions that researchers in this and related fields can utilize as valuable resources in their work.

TABLE V
COMPARISON RESULTS OF OUR PROPOSED APPROACH WITH OTHER APPROACHES USING THE SAME DATASET.

V. CONCLUSION

Our proposed approach to Out-Of-Context detection uses synthetic data generation. The dataset and detector we developed enable the accurate identification of misinformation across various modalities. The results of extensive experimentation and evaluation validate the effectiveness of the proposed approach, with which a promising classification accuracy rate of 68% was achieved for misinformation detection. The dataset and detector should prove valuable for future research and facilitate the development of robust misinformation detection systems.

***Abstract*—The gait recognition system uses the characteristics of a person's gait to authenticate the individual. Generally, it applies a walking model to extract features from a captured video. In the conventional works, two types of methods have been studied: model-based methods, which extract features by fitting a person model on an image, and appearance-based methods, which extract features based on time-series silhouette images. In this study, we introduce a prediction operation to extract features in the model-based method. The proposed method consists of two machine learning models. One is a *keypoint prediction model* that uses OpenPose to estimate the skeleton and predict skeletal movements of a typical person. The other is an *identification model* that identifies individuals based on the difference between the keypoints and predictions of the target person. Our computer simulations show that the proposed method performs better in terms of identification accuracy than the method that directly uses skeletal coordinate data.**

I. Introduction

Since the stride length, arm swing, and posture during walking vary from person to person, gait is considered one of the biometric (biometa risk) methods for identifying individuals. In addition, in 2017, gait was taken up as a personal identification code in the enforcement order for laws and regulations concerning the protection of individuals under the revised Personal Information Protection Law in Japan, and is recognized as one of the biometric authentication methods. The method of authenticating individuals based on the individuality of their gait is called "gait authentication" [1]. Unlike biometric conditions such as fingerprints and iris, gait can be authenticated even when the subject is far away from the camera, making it the only modality that can authenticate individuals from a distance. For example, it is expected to be applied to forensic science using the images from security cameras, because it can be used even when face recognition is not possible due to low resolution.

The gait recognition is based on extracting feature expressions from video frames of the subject and matching them with stored data or using machine learning models to identify the subject. The approaches can be classified into two methods: model-based and appearance-based [2]. In model-based methods, gait parameters such as stride length and time series of joint nuclei are extracted as features by fitting a human body model to the target person in the input image. Appearance-based methods extract features from input video or silhouette image sequences by analyzing the components of variation over time and space. When using deep learning techniques to discriminate based on these features, high discrimination accuracy can be achieved if the features are computed in a feature space or metric space that is more suitable for discrimination.

Many model-based methods estimate skeleton by analyzing an video frames to extract features of them. One of popular skeletal estimation tool is OpenPose [3], [4]. Some studies perform repair and interpolation of skeletal estimation, while others discriminate gait features by latent intra-individual variation factors in the observed direction and gait recognition. In these studies, the feature points detected by the skeletal estimation are represented by XY coordinates and are directly used to the identification of individuals. However, due to characteristics such as camera angle and distance from the object, the amount of change in coordinates varies depending on the position of the person in the image, affecting the accuracy of identification.

In this study, we propose an identification method using the difference between the skeletal and predicted coordinates of the target person. The environment in which the proposed method is used is assumed to be an entry system in which a fixed camera is used to capture the entrance. Therefore, observers are limited to walking in one direction. Thus, we assume that a surveillance camera is capturing a pedestrian in front of it, the proposed gait recognition scheme attempts to identify the individual only from the video. In each frame of the captured video, the distance that the person's skeletal coordinates have moved horizontally and vertically is calculated. For feature points, preprocessing is performed such that the change in their coordinates is normalized. The proposed method composed of two machine-learning models: Keypoint Prediction Model (KPM) and Identification Model (IM). KPM is constructed by the long short term memory (LSTM) [5] trained to output the walking pattern of typical human. At first, we detect 25 skeleton keypoints by using OpenPose, and normalize them. Then, the future coordinates at each key point are then predicted, and the horizontal and vertical

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

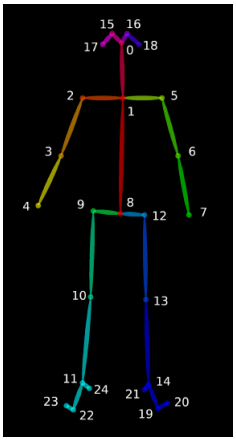

Fig. 1: 25 skeletal keypoints detected by OpenPose.

prediction errors are calculated as the feature values to be input to IM. Finally, individuals are identified from the IM output. Compared to methods that directly use the coordinates of skeletal keypoints, our computer simulations confirm that prediction errors are effective in obtaining feature components suitable for individual identification.

II. Related Studies

A. OpenPose

OpenPose [3], [4] is a real-time skeleton estimation algorithm developed at the Center for Technology Transfer and Enterprise Creation (CTTEC) at Carnegie Mellon University. It is capable of detecting a total of 130 key points in an image, including the human body, hands, and face. The execution time is constant regardless of the number of people in the image. It is a flexible, easy-to-configure, multi-threaded module that can save and load images in a variety of formats, including JSON, XML, PNG, and JPG. It uses Caffe, but the code can be ported to other frameworks such as Tensorflow and PyTorch. The keypoints of human the skeleton are the points estimated as joint points in the 25 regions shown in Fig. 1. In this study, we use these 25 keypoints for the Gait recognition.

B. LSTM

LSTM [5] is a machine learning technique that improves the layer that considers time series of RNN (Recurrent Neural Network) and eliminates the gradient loss problem. It solves the gradient loss problem by using gates to selectively retain relevant information and forget irrelevant information. Due to its low sensitivity to time differences, LSTM is better suited for analyzing time-series data than simple RNNs.

A typical LSTM block has memory cells, input gates, output gates, and forget gates, in addition to the hidden states in a conventional RNN. The memory cells store values over an arbitrary time interval. Weights and biases for the input gates control the amount of new values flowing into the cells. The weights and biases for the forget gates control how much value is retained in the cell, and the output gates control how much of the value in the cell is used to compute the activation state of the output of the LSTM block.

LSTM is widely used in natural language processing and has many other applications in speech and acoustic signal processing. We believe that LSTM can be applied to video images to effectively extract hidden features because the information in the frames changes over time.

The central idea of the LSTM architecture is a memory cell that can maintain its state over time and a nonlinear gate unit that controls the flow of information into and out of the cell. Several variants of the LSTM architecture have been investigated since the initial formulation of the LSTM architecture [5]. Due to the simplicity, we use the standard LSTM architecture implemented on the Keras environment in this study.

C. Previous Work

Many of the previous model-based studies on gait recognition have used skeletal information as it is. For example, there have also been studies on the influence of external factors such as camera position on identification accuracy [6], and identification using deep generative models that consider person labels such as age and gender as latent variables in the skeletal information [7]. These studies have improved identification accuracy by adding camera positions and latent variables as additional labels to skeletal information. Fig. 2 shows the flow of identification common to the previous studies. The video is divided into images at the frame rate, and skeletal estimation is performed. Since the video is divided into images, it is necessary to add the person ID, the video ID, and the time on the video as labels to the skeletal information for each image. In addition, the camera position and latent variables of the target person are added as labels. These datasets are identified using a discriminator.

III. Proposed Identification Method

A. Overview

The flow of the identification method proposed in this study is shown in Fig. 4 and Fig. 5. First, each frame of a video file is extracted with a specified frame rate using the FFMPEG tool[1]. Next, the human skeleton represented by 25 keypoints is detected by the OpenPose from each frame. Each keypoint is represented as XY coordinates $(x_i, y_i), (1 \leq i \leq 25)$ on the image. For each person, the coordinate of 25 keypoints at a certain time period is stored as a training data for keypoint prediction model (KPM). The model can predict the changes in 25 keyoints when a typical person walks. The difference between the predictions from LSTM and the keypoint coordinate values obtained directly from the training video by OpenPose (hereafter, the difference value) is calculated. Finally, the discriminator discriminates the video based on the difference values obtained from LSTM and the subject's label.

[1] https://ffmpeg.org/

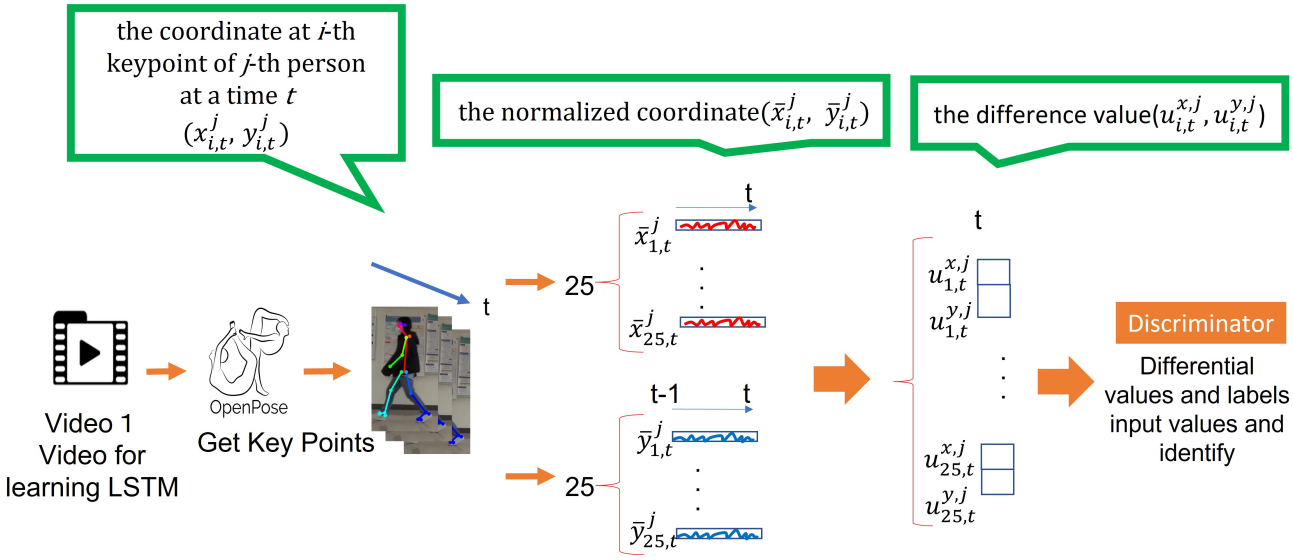

Fig. 2: Identification process using skeletal information.

B. Data Preprocessing

Skeletal coordinates obtained by OpenPose may be biased due to the difference of environmental perturbations. For example, If a person is walking left or right in front of the surveillance camera, the position of the person in the captured video frame will change, and the amount of difference in position will depend on the camera angle and distance from the object. Therefore, the range of coordinate changes will be biased. A normalization is performed on the skeletal coordinates of each person to cancel such a bias.

Suppose that a person is walking down a street on either side and the movements are captured by a surveillance camera at a certain continuous time. Let N be the number of individuals. The coordinate at i-th keypoint of j-th person at a time t is represented by $(x^j_{i,t}, y^j_{i,t})$. Then, the normalized coordinate $(\overline{x}^j_{i,t}, \overline{y}^j_{i,t})$ is calculated as follows:

$$\begin{cases} \overline{x}^j_{i,t} = \dfrac{x^j_{i,t} - x^j_{i,max}}{x^j_{i,max} - x^j_{i,min}} \\ \overline{y}^j_{i,t} = \dfrac{y^j_{i,t} - y^j_{i,max}}{y^j_{i,max} - y^j_{i,min}} \end{cases} \tag{1}$$

where

$$\begin{cases} x^j_{i,max} = \max\limits_t x^j_{i,t} \\ x^j_{i,min} = \min\limits_t x^j_{i,t} \\ y^j_{i,max} = \max\limits_t y^j_{i,t} \\ y^j_{i,min} = \min\limits_t y^j_{i,t} \end{cases} \tag{2}$$

C. Keypoint Prediction Model (KPM)

For predicting the changes of keypoint in captured video frames, we use two LSTM models for horizontal and vertical directions. In this study, we predict the XY coordinates at time t from the previous t_p consecutive coordinates. If these models are trained on a specific person's data set, high accuracy can be achieved in predicting XY coordinates. However, the need to train two LSTM models for each individual is time consuming and results in storage waste. The goal of KPM is to calculate horizontal and vertical prediction errors that are useful for individual identification. Therefore, we train these two LSTM models to output the general variation of pedestrians walking in front of a surveillance camera.

Two LSTM models shown in Fig. 3 are used to predict the time-series skeletal coordinate data. There are some hyper-parameters in LSTM in Keras environment. As 25 keypoints are detected by OpenPose, these LSTMs have a dimension of 25 for the input values. For its simplicity, we fix the number of nodes in hidden layer is 64. For these 25 coordinates at a time t, we use the coordinates at the last consecutive t_p time for prediction. The differences between the obtained 25 coordinates and predicted 25 coordinates are stored in a CSV file along with the person labels as prediction errors. This dataset is used as input values for the identification model.

The predicted coordinate $(\hat{x}^j_{i,t}, \hat{y}^j_{i,t})$ at i-th keypoint of j-th person at a time t is calculated by the following equation.

$$\begin{cases} \hat{x}^j_{i,t} = \text{LSTM}(\tilde{\boldsymbol{x}}^{\boldsymbol{j}}_{\boldsymbol{i,t-1}}) \\ \hat{y}^j_{i,t} = \text{LSTM}(\tilde{\boldsymbol{y}}^{\boldsymbol{j}}_{\boldsymbol{i,t-1}}) \end{cases} \tag{3}$$

where

$$\begin{cases} \tilde{\boldsymbol{x}}^{\boldsymbol{j}}_{\boldsymbol{i,t-1}} = \{\overline{x}^j_{i,t-t'} | 1 \le t' \le t_p\} \\ \tilde{\boldsymbol{y}}^{\boldsymbol{j}}_{\boldsymbol{i,t-1}} = \{\overline{y}^j_{i,t-t'} | 1 \le t' \le t_p\} \end{cases} \tag{4}$$

Then, the prediction errors $\delta^{x,j}_{i,t}$ and $\delta^{y,j}_{i,t}$ for horizontal and vertical directions are respectively obtained as follows:

$$\begin{cases} \delta^{x,j}_{i,t} = \overline{x}^j_{i,t} - \hat{x}^j_{i,t} \\ \delta^{y,j}_{i,t} = \overline{y}^j_{i,t} - \hat{y}^j_{i,t} \end{cases} \tag{5}$$

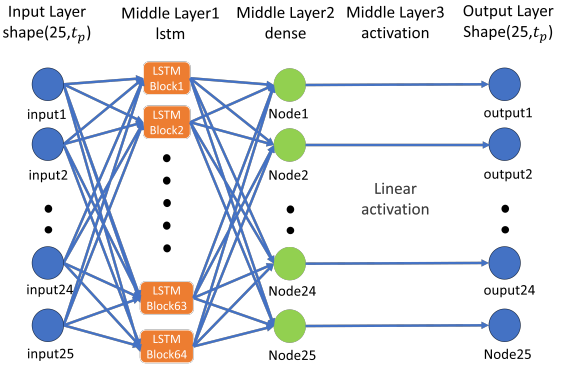

Fig. 3: Parameters in the LSTM model.

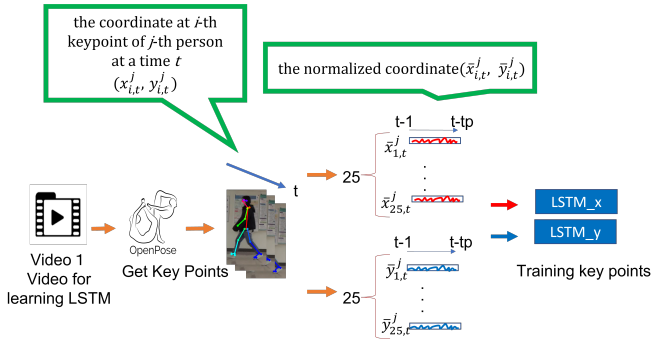

Fig. 4: Operation flow in the keypoint prediction model.

For training these LSTM models, the choice of optimization algorithm and loss function are important to improve the performance. In this study, Adam [8] is used as the optimization algorithm. Adam is a very popular optimization algorithm that combines conventional momentum and RMSprop [9]. Momentum is an algorithm that suppresses oscillations by moving averages, while RMSprop is an algorithm that suppresses oscillations by adjusting the learning rate.

We use the mean squared error (MSE) as the loss function, which is the sum of the squares of the differences between the correct and predicted values. Let $(\overline{x}_i, \overline{y}_i)$ and $(\hat{x}_i, \hat{y}_i)$ be the coordinates of the i-th keypoint for correct and predicted coordinates, respectively. Then, the MSE is calculated by the following equation.

$$MSE = \frac{1}{25}\sum_{i=1}^{25}\sqrt{(\overline{x}_i - \hat{x}_i)^2 + (\overline{y}_i - \hat{y}_i)^2} \tag{6}$$

This function overestimates errors because the larger the error, the easier it is to evaluate the error. On the other hand, it also overreacts to outliers in the dataset, which may result in learning that adapts to outliers (over-fitting).

D. Identification Model (IM)

IM identifies individuals based on the horizontal and vertical prediction errors obtained by KPM. The predictions (δ_x, δ_y) obtained by LSTM are converted to a 1D tensor and input to the discriminator. Without loss of generality, we assume that the video frame is consecutively captured at each time, and the horizontal and vertical directions of prediction error $\delta_i^{x,j}$ and $\delta_i^{y,j}$ are extracted during a time range from 1 to T.

$$\begin{cases} \Delta_i^{x,j} = (\delta_{i,1}^{x,j}, \ldots, \delta_{i,T}^{x,j}) \\ \Delta_i^{y,j} = (\delta_{i,1}^{y,j}, \ldots, \delta_{i,T}^{y,j}) \end{cases} \tag{7}$$

$$\Delta^j = \Delta_1^{x,j} || \Delta_1^{y,j} || \ldots || \Delta_{25}^{x,j} || \Delta_{25}^{y,j} \tag{8}$$

where "||" stands for a concatenation.

The discriminator identifies person labels (individual numbers) based on the difference values of skeletal coordinate data in XY coordinates. For this purpose, a 1D CNN as shown in Fig. 6 is used. In this study, since the identification target is not an image but XY coordinates, and the data is time series, we use 1D convolution and total. Since the identification target is not an image but XY coordinates and the data are time series, we use a combination of 1D convolution and all-connected layers [10]. Adam is used for optimization and categorical cross-entropy is used for the loss function in KPM.

IV. Experiments

In this experiment, we test whether the proposed method improves the accuracy of identification using difference values compared to identification using skeletal information as is. The same model discriminator was used for both methods, and the parameters were fixed. In addition, simulations were performed 10 times with the data randomly divided into 10 pieces. Experimental results are presented in terms of Accuracy and Loss for the Test of each simulation.

A. CASIA Gait

CASIA Gait [11] is a database created by the Chinese Academy of Sciences Institute of Automation (CASIA) for gait certification. There are three datasets in the database: Dataset A, Dataset B (multi-view dataset), and Dataset C (infrared dataset). The subjects in the video walk a predetermined straight course and are captured from various angles. The camera angle is recorded as 0° when horizontal and 90° when vertical to the direction of travel. In Database A, the camera angles are recorded at 0°, 45°, and 90°. In Database B, the camera angles are recorded from 0° horizontally to 180° in increments of 18°. Since the data used in this study is a walk from the right side of the screen to the left side, an angle of 90 degrees was used in the database. The camera used was a USB camera (Famtech 318SC) with a frame rate of 25 fps and an image size of 320×240 pixels. The data is stored in motion JPEG format. Details of the databases are shown in Table I. In this study, Dataset A and Dataset B are used.

B. Experiental Conditions

The CASIA Gait database was used in this simulation as shown in Table I. Two types of videos were used, DatasetA and DatasetB, each with 10 men and 10 women. In this study, LSTM learns up to the past 30 ($t_p = 30$). In IM, data are acquired with a sample time of 2 seconds ($T = 60$). Each video was divided into 2-second segments and treated as a single

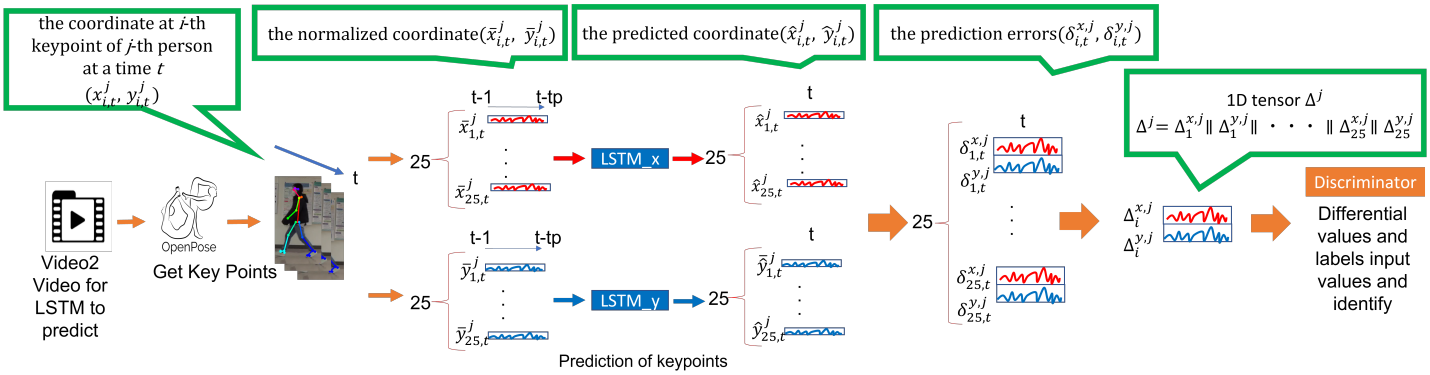

Fig. 5: Operation flow in the identification model.

TABLE I: CASIA Gait.

	Subjects	Sequences	Scenes	Condition change
DataSetA	20	240	Outdoors	Observation direction (3: front, oblique, side)
DataSetB	124	13640	Indoor	Observation direction (11:18° increments), clothing, objects carried
DataSetC	153	612	Night/Infrared	Speed, Objects carried

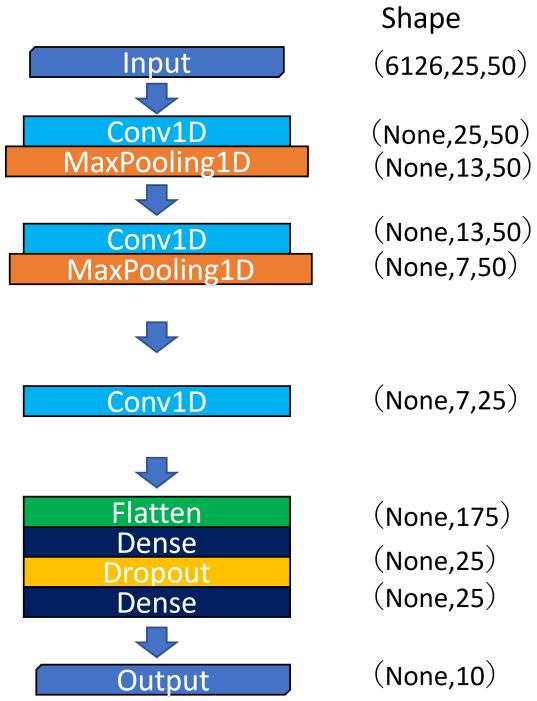

Fig. 6: Parameters in the discriminator.

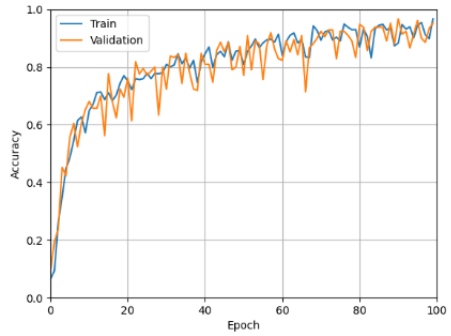
data set. The total number of videos is 40 and the number of data is 2400. Since data augmentation was performed, the total number of data is 4800.

Two types of datasets are used in this study. One is the skeletal coordinate data and person labels of the videos used as the LSTM dataset, and the other is the prediction errors and person labels used as the discriminator dataset. The datasets are divided into train for training, validation for validation, and test for testing, respectively, to verify the accuracy and loss of the model. In this study, we use 10% of the dataset as validation for the LSTM dataset and 20% of the dataset as validation for the discriminator dataset. In addition, test is performed when all training has been completed.

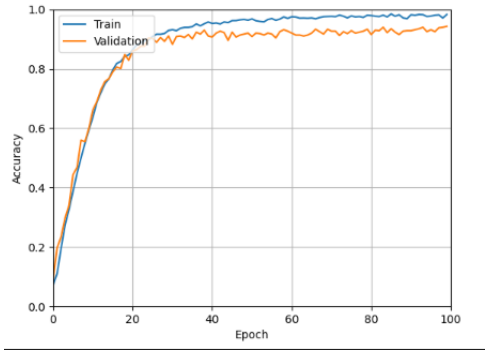
The CASIA Gait video used as the database is a 412KB AVI file. The frame rate is 30 fps, and it is divided into images with a similar frame rate for skeletal estimation in OpenPose. The performance of the computer used is based on the recommended specifications of OpenPose. The performance of the computer used in this study is based on Windows 10 OS, Core(TM) i7-1165G7 CPU, and 16 GB memory.

C. Methods using Skeletal Information



The flow of the identification method without LSTM (This method is henceforth referred to as Baseline.) is shown in Fig. 2. Compared to the proposed method, it does not calculate the prediction error in LSTM. This method uses only skeletal information obtained from the video using OpenPose. When the normalized coordinates are $(\overline{x}^j_{i,t}, \overline{y}^j_{i,t})$, the amount of movement $(u^{x,j}_{i,t}, u^{y,j}_{i,t})$ from the time $t-1$ to t is calculated as follows:

$$\begin{cases} u^{x,j}_{i,t} = \overline{x}^j_{i,t} - \overline{x}^j_{i,t-1} \\ u^{y,j}_{i,t} = \overline{y}^j_{i,t} - \overline{y}^j_{i,t-1} \end{cases} \tag{9}$$



In addition, the same discriminator is used for both the conventional and the proposed methods in order to correctly detect the effect of LSTM on discrimination accuracy. In addition, the Baseline method uses the same video set that was used to train the IM for the prediction method. On the other hand, the Baseline method does not use the same dataset used in training KPM.

D. Identification Accuracy and Loss

The training accuracies of the proposed method and the method using skeletal information are shown in Fig. 7. From

(a) Baseline

(b) Proposed

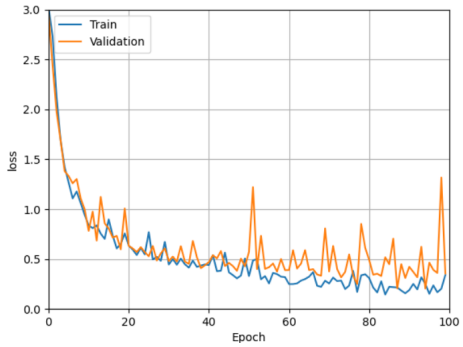


Fig. 7: Transition of discrimination accuracy in the training process.

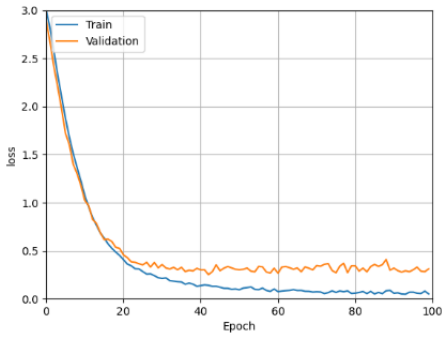
TABLE II: Test accuracy in IM.



Proposed	0.9785
Baseline	0.9546

the trains in the figure, we can see that the accuracy of both methods is high during training. The accuracy of the skeleton-based method is higher than that of the proposed method at each epoch. This is due to differences in the input values used by each method. The proposed method uses prediction errors, therefore, fluctuations in accuracy and loss values are small. On the other hand, the Baseline method is varies widely even if normalization is performed. The same cause as the training accuracy can be considered from the loss during the training of Fig. 8.

The average of 10 trials in test accuracy is shown in Table II. The test accuracy of the proposed method is 2.5% higher than that of the method using the skeleton information. The mean values of the test losses are shown in Table III. Due to the fluctuations on the loss values in the Baseline method, the average of test loss becomes much larger than the proposed method in this experiment. Because of the stability of the performance, we can say that the prediction errors introduced in the proposed method is useful for the gait recognition system.

(a) Baseline

(b) Proposed

Fig. 8: Transition of loss values in the training process.

TABLE III: Test loss in IM.

Proposed	0.0819
Baseline	0.9710

E. Time Consumption

The proposed method and the Baseline method are shown in Fig. 9. From each method, the processing time is divided into the video segmentation time, OpenPose processing time, LSTM prediction time, and discriminator time. For both methods, OpenPose accounted for about 90% of the total processing time. On the other hand, LSTM's forecasting time was about 3% of the total. This result indicates that the processing time of the forecasting methods is about the same as that of the Baseline method. The processing time of the proposed method increased by about 4% compared to the processing time of the baseline method.

V. Conclusions

In this study, we proposed a method to identify skeletal coordinate data of video images by calculating prediction errors using LSTM. Specifically, we proposed a method for discriminating skeletal coordinate data from videos using OpenPose and LSTM, and compared the accuracy of the proposed method with a method using skeletal coordinate data from videos without LSTM. In the future, we aim to further improve the accuracy by adjusting the LSTM model to obtain the prediction error and the discriminator model. In this study,

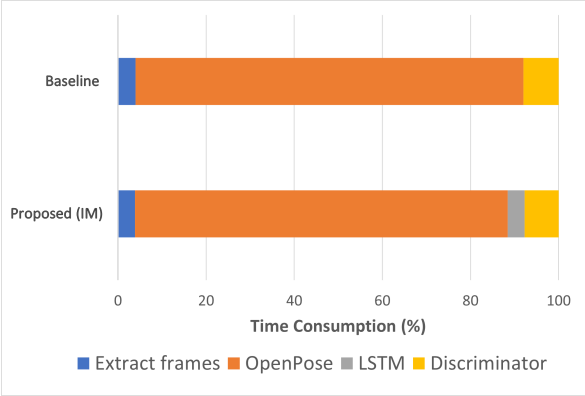


Fig. 9: Percentage of time consumption in each operations.

only time-series skeletal coordinate data and person labels were used to create the dataset. However, actual time-series skeletal coordinate data is strongly affected by intra-individual variables such as observation direction, clothing, and presence or absence of luggage. In the future, we aim to improve the discrimination performance by constructing a discrimination model that takes such factors into account.

***Abstract*—Federated Learning (FL) is a method to perform a deep learning technique with distributed nodes without aggregating their individually collected data. Each node can keep its own dataset secret, and a central server aggregates the updated parameters in a deep learning model from each node. However, it is reported that FL is vulnerable to poisoning attacks on training data. In this study, we propose a method to exclude biased nodes by analyzing the statistical characteristics of the weight parameters sent by each node to the central server. In the computer simulation, we evaluate the detection accuracy of biased node, and conduct discussions.**

I. Introduction

With the improvement of data mining technology, various studies have been conducted on deep learning to extract useful information from data collected and accumulated everywhere. In fact, there is a growing trend of utilizing deep learning with the data possessed by companies and hospitals. However, there are limitations to the data that each organization can collect. Furthermore, there are challenges in using such data for training across organizations due to privacy concerns, as the data held by organizations often contains personal information.

To address this problem, the idea of Federated Learning (FL) was proposed by McMahan et al. in 2017 [1]. FL allows machine learning to be performed in a decentralized manner without aggregating the data. FL has been studied using various techniques [2], and one of the representative methods is Federated Averaging (FedAvg) [1]. In FedAvg, each node holds its own dataset for privacy protection, and communication between distributed nodes is facilitated through a central server. This central server distributes the parameters of the Deep Neural Network (DNN) model to each node and aggregates the updated parameters from each node.

However, FedAvg faces the problem of performance degradation when there are malicious nodes among the distributed nodes. If the parameters received from such malicious nodes are aggregated to update the DNN model, the overall performance of the system can be compromised. In fact, research by Bagdasaryan et al. [3] demonstrates the vulnerability of FL to poisoning attacks against the training data, and even more so to poisoning attacks against the learning model. As the number of nodes participating in FL increases, the threat of data poisoning, whether intentional or unintentional, is heightened. Some nodes may intentionally set a backdoor in their trained DNN model and upload the parameters to the central server. Additionally, there is a possibility that the collected data from each node may lack reliability due to fluctuations caused by device and environmental differences. Concerning poisoning by malicious nodes, there must be a significant bias in the weight parameters, as the model may be trained to classify samples with labels different from their true labels. On the other hand, addressing the impact of fluctuations caused by non-malicious nodes remains a challenge. Additionally, when the number of malicious or non-malicious nodes changes per round, the number of nodes to be removed may vary. It is necessary to calculate and consider the number of nodes to be removed for each round by taking into account this variation.

In this study, we propose and evaluate a method for excluding biased nodes in FL so that the DNN model is protected against malicious party and it is correctly updated in the distributed training process, where biased nodes includes malicious and non-malicious ones. It is assumed that the number of biased nodes varies per round. The proposed method attempts to find biased nodes whose proportion of weight parameters following a Gaussian distribution falls below a certain threshold. We focus on the weight parameters that each node sends to the central server and explore a method to prevent performance degradation by excluding nodes that exhibit outliers compared to legitimate nodes. To numerically validate the effectiveness of this proposed method, we perform statistical analysis using hypothesis testing on the received parameters from each node. We demonstrate the relationship between the analyzed parameter characteristics and the accuracy of the global model, thereby confirming the validity of the approach.

From our computer simulations, it is possible to determine with a proposed measurement for the confidence level whether biased nodes are participating. Furthermore, it has been confirmed that excluding such nodes with a significant number of weight parameters that do not follow a normal distribution among the weight parameters transmitted from each node during the training process of FedAvg is beneficial.

II. Federated Learning

FL [4] is a method of performing machine learning in a distributed manner without aggregating data.

A. Overview of FL

Consider a general FL system consisting of one server and N nodes as shown in Fig. 1. Let D_i denote the local database held by node C_i, and M_i denote the local model, where $i \in \{1, 2, \ldots, N\}$.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

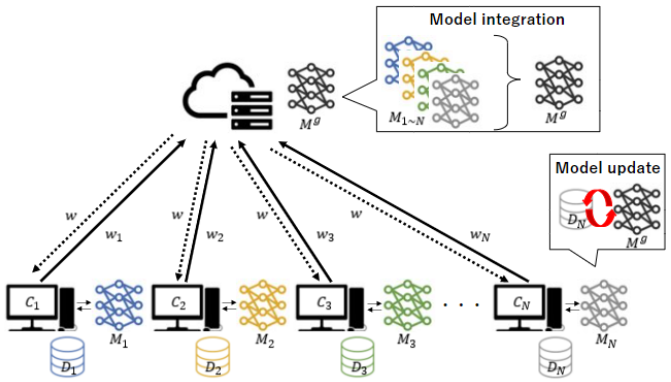

Fig. 1. Federated Learning

The purpose of the server is to train a model on the data present on N nodes. The active clients participating in local training need to find the weight vector $\boldsymbol{w}$ of the deep learning model that minimizes the loss function. Generally, the server aggregates the weight parameters received from N nodes as shown in the following equation.

$$\boldsymbol{w} = \sum_{i=1}^{N} p_i \boldsymbol{w_i}, \tag{1}$$

where $\boldsymbol{w_i}$ is the vector of weight parameters trained at node i, $\boldsymbol{w}$ is the parameter vector aggregated by the server, and p_i is calculated $p_i = \frac{|D_i|}{|D|} \geq 0 \quad (\sum_{i=1}^{N} p_i = 1)$, $|D| = \sum_{i=1}^{N} |D_i|$. Here, $|D_i|$ is the total amount of data samples held by node i. Furthermore, the optimization problem of these weight parameters can be formulated to find $\boldsymbol{w}^\star$ as shown in Eq. (2).

$$\boldsymbol{w}^\star = \arg\min_{w} \sum_{i=1}^{N} p_i F_i(\boldsymbol{w}, D_i), \tag{2}$$

where $F_i(\cdot)$ is the local loss function of node i, which is given by the local empirical risk. The learning process of such an FL system usually involves the following five steps, repeated to update the model. This sequence of steps is referred to as a round.

Step 1: Node selection: The server selects the nodes to participate in the round.
Step 2: Distribution of global model to selected nodes. (In the first round, the parameters of the global model are randomly determined.)
Step 3: Local model update: Nodes train and update the distributed model using their own locally held data. The updated model is referred to as the local model.
Step 4: Transmission of local model parameters to the server.
Step 5: Global model update: The server aggregates the transmitted parameters and updates the global model.

In FL, N nodes with the same data structure collaboratively train deep learning models using the server. After a sufficient number of local training and updates between the server and the nodes, the solution to the optimization problem in Eq. (2) can converge to the global optimal solution of the learning model. In this study, we used the Flower [5] FL library to conduct FL.

B. Federated Averaging

FedAvg [1] is one of the representative methods in the research on FL. In FedAvg, each node holds its own dataset for privacy protection, and communication among distributed nodes is facilitated through a central server. This server distributes the parameters of the learning model to each node and aggregates the updated parameters from each node. The aggregated parameters are then integrated into a single model for learning by taking the weighted average.

In FedAvg, the aggregated parameters are computed by taking the weighted average as shown in Eq. (3) in each round.

$$\boldsymbol{w^t} = \sum_{i=1}^{N} \frac{n_i}{n} \boldsymbol{w_i^t}, \tag{3}$$

where t represents the round number, $\boldsymbol{w^t}$ is the parameter of the global model integrated by the server in the t-th round, n_i is the number of data samples for node i, n is the total number of data samples, and $\boldsymbol{w_i^t}$ is the parameter of the local model trained by node i and sent to the server in the t-th round. The following shows Algorithm1 for FedAvg.

Algorithm 1 Calculate Federated Averaging. C is the fraction of nodes that perform computation on each round. The N nodes are indexed by i; B is the number of local epochs, and η is the learning rate. $P_i = n_i$. $\nabla l(\boldsymbol{w}; b)$ is the gradient for loss function.

Server executes:
  initialize $\boldsymbol{w^0}$
  for each round $t = 1, 2, \cdots$ **do**
    $m \leftarrow \max(C \cdot N, 1)$
    $S_t \leftarrow$ (random set of m nodes)
    for each node $i \in S_t$ in parallel **do**
      $\boldsymbol{w_i^t} \leftarrow \text{NodeUpdate}(i, \boldsymbol{w^{t-1}})$
    $\boldsymbol{w^t} \leftarrow \sum_{i=1}^{N} \frac{n_i}{n} \boldsymbol{w_i^t}$
NodeUpdates(i,w): //Run on node i
  $B \leftarrow$ (**split** P_i **into batches of size** B)
  for each local epoch k from 1 to E **do**
    for batch $b \in B$ **do**
      $\boldsymbol{w} \leftarrow \boldsymbol{w} - \eta \nabla l(\boldsymbol{w}; b)$
  return w **to server**

C. Existing Model Poisoning Attacks in Federated Learning

Various attacks [3],[6]–[9] have been proposed to poison the global model in FL, and all these attacks rely on compromised legitimate nodes. Based on the attacker's objective, these attacks can be categorized into two types: non-targeted model poisoning attacks [7],[9] and targeted model poisoning attacks [3],[6],[8]. Non-targeted model poisoning attacks aim to decrease the test accuracy of the global model. On the other hand, targeted model poisoning attacks, which is known as Byzantine attack [10] aim

to make the global model output the attacker's chosen target label for a selected target input. The objective of the attacker is to maximize the accuracy of the trained model on the specific data, while ensuring that the model performance on the other data does not degrade significantly. The attacker makes a backdoor in the model during the training phase by injecting the data which label is flipped to one of the labels. This research focuses on untargeted poisoning attacks.

D. Defense Strategies Against Model Poisoning Attacks

Several defense strategies[7],[10]–[16] have been proposed to mitigate model poisoning attacks in FL, and they can primarily be divided into two categories. The first type of defense strategies [10]–[14], [16] focuses on designing Byzantine-robust aggregation rules. Their idea is to reduce the influence of statistical outliers in the updates of local models. For example, Trimmed-mean [10] removes the maximum and minimum values from the local model updates before calculating the average. In addition, SparseFed [17] employs a technique where the central server calculates the aggregated gradients and only updates the parameters corresponding to the top k absolute values in the model. The second type of defense strategies [18],[19] aim to provide provable guarantees against poisoning attacks.

III. Proposed Method

In this study, we investigate methods to prevent the degradation of overall system performance in FedAvg caused by the bias in the weight parameters. First, we consider the biased nodes assumed in this study and examine the impact of their participation on the system performance. Next, we focus on the weight parameters sent to the central server and investigate the differences between biased nodes and legitimate nodes. We propose a method based on a statistical analysis to protect the model by excluding outliers in the weight parameters transmitted from each node. Specifically, we propose a method for excluding nodes in FedAvg where the number of biased nodes varies from round to round, and the number of nodes to be removed changes accordingly, by excluding nodes that have a proportion of parameters following a Gaussian distribution below a certain threshold.

To numerically validate the effectiveness of this proposed method, we will conduct statistical analysis using hypothesis testing on the parameters received from each node. We will demonstrate the relationship between the analyzed parameter characteristics and the accuracy of the global model, thus confirming its validity.

A. Biased Node

As the number of nodes grows, it becomes more difficult to manage the soundness of the FL framework. A malicious party could inject poisoning data into the training dataset at some nodes and secretly embed a backdoor into the model centralized on a central server. Even if all nodes are trusted, the local data obtained at each node could be biased by environmental differences or unintended bugs in the system.

We suppose to train a CNN-based image classifier which predicts a label of given image. It is assumed that the biased nodes include both malicious and non-malicious nodes. The difference of these nodes are described as follows.

- Malicious node
  Images which labels have been changed from ground-truth are intentionally added to the training dataset in the node.
- Non-malicious node
  Some images collected at the node may have labels different from the ground-truth due to some occasional reasons such as environmental noise or system bugs.

It is reasonable to assume that the number of malicious nodes is rather smaller than the non-malicious nodes. In addition, the number of mislabeled images in the dataset at the malicious nodes are assumed to small so that the amount of changes in the DNN model parameters is managed to be as small as possible.

Here, we consider the following two rates in the biased nodes.

- Poisoning Rate: R^{poison}
  It is the rate of images in the dataset that are mislabeled.
- Bias Rate: R^{bias}
  It is the rate of biased nodes among all nodes in FL framework.

In both cases, we attempt to detect the biased nodes by analyzing the irregularity in the weight parameters transmitted to a central server.

B. Consideration on Excluding Outlier Weight Parameters

It is conceivable that weight parameters transmitted from biased nodes within the distributed network deviate significantly from the weight parameters of legitimate nodes, potentially exhibiting outliers. In this study, we examine whether excluding nodes that transmit outlier weight parameters is a valid approach in FedAvg.

We focus on the weight parameters transmitted to the central server, and the differences between biased and legitimate nodes. At each epoch, the central server checks the validity of weight parameters uploaded from each node by calculating the difference between the weight parameters at the server in the previous epoch and the weight parameters updated at each node. In general, the differences are assumed to follows a Gaussian distribution with zero mean. If the dataset for training at a certain node is biased, the Gaussian assumption is no longer valid.

In this study, we use a CNN model as an image classifier. As shown in Fig. 2. We observe all weight parameters of the fully connected layer, which is composed of the nearest to the output of the CNN. The weight observations are performed at the same position for each node to ensure consistency.

The validity of the weight parameters transmitted from each node is determined by assessing whether they follow a normal distribution. The accuracy of the globally integrated model at the central server is used to perform a comparative analysis between models that include biased nodes and models composed only of legitimate nodes.

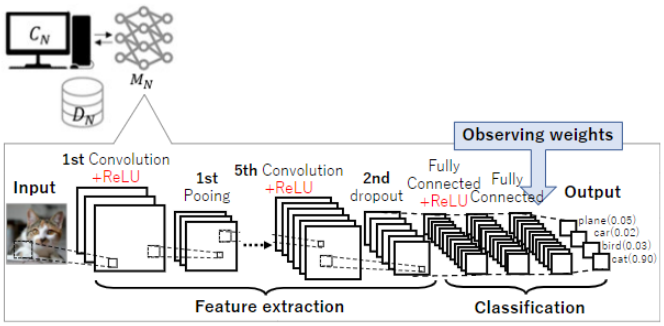

Fig. 2. Observation of weight parameters at the same location

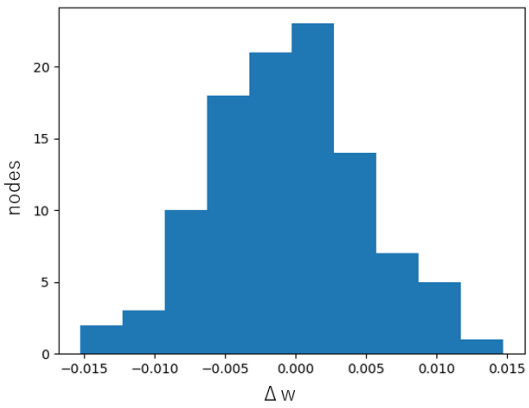

Fig. 3. Histogram of weight parameters of legitimate nodes.

C. Analyzing Weight Distributions

We investigate the statistical distribution of weight parameters received from each node. When evaluating the statistical distribution of weight values, we employ a histogram, quantile-quantile (Q-Q) plot, and the Shapiro-Wilk test. The Q-Q plot is a probability plot that takes the expected values of observations based on a normal distribution on the y-axis and the observations themselves on the x-axis. By determining the percentiles (cumulative probabilities) from the ranked order of observations and predicting the expected values using the inverse function of the probability density function of the normal distribution, we can assess if the observations follow a normal distribution. If the plot aligns along a straight line, it indicates that the observations follow a normal distribution.

The Shapiro-Wilk test [20] is a statistical method used to examine whether data follows a normal distribution by calculating the test statistic W and p-value and performing a hypothesis test to determine if the data follows a normal distribution. There are two types of tests for normality: the Shapiro-Wilk test and the Kolmogorov-Smirnov test. In this study, we utilize the Shapiro-Wilk test due to the small sample size (100 data points) obtained. The definitions of the test statistic W and p-value are provided in Eq. (4) and Eq. (5).

$$W = \frac{\left(\sum_{i=1}^{n} a_i x_{(i)}\right)^2}{\sum_{i=1}^{n}(x_i - \bar{x})^2}, \tag{4}$$

where n represents the sample size, a_i denotes the ranks of the samples, x_i is the sample data, $x_{(i)}$ represents the ranked sample data, and $\bar{x}$ is the sample mean.

$$p = 1 - \left(\frac{\sum_{i=1}^{k} b_i^2}{\sum_{i=1}^{n}(x_i - \bar{x})^2}\right), \tag{5}$$

where k represents the sample size, b_i represents the standard normal percentiles of the ranks, x_i is the sample data, and $\bar{x}$ is the sample mean.

In this study, the null hypothesis (H0) and the alternative hypothesis (H1) are set as follows:

Null hypothesis (H0): The data follows a normal distribution.

Alternative hypothesis (H1): The data does not follow a normal distribution.

The confidence level is set to 95[%], and when $p < 0.05$, it is considered statistically significant. Thus, if the test result shows $p < 0.05$, it is concluded that the data does not follow a normal distribution, while $p \geqq 0.05$ indicates that it cannot be concluded that the data does not follow a normal distribution (i.e., it follows a normal distribution).

D. Preliminary Experiment

To examine the characteristics of the weight parameters transmitted from biased nodes, we conducted partial observations of the same positions of the parameters transmitted from legitimate nodes and the biased nodes subjected to an extreme poisoning attack.

In the case of legitimate nodes, the histogram and Q-Q plot results of the weight parameters are shown in Fig. 3 and Fig. 4. It is observed from the figures that the weight parameters follow normal distribution. The Shapiro-Wilk test calculated based on Eq. (5) yields $p = 0.8845 \geqq 0.05$, indicating that the weight parameters follow a normal distribution at a significance level of 5[%].

Next, we measure the weight parameters of biased nodes subjected to the case of $(R^{\text{bias}}, R^{\text{poison}}) = (1.0, 0.5)$, which

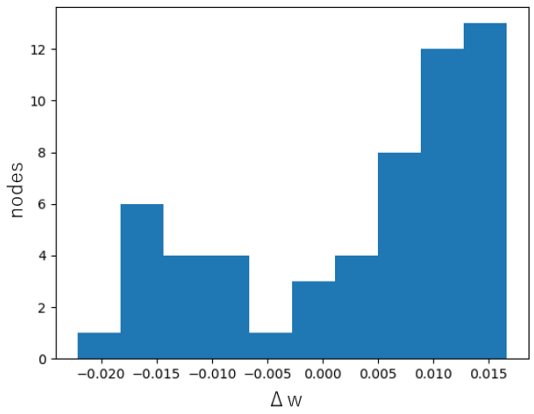

Fig. 5. Histogram of weight parameters in the case of $(R^{\text{bias}}, R^{\text{poison}}) = (1.0, 0.5)$.

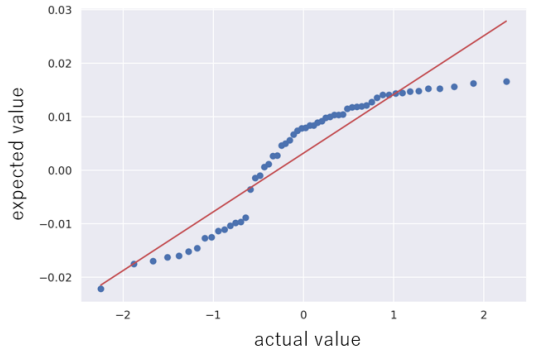

Fig. 6. Q-Q plot of weight parameters in the case of $(R^{\text{bias}}, R^{\text{poison}}) = (1.0, 0.5)$.

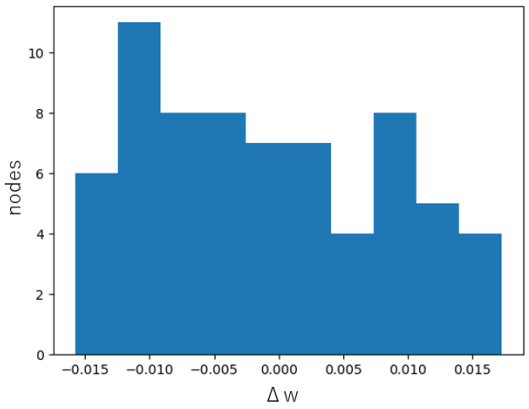

Fig. 7. Histogram of weight parameters in the case of $(R^{\text{bias}}, R^{\text{poison}}) = (0.5, 1.0)$.

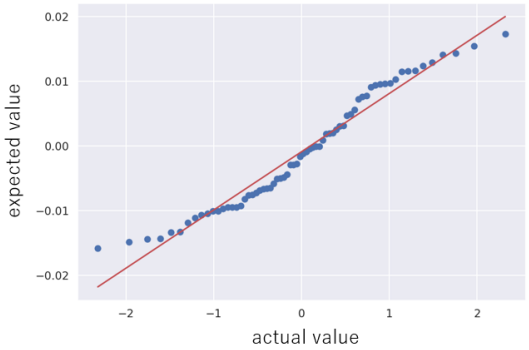

Fig. 8. Q-Q plot of weight parameters in the case of $(R^{\text{bias}}, R^{\text{poison}}) = (0.5, 1.0)$.

results are shown in Fig. 5 and Fig. 6. The Shapiro-Wilk test calculated using Eq. (5) gives $p = 0.0172 < 0.05$, indicating that the weight parameters do not follow a normal distribution at a significance level of 5[%]. In case of $(R^{\text{bias}}, R^{\text{poison}}) = (0.5, 1.0)$, the results are shown in Fig. 7 and Fig. 8. Since the Shapiro-Wilk test is $p = 0.00003 < 0.05$, the weight parameters also do not follow a normal distribution.

From these results, it can be speculated that as the poisoning rate increases for both nodes and data, the proportion of parameters in the fully connected layer of the CNN that do not follow a normal distribution increases. In other words, for each position of the parameters sent by all nodes, the number of parameters with Shapiro-Wilk test statistic $p < 0.05$ is increasing. Therefore, we examined the change in the proportion of normally distributed parameters for all parameters in each node as the poisoning rate varies.

E. Integration

Let $\boldsymbol{w}^t$ represent the weight parameters of the initial model (global model) distributed to the N nodes in the t-th round, and let $\boldsymbol{w}_i^t$ represent the weight parameters transmitted from the i-th node. The difference in weight parameters between the weight parameters transmitted from each node and the weight parameters of the initially distributed model, denoted as $\Delta \boldsymbol{w}_i^t$, can be calculated using Eq. (6).

$$\Delta \boldsymbol{w}_i^t = |\boldsymbol{w}_i^t - \boldsymbol{w}^t| \tag{6}$$

In this study, an analysis was conducted on all L weight parameters comprising the fully connected layers. The update amount, $\Delta \boldsymbol{w}_i^t$, of the L weight parameters $\boldsymbol{w}^t$ was calculated every N nodes. Subsequently, the normality of the update amounts, $\Delta \boldsymbol{w}_i^t$, for the same locations sent by each of the α nodes was determined using the Shapiro-Wilk test statistic, $\mathcal{P}' = \{p_i \mid p_i < 0.05, (1 \leq i \leq L)\}$. Then, the ratio of weight parameters with normality among all weight parameters in the fully connected layers, denoted as p_{rate}, can be calculated using the following Eq. (7):

$$p_{\text{rate}} = \frac{L - |\mathcal{P}'|}{L} \tag{7}$$

IV. Computer Simulation

We conducted experiments to measure the irregularity observed at the weight parameters transmitted from biased nodes.

A. Experimental Conditions

In this study, a CNN image classifier with the structure shown in Fig. 9 was used for the classification of 10 classes using the MNIST dataset. The MNIST dataset consists of a total of 70,000 images and labels, with 60,000 images used for training and 10,000 images used for testing. Among the training data, 90[%] (54,000 images) were used for training, 10[%] (6,000 images) for validation, and all 10,000 images from the test data were used for testing. Additionally, these datasets were divided equally among the nodes of FL, meaning that each node used $54,000/N$ images for training, $6,000/N$ images for validation, and $10,000/N$ images for testing, where N represents the number of nodes. Therefore, each node had its own unique dataset, replicating the scenario where each node possesses distinct data in the FL process.

The FedAvg algorithm used in this study trained the model with $\alpha = 100$ nodes. The number of weight parameters observed in this experiment is $L = 5120$, where the last FC layers has 512 nodes and the output is 10 classes. Fig. 10 shows that the accuracy converged to 99.25[%] after 500 rounds of training with a local minibatch size of 10 and a local epoch of 1. The hyper-parameters used in the FedAvg implementation in this study are shown in Table I.

There are various types of malicious nodes that can be considered in FedAvg. In this study, we use FedAvg to train a deep learning model for image classification on the MNIST dataset. Therefore, the malicious nodes considered in this study are nodes that have maliciously modified the labels of the MNIST dataset's 10 classes. Such poisoned data are crafted by modifying the label number ℓ of the MNIST dataset to a new label number ℓ' as follows:

$$\ell' = (\ell + 1) \mod 10 \tag{8}$$

This modification changes the original label ℓ to a different label ℓ' by incrementing it by 1 and taking the modulo 10. In case of non-malicious node, we also use the same modification as the malicious node in the experiments. Thus, biased nodes with the bias rate R^{bias} are trained by the poisoned data crafted by Eq.(8) with the poisoning rate R^{poison}.

The change in image classification accuracy of the integrated model at the central server due to the participation of biased nodes, as compared to when only legitimate nodes participate, was examined in this study.

B. Experimental Results

Based on the proposed method described in Section III-C, we evaluate the changes in classification accuracy and the proportion of normally distributed parameters in the weight parameters using computer simulations by varying the poisoning rates of each node and dataset in FedAvg. For each node and its dataset, we observed the changes in the proportion of normally distributed parameters by varying the poisoning rates as described in Scenarios 1 and 2 below:

- Scenario 1: malicious
  The number of malicious nodes is small, and the biased rate is fixed to $R^{\text{bias}} = 0.01$. The poisoning rate is varying from the following range: $R^{\text{poison}} \in [0.02, 0.5]$.
- Scenario 2: non-malicious
  The number of non-malicious nodes is relatively large, and the poisoning rate and bias rate are varying from the following range: $R^{\text{poison}} \in [0.2, 1.0]$ and $R^{\text{bias}} \in [0.02, 0.5]$

The changes in classification accuracy and the proportion of normally distributed parameters for Scenarios 1 and 2 are shown in Fig. 11 and Fig. 12, respectively. Both values are calculated from an average of five simulations. As the poisoning rates increase, both the classification accuracy and the proportion of normally distributed parameters decrease.

When $R^{\text{bias}} = 0.01$, which means even when one node contains poisoned data, an increase in the data poisoning rate leads to a tendency of decreasing both the classification accuracy and the proportion of normal distribution parameters. Furthermore, it was observed that an increase in R^{bias}, rather than R^{poison}, leads to a decrease in the proportion of normal distribution parameters.

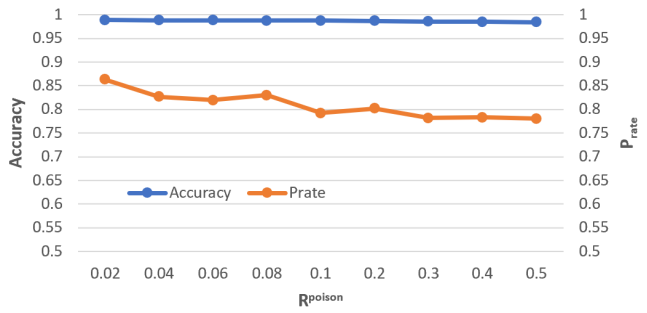

Fig. 11. Comparison of accuracy and p_{rate} in Scenario 1.

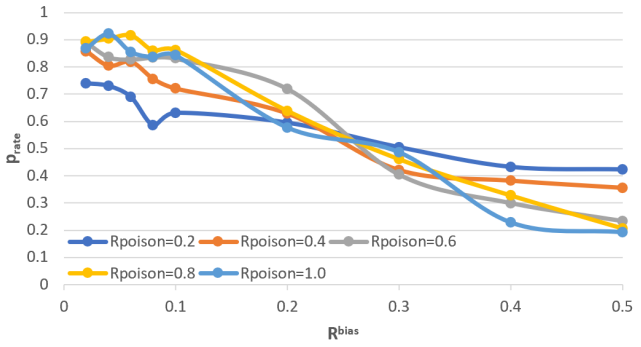

Fig. 12. Comparison of p_{rate} in Scenario 2.

C. Discussion and Challenges

In this study, we conducted an investigation and proposed a method to prevent the overall performance degradation of the system by excluding biased nodes in FedAvg.

Based on the results in Section IV-B, it was observed that the classification accuracy of the aggregated model decreases as the poisoning rates increase. Additionally, regarding the normality of weight values, it was shown that increasing poisoning rates lead to biases away from the normal distribution, resulting in a higher proportion of weight values with non-normal distributions.

The evaluation of the proportion of normally distributed parameters with respect to the poisoning rates indicated a tendency for more weight values to become non-normal as the poisoning rates increase.

From these results, it can be inferred that as the poisoning rates increase, the performance of the aggregated model decreases, and there is an increase in the proportion of weight values with non-normal distributions. Therefore, when the proportion of normally distributed parameters is low for all parameters in FedAvg, it indicates the presence of biased nodes.

To minimize the impact of poisoning, it is crucial to manage the poisoning rates of each node and dataset and limit the increase in non-normal weight values. One potential approach could be excluding nodes that contributed to lowering the proportion, i.e., nodes with a higher number of outlier parameters during p-value calculation.

Furthermore, considering the non-normal distribution of weight values, it is important to explore weight aggregation methods and retraining strategies that account for the impact of poisoning.

V. Conclusions

In this study, we investigated a method to protect the performance of the aggregated model in the FedAvg algorithm by excluding nodes that transmit outlier weight values, aiming to mitigate the impact of biased nodes.

Through the experiments, we demonstrated that the weight values transmitted from legitimate nodes in FedAvg tend to follow a normal distribution. This understanding of the statistical properties of weight distributions is valuable and can contribute to the development of techniques for detecting and handling outlier weight values.

Furthermore, we found that by examining the proportion of parameters that follow a normal distribution, we can consider the possibility of the participation of biased nodes. By excluding nodes that contribute to the decrease in the proportion of normally distributed parameters, which include more parameters that contribute to the decrease, we can effectively exclude biased nodes.

For future prospects, it is important to further research and improve methods for detecting and excluding biased nodes in federated learning. Exploring approaches that consider a larger number of weight locations can accurately identify outlier weight values, leading to more effective protection of model performance. Additionally, it is necessary to validate the effectiveness of these methods in FL approaches other than FedAvg. Moreover, we should consider extending experiments to different datasets, like RGB images (e.g., CIFAR-10). This will allow us to assess the generalizability of our proposed bias detection and exclusion methods across various data types. Additionally, it is crucial to evaluate the proposed method with different network architectures, such as ViT, to ensure its applicability and robustness in various neural network structures.

***Abstract*—StArtGAN is a constructive-based coverless data hiding framework, that generates various classes of art images to represent secret bits. These generated art images will be collated to form a collage image that carries the secret data. In certain data hiding applications such as watermarking applications, robustness is an important factor to be considered in such a data hiding framework. Therefore, in this paper, we will investigate the robustness level of StArtGAN. Six common image processing operations with multiple variants are applied as the robustness attacks to the collage image output from StArtGAN to examine its classification accuracy (or secret data extraction accuracy) and its perceptual qualities after these attacks. The result proves that this framework is robust to Salt & Pepper Noise, Gaussian Noise, Sharpening, Gaussian Filter, and Compression Attacks.**

I. Introduction

Coverless image data hiding abolishes the utilization of cover images during the secret data embedding process. There are two types of coverless data hiding in image [1], namely the non-constructive- and the constructive-based methods.

The non-constructive-based coverless image data hiding methods usually involve selecting suitable images from the image dataset to represent secret data using special formulas [2], [3]. These methods can perform data hiding without embedding; however, a large image dataset is required to identify a set of suitable images. Besides, they also suffer from low embedding capacity and often have tedious output image transmission protocol since it involves more than one image.

On the other hand, constructive-based coverless data hiding approaches generate stego images from secret. The first approach was introduced by Otori and Kuriyama in 2007 [4] and 2009 [5]. Otori and Kuriyama propose to create a textual output image by generating local binary patterns in the blank image based on the secret data. In the early years of the constructive-based coverless data hiding domain, most of the works are focusing on generating pattern or texture images [6], [7], [8]. The application is rather limited due to the restriction of the constructed output.

Later, inspired by the generative adversarial network (GAN) [9], [10], various constructive-based data hiding models using GAN are proposed [11], [12], [13], [14]. However, [12] and [13] methods are not coverless as they used the GAN model to generate a cover image for data hiding to reduce the detection rate and enhance the robustness level. Hu et. al method [11] uses GAN to embed secret data directly while the image is generated; however, this method suffers from a high bit error rate. In 2021, Ng et. al proposed StArtGAN [14] that generates classes of tiny art images to represent secret bits. These art images will be selected and arranged according to the secret data, and combined as a collage image. This method is not only able to achieve scalable embedding capacity, but the bit error rate is also lower as compared to the other similar methods.

However, can StArtGAN withstand image processing attacks? High robustness to image processing attacks is crucial in some applications, such as watermarking applications, or applications that require noisy transmissions or storage in the cloud, to ensure that the embedded secret data remains recognizable or readable after some interruption. Hence, in this paper, we investigate the robustness level of StArtGAN against some common image processing attacks, which include various noises, filters, and image compression. Section II will present a brief review of the StArtGAN constructive-based coverless data hiding framework. Then, Section III will show the experiment results and analysis for robustness tests using various image processing operations. Section IV will discuss the overall robustness level of the StArtGAN and other similar methods. Finally, Section V concludes the findings of this paper.

II. Revisiting StArtGAN [14]

A. StArtGAN Framework

StArtGAN framework prioritizes the generation of ambiguous art images with high classification accuracy. It consists of a generator and a discriminator. The trained generator will be used as the encoder to generate the art images based on the secret classes, whereas the trained discriminator will act as the decoder to decode the classes of the generated image. For more information on the StArtGAN framework, we refer the readers to [14].

B. Embedding Steps

In this work, the grayscale secret image $G(i, j)$ consists of $W \times H$ pixels will be first converted into 8 bits binary secret, $\Gamma(i, j)$. The $\Gamma(i, j)$ is reshaped into 1 dimension array, ϕ, and divided into multiple chunks $\rho = \phi/\gamma$, where each chunk $\gamma = \log_2 \eta$ bits each and η is the total number of image classes. The ρ is relabelled into φ by performing an XOR operation using a key κ and mapped to the corresponding art image class c to be fed into trained StArtGAN for generation of art images G_A. The G_A are then combined into collage images G_C for transmission.

Aerial Baboon Boat Cameraman Clock Lena Pepper Pirate Plan Woman

Fig. 1: The 10 secret images.

TABLE I: Sample binary secret relabelling using $\kappa = 101$ when given $\eta = 8$.

Secret Relabelling								
γ	000	001	010	011	100	101	110	111
φ	101	100	111	110	001	000	011	010
c	5	7	6	2	4	3	0	1

As an illustration, when $\eta = 8$ classes of art images are generated, each chunk $\gamma = \log_2 8$ represents 3 bits. By using $\kappa = 101$ to perform the XOR operation, every different 3 bits will be relabelled into φ and mapped to the corresponding classes. The sample of relabelling and mapping is illustrated in Table I.

C. Decoding Steps

At the receiver end, the G'_A will be extracted from the received G_C and fed into the trained discriminator of StArtGAN to output the corresponding image image class c'. The c' will be reversely mapped to the φ' and relabelled into γ' using κ. The γ will be joined into a string of ϕ'. Every 8 bits of the ϕ' will be converted into the corresponding pixels to regenerate the original grayscale image $G(i, j)$' with $W \times H$ pixels.

III. Experiment Results

In this experiment, 10 images are obtained from the USC-SIPI Image Dataset [15] and used as the secret image. To prepare these secret images, they are first transformed into 8-bit grayscale images of size 64×64 pixels. These transformed grayscale images are shown in Fig. 1. Then, for each image, the image pixels are collected and linearized in a top-down, left-right manner. Finally, the linearized pixels are converted into binary form as secret bits. The rest of the secret image embedding process will be similar to those steps mentioned in Section II. The StArtGAN is trained using the WikiArt Dataset [16] to generate the secret class into multiple 32×32 art images and combine them into collages.

A. The Image Processing Operations

In the experiments, the collage images generated from the StArtGAN model will be put on the robustness test. In particular, six common image processing operations are applied and act as an attack in the robustness experiments: (1) Salt & Pepper Noise, (2) Gaussian Noise, (3) Image Sharpening, (4) Median Filter, (5) Gaussian Filter, and (6) Image Compression.

Salt & Pepper Noise is an impulsive noise that presents itself as sparsely white and black pixels, that often mimic the unanticipated disturbance on the image, while Gaussian Noise is an additive noise that has a uniform (normal) distribution that models many random noise distributions in natural settings. On another spectrum, image sharpening is a special filter that emphasizes the image edges, while Median Filter and Gaussian Filter are the linear and non-linear smoothing techniques used to reduce noises in the image while preserving the edges. Finally, the last image processing operation used is image compression because it removes the insignificant parts of the image to reduce the file size, which applies to most of the cloud systems nowadays.

TABLE II: The Image Processing Attacks and their variants.

Attacks	Variance	Levels
Salt & Pepper Noise	Noise Density	0.01, 0.03, 0.05
Gaussian Noise	Noise Variance	0.01, 0.03, 0.05
Image Sharpening	Effect Strength	0.4, 0.6, 0.8
Median Filter	Neighbourhood Size	3×3, 5×5, 7×7
Gaussian Filter	Distribution S.D.	0.1, 0.3, 0.5
Image Compression	Quality Factor	50, 70, 90

The attacks using these image processing operations are implemented using MATLAB2023a. These operations are applied on the collage image (viz., the image with hidden secret image) using the functions in the Image Processing Toolbox, which includes the *imnoise* [17] function, *medfilt2* [18] function, *imgausfilt* [19] function, and *imsharpen* [20] function.

For each operation, two to three different variance levels are added to the images. For the details of the variants, please refer to Table II.

B. Secret Recovery

The decoding of the collage image will be performed using the trained decoder of the StArtGAN to recover the secret classes. The result of classifying the attacked collage images is shown in Table III.

In terms of Salt & Pepper Noise, it can almost perfectly recover the secret, which is up to 99% when the added noise intensity is as low as 0.01. This shows that the collage images with added Salt & Pepper noises with low intensity do not have much interference with the classification of the collage images for secret recovery since the Salt & Pepper noises are distributed in a sparse and tiny manner. However, when the noise intensity increases, it will consequently reduce the secret recovery. However, the secret recovery still can achieve an average above 92% even when the noise increases to 0.05.

Regarding the Gaussian noise, the secret recovery is lower compared to the added Salt & Pepper Noise. It achieves around 88% secret recovery for the intensity of the 0.01 added noise

TABLE III: Classification accuracy of attacked images [normalized to $[0, 1]$].

since the added noise in a normal distribution will change the most pixels of the original collage image. When the intensity of the added noise increases, the effect of the wrong classification also slightly increases. Generally, the classification accuracy

still can be maintained above 80%.

When sharpening is performed on the images, the collage images can fully recover the secret class regardless of the applied strength. This shows that sharpening the image helps emphasize the edges and image features, and would not degrade the image quality, thus ensuring the collage images are always classified correctly.

On the other hand, the median filter applied to the collage images causes a smoothening effect on them, especially on the edges, making the images unrecognizable by the decoder. Thus, the secret recovery is the lowest among all these attacks, which is below 70% secret recovery, even with the smallest window size of 3×3 is applied. It shows a drastic drop in secret recovery accuracy when the window size increases to 5×5 and 7×7, which is below 30% secret recovery.

The Gaussian filter preserves edges better compared to median filtering. Thus, the Gaussian filter applied to the images does not have a huge effect on the collage image where it shows perfect recovery.

Lastly, a compression attack has also been performed on the collage image. From the results, the attack does not show much impact when the quality factor (QF) is 70 and above. When it comes to $QF = 50$, it shows a slight error in secret recovery, which the error is below 1%.

All in all, the generated collage images using the StArtGAN framework are able to resist Salt & Pepper Noise, Gaussian Noise, Sharpening, Gaussian Filter, and Compression Attacks. However, it has the least resistance to median filtering since the smoothen effects that remove the edges and important features from images will cause misclassification of the decoder.

C. Image Quality

1) Image Quality of the Collage Image: One of the generated 8×8 original collage images and collage images after the application of image processing of size are shown in Fig. 2. From the figure, we can see that the Salt & Pepper Noise does not have too much effect on the collage images, and the noise is distributed in a sparse manner. Higher intensity of noise will have a more obvious effect on the collage image. Even though the noises are visible from the collage image, we can still see the underlying original images. However, when the noise intensities increase, the PSNR and SSIM scores reduce, showing more intense effects on the image.

Besides, the application of Gaussian Noise in a normal distribution causes manipulation in most of the image pixels. When it comes to Gaussian Noise, a more obvious effect is observed from the images. When the intensity increases, the visual effect slightly becomes more intense. Similarly, the PSNR and SSIM scores are likely the same with a slight dropping, indicating the increase in noise intensity does not

	$QF = 90$	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000

have a huge effect on the image.

Sharpening of strength 0.4, 0.6, and 0.8 are applied to the collage image. This effect enhances the edges and fine details to ensure the collage images have sharper image quality. The lower strength in sharpening can preserve the original image better, thus maintaining higher SSIM and PSNR scores.

In terms of the median filter, when the window sizes increase, the smoothening effect on the collage image becomes more obvious, and the edges of the images are less visible. It makes the collage image very different from the original collage image. By using a smaller neighborhood size for median filtering, the images will have less distortion and thus have higher PSNR and SSIM scores.

Gaussian Filter can completely maintain the quality of the original image when the Gaussian filter with a 0.1 S.D. is applied. Even when S.D. is increased to 0.3, it can still preserve the image quality with high PSNR and SSIM. However, when it comes to an S.D. of 0.5, the image quality significantly drops.

Lastly, in terms of Compression, the images can still preserve the image quality with high PSNR and SSIM scores. Hence, the effect of compression does not have much effect on the image quality.

In short, among all these methods, the Salt & Pepper Noise, Gaussian Noise, Image Sharpening, Gaussian Filter and Compression applied on images do not cause huge degradation in the image quality. On the other hand, when the median filter is applied, the loss in edges and lines of images will cause image distortion, causing low PSNR and SSIM scores.

2) Image Quality of the Recovered Image: The collage image will be decoded into their corresponding secret class and finally recover the secret image. Figure 3 shows the secret images before the attack and outputs of the secret image regenerations after the image processing is applied. From the recovered image, the effect of the image processing can also be

observed. In terms of Salt & Pepper, when the noise intensity increases, the effect seems to be more obvious and the images become harder to visible. Besides, for the Gaussian Noise with different intensities, the contents of the images are likely almost invisible. Besides, for the median filter, the content of the recovered images is totally unrecognizable. The image with Sharpening, Gaussian Filter, and Image Compression with a quality factor of 90 and 70, the recovered secret image is highly similar to the original image. Lastly, in image compression with a quality factor of 50, distortion is visible in the images as compared to the other quality factor.

The PSNR and SSIM scores between the secret image with the recovered image are evaluated and shown in Table IV and V. The results show that the secret image can be fully recovered after sharpening, a Gaussian filter, or compression with a quality factor of above 70 is applied. On the other hand, the images still have good performance in preserving the secret image after the Salt & Pepper attack and Compression attack with a quality factor of 70 is performed. Gaussian Noise has a lower recovery of the original image. Lastly, a median filter attack can preserve the lowest image quality among all these methods. From the result, low PSNR and SSIM scores are shown for the median filter with various neighborhood sizes.

D. Embedding Capacity and other Data Hiding Properties

In this experiment, the size of the secret image is 64×64 pixels, and they are converted into 8-bit grayscale images. Therefore, the total capacity that can be hidden in the collage image is 32,769 bits. However, StArtGAN is a generative data hiding model that can output collage images of various sizes in accommodating various capacities. For more information on the flexible embedding capacity and performance of other data hiding properties in StArtGAN when compared with relevant works, we refer the readers to [14].

IV. Discussion

From the result, the images that are applied with median filtering attacks are hard to identify. The smoothening effect performed on the images has reduced the visibility of the edges and thus, the decoder is unable to identify the image content. This consequently leads to the misclassification of the collage images, and finally the inability to recover the secret image. Sharpening will emphasize the image content, thus making the secret recovery can be performed easier. The compression performed on the images does not have much impact on degrading the image quality unless the quality factor achieves up to 50. For the Gaussian filter, the image quality can still be preserved even when the standard deviation achieves up to 0.5.

All in all, the experiment results indicate that StArtGAN can resist image processing attacks, especially in noise, sharpening, and image compression operations. It is weak against the median filter because it blurs the art images, and weakens the distinctive feature of each class. Low classification accuracy then severely degrades the image quality of the extracted secret image.

For non-constructive-based data hiding methods, most of them couldn't be able to resist image processing attacks due to the special formula that they used in selecting the images to represent secret data. When the pixel values change by the image processing operations, it affects the formula calculation and hence might cause wrong secret data extraction.

For constructive-based data hiding methods, patterns and texture image generation should be able to achieve similar performance as StArtGAN because the secret data is usually embedded on patch level ($w \times w$ pixels per unit) but not on pixel level (one pixel per unit). Therefore, secret data can still be accurately extracted if the majority of the pixels or structures stay intact.

V. Conclusion

In conclusion, the results show the StArtGAN [14] method can resist various image processing operations such as the Salt & Pepper noise, Gaussian noise, Sharpening, Gaussian Filter, and Compression attacks to classify the collage image using the trained decoder and to recover the original images. On the other hand, a median filtering attack smoothens the edges of images, consequently leading to the misclassification of collage images, causing low recovery of the original image.

***Abstract*—In this paper, we investigate the effectiveness of using quantum machine learning for privacy protection in audio-visual speech processing. Quantum machine learning has made significant theoretical advancements and has been shown to possess natural advantages in privacy protection over conventional techniques. Here, we first apply quantum circuits to a word-level audio-visual speech recognition task. We then propose a novel metric, an inter-class intra-class similarity ratio, for measuring the privacy-protecting capabilities of quantum circuits. Finally, we conduct an in-depth analysis of the differences in privacy protection between quantum privacy methods and traditional methods, evaluating their working principles, strengths, and limitations. Experiments results on the LRW data set show that the quantum privacy-preserving approach performs well in word-level speech recognition tasks, demonstrating excellent privacy-preserving capabilities through selective retention of features.**

I. Introduction

With the rapid development of deep learning, face recognition, automatic speech recognition and audio-visual technology have been gradually applied in daily life scenarios in recent years. The sensitivity of face image data and speech data has led to growing concerns about data privacy. In this context, it is crucial to develop effective methods for protecting audio and video privatized data to comply with new privacy protection regulations, e.g. the EU General Data Protection Regulation (GDPR) [1].

There are many traditional algorithms in the field of privacy protection, such as homomorphic encryption [2] and differential privacy [3], [4]. Homomorphic encryption is a cryptographic technique based on the computational complexity theory of mathematical puzzles. This algorithm offers the property that the result of performing an operation on plaintext and then encrypting it is equivalent to the result of performing the corresponding operation on the ciphertext after encryption. Due to this desirable feature, it can maintain high recognition accuracy while protecting data privacy. However, its application scenarios are greatly limited due to the large amount of additional computation required for the encryption process. Differential privacy methods add specific noise to the input data to prevent attackers from inferring sensitive information based on the output. However, in practical applications, it is often caught in the dilemma of trade-off between privacy-preserving capability and downstream task accuracy. To address the above challenges, [5] proposed a differential privacy method based on frequency domain transform and learnable privacy budget, which demonstrated outstanding results in face recognition tasks.

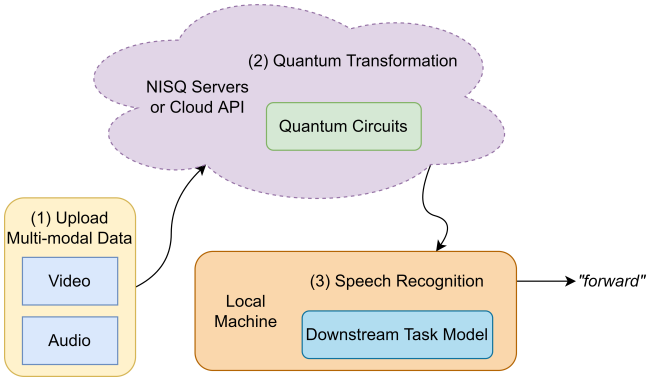

Fig. 1: Quantum privacy-preserving architecture for speech recognition task in a vertical federated learning process. Quantum circuits on the Noisy Intermediate-Scale Quantum (NISQ) server transform the input multi-modal data into quantum private data and transfer it to the speech recognition model on local machine.

In recent years, federated learning has also emerged as a common privacy-preserving approach. For example, vertical federated learning (VFL) [6] is a potential data protection strategy that decentralizes the end-to-end deep learning framework and separates feature extraction from the downstream task system. And with the recent advances in commercial quantum technologies, quantum machine learning (QML) [7] becomes an ideal building block for VFL due to its parameter encryption and data isolation advantages. The distinction between quantum machine learning and traditional machine learning lies in the utilization of quantum circuits. These circuits consist of a series of quantum gates that operate on quantum bits (qubits), which are the fundamental units of

quantum information. The VFL architecture using quantum circuits as a building block are shown in Fig. 1. Based on the above, Yang et al. [8] proposed a decentralized acoustic modeling scheme and designed a quantum convolutional neural network, resulting in impressive outcomes by combining the learning paradigm of variable quantum circuit [7] and deep neural network.

The contributions of this paper are as follows:

• Demonstrates the effectiveness of quantum circuits-based methods for privacy preservation in a word-level audio-visual speech recognition task.

• Proposes the inter-class intra-class similarity ratio as a privacy protection effect metric, and use it to thoroughly analyze the differences between quantum privacy methods and traditional methods.

II. RELATED WORK

A. Quantum Machine Learning for Signal Processing

The current phase of quantum computing is often referred to as the noisy intermediate-scale quantum era. During this era, quantum processors consist of intermediate-scale qubits, which are not yet advanced enough to achieve fault-tolerance or reach the threshold for quantum supremacy. These processors are sensitive to external factors (noisy) and susceptible to quantum decoherence and not capable of continuous quantum error correction, which limits the potential applications of NISQ technology. However, Mitarai *et al.* [7] build a pioneering framework for building machine learning models on NISQ devices by the use of variable quantum circuit (VQC) [9]. VQC can be progressively iteratively optimized, allowing noise effects in NISQ devices to potentially be absorbed into these learned circuit parameters. Several successful machine learning applications based on VQC have been reported in the recent literature, such as transfer learning [10] and deep reinforcement learning [11]. It is worth noting that recent studies [12], [13] have shown that quantum machine learning (QML) has advantages over classical machine learning in terms of lower memory storage, secure encryption of model parameters, and good feature representation capabilities.

While still a nascent technology, quantum machine learning has already been applied in various fields. For instance, [14] successfully implemented image recognition using quantum deep convolutional networks, [15] proposed a speech recognition system using quantum backpropagation (QBP) simulated by fuzzy logic computation, and [16] successfully applied quantum transfer learning techniques to the synthetic speech detection task.

B. Privacy Preservation

In the realm of privacy protection, research can be broadly classified into three categories, depending on how the input data is processed: data anonymization methods, data encryption methods, and data perturbation methods. Data anonymization methods, such as k-anonymity [17] and t-closeness [18], work by desensitizing sensitive information to protect privacy. While these methods allow data to be analyzed and utilized to some extent, they may also undermine the integrity and accuracy of the data, reducing its validity. Homomorphic encryption and secure multi-party computation [19] are classical data encryption methods that effectively protect data security while achieving excellent results on downstream tasks. However, the high computational costs associated with encryption and decryption make these methods difficult to apply in practice. In contrast, data perturbation methods avoid the high costs of encryption by perturbing the original input. Differential privacy is a widely used data perturbation method. [20] employed differential privacy to perturb eigenfaces and distributed the privacy budget equally to each eigenface, which resulted in a significant loss of accuracy. Besides, [21] uses the Mixup [22] method to perturb the data, and [23] proposed a Gaussian noise perturbation method to suppress the unimportant pixels before sending them to the cloud. Recent studies [24] have started to investigate how to incorporate differential privacy into speech processing, but these efforts have not extended into the multi-modal learning setting. In summary, privacy concerns regarding audio-visual patterns deserve further investigation.

C. Word-Level Audio-Visual Speech Recognition

Traditional Audio-Visual Speech Recognition (AVSR) methods follow a two-step process that involves feature extraction and recognition [25]. However, recent advancements have significantly improved the performance of Visual Speech Recognition (VSR) and Automatic Speech Recognition (ASR) by combining feature extraction and recognition inside deep neural networks. In VSR, [26] proposed an end-to-end network called Visual to Phoneme. [27] proposed Spatio-Temporal Fusion Module to maintain the local spatial information and reduce the feature dimensions. [28] designs a novel deep learning architecture using hierarchical pyramidal convolution and self-attention, thereby enhancing the model's ability to discover fine-grained lip movements. In ASR, [29] demonstrated the superiority of deep representations of the network over hand-crafted features such as filterbank features.

III. METHOD

A. Audio-Visual Quantum Privacy Protection

Figure 2 illustrates the pipeline of the audio-visual quantum privacy protection method. It comprises two modules: quantum

transformation and word-level audio-visual speech recognition. In the quantum transformation module, we pre-process the audio-video data first. For audio data, we extract its FBank features; for video data, we read its grayscale image and split it into different frames for subsequent processing. Next, we chunk the processed audio and video data into patches and feed them into a quantum gate for quantum encoding into the initial quantum states. We then perform further quantum transformations using quantum circuits. Finally, the quantum state is decoded by a measurement function to output quantum privatized data.

For the word-level audio-visual speech recognition task, referring to the system in [28], [30], our system utilizes a 3D convolutional layer and an 18-layer residual network (ResNet-18) [31] as the frontend for the video modality, a mask module and a ResNet-18 as the frontend for the audio modality. The features extracted by the two frontends are concatenated and fed into a multi-scale temporal convolutional network (MS-TCN) backend, which then goes through the self-attention based consensus module to output the words probabilities.

B. Quantum Gates

In this section, we briefly introduce several basic quantum gates: R_x, R_y, R_z, and $CNOT$. Unlike a classical bit, which has two states (0 and 1), a quantum bit can be represented as $|\phi\rangle = \alpha|0\rangle + \beta|0\rangle, |\alpha|^2 + |\beta|^2 = 1$. We can also express it in the form $|\phi\rangle = \cos\theta|0\rangle + e^{-i\phi}\sin\theta|1\rangle, \theta, \phi \in R$. The density matrix of this quantum bit is:

$$\rho = |\varphi\rangle\langle\varphi| = \begin{bmatrix} \cos^2\frac{\theta}{2} & e^{-i\phi}\sin\frac{\theta}{2}\cos\frac{\theta}{2} \\ e^{i\phi}\sin\frac{\theta}{2}\cos\frac{\theta}{2} & \sin^2\frac{\theta}{2} \end{bmatrix}. \quad (1)$$

$\langle\phi|$ represents the conjugate transpose of $|\phi\rangle$.

Alternatively, we can construct the density matrix space using the four Pauli matrices as its basis, which is:

$$I = \sigma_0 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \sigma_x = \sigma_1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix},$$
$$\sigma_y = \sigma_2 = \begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}, \sigma_z = \sigma_3 = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

Any matrix can be decomposed into $\rho = \sum_{i=0}^{4} a_i\sigma_i$. Considering $Tr\rho = \sum_{i=0}^{4} a_i Tr\sigma_i$, we can determine that $a_0 = 1/2$. Therefore, the density matrix can be expressed as:

$$\rho = \frac{1}{2}(I + \vec{r}\cdot\sigma) = \rho(\vec{r}),$$
$$\vec{r} = 2\,(a_1, a_2, a_3) = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta).$$

Substituted the expression of $\vec{r}$ into the density matrix yields:

$$\rho = \frac{1}{2}\left(I + \begin{bmatrix} \cos\theta & e^{-i\phi}\sin\theta \\ e^{-i\phi}\sin\theta & -\cos\theta \end{bmatrix}\right)$$
$$= \begin{bmatrix} \cos^2\frac{\theta}{2} & e^{-i\phi}\sin\frac{\theta}{2}\cos\frac{\theta}{2} \\ e^{i\phi}\sin\frac{\theta}{2}\cos\frac{\theta}{2} & \sin^2\frac{\theta}{2} \end{bmatrix}.$$

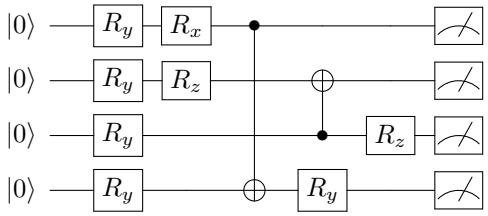

Fig. 3: An example of random quantum circuit.

This is equal to Equation 1, thus we establish the mapping relation from the quantum state to the 3D sphere, commonly known as the Bloch sphere [32].

Next, we define the quantum gates R_x, R_y, R_z to mean the representation of the quantum bit in the Bloch sphere rotating around the x, y, z axes respectively. It is then straightforward to determine their corresponding matrices as:

$$R_X(\theta) = \begin{bmatrix} \cos\frac{\theta}{2} & -i\sin\frac{\theta}{2} \\ -i\sin\frac{\theta}{2} & \cos\frac{\theta}{2} \end{bmatrix}, R_Y(\theta) = \begin{bmatrix} \cos\frac{\theta}{2} & -\sin\frac{\theta}{2} \\ \sin\frac{\theta}{2} & \cos\frac{\theta}{2} \end{bmatrix},$$
$$R_X(\theta) = \begin{bmatrix} e^{-i\frac{\theta}{2}} & 0 \\ 0 & e^{-i\frac{\theta}{2}} \end{bmatrix}.$$

Similarly, with reference to the Exclusive-OR gate in classical logic gates, we can express the $CNOT$ gate as a matrix:

$$CNOT = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}.$$

C. Quantum Circuits

For better privacy protection effect, the structure and parameters of quantum circuits are randomly generated. Fig. 3 gives a diagram of a random quantum circuit, where only the most basic quantum gates R_x, R_y, R_z, and $CNOT$ are applied. The classical vectors are initially encoded into a quantum state $|\phi\rangle = |0000\rangle$, and the encoded quantum states go through the quantum circuit for the following steps:

Step 1: $\Phi_1 = R_y|0\rangle R_y|0\rangle R_y|0\rangle R_y|0\rangle$.
Step 2: $\Phi_2 = R_x R_y|0\rangle R_z R_y|0\rangle R_y|0\rangle R_y|0\rangle$.
Step 3: $\Phi_3 = R_x R_y|0\rangle R_z R_y|0\rangle R_y|0\rangle CNOT\,(R_y|0\rangle)$.
Step 4: $\Phi_4 = R_x R_y|0\rangle CNOT\,(R_z R_y|0\rangle)\,R_y|0\rangle R_y\,\mathrm{CNOT}\,(R_y|0\rangle)$.
Step 5: $\Phi_5 = R_x R_y|0\rangle CNOT\,(R_z R_y|0\rangle)\,R_z R_y|0\rangle R_y CNOT\,(R_y|0\rangle)$.

Furthermore, due to the potential for many unexpected noisy signals from $CNOT$ gates, particularly with our current non-error-corrected quantum devices and the connectivity of physical qubits, we limit the number of qubits in our random quantum circuit to ensure it falls within the noise tolerance capabilities of VQC.

IV. Privacy Protection Capability Measurement

A. Inter-class Intra-class Similarity Ratio

To quantitatively analyze the privacy protection capability of different methods, we introduce a new metric called the inter-

class intra-class similarity ratio (IISR).

To process video data, we group frames from the same video together as one class, while frames from different videos are treated as separate classes. Audio data is handled in a similar fashion. Suppose there are n video segments in total, and each video segment has m frames, the j-th frame image of the i-th video segment is $\mathrm{fig}_{i,j}$.

First, we utilize SSIM as the measure of the similarity between data. From there, we can calculate the intra-class similarity by employing the following formula:

$$\mathrm{ssim}_{\mathrm{intra}} = \frac{1}{n * m * (m-1)} \sum_{i=1}^{n} \sum_{\substack{j,k=1 \\ j \neq k}}^{m} \mathrm{ssim}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{i,k}\right).$$

Similarly, the inter-class similarity function is:

$$\mathrm{ssim}_{\mathrm{inter}} = \frac{1}{n * (n-1) * m^2} \sum_{\substack{i,l=1 \\ i \neq l}}^{n} \sum_{j,k=1}^{m} \mathrm{ssim}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{l,k}\right).$$

To calculate the IISR of SSIM, we can express it as the ratio of inter-class similarity to intra-class similarity:

$$\mathrm{IISR}_{\mathrm{ssim}} = \frac{(m-1) \sum_{\substack{i,l=1 \\ i \neq l}}^{n} \sum_{j,k=1}^{m} \mathrm{ssim}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{l,k}\right)}{m * (n-1) \sum_{i=1}^{n} \sum_{\substack{j,k=1 \\ j \neq k}}^{m} \mathrm{ssim}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{i,k}\right)}.$$

Similarly, the formulas for the IISR of RMSE and PSNR are:

$$\mathrm{IISR}_{\mathrm{rmse}} = \frac{(m-1) \sum_{\substack{i,l=1 \\ i \neq l}}^{n} \sum_{j,k=1}^{m} 1/\mathrm{rmse}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{l,k}\right)}{m * (n-1) \sum_{i=1}^{n} \sum_{\substack{j,k=1 \\ j \neq k}}^{m} 1/\mathrm{rmse}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{i,k}\right)}.$$

$$\mathrm{IISR}_{\mathrm{psnr}} = \frac{(m-1) \sum_{\substack{i,l=1 \\ i \neq l}}^{n} \sum_{j,k=1}^{m} \mathrm{psnr}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{l,k}\right)}{m * (n-1) \sum_{i=1}^{n} \sum_{\substack{j,k=1 \\ j \neq k}}^{m} \mathrm{psnr}\left(\mathrm{fig}_{i,j}, \mathrm{fig}_{i,k}\right)}.$$

Inter-class and intra-class similarities respectively denote the proportion of shared information contained within inter-class and intra-class data. Greater similarity indicates more compact data. The IISR represents the proportion of common information contained within inter-class and intra-class data. A smaller ratio implies that the intra-class data is more compact than the inter-class data, making it easier to differentiate whether the two data belong to the same class, which in turn means more information is preserved.

B. Privacy Attack

To assess the effectiveness of privacy protection methods, privacy attacks [24] are often employed. It can be broadly classified into white-box attacks and black-box attacks.

1) White-box attack: White-box attacker has access to all of our operations. With this knowledge, in order to attack the quantum privacy protection method, they can take all parameters in the quantum circuits and inverse them to get inverse quantum circuits, and then feed the quantum privatized data into the inverse quantum circuits to get the output.

2) Black-box attack: A black-box attack assumes that the attacker does not possess any knowledge regarding the model's internal structure and parameters. Nevertheless, attackers can collect large amounts of audio and video data and input the data into the model to obtain processed data. Subsequently, they can train a decoder to restore the processed results to the original input. Finally, attackers can leverage the trained decoder to recover users' private data. For our subsequent experiments, we will use UNet [33] as our decoder to reconstruct the original data from the processed data.

V. Experiments

A. Experimental Setup

To evaluate the impact of two privacy-preserving methods on downstream tasks, we selected a moderately challenging yet feasible task: word-level speech recognition. For the dataset, we use the Lip Reading in the Wild (LRW) [34], which consists of about 500,000 audio-visual speech segments extracted from BBC TV broadcasts. It encompasses 500 target words and numerous speakers, and provides a word-level label for each audio-visual speech segment.

To account for practical application factors, we introduce noise to the original speech. A total of 115 noise types including 100 noise types from [35] and 15 homemade noise types corrupted the corpus in the training set at 5 SNR levels (i.e., 15 dB, 10 dB, 5 dB, 0 dB, and -5 dB). The validation and test sets were corrupted by three unseen noise types at the aforementioned SNR levels, i.e., Speech Babble, Buccaneer1, and Destroyer Engine. All unseen noises were collected from the NOISEX92 corpus [36]. Following the addition of noise, we extracted its 40-dim Fbank features from the noisy speech as the input. Regarding the video modality, we utilize grayscale images directly as input.

We employed the method proposed by [5] as the baseline for privacy protection. In the frequency domain transform part, we use some functions in TorchJPEG [37] to transform the input data into BDCT coefficients and then remove its direct part. And for the initial value of the learnable budget allocation parameter, we set it to 0 so that the privacy budget of each location is equal in the initial stage.

For the quantum privacy-preserving method, we use Pennylane to build a 4-bits random quantum circuits and divide the input data into 2×2 patches into the quantum circuits to generate quantum privatized data.

B. Performance of Word-level Audio-visual Speech Recognition

We conducted a comparative analysis of the classification accuracy for speech recognition task using original data, baseline

TABLE I: Speech recognition accuracy(Acc) in different data types and modalities.

Acc	Original	Baseline	**Quantum**
ASR	69.00	65.92	**68.12**
VSR	86.43	84.23	**85.42**
AVSR	89.23	87.13	**88.26**

privatized data, and quantum privatized data, respectively. The results are shown in Table I.

Based on the table, it is apparent that the classification accuracy of the original data is the highest, irrespective of the modality. This implies that both privacy-preserving methods lead to some information loss. Nonetheless, we observed that the training results of the quantum privatized data are superior to the baseline approach, suggesting that the quantum privacy-preserving method loses less information for the downstream task required.

C. privatized data Analysis

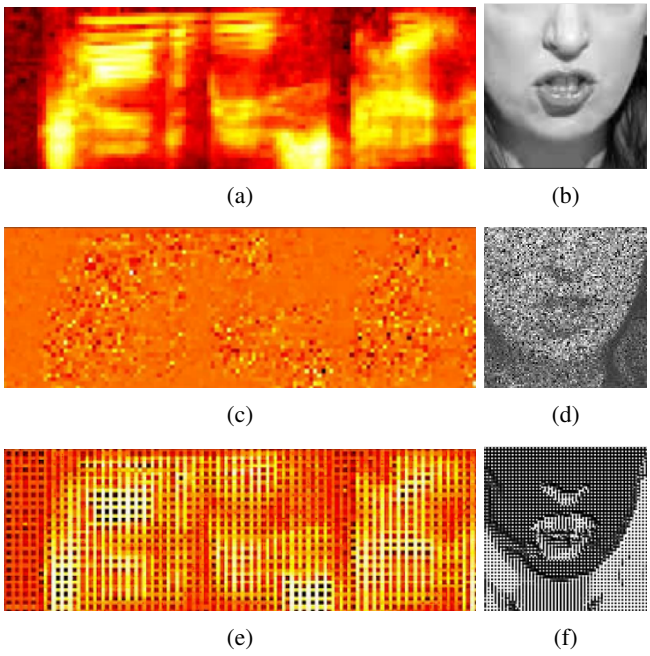

Fig. 4: Visualization of privatized data. (a) Spectrogram of original audio data; (b) Grayscale plot of original video data; (c) Spectrogram of audio baseline privatized data; (d) Grayscale plot of video baseline privatized data; (e) Spectrogram of audio quantum privatized data; (f) Grayscale plot of video quantum privatized data.

As the first step of our analysis, we performed visualization operations on the dataset. Specifically, We randomly select an audio-video segments from the original dataset, generated the grayscale map of the first frame of the video and the audio spectrogram, and repeated the same visualization procedure for the baseline privatized data and quantum privatized data

TABLE II: privatized data analysis.

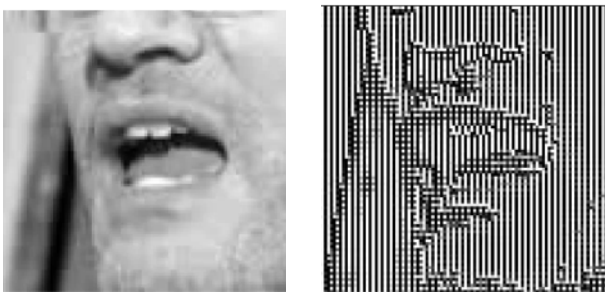
Modality	Data_type	IISR_{rmse}	IISR_{psnr}	IISR_{ssim}
Video	Original	0.314	0.611	0.491
	Baseline	0.532	0.741	0.585
	Quantum	**0.539**	**0.772**	**0.680**
Audio	Original	0.611	0.824	0.407
	Baseline	0.855	0.925	0.675
	Quantum	**0.926**	**0.973**	**0.776**
Video_lip	Original	0.457	0.738	0.533
	Baseline	**0.693**	**0.856**	**0.663**
	Quantum	0.641	0.818	0.635

TABLE III: Data analysis of white-box attack in video modality.

Data_type	IISR_{rmse}	IISR_{psnr}	IISR_{ssim}
Original	0.314	0.611	0.491
Quantum	0.539	0.772	0.680
White-box Attack	0.536	0.761	0.662

corresponding to this segments. The resulting visualizations are shown in Fig. 4.

As per our analysis of the visualizations, we observed that the quantum privatized data the quantum privatized data better preserves the lip area compared to the baseline data while worse in other area. Similarly, we noted that quantum privatized data captures high-frequency information better than the baseline privatized data from the audio spectrograms.



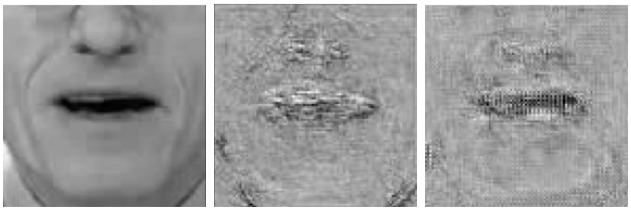
For further analysis, we employ the IISR metric. We randomly select 10 words and 30 audio-video segments for each word, and calculate IISR for the audio and video data separately. Moreover, given the significant reliance of the VSR task on the lip area in the video, we extracte the lip area of the video segments and compute its IISR. The results are shown in Table II.

From the first two rows of the table, we can see that for both the video and audio data, the IISR values for the original, baseline, and quantum privatized data follow the trend of $Original_{\text{IISR}} < Baseline_{\text{IISR}} < Quantum_{\text{IISR}}$, regardless of the IISR_{rmse}, IISR_{psnr} or IISR_{ssim}. This suggests that the quantum privatized data retains relatively less information compared to the baseline method, thereby providing stronger privacy protection. By further analyzing the IISR of lip area data, we can find that there is $Original_{\text{IISR}} < Quantum_{\text{IISR}} < Baseline_{\text{IISR}}$, which is different from previous results and indicating that quantum privatized data retain more information in the lip region, thus performing better in downstream tasks.

D. White-box Attacking Experiments

The white-box attack results is visualized in Fig. 5. Additionally, we calculated the IISR for the white-box attack results, with the results shown in Table III.

As we can see from the figure or the table, the impact of white-box attacks is very limited. The quantum privacy protection method exhibited strong resistance to white-box

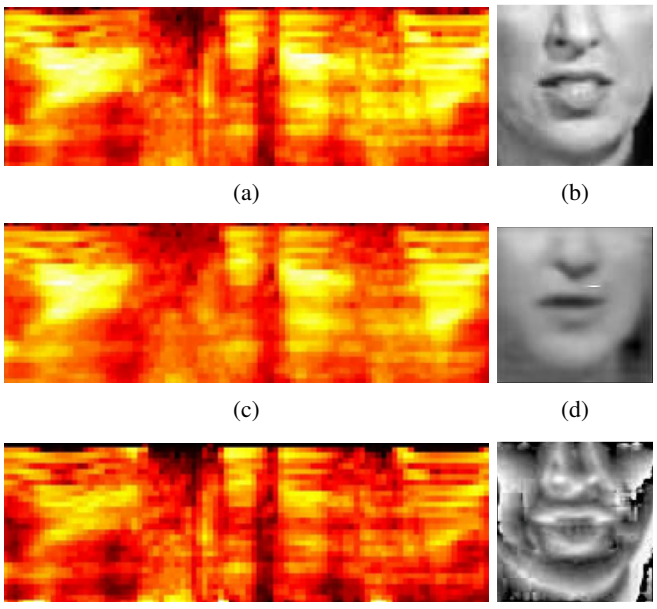


(a) (b)

Fig. 5: Visualization of white-box attack. (a) Grayscale plot of original video data; (b) Grayscale plot of white-box attack results of video quantum privatized data.

attacks, which is indicative of the irreversibility of quantum circuits.

E. Black-box Attacking Experiments



(a) (b) (c)

Fig. 6: Visualization of untrained black-box attack. (a) Grayscale plot of original video data; (b) Grayscale plot of untrained black-box attack results of video baseline privatized data; (c) Grayscale plot of untrained black-box attack results of video quantum privatized data.

In this section, we discuss the privacy-preserving reliability of the two approaches under black-box attacks.

Since the quantum privacy method does not require any trainable parameters and the number of parameters required for the baseline method is small, we examined the reconstruction results of the untrained attack network after initialization. The results are visualized in Fig. 6. From the figure, it is evident that compared to the baseline, the quantum privatized data reconstruction results are better restored near the lips, but worse restored in other regions.

The visualization results of the audio and video data reconstructed by the trained black-box attack network are also shown in Fig. 7. The video visualizations reveal that while both the quantum privacy protection method and the baseline method are effective at resisting black-box attacks, the restoration results for the video quantum privatized data are superior to those of the video baseline privatized data in the lip region. Similarly, the audio quantum privatized data exhibits better restoration capability for high-frequency information compared to the audio baseline privatized data.

(a) (b) (c) (d) (e) (f)

Fig. 7: Visualization of black-box attack. (a) Spectrogram of original audio data; (b) Grayscale plot of original video data; (c) Spectrogram of black-box attack results of audio baseline privatized data; (d) Grayscale plot of black-box attack results of video baseline privatized data; (e) Spectrogram of black-box attack results of audio quantum privatized data; (f) Grayscale plot of black-box attack results of video quantum privatized data.

TABLE IV: Data analysis of black-box attack.

Modality	Data_type	IISR_{rmse}	IISR_{psnr}	IISR_{ssim}
Video	Original	0.314	0.611	0.491
	Baseline	0.489	0.838	0.773
	Quantum	**0.632**	**0.867**	**0.892**
Audio	Original	0.611	0.824	0.407
	Baseline	0.798	0.956	0.882
	Quantum	**0.914**	**0.984**	**0.947**
Video_lip	Original	0.457	0.738	0.533
	Baseline	**0.589**	**0.864**	**0.894**
	Quantum	0.562	0.839	0.848

We compute the IISR values of the reconstructed audio and video data, with the results depicted in Table IV. From the table, we can see that for both audio and video modalities, the reconstruction results of quantum privatized data are inferior to those of the baseline privatized data, indicating that the quantum protection approach is more resistant to black-box attack than the baseline. Furthermore, we analyze the lip region data separately and find that the reconstruction results of quantum privatized data are better than those of the baseline privatized data. This observation provides further evidence to support the superior performance of the quantum privatized data for word-level speech recognition tasks.

VI. Conclusions

This paper successfully demonstrates the effectiveness of quantum circuits-based privacy-preserving methods in audio and video modalities. Through visualizations and the IISR metric, we are able to analyze the privacy-preserving ability of the two methods in terms of privatized data, resistance to white-box privacy attacks, and black-box privacy attacks. Furthermore, by analyzing the data in the lip region, we can find that the quantum privacy-preserving methods can maintain the features required for downstream tasks while discarding other information, thereby enabling excellent privacy-preserving capabilities while performing well in downstream tasks, which is inseparable from the advantage of quantum circuits in feature representation capability.

***Abstract*—The lack of human-level interpretability in the decision-making process of computer vision is one of the obstacles to further its application and performance improvement. This issue is investigated by eXplainable Artificial Intelligence (XAI), and a range of interpretable XAI networks has been proposed to mitigate the black box issue. Most of them attempt to implement case-based reasoning in image recognition that is similar to humans. This cognitive process includes dissecting the image and identifying prototypical parts that distinct one class from another. However, only a few works take into consideration the hierarchical principle of this process and visual data. In contrast to previously introduced XAI approaches that utilize Euclidean space to design a network, hyperbolic space with its ability to embed hierarchical structures is exploited in this work. The proposed prototype-based hyperbolic network, namely ProtoHyp, first learns prototypes that play key roles in identifying classes. Then, using the similarity between them and an image, the human-understandable classification of an image is conducted in hyperbolic space. Experimental results on two image recognition datasets, Birds CUB-200-2011 and Stanford Dogs, have demonstrated the improvement of state-of-the-art interpretable image recognition in terms of both accuracy and interpretability.**

I. Introduction

Despite recent advances in computer vision, there is a big gap between the way machines and humans perceive an image and recognize objects [1], [2]. The black box issue of deep learning limits not only the improvement of computer vision but also its application [3], [4]. EXplainable Artificial Intelligence (XAI) addresses the black box issue and aims to bring the decision-making process in AI closer to human reasoning. The current XAI includes post-hoc and interpretable approaches. Although the former ones that produce posterior explanations of deep learning models have attracted a lot of interest, their results are often misleading and not reliable [1]. Interpretable XAI methods are superior due to their ability to automatically provide human-interpretable explanations alongside their predictions [3].

Most interpretable XAI approaches are represented by prototype-based networks [5], [6]. The underlying idea is to reproduce the human reasoning process in image classification. This process includes dissecting an image and identifying prototypical parts that distinguish one class from another [7], [8]. The principle of this cognitive process is illustrated in Fig. 1. After learning prototypical parts, the similarity between an input image and these prototypes is utilized to conduct human-explainable classification. The ProtoPNet network [5], the first attempt to implement this principle, has achieved reasonable accuracy and interpretability. However, it has a range of issues that have been addressed in the subsequent works. The deformable ProtoPNet exploits prototypes that adaptively change their relative positions instead of spatially rigid ones [9]. ProtoPShape [10] and ProtoPool [7] enhance the network by decreasing the number of prototypes and simplifying the training process.

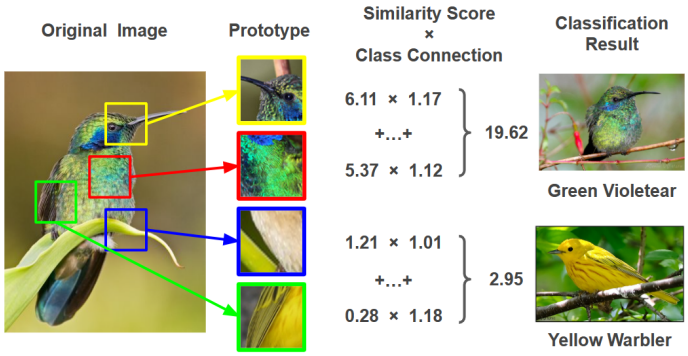

Fig. 1. The result of the proposed ProtoHyp network on Birds CUB-200-2011 - an example of case-based reasoning in image recognition. The interpretable classification is achieved by representing each prediction score as a linear combination of similarities between an image and prototypes learned in the training phase.

Although the case-based reasoning described above has the hierarchical nature [6], only a few works explore and exploit it to improve interpretable XAI. The hierarchy of class labels is utilized to interpretably recognize unseen objects at their parent node of the taxonomy [11]. Hierarchical trees are exploited for multi-grained interpretable recognition [12]. The hierarchical nature is inherent not only to reasoning in image recognition but is also a feature of visual data [13]. The consideration of hierarchical relations between images and their parts have already demonstrated the improvement of the state-of-the-art

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

in metric [14], [15] and few-shot recognition [13], [16].

Hyperbolic space (HS) with its negative curvature and exponential growth has a better ability to embed hierarchical structures than Euclidean space (ES). However, its usage has not yet been investigated for interpretable image recognition. Only polynomially expanding Euclidean space (ES) with zero curvature has been exploited to design interpretable image recognition networks.

In this work, this gap has been narrowed, and a novel interpretable image recognition network, namely ProtoHyp, is introduced. Deformable prototypes [9] are first learned. Then, the similarity score between an input image and the prototypes is obtained. The third step is exponential mapping from Euclidean space to hyperbolic space. Poincarè ball is selected as the hyperbolic space model due to the differentiability of its distance function and its capacity for gradient-based optimization [15]. Finally, the formalism of Möbius gyrovector spaces is utilized to carry out the interpretable classification process in Poincarè ball. Since, to the best of our knowledge, this work is the first attempt to utilize hyperbolic space for the purpose of XAI, only the last (interpretable classification) layer is implemented in HS for a better comparison to its performance in Euclidean space.

To evaluate the performance of the proposed ProtoHyp network, the following experiments are conducted on two image recognition datasets, Birds CUB-200-2011 [17] and Stanford Dogs [18]. Firstly, the results of the model with various backbone architectures, such as VGG-16 [19], ResNet34 [20], ResNet152 [20], and Dense161 [21], on cropped and full images are presented. Secondly, different combinations of hyperbolic parameters in Poincarè ball, such as its curvature and dimentionality, are evaluated as an ablation study. Thirdly, the quantitative and qualitative comparisons to the state-of-the-art XAI in terms of prediction accuracy and interpretability are demonstrated.

Our main contributions are summarized as follows:

- To the best of our knowledge, we have made the first attempt to explore hyperbolic space due to its ability to embed hierarchical structure for the purpose of interpretable image recognition.
- A novel interpretable XAI network, namely ProtoHyp, that imitates human reasoning process in image recognition is introduced. It makes an explainable decision in hyperbolic space using the similarity to prototypes that play key roles in the class definition.
- Extensive experiments on Birds CUB-200-2021 and Stanford Dogs datasets demonstrate that the proposed ProtoHyp overcomes the state-of-the-art XAI in terms of accuracy and interpretability.
- Various hyperbolic parameters of Poincarè ball, such as its curvature and dimensionality, have been evaluated. Their best combination, as well as backbone architectures, has been empirically selected for the purpose of interpretable recognition.

II. Related Work

In this section, we first review the relevant literature on interpretable XAI. Then, a brief survey of vision models implemented in hyperbolic space is presented.

A. Interpretable Vision Models

ProtoPNet [5] is the first interpretable network that implements case-based reasoning in image recognition similar to humans. It achieves interpretable image classification by comparing crucial image parts with a set of prototypes assigned to a class. However, the network has a range of issues that have been addressed in the following works. First of all, ProtoPNet uses spatially rigid prototypes that have negative influence on its performance even on images preprocessed by cropping. This shortcoming is addressed in [9], and a deformable prototypical network based on prototypes that adaptively change their relative spatial positions is proposed.

Another issue of the ProtoPNet network is the separate usage of prototypes for each class. ProtoPShape [10] and ProtoPool [7] have been designed in order to overcome this problem. The former network shares the prototypes between classes by pruning prototypical parts using data-dependent similarity. ProtoPool decreases the number of prototypes by reusing them in classes and allows fully automatic differentiable assignment of prototypes to classes to simplify the training process [7]. The issue of complex data structure and confusing the effect of individual prototypes on the output category is addressed in [8]. In this study, the interpretable network TesNet constructs prototypes on the Grassmann manifold with several regularization loss functions as constraints.

The hierarchical principle of human reasoning in image recognition is also explored in a range of studies. The predefined hierarchy of class labels is utilized to classify objects at each level and interpretably recognize images from unseen classes at their parent level in the taxonomy [11]. A multi-grained interpretable network that organizes classes into different granularities within a class hierarchy tree and provides decision pathways with different granularity explanations is proposed in [12]. An interpretable deep learning method that combines prototype-based XAI with decision trees is introduced in [6]. It can explain a single prediction by outlining a hierarchical path through the decision tree.

In contrast to previously proposed interpretable vision models that are fully designed in Euclidean space, the proposed ProtoHyp is constructed in hyperbolic space (Poincarè ball). Since HS has a better ability to embed hierarchical structure [13], its usage potentially improves the interpretable image classification in both accuracy and interpretability points of view.

B. Hyperbolic Vision Models

It is common in deep learning to represent data in Euclidean space due to its vectorial structure, continuity and closed-form formulas of distance and inner-product [22]. However, many scientific fields study data with non-Euclidean structures. Hyperbolic space with its tree-like properties that help embed

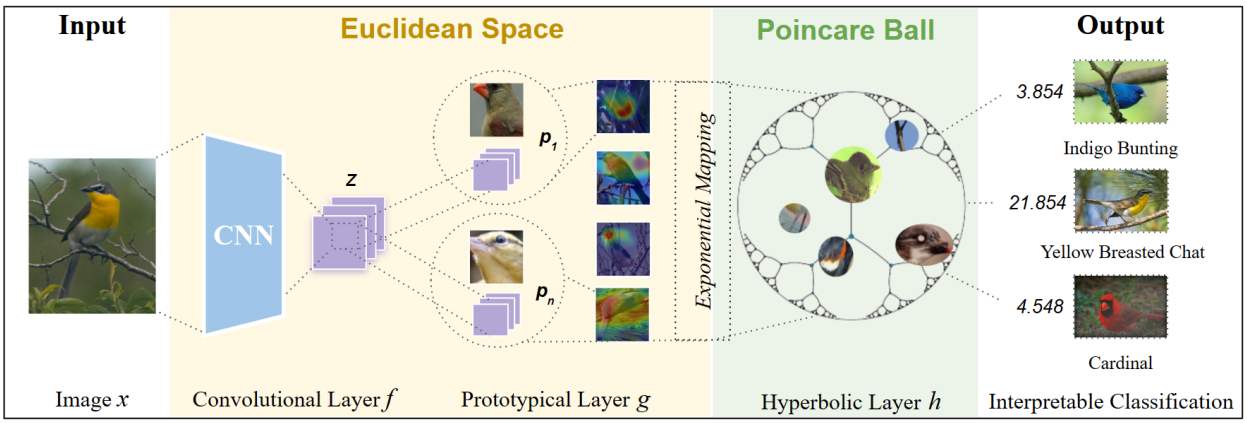

Fig. 2. The flowchart of the proposed ProtoHyp network. Its convolutional layer is responsible for feature extraction, prototypical one obtains image regions playing key roles in recognition, while the hyperbolic layer conducts interpretable classification.

taxonomies is one of the alternatives to ES [15]. Although the advantages of HS have successfully been applied in the NLP area, less investigation has been done to improve computer vision models by using hyperbolic space [13].

The first attempt to apply the machinery of hyperbolic networks to computer vision was made in [13]. The work demonstrates that HS is beneficial for visual data and exploits it for few-shot learning and person re-identification. Moreover, an approach for evaluation of the dataset hyperbolicity based on the concept of Gromov δ - hyperbolicity is introduced. Few-shot learning in HS is also explored in [16] where a hyperbolic knowledge transfer framework with hierarchical classification and relation reconstruction loss is proposed to learn the tree-like structure of class hierarchy.

A range of works have addressed metric learning in HS [15], [23]. The joint usage of vision transformers, hyperbolic embeddings, and pairwise cross-entropy loss is utilized in [14]. Contrastive learning is explored and a novel framework for self-supervised image representation learning is proposed in [15]. The noisy label issue in metric learning is addressed in [23], and an adaptive hierarchical similarity approach is introduced.

Compared to existing hyperbolic networks, in this work, the advantages of HS are explored for another task - interpretable image recognition. Hyperbolic space is utilized to design the ProtoHyp network that conducts human-explainable classification by using the similarity of prototypes that play key roles in the class definition. Since these prototypes have hierarchical principle, the usage of HS can improve the performance of interpretable recognition.

III. The ProtoHyp Network

In this section, the main points of the hyperbolic geometry that are necessary for the proposed approach are briefly introduced. The ProtoHyp architecture, including its prototype learning, mapping to Poincarè ball and hyperbolic layer, is described.

A. Hyperbolic Geometry

In contrast to Euclidean space, HS is not a vector space in the traditional sense. Thus, standard operations, such as multiplication and addition, cannot be utilized. The non-associative algebraic formalism of Möbius gyrovector space allows to generalize many operations to hyperbolic space [22].

Among the various isometric models used to describe hyperbolic spaces, Poincarè ball has to be selected due to the differentiability of its distance function and ability for gradient-based optimization [15]. The model is defined as $D_c^m = \{a \in R^m : c\|a\|^2 < 1, c \geq 0\}$, where c is the curvature of Poincarè ball, m - its dimensionality. The corresponding conformal factor that denotes the Euclidean metric tensor takes the form $\lambda_a^c = \frac{2}{1-c\|a\|^2}$.

For two vectors $a, b \in D_c^m$, the Möbius addition is defined as follows:

$$a \oplus_c b = \frac{(1 + 2c\langle a, b\rangle + c\|b\|^2)a + (1 - c\|a\|^2)b}{(1 + 2c\langle a, b\rangle + c^2\|a\|^2\|b\|^2)}. \quad (1)$$

The hyperbolic distance is calculated by:

$$d_c(a, b) = \frac{2}{\sqrt{c}}\text{arctanh}(\sqrt{c}\| - a \oplus_c b\|). \quad (2)$$

If $c = 0$, the HS model loses its curvature, and all the operations presented below take their usual Euclidean form $\lim_{c\to 0} d_c(a, b) = 2\|a - b\|$. The curvature parameter c allows the balance between Euclidean and hyperbolic geometries. In Section IV-C, the performance of ProtoHyp with various curvature parameters from 0.1 to 0.9 is demonstrated, and its influence on the results is discussed.

B. ProtoHyp

1) The overall architecture: The structure of the proposed network is illustrated in Fig. 2. The architecture of the ProtoHyp network is generally inspired by ProtoPNet, the fundamental work that made the first attempt to implement

case-based reasoning in image recognition [5]. Similar to ProtoPNet, our network includes the convolutional neural network f, prototypical layer g. However, in contrast, the last layer of the proposed network is a layer in hyperbolic space (III-B4) and the prototypical layer (III-B2) has a different structure as well. The mapping to Poincarè ball is also added to the architecture. Regarding the convolutional layer, various models such as VGG-16 [19], ResNet34 [20], ResNet152 [20], and Dense161 [21] are employed as its backbone networks. The performances of ProtoHyp with different models are discussed in Section IV-C.

2) Prototypical Layer: Let $[X, Y] = (x_i, y_i)_{i=1}^n$ be the training set, $f(x)$ the image features extracted by the convolutional layer. The next step is to obtain the deformable prototypes P in g. The approach to learning deformable prototypes presented in [9] is adapted to ProtoHyp. After the normalization and interpolation of the image features $f(x)$ as described in the work, we get the feature tensor z and compare it with a l-deformable prototype $p^{(k,l)}$. $z_{s,t}$ is used as the d-dimensional vector at the spatial location (s, t) of the feature tensor z. In contrast to ProtoPNet, where L^2-based similarity is utilized to compare a prototype and an image, ProtoHyp utilizes cosine similarity, and the final function of the prototypical layer is:

$$g(z_{s,t}^{(k,l)}) = p^{(k,l)} \cdot z_{s,t} = \cos(\theta(p^{(k,l)}, z_{s,t})) \tag{3}$$

The convolutional f and prototypical g layers of ProtoHyp are trained while keeping its hyperbolic layer fixed. For this purpose, stochastic gradient descent is performed, and features $z_{s,t}$ of class k are clustered around prototypes $p^{(k,l)}$ of the class. Cluster, separation, and orthogonality loss functions [9] are utilized for the training of these layers.

3) Mapping to Poincarè Ball: In order to perform operations in hyperbolic space, the mapping of Euclidean vectors to HS is defined. It is called the exponential map, while mapping from the Poincarè model to Euclidean space is termed the logarithmic map [13].

$$\exp_a^c(v) = a \oplus_c \Big(\tanh\Big(\sqrt{c}\frac{\lambda_a^c \|v\|}{2}\Big) \frac{v}{\sqrt{c}\|v\|} \Big), \tag{4}$$

where the notations are as same as in Section III-A. In this work, the practice of previous hyperbolic vision models is followed, and a is set to 0. Then, $\exp_a^c$ makes the calculation less cumbersome with little impact on the results [14], [15].

4) Hyperbolic Layer: The last layer of ProtoHyp produces interpretable prediction results in Poincarè ball by applying hyperbolic geometry described in Section III-A. Similar to existing interpretable image recognition networks that are designed in Euclidean space, a fully connected layer is considered and implemented in HS. For this purpose, the Möbius matrix is defined by the vector product:

$$M^{\oplus_c}(a) = \frac{1}{\sqrt{c}} \tanh\Big(\frac{\|Ma\|}{\|a\|}(\sqrt{c}\|a\|)\Big) \frac{Ma}{\|Ma\|}, \tag{5}$$

if $Ma = 0$, $M^{\oplus_c}(\mathrm{a}) = 0$. Then, the operation underlying the hyperbolic fully connected layer is given by $M^{\oplus_c}(\mathrm{a}) \oplus_c \mathrm{b}$ for a bias vector $\mathrm{b} \in D_c^n$.

The loss function utilized for the training of the hyperbolic layer is defined as:

$$loss_{hyp} = CE + \lambda \sum_{k,l} \sum_{k \neq k'} |w_h^{((k,l),k')}|, \tag{6}$$

where CE is the standard cross entropy loss, λ is a learning rate, w_h is the weights of the hyperbolic layer. The right part of the loss discourages the negative reasoning processes and is explained in [5].

The examples of the network output are illustrated in Fig. 1. The output is logits that represent each class, and the one with the highest score is selected as the result. Along with the predicted class, the approach demonstrates all the prototypes that influence the final decision and their "weights" in it.

IV. Experimental Results

In this section, the datasets utilized for experiments are first described. Then, the performance of the proposed interpretable neural network with various backbone architectures and preprocessing approaches is evaluated in Section IV-C. Thirdly, the ablation study with different combinations of hyperbolic parameters is demonstrated in IV-D. The quantitative IV-E and qualitative IV-F comparisons to the state-of-the-art of interpretable XAI architectures are also presented.

A. Datasets

1) Birds CUB-200-2011 [17]: The dataset includes 200 species of birds, presented by 11788 images in total. Annotations include bounding boxes and segmentation labels. The train/test separation is predefined. The dataset can be found by following this link[1].

2) Stanford Dogs [18]: It contains 120 breeds of dogs. There are 20580 images in all, with 12000 being the training set and 8580 constitute a testing set. The coordinates of bounding boxes are also provided [2].

B. Implementation Details

The number of prototypes is selected at 2000, following the previous prototype-based approaches [5]. The backbone networks utilized for the experiments, including the state-of-the-art comparison, are pretrained on ImageNet [24]. With regard to the training process, the number of epochs is set to 25, and the learning rate of 0.0001 is experimentally selected. All experiments in this work are run on Amazon Elastic Compute Cloud [3]. A GPU-based deep learning virtual machine with Ubuntu 20.04 and CUDA 11.7 are selected to conduct the experiments. The ProtoHyp network is implemented in Pytorch 1.13, Python 3.9.

C. ProtoHyp Performance Evaluation

Table I demonstrates the accuracy of the proposed ProtoHyp with various backbone networks, including VGG-16 [19], ResNet34 [20], ResNet152 [20], and Dense161 [21]. The experiments have been conducted on full images, as well as cropped ones by using bounding boxes. The results obtained on Birds CUB-200-2011 and Stanford Dogs described in Section IV-A are presented. To begin, the parameters of hyperbolic space recommended by the authors in [13] and their implementation are utilized for the experiments. The dimensionality of Poincarè Ball is set to 500, while its curvature is selected to be 0.5.

Since image cropping is essential for some of the previously proposed interpretable neural networks [5], [7], skipping this step results in significantly lower classification accuracy, the effectiveness of ProtoHyp in both scenarios - with and without image preprocessing is presented. As we can see, the model demonstrates almost the same performance in all cases due to the usage of spatially flexible prototypes. It is quite predictable that the best accuracy among all the backbone architectures presented in Table I has been achieved with the network with the highest number of parameters - ResNet152 and Dense161. This difference is especially obvious on full images.

D. Ablation Study

Various parameters of the Poincarè ball model, such as its curvature, its dimensionality has been evaluated in order to find their optimal practical combination and compare the results with the theory given in previous works [13]. Table II demonstrates the performance of the model in terms of accuracy with different parameters on Birds CUB-200-2011. Since both datasets utilized in this work has similar consistency, fine-grained and in-the-wild, ablation study is conducted on the birds dataset, and the same hyperbolic parameters are applied to Stanford Dogs. The backbone architecture used in these experiments is Dense161. The highest accuracy achieved is with a curvature of 0.4. This value is close to the hyperbolicity value of the Birds CUB-200-2011 dataset [13]. The dimensionalities of 2, 20, 200, and 2000 is selected due to the lowest possible dimensionality of the Poincarè model that equals 2 (Poincarè Disk). Then, we multiply it by 10. The best performance is achieved with $dim = 200$, while it starts decreasing with a higher dimensionality.

The experiments have also revealed the dependency of the network convergence on the curvature of Poincarè ball. Fig. 3 demonstrates the training process of ProtoHyp with different curvature values. Moreover, it also shows the graph of the accuracy vs. the number of epochs during the training of the network in Euclidean space (red line). As it is mentioned in [13], the hyperbolic space with $c = 0$ is the analogy of ES, and $c = 0.1$ (blue line) demonstrates the most similar training process. The faster convergence with a slight loss in accuracy is produced by $c = 0.9$ (yellow line). It can be concluded that ProtoHyp and models in HS, as a whole, are superior to neural networks designed in ES in terms of convergence.

E. Quantitative Comparison to the State-of-the-Art

In order to demonstrate the advantages of the proposed ProtoHyp network and the usage of hyperbolic space for interpretable XAI as a whole, quantitative evaluations of existing interpretable networks in terms of accuracy are first presented in Table III. The reimplementation of the state-of-the-art approaches is conducted using the official codes created by the respective authors with their recommended hyperparameters. The fundamental case-based reasoning architecture ProtoPNet [5], its enhanced versions ProtoPool [7], TesNet [8], ProtoTree [6], Deformable ProtoPnet [9], are used for the comparison. More details about the works can be found in Section II-A. Their performances with various backbone networks achieved on the datasets are evaluated. The results of the proposed ProtoHyp with the hyperbolic parameters that demonstrated the highest accuracy in Section IV-D are selected for comparison to the state-of-the-art ($c = 0.4, dim = 200$).

Regarding the performances of ProtoPNet and ProtoPool presented in Table III, these results have been obtained by

using bounding boxes. In other words, cropped and augmented images of the datasets are used for training and testing (in this case, without augmentation). In contrast, other models presented in the table are able to produce reasonable accuracy on full images of the datasets without any preprocessing. However, only the deformable ProtoPNet that exploits flexible prototypes instead of spatially rigid overcomes the "in-the-wild" issue and demonstrates the highest classification accuracy among all the previously proposed models.

It must be mentioned that the main goal of ProtoPool network is to enhance ProtoPNet by reducing the number of utilized prototypes. While other frameworks presented in Table III are based on 2000 prototypes, ProtoPool produces similar accuracy on only 200 of them. The results of ProtoTree [6] have been achieved on a single interpretable tree, not on their ensembles.

The proposed ProtoHyp network has achieved the highest accuracy among all the presented case-based reasoning interpretable XAI models. It does not require any image preprocessing due to the usage of spatially flexible prototypes. In contrast to current interpretable frameworks, ProtoHyp is designed and trained by using hyperbolic space that allows it to outperform the state-of-the-art in interpretable image recognition.

F. Qualitative Comparison of Interpretability

Although there is still no benchmark approach and metrics to evaluate the interpretability of explainable AI models [4], attempts to compare the results of the proposed ProtoHyp network and fundamental ProtoPNet [5] have been made in this work. Fig. 4 and Fig. 5 illustrate the quantitative analysis of their performances on Birds CUB-200-2011 and Stanford Dogs, respectively. Three images are randomly selected from a testing set. Then, ProtoPNet and ProtoHyp are utilized for their classification. If the predicted class is not the same as its ground-truth, it turns red. Most importantly, the figures demonstrate three prototypes that the networks found the most similar to the images. Their corresponding similarity scores are also presented. Since the main goal of explainable AI is to produce a human-understandable decision, it can be concluded that the prototypes caught by ProtoHyp are more reasonable than ProtoPNet, and the proposed network has a higher level of interpretability.

V. Conclusion and Future Work

In this work, hyperbolic space with its ability to embed hierarchical structures has been utilized to design and train an interpretable image recognition network. Prototypes with the highest influence in the final decision are first learned. After mapping into Poincarè ball, an intepretable classification is conducted. Extensive experiments have been carried out on two image recognition datasets, Birds CUB-200-2011 and Stanford Dogs. Various backbone networks and hyperbolic parameters have been evaluated in order to find the optimal configuration of the network and HS for the XAI, as a whole. Comparison to the interpretable state-of-the-art has shown its improvement in terms of accuracy and interpretability.

The research in the interpretable image recognition area suffers from the lack of approaches to compare the interpretability level of benchmarks. Our future research is going to address this issue and a dataset augmented with human perception of image interpretability is going to be collected. The usage of HS not only in the interpretable classification layer but also in lower layers is another future research direction. Taking into account the effectiveness of few-shot and representation learning in hyperbolic space, attempts to achieve transparency and interpretability of this research by utilizing hyperbolic space will be explored.

***Abstract*—Low-light images challenge both human perception and computer vision algorithms. Despite notable progress in this field, there are still various gaps that are yet to be investigated, such as the significance of low-light illumination characteristics towards image enhancement and object classification. Therefore, this paper details various analyses to study this phenomenon and provide insights for future developments of algorithms and solutions. Specifically, comparative analysis was done to investigate human and machine perception towards "low-light types", followed by empirical studies on the effect of illumination types towards state-of-the-art image enhancement quality and also their pre-processing capability for downstream task, namely object classification. It is found that illumination types significantly influences the performance of enhancement algorithms that tend to cater for a "general" type of low-light illumination. This lack of illumination type awareness therefore leads models to perform well in certain conditions, but severely underperforms in others. Thus, it is imperative for upcoming works to incorporate such illumination information for potential breakthroughs in this area.**

I. Introduction

Computer vision is an automated system modeled after human vision for a machine to visually perceive and interpret the environment via digital images or videos. However, visual data taken under substandard lighting conditions, namely low-light, suffer from compromised aesthetic quality and affects the perceptibility of information. Consequently, high-level tasks such as object recognition and tracking become more challenging, even for human vision. Nonetheless, there are extensive application possibilities for intelligent visual systems that is robust to low-light conditions, for instance, smart surveillance, self-driving vehicles, and more.

In light of such potential, interest in this research domain has been growing exponentially in the recent years, particularly in low-light image enhancement (LLIE), yet there is still a noticeable gap in the existing works in terms of understanding the low-light phenomenon in image data. Typically, low-light images can be caused by various factors, such as capturing them in environments with uneven lighting, light source intensity limitations, or even limited exposure time of the capturing process. This can result in notably different visual characteristics despite similar content (e.g. objects) in the images. For instance, images captured in a very dark indoor environment may have significant noise pixels due to an increase in camera ISO to capture more light particles, whereas an image captured on the street at nighttime may have less noise pixels but exhibits a warm color tone due to the yellowish or orange glow of the street lights. Such differing visual characteristics can be termed as illumination variations.

Despite such clear visual differences in low-light images, most LLIE works aim to improve the perceptual quality or decipherability of the content within, regardless of the variations in illuminations. As such, the enhancement outcomes of LLIE may not be effective for all illumination types, not only in terms of visual quality but also as input for downstream applications like object classification. This is because ineffective enhancement may not improve object visibility and also potentially distort object features, thus causing models to fail at the classification task. Even so, there is very limited research works that look into this problem in the LLIE domain.

Therefore, this work investigates the impact of this phenomena on LLIE to derive insights and directions for future studies. Specifically, we devised quantitative and qualitative experiments in order to empirically study the impact of varying low-light image illuminations on notable LLIE methods, as well as their impact on the effectiveness of LLIE in supporting downstream tasks. The contribution of this work is three-fold:

1) A comparative analysis to explore and compare human acumen with the acuity of unsupervised machine learning at distinguishing low-light illumination types.
2) An empirical analysis to provide a comprehensive view on the impact of low-light illumination types towards the resultant image quality of various state-of-the-art LLIE methods from quantitative and qualitative perspectives.
3) An empirical study on the impact of illumination types towards the effectiveness of LLIE methods as preprocessing for downstream application task, namely object image classification.

These analyses validate the hypothesis that low-light images has varying illumination types and these variations has notable impact on the LLIE outcomes in more ways than image quality. Thus, we discuss several open issues in this domain of research

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

and invite all to explore and devise more holistic solutions for future breakthroughs in this area.

II. Review of LLIE Methods

Low-light vision related research has been focused on image enhancement for years, and the most recently notable approaches can be distinguished into two main categories, Retinex-based methods [1] and Deep Learning-based methods. Firstly, Single Scale Retinex (SSR)[2] synthesizes contrast enhancement and color constancy by performing a non-linear spatial transform to mimic the human visual system. A combination of several SSR outputs [3] produces a single output image that has both good dynamic range compression, color constancy and good tonal rendition by using Gaussian distribution to determine the weighting factors. Alongside these methods, the illumination map estimation approach proposed by [4], LIME is one of the most effective at producing visually pleasing images by estimating a single illumination map, thus reducing computational cost. However, illumination map estimations by these methods do not take into consideration the relationship between colors and low-light thus significantly affects the enhancement outcomes when faced with significantly low-light images with limited color content.

Deep learning methods on the other hand can be sub-divided into supervised models [5]–[9], unsupervised models[10]–[12], and zero-shot models [13], [14]. Zero-shot models have shown significant potential as it strikes a balance between supervised and unsupervised methods with a loose requirement on reference images for training, yet achieve competitive enhancement outcomes. The ExCNet [14] is a method that demonstrates this concept by training image-specific curve estimation networks at testing time using a small amount of training images, whereas the ZeroDCE [13] focused on formulating a set of non-reference loss functions in order to train a network model to estimate pixel-wise high-order estimation curves. Nonetheless, the network architectures as well as loss functions that are still formulated to generalize the estimation curves across "all" low-light conditions without specific consideration of illumination differences, thus only reaching a standard outcome across the board.

III. Dataset and Experiment Design

The main goal of this study can be summed up as an investigation to verify the existence and impact of varying low-light illumination types on enhancement outcomes and downstream task performance, an aspect that has been mostly overlooked in LLIE research. To this end, this study can be distinguished into two major elements, (1) comparative analysis on perceptions of low-light illuminations between human vision and unsupervised machine learning, and (2) empirical analyses on LLIE performance differences in image quality and post-enhancement object image classification when subjected to different categories of low-light illuminations.

A. Dataset

The emphasis of this work is the analyses relating to specifically low-light illumination types, an element that is not present in most notable publicly available low-light image datasets catered for enhancement research, such as LoL [15], SID [16], and SICE [17]. Therefore, the ExDark [18] is selected as the dataset for this study because to the best of our knowledge, this is the only dataset which provides a collection of low-light images with illumination type annotation as well as image and bounding box level object class labels. Specifically, the ExDark contains up to 7363 challenging real-world low-light images with human categorized illumination classes, namely *low, ambient, object, single, weak, strong, screen, window, shadow* and *twilight* as shown in Fig. 1. This categorization would facilitate the comparative analysis as well as condition the empirical analyses to understand their impact towards performances. Alongside, the dataset image level annotation of twelve object classes, which are *bicycle, boat, bottle, bus, car, cat, chair, cup, dog, motorbike, people* and *table* will be used for the downstream task evaluation.

B. Human Perception vs. Unsupervised Machine Learning

The categorization of low-light images into the 10 illumination types has been briefly discussed in [18], whereby the categorization was done wholly on observable characteristics without statistical or mathematical basis. Therefore, this work further investigates this and contrast it with categorizations that is generated via machine learning in an unsupervised manner. In particular, the color histograms of these low-light images were studied in order to formulate statistical illumination features. These features are then used to train a clustering algorithm in order to form potential groupings, so as to find out if such illumination differences can be identified purely from the statistics. Subsequently, both perspectives of illumination categorizations are used in the empirical analyses to ascertain and compare the impact of illumination on image enhancement quality and object classification accuracy.

1) Feature Extraction: In order to formulate relevant features, the color histograms (i.e. intensity histograms of RGB channel) of the low-light images were explored and two key characteristics were found. Firstly, there is a notable amount of images with histograms having a large number "empty" bins in the higher intensity levels and high frequency in the lower intensity bins. This can be associated with the lack of color in very low-light images as the images contain mostly "black" pixels. Such pattern of histograms are observable in a few illumination types shown in Fig. 1, such as *low*, *ambient*, and *object*. This characteristic is therefore quantified using the sum of bins with frequencies between each logarithm of 10, from 10^0 till 10^4 including the count of "empty" bins of each color channel as a representation of histogram bins *sparsity* with 18-dimensions (6 for each channel). Secondly, it is also found that there are a few modalities in the histograms, for instance unimodal for types like *strong* and *object*, bimodal in *weak*, *window* and *shadow*, and multimodal for *single*, *screen*,

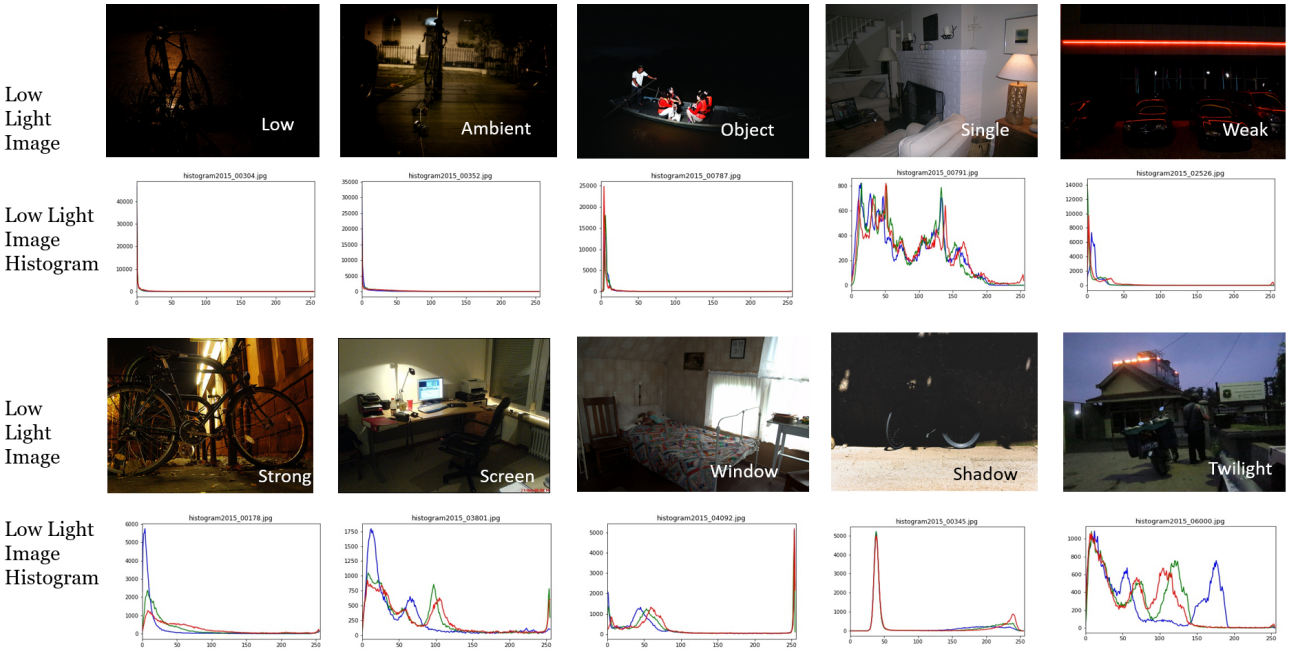

Fig. 1. ExDark Low-light images and its corresponding histogram. There are ten illumination types by human annotations namely low, ambient, object, single, weak, strong, screen, window, shadow and twilight. Each type of low-light image exhibit a different histogram behavior.

and *twilight*. Hence, another 3-dimensions are used to indicate the histograms' *modality*. Finally, for the overall feature, the intensity histograms for all three RGB channels are included as well to form a 789-dimension feature vector to represent the low-light images.

2) Clustering: The k-means algorithm is implemented to perform clustering with Euclidean Distance as the measure of dissimilarity in order to investigate the unsupervised clustering of low-light illumination types based on the formulated feature vector. The Elbow Approach is used to determine the best number of clusters that can be formed, based on Within-Cluster Sum of Square (WCSS) values as shown in Fig. 3. According to this assessment, 3 is found to be the optimal number of clusters based on the elbow of the curve which is a notable departure from the human categorized 10 illuminations. Thus, the comparative analysis in Section IV-A discusses the commonality and differences between these categorizations of illumination types.

C. Image Enhancement against Illumination Types

A main hypothesis in this research work is that current LLIE methods may lack of robustness towards illumination variations as there is a common general assumption that low-light itself is a "single" type of illumination. Thus, in order to explore and highlight potential key challenges in such models, state-of-the-art enhancement algorithms are implemented to enhance the ExDark images and evaluated both qualitatively and quantitatively, with respect to the 10 illumination types, as well as the 3 clusters found in Section III-B2. Specifically, the notable LIME [4] and Zero-DCE [13] are the selected methods for this evaluation, and the no-reference Image Quality Assessment (IQA) metric, BRISQUE [19] is adopted as the quantitative measure of enhanced image quality.

D. Object Classification against Illumination Types

Recent works in LLIE research also investigates their effectiveness at supporting downstream tasks like object classification and detection, but similarly, the impact of illumination types on such task has not been explicitly discussed [10], [20], [21]. Therefore, we approach this investigation by using object classification as the downstream task, and the classification accuracy as the task-driven metric to evaluate the influence of illumination as well as the effectiveness of the LLIE methods at supporting classification models in such conditions.

Particularly, the MobileNetv2 [22] classifier is selected as the model for object classification, following the 12 object classes provided in the ExDark. The experiments involve training 3 separate models of the classifier with different sets of images, namely, the original ExDark images, ExDark enhanced by LIME, and ExDark enhanced by Zero-DCE. Similar to the enhancement analysis, the classification performance of each of these models were scrunized with consideration of the 10 illuminations types provided by the ExDark, as well as the 3 cluster groups found in Section III-B2.

IV. Benchmarking and Analysis

This section provides the results of the comparative and empirical analyses, whereby the illumination types produced by clustering are contrasted with the 10 illumination types from the ExDark. This is followed by the empirical analysis on image quality enhancement using LIME and Zero-DCE and object classification performance of MobileNetV2 trained using different sets of training images. All of which will be discussed in view of the different illumination types.

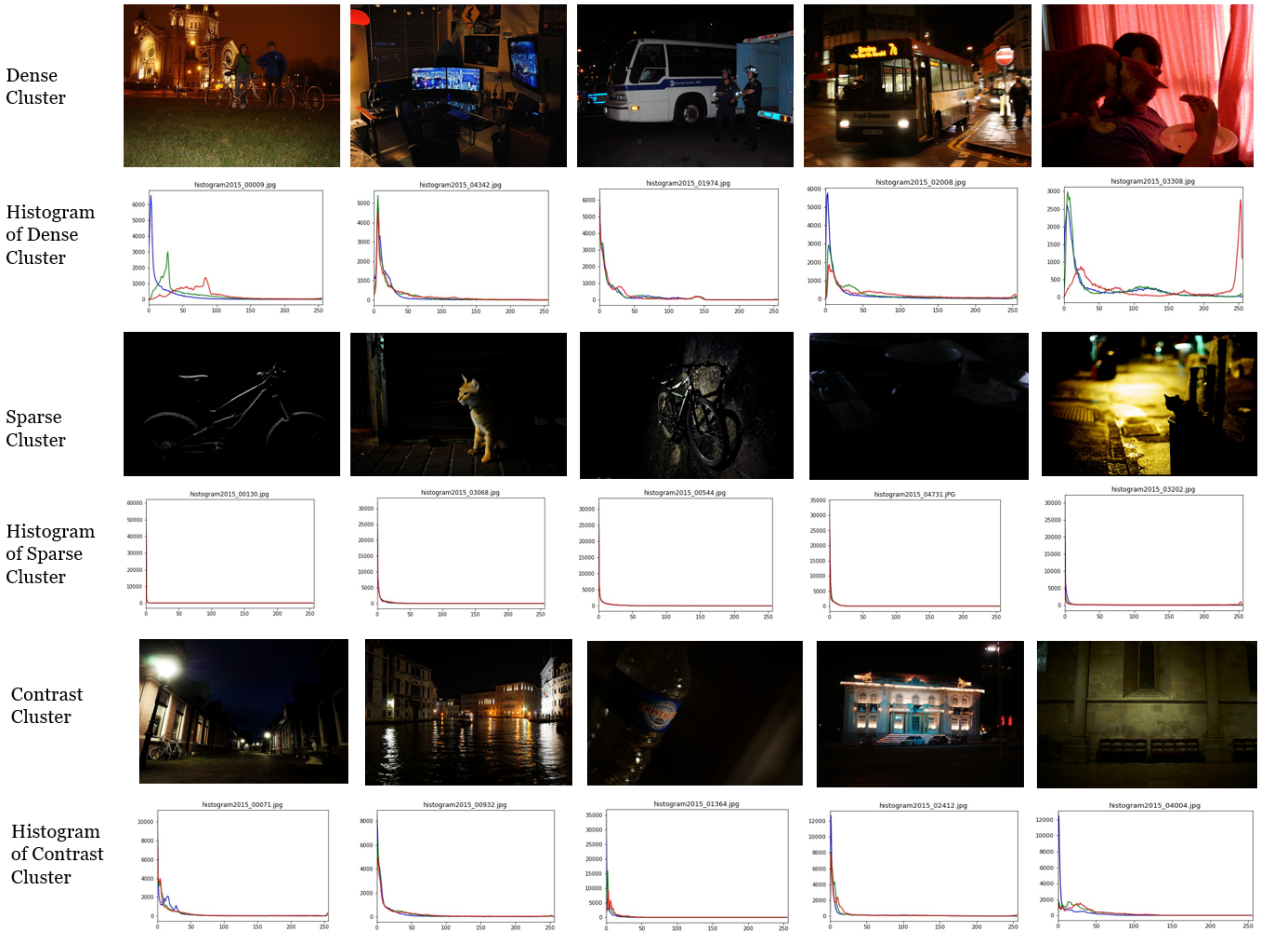

Fig. 2. Histogram of different clusters using ExDark Dataset.

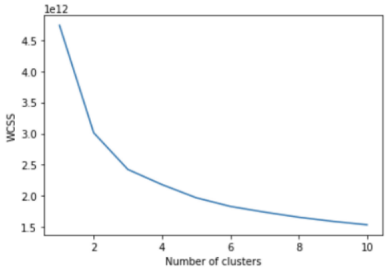

Fig. 3. ExDark Dataset is found to have 3 clusters based on the machine clustering illumination type using WCSS.

A. Comparative Analysis of Illumination Types

The 10 illuminations types specified in the ExDark dataset were manually categorized. Fig. 1 are selected samples of images from each illumination type with the respective histograms. It can be observed that there are certain patterns that distinguishes the types from one another. For instance, *low* and *ambient* types exhibit the highest bin sparsity and is positively skewed towards lower intensity values. The image itself exhibits with very few color shades, and the histograms of the RGB channels are very similar. On the other hand, *object, weak* and *strong* types also have high sparsity but with slightly wider distribution, and visually, the images have more color shades but still very similar histograms between the RGB channels. The *single* illumination type however has a histogram with notably wider distribution pattern, and visually more apparent colors though similar histogram patterns between the channels. This is similarly seen in the *twilight* type but the main distinguishing aspect is the significant differences between the histograms of the RGB channels. Lastly, the *shadow, screen* and *window* types has notable bimodal/multimodal histograms with distinct peaks on the two extremes of low and high intensity values.A lot more color shades can also be seen in such images as well for the parts with sufficient lighting.

Contrarily, the cluster groups formed by the k-means algorithm are more generalized in comparison. From observations, the clusters can be distinguished into *dense, sparse*, and *contrast* clusters as seen in the samples in Fig. 2. The largest cluster is the the *dense* cluster containing 4911 images and their histograms have relatively mixed patterns with wide distributions and the maximum frequency recorded in the histograms are lower in comparison to the images in the other two clusters. Moreover, images with marked differences in each of the RGB channel histograms are also clustered into this group. Visually, the images are relatively "bright" where the contents are still relatively easy to discern and more color shades can be observed. Comparing to the ExDark illumination types, it seems that the *single, strong, screen, window, shadow,*

and *twilight* types have been grouped into this cluster.

Separately, the *sparse* cluster is the smallest among the 3 clusters with only 620 images. Visually, the images in this cluster are darker and the objects can be "hidden" in the darkness, as shown in Fig. 2. The color histogram of these images has high bin sparsity, yet the maximum frequency of bins are the highest among the clusters. The histograms of the individual RGB channels are also very similar, signifying a lack of color shades as seen in the image samples. The characteristic of this cluster is very similar to the *low* and *weak* types in ExDark.

Lastly, the *contrast* cluster contains 1830 images with very similar histogram distributions to the *sparse* cluster but the maximum histogram frequency is lower and a slightly wider distribution. The images has more color shades as well, though there are still noticeably large dark regions. The *ambient* and *object* types appears to fall into this category. Overall, the clustering by k-means has some commonality with the types given by ExDark, but the groupings are less granular whereby the main segregation is mainly based on color shades and general content/object visibility as compared to more contextual categorization done by humans, e.g. twilight, screen, and shadow. This leads to the question, if there are notable differences in enhancement performance following these any of types of illumination.

B. Empirical Analyses of LLIE

1) Quantitative Assessment:: Table I shows the summary of the BRISQUE scores of the enhanced low-light images of the three clusters. Enhanced images from the *dense* cluster are found to have the best results irregardless of LIME or ZERO DCE as the enhancement approach as they have the lowest score across all statistics, implying best image quality as well as consistent enhancement results. This performance is followed by the *contrast* cluster and lastly the *sparse* cluster. We note that the quality of images from the *sparse* cluster are the worst with the average BRISQUE score that almost doubles that of the *dense* and *contrast* clusters. Moreover, the highest standard deviation also indicates that the scores of enhanced *sparse* cluster images have significant variations, implying an unstable enhancement outcome.

Conversely, Table II shows the summary of the BRISQUE comparison for the enhanced low-light images with respect to the 10 illumination types from ExDark. From these ten human annotated illumination types, the BRISQUE scores of the *low* type have the worst average score for both LIME and ZERO DCE enhancement. This is consistent with the results of the cluster groups as the *low* and *ambient* types are parts of the *sparse* cluster. Similarly, the enhanced results of the *weak* type are the third worst. The illumination type that records the best enhanced outcome is the *twilight* type which records the lowest BRISQUE scores for all statistical measures and approximately 2 times lower than the scores of enhanced images from the *low* and *ambient* types. This result is followed by the *strong* and *screen* types, both of which are also part of the *dense* cluster with the *twilight* type, thus concurring with the clusterring-based results in Table I.

However, an interesting finding is that the second worst enhancement comes from the *shadow* type images which falls into the *dense* cluster and mostly having bimodal histogram distribution, thus contradicting the results of Table I. This implies that there are more nuance in low-light illuminations that is not captured in histogram distributions, and the performance of image enhancement methods varies greatly depending on the illumination type.

As a whole, different types of low-light images have varying impact on the enhancement results as shown in Tables I and II. Both of the state-of-the-art enhancement models work better on images with more visible color shade and notably different histogram distributions in the RGB channels, e.g. images in the *dense* cluster or from the *twilight* and *strong* types. Images that have significant dark regions with less color shades and low difference in the RGB channel histograms record the worst enhancement results, with BRISQUE scores almost 2 times of the best enhanced group of images.

TABLE I
BRISQUE SCORE COMPARISON OF THREE CLUSTERS WITH KMEANS ALGORITHM USING EXDARK DATASET FOR DENSE CLUSTER, SPARSE CLUSTER AND CONTRAST CLUSTER.

Cluster (Number of images)	dense cluster (4911)		sparse cluster (620)		contrast cluster (1830)	
Algorithm	LIME	ZERO DCE	LIME	ZERO DCE	LIME	ZERO DCE
Min	-28	-21	8	4	-8	-5
Max	102	99	183	179	136	142
Average	**31**	**30**	69	65	**39**	**38**
Std. Dev.	14	13	27	22	17	16

2) Qualitative Assessment: The qualitative evaluation using BRISQUE score has shown that the LIME and Zero-DCE shows varying enhancement performance when given images with differing types. This section takes a further look into the enhancement results to visually assess the image quality.

Fig. 4 shows visual samples of low-light images before and after enhancement using Zero-DCE and LIME. Notably, enhanced images from several illumination types have issues with enhanced artifacts, noise pixels, and over-enhancement. For instance, the samples of *low* and *object* types show significant noises after enhancement, whereas the *window* type is over-enhanced, and the *screen* example has lingering artifacts.

While different illumination types seem to exhibit quality issues at random, the general observations are that, enhancing significantly low-light images such as *low* commonly "reveals" noises and artifacts. This is also true for illumination types where the images are only partially dark but the intensities of those dark regions are severely low, such as *screen, window*, and even *shadow*. Thus the observation in Table II where *shadow* types recorded second worst average quality is due to the darker regions that affected the enhancement results.

On the contrary, enhancement results of images that has more color shades originally, as opposed to mostly dark regions, tend to yield better visual results. This is typically

TABLE II
BRISQUE SCORE COMPARISON OF THE ORIGINAL TEN ILLUMINATION TYPES USING EXDARK DATASET FOR LOW, AMBIENT, OBJECT, SINGLE AND WEAK ILLUMINATION TYPES.

	Low		Ambient		Object		Single		Weak	
Total Images	241		2098		498		762		704

observable in the *strong* type of images but other types may have similar results provided there is sufficient color.

In terms of the methods, the results of Zero-DCE tend to have less color and are whitish compared to LIME. Contrasting, LIME enhanced images tend to have more color but at the same time more noise as well. Nonetheless, both methods perform well on image types with more color originally like *twilight* and *strong* types but the quality deteriorates for darker types like *low*.

3) Object Image Classification: This section details the analysis using image classification accuracy as a task-driven metric to measure the effectiveness of image enhancement at supporting object classification performance in varying illumination conditions.

Fig. 5 illustrates the classification performance of the MobileNetV2 at classifying objects when trained using the original ExDark images, as well as images enhanced by LIME and Zero-DCE and tested on the respective test sets. The bars show the object classification accuracy sorted by the cluster groups. From this visualization, it can be seen that object classification accuracy is consistently highest for images from the dense cluster followed by the contrast cluster and lastly the sparse cluster, regardless if the images are enhanced or not. This observation is in line with the quality evaluations, however, it should be noted that the performance differences are not significant between the clusters. Thus, implies that the illumination may not have a significant impact.

Following that, Fig. 6 shows the same object classification results but with respect to the 10 illumination types of the ExDark. It can be clearly seen that the object classification accuracy varies significantly based on the image illumination type. Images from the *twilight* type is found to have the highest accuracy with an average of 89%, whereas *screen* and *single* are shown to have the lowest accuracy with averages of 50% to 60% respectively. This result clearly shows the significant impact that illumination types have on downstream task, as well as the relatively weak effect the enhancement of LIME and Zero-DCE has on the performance.

From these results, it can be stated that the current state-of-the-art image enhancement models are not optimized to handle different types of low-light images, especially those with high sparsity in the histogram pattern. This include images with large number of pixels that are dark and lack colors.

V. OPEN ISSUES

Based on the analyses, we present the following open issues in low-light research that we believe warrants attention:

1) **Over generalization of low-light**. Although significant progress has been made in various areas of low-light vision research in recent years, low-light is still addressed in a singular categorization which under-represents the various characteristics that are imperative to various tasks, including enhancement and recognition. This can be seen from the various notable datasets which provides "uniform low-light" images by varying exposures, as well as approaches utilizing synthetic data generated using power functions, both of which do not represent the diverse characteristics of low-light environments.
2) **Lack of low-light characteristics awareness in enhancement frameworks**. Due to the common over-generalization of low-light, image enhancement methods are often not adaptable towards specific illumination types. In our analyses, despite localized pixel-level enhancement estimations, current enhancement methods are unable to handle the "cross-illumination differences" in the images, thus resulting in sub-par enhancement results, like noise amplification as well as over- and under-enhancement for particular types of low-light images.
3) **Bottleneck for downstream tasks**. Downstream tasks like object classification are still under-performing in low-quality conditions like low-light, mainly due to the lack of data to train a sufficiently reliable model. The support of enhancement as pre-processing is still inferior in comparison to the outstanding performance in regular light conditions, especially considering the more "severe" low-light types. Hence, there is a need for more work to address the underperformance of enhancement methods in these cases to overcome this bottleneck.

Fig. 4. Visual results of original ExDark Dataset, ZERO DCE and LIME on Exark Dataset's ten types of low-light images namely low, ambient, object, single, weak, strong, screen, window, shadow and twilight

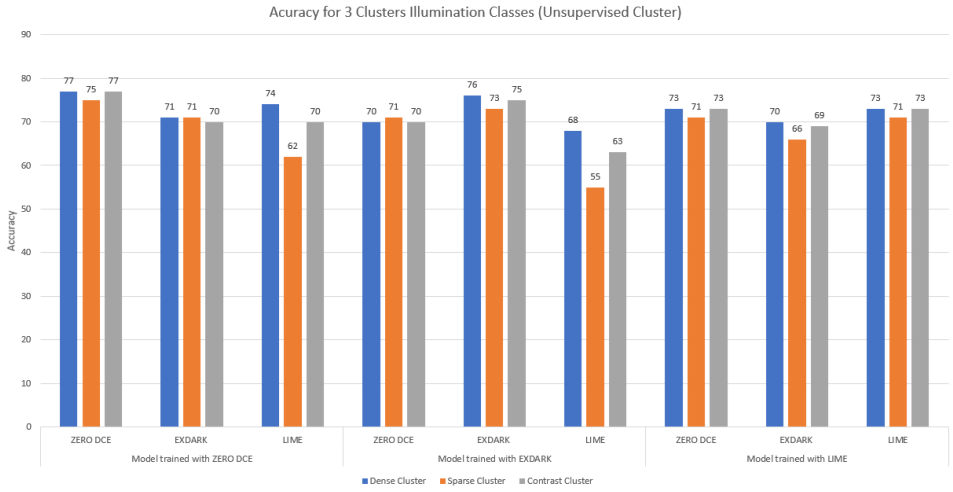

Fig. 5. ExDark Low-light images object classification with KMeans clusters (Machine)

VI. Conclusion

Low-light vision is a challenging topic with notable gaps still yet to be addressed. In this paper, we conduct several analyses to investigate and validate the presence of diverse illumination types in low-light environment. It is found that low-light can be diversified into various types and they have notable impact towards image enhancement performance and subsequently affect downstream tasks. Thus, we discuss several open issues that is worth further attention that can potentially push forward the research in this area.

***Abstract*—Training accurate convolutional neural networks (CNNs) is essential for achieving high-performance machine learning models. However, limited training data pose a challenge, reducing model accuracy. This research investigates the selection and utilization of misclassified training samples to enhance the accuracy of CNNs where the dataset is long-tail distributed. Unlike classical resampling methods involving oversampling of tail classes and undersampling of head classes, we propose an approach that allocates more misclassified training samples into the training process to learn more (namely, MoMo strategy), with ratios of 50:50 and 70:30 for the wrongly predicted and correctly predicted samples, respectively. Additionally, we propose incorporating a balanced sample selection method, whereby the maximum training sample per class in an epoch is assigned to address the long-tail dataset problem. Our experimental results on a subset of the current largest plant dataset, PlantCLEF 2023, demonstrate an increase of 1%-2% in overall validation accuracy and a 2%-5% increase in tail class identification. By selectively focusing on more misclassified samples in training, at the same time, integrating a balanced sample selection achieves a significant boost in accuracy compared to traditional training methods. These findings emphasize the significance of adding more misclassified samples into training, encouraging researchers to rethink the sampling strategies before implementing more complex and robust network architectures and modules.**

I. Introduction

Limited training samples are a common challenge in real-world machine-learning applications such as in face [1], traffic scene [2], medical image [3], and species recognition [4]. In reality, training data is typically scarce and follow a long-tail distribution. This distribution has fewer classes with many training samples and many classes with fewer training samples. When lacking training data, models may struggle to generalize and accurately classify new or unseen instances. Similarly, in datasets with a long tail distribution, the model may output higher prediction scores for the classes with many training samples (head classes) but lower prediction scores for the classes with fewer training samples (tail classes) [5]. This results in models being biased towards the head classes, often leading to poor performance in the tail classes, or rather the minority and rare.

In the context of plant identification, deep learning has shown significant progress in recent years and even performed comparably with human experts [6]. Nonetheless, this classification is supplied with ample training samples representing only tens of thousands of species, whereas the global plant species consists of approximately four hundred thousand [7].

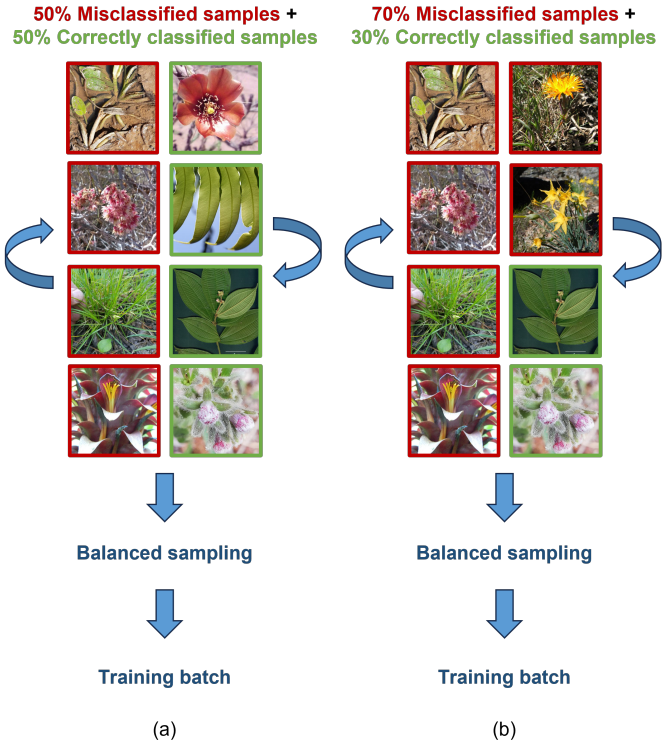

Fig. 1. An overview of the two different MoMo strategies experimented on. (a) illustrates the allocation of 50% misclassified training samples and 50% correctly classified training samples. (b) represents the allocation of 70% misclassified training samples and 30% correctly classified samples. Each batching will be further selected according to the limit set to ensure the samples are balanced in the epoch and finally used in training.

Most plant species universally are less observed and significantly lower in samples as they are located in remote areas that are difficult to access. Consequently, rare or new plant species are commonly under-represented in training data, making them difficult to be identified. It was shown in [7] where the training dataset size used is significantly lower per species and suffered from a higher degree of noise, accurately representing the challenges in global species identification.

Various methods have been proposed to address this long-tailed class imbalance issue, which includes class re-balancing [8], [9], information augmentation [10], and module improvement [11]. However, in the field of plant classification, more

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

work has yet to be explored to tackle this problem. Many researchers focused on feature extraction approaches [12], [13], altering model loss functions [14]–[16], data augmentation [17], [18], and using varying network architectures [19]–[21] but not directly taking on the long-tailed dataset itself at the sample level despite it being the most straightforward approach among them.

In this paper, we conduct extensive experiments on a subset of the current largest plant dataset, PlantCLEF 2023, where we randomly selected ten thousand species to investigate the significance of devising the batching samples in training long-tailed deep plant models. Classical resampling methods involve the random over-sampling (ROS) and random under-sampling (RUS) techniques where ROS repeats the samples of the tail classes in training, and RUS removes the samples of the head classes in training [22]. Although these methods ultimately result in good predictions, ROS might overfit the tail classes, while RUS might underfit the whole data distribution, reducing the performance of the head classes [23].

Conversely, instead of resampling or re-balancing the head and tail classes, we propose to use more misclassified training samples to allow the model to learn more from its mistakes, hereinafter referred to as MoMo strategy. Fig. 1 illustrates the overview of the strategy. We hypothesize that giving more attention to misclassified instances increases the representation of the difficult samples, allowing the model to allocate more learning resources to those instances. It can be particularly beneficial for the rare or underrepresented classes, as the model gets more opportunities to refine its decision boundaries and better capture their intricacies. Besides this, we hypothesize that it can help the model to focus on the regions of the feature space where it struggles the most, promoting better generalization and reducing the risk of overfitting the majority classes. In addition, we propose to set a limit to the maximum class samples for training to study the effects of MoMo strategy in a balanced and unbalanced scenario.

Our experiments show that our proposed MoMo strategy with a balanced class distribution achieves a significant boost in accuracy compared to traditional batching methods, particularly in tail class recognition. This finding emphasizes the importance of adding misclassified samples to enhance the training of deep learning models. It provides new experimental evidence and discussion for the need to leverage misclassified samples in addition to implementing more intricate approaches, such as network alteration and module improvement, when addressing the curse of long-tail datasets.

II. Methodology

A. Network Setup

The networks implemented in this work are classical CNNs optimized by a softmax loss function. They are constructed based on the Inception-ResNet-v2 [24] model and pre-trained from the ImageNet Large Scale Visual Recognition Challenge 2012 (ILSVRC 2012) dataset [25] available in the TensorFlow-Slim image classification library [26]. We used a batch size of 128, an initial learning rate of 0.00001 for the front layers, 0.0001 for the classification layers, an Adam optimizer, a weight decay of 0.00004, and an image input size of 299 $\times$ 299 $\times$ 3. Inception-ResNet-v2 is adopted as our backbone (base) network because it achieved the lowest Top-1 Error and Top-5 Error on the non-blacklisted subset of the validation set of ILSVRC 2012, when proposed in [24]. In addition, the Inception-ResNet-v2 model is one of the highest performing and lighter pre-trained models in the TensorFlow-Slim image classification library without significantly compromising the accuracy. Lastly, it is among the top-performing models in the plant identification challenges, PlantCLEF 2017 [27], PlantCLEF 2019 [7], PlantCLEF 2020 [28], PlantCLEF 2021 [29], and PlantCLEF 2022 [30].

B. Training Strategies

Our training strategies emphasize the incorporation of misclassified training samples during model training. To implement our approach, we devise a sample selection strategy for each training epoch. We assign a ratio for misclassified and correctly classified samples, ensuring they receive suitable focus and attention in training. This prioritization is achieved by hard-coding the sampling strategy to include more misclassified instances than correctly classified samples. The ratios we experimented on are 50% and 70% for misclassified samples. The prioritized misclassified samples are then combined with correctly classified samples (50% and 30%) during each epoch to form each training batch. In addition, to maintain a balanced sample selection without over-picking the head classes, the training samples per class were limited to a maximum of 16 in each epoch. It aims to prevent classes with more samples from being selected more frequently to minimize class bias. In short, two kinds of experimental training strategies are carried out, one on the ratio of misclassified samples incorporated in the training and the other with or without a balanced sample selection between classes. Moreover, we employ data augmentation techniques to enhance the learning process further. Data augmentation introduces variations and perturbations to the samples, enabling the model to understand better and generalize from these challenging instances.

C. Inference Method

The model predictions are obtained using the softmax function where it transforms the output of the previous layers to the final layer into a probability distribution over the total classes. It can be represented in (1)

$$p_i = \frac{e^{z_i}}{\sum_{j=1}^{n} e^{z_j}}, \tag{1}$$

where p_i denotes the probability of the input belonging to the *i*-th class, e^{z_i} represents the exponential function applied to the *i*-th element of the input vector, z_i. The exponential function raises Euler's number (e) to the power of z_i, resulting in a positive value. Meanwhile, $\sum_{j=1}^{n} e^{z_j}$ denotes the sum of the exponential values across all elements of the input vector. It calculates the sum of the exponential values for each z_j. After

TABLE I
DETAILS OF THE TRAINING AND VALIDATION DATASETS.

Dataset	Number of species	Number of images
Training (Unbalanced)	10,000	298,669
Training (Balanced)	10,000	128,040
Validation (Overall)	9,402	9,402
Validation (Head)	1,238	1,238
Validation (Middle)	2,163	2,163
Validation (Tail)	6,001	6,001

TABLE II
THE LONG-TAIL TRAINING DATASET DISTRIBUTION.

Category	Number of training samples	Number of species
Tail	5 - 10	3,091
	11 - 20	2,201
	21 - 30	1,302
Middle	31 - 40	751
	41 - 50	603
	51 - 60	449
	61 - 70	364
Head	71 - 80	292
	81 - 495	495
	91 - 112	452

obtaining the probability of the predicted class, we used the Top-1 and Top-5 accuracy to measure the performance of the model. Prior to obtaining the prediction probability, we crop the target images into multiple crops, specifically ten crops (center, top-left, top-right, bottom-left, bottom-right, and each flipped horizontally) instead of a single crop during inference.

D. Dataset

The experiments are performed on a subset of the largest plant benchmark dataset, PlantCLEF 2023. The original dataset contains 4 million images of eighty thousand species from trusted academic sources and the web. However, we randomly selected only ten thousand species from their trusted dataset to reduce the computing resources needed. We also ensured that the dataset followed a long-tail distribution by confirming that the classes have a minimum of 5 training image samples and a maximum of 112 training image samples per class. Consequently, the training dataset totaled 298,669 images, while the validation totaled 9,408. On the other hand, when the training samples are limited to 16 per class in each epoch, the training dataset totaled 128,040. In addition, we grouped the validation dataset into head, middle, and tail categories to examine the performance of each category. The head category consists of classes with 71 to over 100 training samples; the middle category consists of classes with 31 to 70 training samples; and the tail consists of classes with 5 to 30 images. The training and validation datasets are detailed in Table I, while the long-tail training dataset and its head, middle, and tail classes are presented in Table II.

III. RESULTS AND ANALYSIS

A. Experimented Models

We conducted experiments on the MoMo strategy with two different misclassified sample ratios: 50% and 70%. Furthermore, we examined the difference between a balanced and unbalanced sample selection between classes in these settings. A balanced sample selection would have a maximum of 16 training samples per class in each epoch. In contrast, the unbalanced sample selection would use all the available training samples in each epoch. We describe our models as follows:

Model 1: The baseline model of our experiments. It is set up with the settings described in Section II. In contrast with the rest, the baseline is trained without the MoMo strategy and with an unbalanced strategy. The training samples are sampled randomly as conventional CNN training, where the head classes are naturally chosen more than the tail classes.

Model 2: This model is set up with the settings described in Section II, trained with MoMo (50% misclassified samples and 50% correctly classified samples), and a maximum of 16 training samples per class in each epoch.

Model 3: This model is set up with the settings described in Section II, trained with MoMo (70% misclassified samples and 30% correctly classified samples), and a maximum of 16 training samples per class in each epoch.

Model 4: This model is set up with the settings described in Section II and trained with MoMo (50% misclassified samples and 50% correctly classified samples) using all the available training samples per class in each epoch. Likewise, in the baseline model, the head classes are sampled more than the tail classes.

Model 5: This model is set up with the settings described in Section II and trained with MoMo (70% misclassified samples and 30% correctly classified samples) using all the available training samples per class in each epoch. Likewise, in the baseline model, the head classes are sampled more than the tail classes.

B. Results of the overall validation set

As shown in Table III, the MoMo strategy generally improves the overall plant classification to 1% - 2% in Top-1 accuracy when comparing the baseline model to models 2, 3, and 4. Fig. 2 shows the baseline model's mistakes corrected with the MoMo strategy. The misclassified validation samples show similar features to its training samples and should be easily corrected when fed more to the model. On the other hand, model 5 with 70% MoMo and an unbalanced approach showed no improvements in both Top-1 and Top-5 accuracies. We suggest that the extended 70% misclassified samples may not contain enough significant features for the overall identification and could be erroneous, as shown in Fig. 3 where the extended misclassified samples mainly constitute non-plant and plant images that are visibly unclear. In addition, MoMo with balanced strategies (models 2 and 3) also improved the Top-5 accuracy compared to the baseline model despite being trained with less training data. It demonstrates the ability of MoMo to generalize class features sufficiently with lower-class samples. Nonetheless, MoMo with an unbalanced strategy (models 4 and 5) does not improve the Top-5 accuracy for the overall validation set but is not too far off from the baseline model.

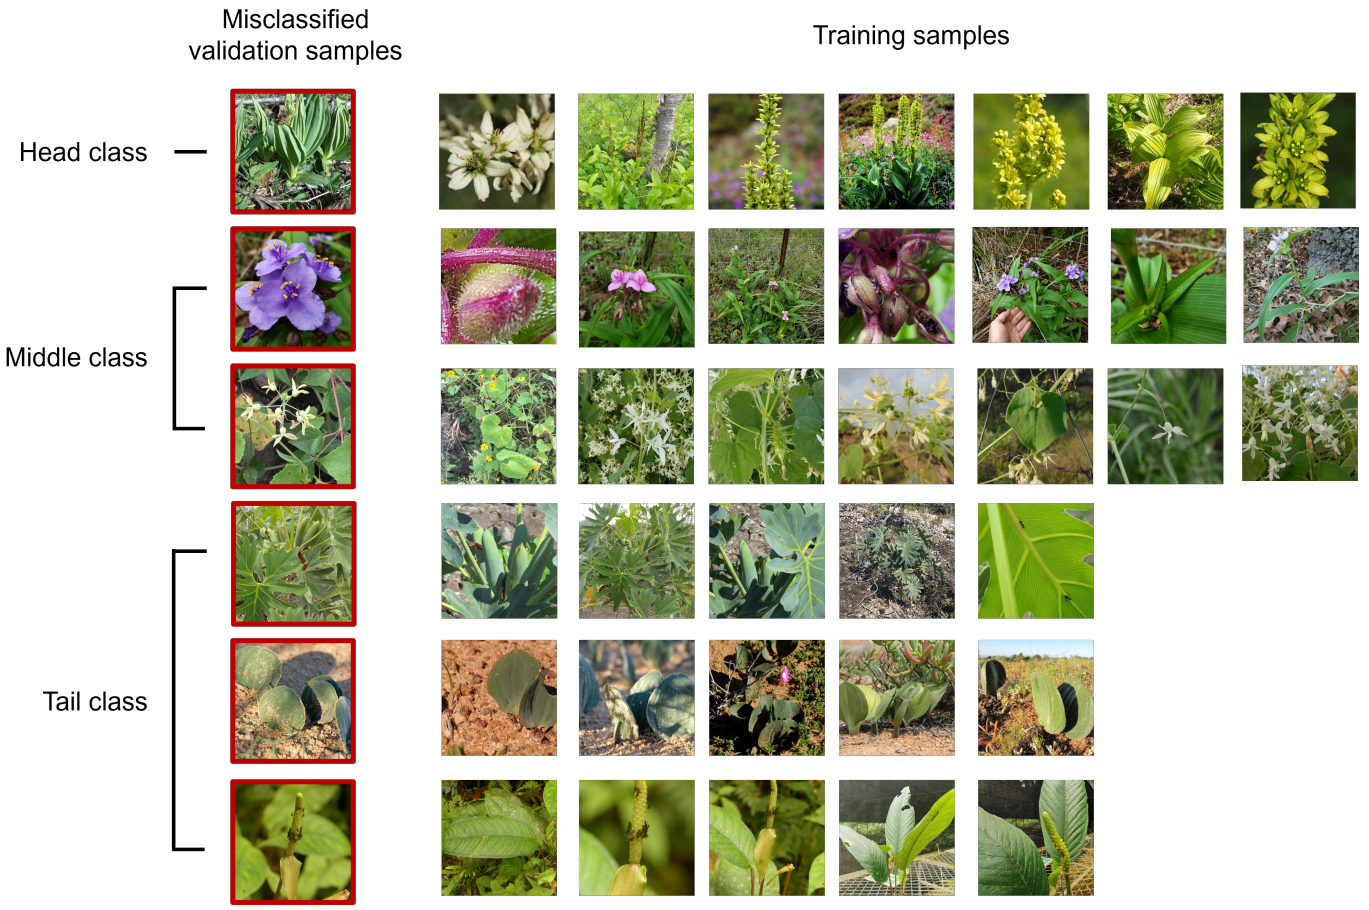

Fig. 2. Several head, middle, and tail class validation samples misclassified by the baseline model but correctly classified by the models with MoMo strategies. The right column of images without red borders represents their respective training samples and features in the dataset.

TABLE III
OVERALL RESULTS OF THE MODELS IN THE VALIDATION SET.

Model	Strategy	Top-1		Top-5	
1	Baseline, + unbalanced	0.6082	5718 / 9402	0.7964	7488 / 9402
2	**50% MoMo, + balanced**	**0.6209**	**5838 / 9402**	**0.7973**	**7496 / 9402**
3	70% MoMo, + balanced	0.6139	5772 / 9402	0.7966	7490 / 9402
4	50% MoMo, + unbalanced	0.6113	5747 / 9402	0.7924	7450 / 9402
5	70% MoMo, + unbalanced	0.6055	5693 / 9402	0.7899	7427 / 9402

TABLE IV
RESULTS OF THE MODELS BASED ON THE HEAD CLASSES IN THE VALIDATION SET.

Model	Strategy	Top-1		Top-5	
1	Baseline, + unbalanced	0.6971	863 / 1238	0.8611	1066 / 1238
2	50% MoMo, + balanced	0.6341	785 / 1238	0.8433	1044 / 1238
3	70% MoMo, + balanced	0.6446	798 / 1238	0.853	1056 / 1238
4	50% MoMo, + unbalanced	0.71	879 / 1238	0.87	1077 / 1238
5	**70% MoMo, + unbalanced**	**0.7132**	**883 / 1238**	**0.8708**	**1078 / 1238**

C. Results of the head classes

In contrast to the above, Table IV shows that MoMo with unbalanced class selection (models 4 and 5) outperforms MoMo with balanced class selection (models 2 and 3) as well as the baseline in both the Top-1 and Top-5 accuracies. It is expected as the unbalanced class selection method would naturally pick the head classes more during training, resulting in a higher head class performance. In other words, the unbalanced class selection MoMo model has seen more of the training data, therefore, it performs better than the balanced class selection MoMo model in this case. By comparing all the unbalanced models (models 1, 4 and 5), we can also confirm the advantage of implementing MoMo strategy in the head classes as it improves the accuracies of models 4 and 5 compared to the baseline.

D. Results of the middle classes

Similarly to the head class performances, MoMo with unbalanced class selection (models 4 and 5) generally performs best in both the Top-1 and Top-5 accuracies in the middle classes,

TABLE V
RESULTS OF THE MODELS BASED ON THE MIDDLE CLASSES IN THE VALIDATION SET.

Model	Strategy	Top-1		Top-5	
1	Baseline, + unbalanced	0.7	1514 / 2163	0.8451	1828 / 2163
2	50% MoMo, + balanced	0.705	1525 / 2163	0.8479	1834 / 2163
3	70% MoMo, + balanced	0.6828	1477 / 2163	0.8497	1838 / 2163
4	**50% MoMo, + unbalanced**	**0.7258**	**1570 / 2163**	0.8687	1879 / 2163
5	70% MoMo, + unbalanced	0.7157	1548 / 2163	**0.8692**	**1880 / 2163**

TABLE VI
RESULTS OF THE MODELS BASED ON THE TAIL CLASSES IN THE VALIDATION SET.

Model	Strategy	Top-1		Top-5	
1	Baseline, + unbalanced	0.5377	3227 / 6001	0.7404	4443 / 6001
2	**50% MoMo, + balanced**	**0.5879**	**3528 / 6001**	**0.7695**	**4618 / 6001**
3	70% MoMo, + balanced	0.5827	3497 / 6001	0.7659	4596 / 6001
4	50% MoMo, + unbalanced	0.5496	3298 / 6001	0.7489	4494 / 6001
5	70% MoMo, + unbalanced	0.5436	3262 / 6001	0.7447	4469 / 6001

as shown in Table V. It is also foreseen as the difference in the number of class samples between the middle and head classes is close to one another. Consequently, the middle class would be picked sufficiently, like in the head class. Models 2 and 3, with a balanced sample selection strategy, would perform slightly worse than the unbalanced strategy (models 4 and 5) because Models 2 and 3 are trained with reduced training samples.

E. Results of the tail classes

From Table VI, we see that the MoMo strategy significantly improves the tail class identification in both the Top-1 and Top-5 accuracies for the balanced and unbalanced sample selection strategies. Notably, with the balanced sample selection method (models 2 and 3), the accuracies increased 5% and 2% in Top-1 and Top-5 accuracies compared to the baseline model. On the other hand, without a balanced sample selection method (models 4 and 5), the MoMo strategy can only increase the performance up to 1%. Therefore, we can conclude that MoMo with a balanced sample selection strategy is essential and most effective for the tail class identification.

IV. CONCLUSION

This research aims to investigate the effects of incorporating more misclassified training samples into the training of a deep-learning plant model. Our findings indicate that this approach, namely MoMo, effectively improved the classification accuracy and generalization capabilities in the overall species identification. In addition, implementing a balanced sample selection batching strategy minimizes the impact of class imbalance during the training process, resulting in a more robust and accurate model that is less biased towards the head classes and enhances the tail classes. Combining both approaches led to further improvements in the model's performance, particularly in the tail classes. The MoMo strategy addresses the difficult feature representation during training, while the balanced batching method ensures a balanced local distribution of instances within each mini-batch or epoch. Notably, the unbalanced strategy works well with the head and middle classes, while the balanced strategy works well with the overall and tail classes. It is expected since the unbalanced class selection method can choose the head and middle classes more during training, resulting in a higher head and middle class performance. Nevertheless, this combined approach of MoMo and balanced strategy effectively maximizes the potential of the deep learning model and enhances its ability to learn and discriminate between different classes straightforwardly.

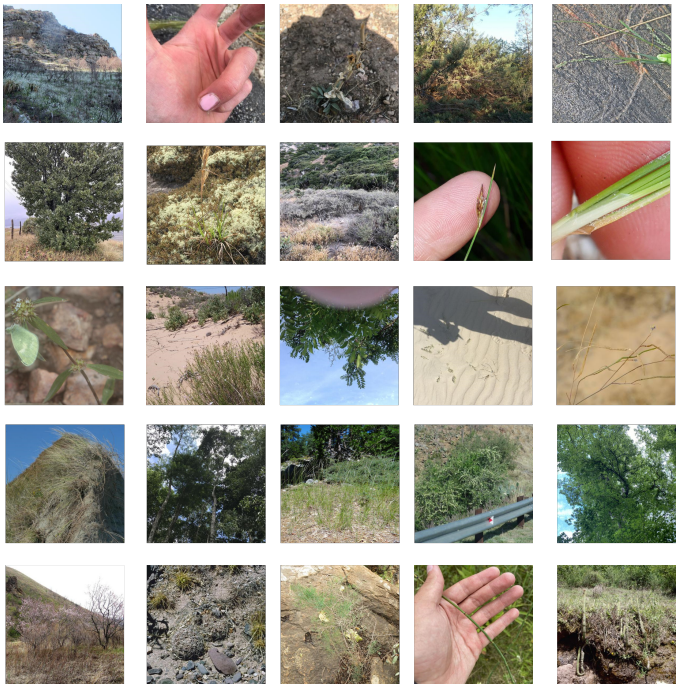

Fig. 3. The common misclassified samples in training and their similar attributes depicting non-plant images and plant samples that are difficult to view.

The findings of this study can be applied to various real-world applications where imbalanced datasets are common, particularly for long-tail distributed datasets. Future research can explore additional techniques for incorporating misclassified samples and advanced batching strategies into existing network architectures. Overall, this research sheds light on the advantages of simply utilizing the existing training samples to further improve the performance of the deep learning models. It encourages the need to leverage misclassified samples before implementing more complex and robust models.

***Abstract*—Deep learning models, such as Convolutional Neural Networks (CNNs), possess the ability to learn robust features that enable effective plant disease classification. However, these models need large and diverse datasets that reflect the variations present in real-world scenarios in order to achieve high performance not only on classes that the model has already seen, but also on new classes that have not been part of the training. To address this challenge, the utilization of Conditional Generative Adversarial Network (CGAN) models offers significant advantages. CGANs can generate diverse synthetic data, thereby expanding our training dataset and enhancing the generalization capability of deep learning models. While the conventional approach typically focuses on training CGANs to generate synthetic plant disease images, our investigation goes a step further by exploring the effectiveness of training CGANs using embedded images as reference points. This research is driven by the challenge of training CGANs on high-dimensional color images, as opposed to their simpler embedding data with a low-dimension. We have discovered that CGAN trained easier in embedding space and performed better in plant disease classification for both seen and unseen compositions. Our visual analysis also showed that the small CGAN model is able to generate better synthetic embedding than the synthetic images, which leads to significant performance in the overall classification results.**

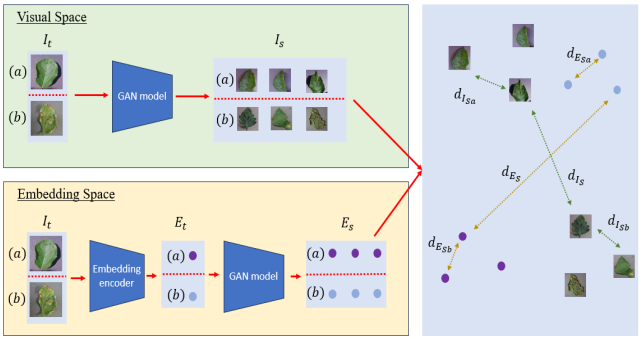

Fig. 1. Overview of our study. We train CGAN model in both visual and embedding space to evaluate the compatibility of CGAN model with deep learning model for downstream plant disease classification task. CGAN model is used to generate synthetic images, I_s and synthetic embeddings, E_s from original image, I_t and original embedding, E_t. This can increase the size and diversity of our training dataset. Furthermore, we also perform in-depth analyses on both synthetic data. The analysis are perform in various aspect which are inter-class separation for images, D_{Isa} / D_{Isb}, intra-class separation for images, D_{Is}, inter-class separation for embeddings, D_{Esa} / D_{Esb}, intra-class separation for embeddings, D_{Es},

I. Introduction

Plant diseases are characterized by deviations from a plant's normal state due to the intrusion of diverse pathogens. These diseases disrupt the plant's growth patterns, leading to diminished crop yields and substantial economic losses. However, these losses can be mitigated through early prevention and detection measures. Unfortunately, the vast knowledge gap between plant pathologists and the general public hinders individuals from independently classifying plant diseases. As a result, people depend on the expertise of plant pathologists or specialists to conduct accurate disease identification processes.

Deep learning models have become increasingly powerful tools for plant disease classification in recent years, as evidenced by various studies [1]–[7]. These models demonstrate remarkable success in extracting dominant features that differentiate between different plant species and disease classes. Despite their versatility, deep learning models heavily rely on data for their performance. To effectively classify objects, these models require a large and diverse training dataset that enables them to learn generalized features. However, real-world data often follows a long-tailed and open-ended distribution, where a small number of classes have a significant number of samples while others are associated with only a few samples. This long-tailed distribution is particularly evident in plant disease datasets due to the scarcity of labeled images and the high cost of data acquisition. Consequently, trained models may exhibit biases or overfitting tendencies towards specific classes, limiting their ability to learn generalized features for plant disease classifications. For a practical recognition system, it is essential not only to be able to classify majority classes effectively but also to account for the minority classes.

In theory, increasing the size of the training dataset could address this issue; however, the process of collecting such data is excessively costly and time-consuming. To this end, two main approaches can be employed to enhance model performance: (1) enhancing feature extraction techniques [8],

*These authors contributed equally to this work

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

[9] and (2) generating synthetic images to enrich the existing training dataset [10]–[14]. For the first main approach, feature extraction techniques continually undergo rapid advancements, giving rise to numerous state-of-the-art (SOTA) models, such as MobileNet, ResNet-152, and various vision transformer models. The fundamental principle underlying this approach revolves around enhancing feature extraction techniques to extract a more generalized features that benefit downstream classification tasks. However, this method encounters bottlenecks when the available samples within the training dataset are limited or unavailable.

Numerous scientific studies have successfully employed Generative Adversarial Network (CGAN) models to produce synthetic plant images, thereby enhancing training datasets for plant disease classification. However, formidable challenges persist, including mode collapse, limited variation, and training instability. Overcoming these hurdles necessitates meticulous architectural design, effective regularization techniques, and sophisticated training strategies. Particularly when dealing with plant disease data, characterized by diverse textures and appearances, imbuing CGAN models with the ability to capture intricate details for synthetic image generation becomes even more arduous. In practice, visual deep learning models are commonly employed, relying on original disease data as a reference for synthetic data. Consequently, CGAN models are compelled to generate visually higher-resolution synthetic images, leading to enlarged model sizes and introducing additional complexities during training. Moreover, generating a diverse array of synthetic images in the visual space poses an additional formidable task, as it requires the CGAN model to leverage both localization information and learned features from the images.

To overcome these obstacles, it is worthwhile to explore embedding-driven deep learning models, where the generative model utilizes embedded images as references instead of the original images for data generation. The utilization of precomputed image embeddings offers several benefits. It enhances training efficiency by leveraging the encoded knowledge within the embeddings, eliminating the need to start from scratch with the original images. This approach potentially simplifies the training of CGAN models, which focus on the embedding space, and improves compatibility with feature extractor networks. Additionally, pretrained embeddings capture relevant information from the data and encode semantic and contextual details, facilitating the extraction of meaningful features. However, one potential challenge is the issue of collapsing, wherein the output of an embedding collapses to a constant vector, deviating from the original distribution. Therefore, it is crucial to compare the performance of CGAN models operating in the visual space versus the embedding space for plant disease identification task. The contribution of this paper are:

1) To the best of our knowledge, our study represents the first evaluation of the effectiveness of CGAN (Conditional Generative Adversarial Network) models in generating representative data to improve plant disease classifiers for both seen and unseen classes. Based on our results, the classifier using the generated embedding data outperforms the classifier based on the generated image.
2) We have experimentally shown that the CGAN model and the deep learning-based classifier operating in the embedding space are able to learn more diverse and generalised features, showing a significant improvement of 30% for plant identification and a further 48% improvement for disease identification compared to models trained based on original images.
3) We present a visualisation analysis to interpret the reason for the better performance of the CGAN model operating in the embedding space. The results show that models operating in the embedding space exhibit better interclass and intraclass separation than those operating only in the image space. These visualisations provide valuable insights into the benefits of the embedding space approach.

The rest of the paper is organized as follows. Section II discusses the literature related to plant disease identification with various models. In section III, we present our methodology as well as the various models we propose to carry out our experiments where, in section IV, we present our findings and provide discussion. Section V concludes our research findings and presents future work.

II. Related work

A. Plant disease classification with deep learning network

Deep learning models have shown remarkable success in plant disease identification. These models leverage the power of deep neural networks to automatically learn and extract meaningful patterns from plant images, enabling robust disease classification. For instance, convolutional neural networks (CNNs) have been employed to perform classification tasks across various crops, such as maize [1], cassava[2], tomato [3], apple[4], wheat[5], citrus [6] or potato [7]. These studies primarily focus on individual crops, wherein the models solely need to learn disease-specific features to accomplish the classification tasks. However, in 2016, the scope of the research expanded to encompass multiple crops and diseases with the introduction of the PlantVillage (PV) dataset [15]. This dataset serves as a largest publicly available dataset, featuring multiple crops and diseases. It comprises 38 classes representing 21 diseases across 14 different crops. The PV dataset presents new challenges to the models as they are now required to simultaneously consider both plant and disease features for classification tasks. Previous studies in [16], [17] use this dataset to train CNN models for plant disease classifications. Although the PV dataset is the largest publicly available dataset, it does not cover the complete range of plant disease compositions. As a result, our study focuses on utilizing CGAN models to generate synthetic data. By doing so, we aim to augment the diversity of plant disease compositions without the requirement for manual acquisition. This approach enables us to expand the dataset

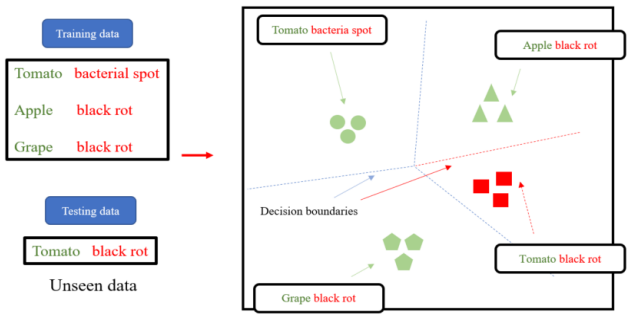

Fig. 2. The concept of unseen plant disease composition. *Tomato bacterial spot*, *Apple black rot* and *Grape black rot* are the seen composition from training data. *Tomato black rot* is the unseen composition from testing data. The individual *Tomato* species and *black rot* disease are exist in the training data.

and enhance the representation of plant diseases for improved training and analysis.

B. Plant disease classification with generative adversarial network

GANs were introduced in 2014 by [18] to generate synthetic images that exhibit a similar distribution to the original images. The synthetic images prove valuable in enriching our training dataset, particularly for classes that lack labeled data or are prohibitively expensive to obtain. This approach also helps prevent bias in our deep learning models towards dominant classes present in the training dataset. For instance, the PlantVillage dataset from [15] consists of 38 classes, with tomato species (10 classes) and healthy plants (11 classes) being the dominant categories. This skewed distribution may lead to a bias in our trained deep learning models, favoring tomato species and healthy plants. To overcome this issue, previous studies [10]–[14] have incorporated various types of GANs with deep learning models to enhance the performance of plant disease classification. These GAN models have been utilized to increase the diversity within each class of the training dataset and augment samples for classes with limited representation. While the conventional approach focuses on training GANs to generate synthetic plant disease images, our investigation takes a step further to assess the effectiveness of training CGANs using embedded images as reference points. This research endeavor is driven by the recognition of the complexities involved in GAN training for high-dimensional colored images, particularly in capturing intricate and diverse disease symptoms.

C. Zero shot classification for plant disease classification

In section II-A, we highlighted the limitation of the PV dataset in encompassing all possible plant disease compositions. Consequently, several studies have aimed to enhance the generalization capability of their models to effectively handle unseen plant disease compositions [17], [19]. The concept of unseen plant disease composition refers to situations where the individual plant species or disease types are present within the training dataset, but their combined composition as a specific plant disease is not represented. Fig. 2 illustrated the concept of unseen plant disease composition. A previous study by [19] introduced the CTML model, which improves upon conventional models by incorporating a conditional link that promotes knowledge sharing between plant features and disease features. However, this approach can only be effective if both plant and disease features are present and generalize well across unseen compositions. To address this challenge, our study takes a two-fold approach. Firstly, we generate synthetic data in both visual and embedding spaces to ensure that our training dataset is diverse enough for the deep learning model to learn generalized features. Secondly, we project both plant and disease features into individual plant and disease feature spaces for both seen and unseen plant disease classifications. By separating the features into distinct spaces, we enable the model to effectively analyze and classify plant diseases based on their unique characteristics, even when certain plant species or disease types are not present in our training dataset.

III. Method

A. Problem formulation

The goal of our plant disease classification is to recognise composition of both plant species and disease types. Our training dataset consist of different combined plant disease compositions, $c = (c_c, c_d) \in C$ where c_c and c_d corresponding to the plant species and disease types such as *Tomato healthy* and *Potato early blight*. Our testing dataset consist of seen compositions $c_s = (c_c, c_d) \in S$ and unseen compositions $c_u = (c_c, c_d) \in U$. Unseen compositions are the compositions that not present in training dataset such as *Potato healthy* but the individual *Potato* species, c_c and *healthy* disease, c_d are present in training dataset, C.

B. Overall framework

Our study aims to explore the compatibility of GAN model with deep learning model in both visual and embedding space for plant disease identification. Therefore, our architecture can be separated into visual-based and embedding-based as shown in Fig. 3. The architectures consist of three main modules: (1) feature extractor module, (2) Conditonal Generative Adversarial Network (CGAN) models for image and embedding space and (3) plant and disease classifiers for prediction. The feature extractor module extract features from images and convert the features from visual space to embedding space. CGAN model will generate synthetic images or embedding to enrich the training dataset. Plant and disease classifiers will performs different classification tasks based on visual images or embedding features.

1) Feature extractor module: The feature extractor module converts visual images into embedding spaces. The backbone of our feature extractors are built from MobileNet-v2 [20]. The classification head of MobileNet-v2 is removed to produce embedding output for our framework. Specifically, it consists of plant feature extractor, $g(\phi)$ and disease feature extractor, $f(\phi)$ as shown in Fig. 4 . Plant feature extractor, $g(\phi)$ takes

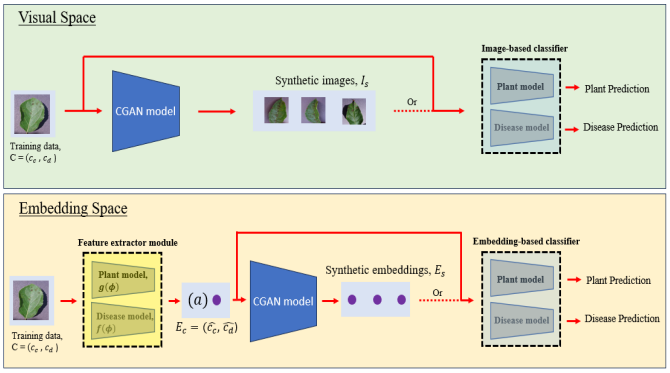

Fig. 3. Overall framework of our study. Our architecture can be separated into visual space and embedding space. For visual space, CGAN model will be used to generate synthetic images, I_s from training data, C. The image-based classifiers will either take real images or real images and synthetic images together to perform classification tasks. For embedding space, feature extractor module is used to convert the visual images from training data, C to embedding, E_c. The CGAN model will generate synthetic embeddings, E_s from real embeddings, E_c. The embedding-based classifiers will either take real embeddings or real and synthetic embeddings together to perform classification tasks.

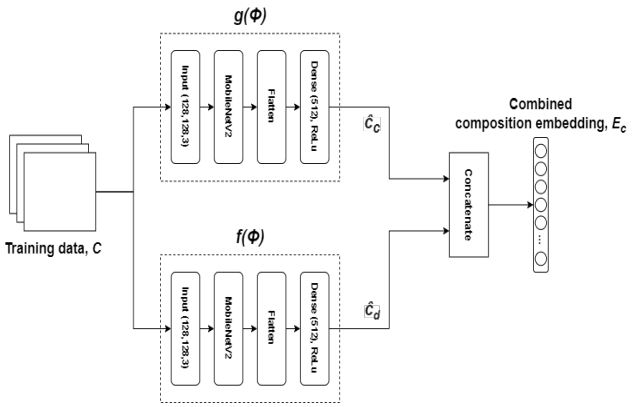

Fig. 4. To create the embedding dataset, we leverage a plant and disease model that use MobileNet-v2 as backbone without a classifier head. The plant and disease model will extract plant features and disease features respectively and will be concatenated to be used by the embedding CGAN model or classifiers.

input from training dataset, C and output plant features, $\hat{c}_c = g(c)$. Disease feature extractor, $f(\phi)$ takes input from training dataset, C and output plant features, $\hat{c}_d = f(c)$. Both feature extractors used pre-trained weight from ImageNet and finetuned with our training dataset by using cross-entropy loss. The combined composition embedding, $E_c = (\hat{c}_c, \hat{c}_d)$ will be generated from concatenation between plant and disease features and will be used by CGAN model or classifier in embedding spaces.

2) Conditional Generative Adversarial Network (CGAN) models: We use CGAN model to generate synthetic data for all classes in our training dataset. CGAN consist of two modules which are generator and discriminator modules. The generator takes class label and Gaussian noise as input and generate synthetic data. The discriminator distinguishes the synthetic data and eventually bring the distribution of

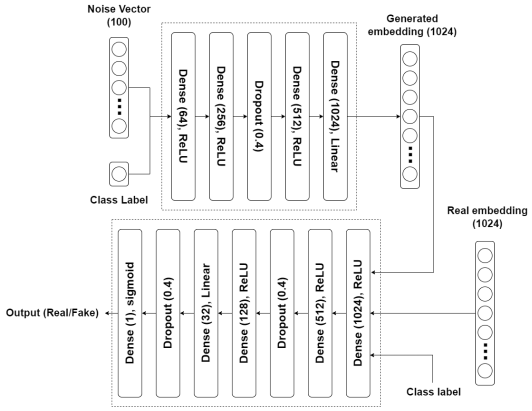

Fig. 6. Our CGAN architecture for generating embeddings of size 1024

synthetic data close to the real data.

Visual space CGAN. The CGAN architecture is shown in Fig. 5. The generator consists of 5 convolutional layers to up-sample the input and product synthetic images, I_s with size of 128x128x3. The discriminator consists of 4 convolutional layers to down-sample and distinguishes the synthetic data. The generator takes a class label and Gaussian noise as input. The discriminator takes real images from training dataset and synthetic images from generator as input.

Embedding space CGAN. The CGAN architecture is shown in Fig. 6. The generator consists of 5 fully connected layers to up-sample the input and product synthetic embedding, E_s with size of 1024. The discriminator consists of 7 fully connected layers to down-sample and distinguish the synthetic data. The generator takes a class label and Gaussian noise as input. The discriminator takes real embedding from feature extractor module and synthetic embedding from generator as input.

3) Plant and disease classifiers: A plant and disease classifier will be used to perform prediction in both the image and embedding space. MobileNet-v2 and 4 fully connected layers will be used for both image-based classifiers or embedding-based classifiers respectively. All classifiers will take in either

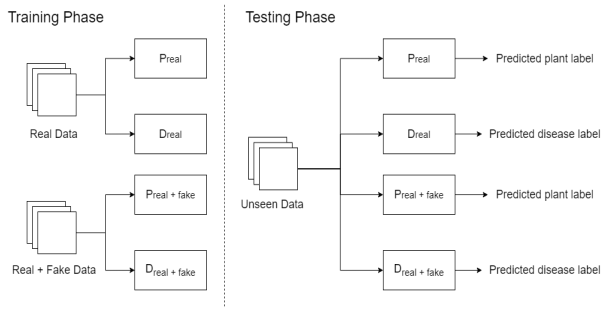

Fig. 7. Our evaluation model architecture, consisting of identical models built upon the MobileNet-v2 weights. P_{real} and D_{real} are trained on real images or embeddings, like wise $P_{real+fake}$ and $D_{real+fake}$ are trained on a combined dataset of real and generated images or embeddings. The models then predict the unseen data to identify the plant and disease

real or real and synthetic data together as training dataset to perform plant disease classification tasks.

IV. Experiments and Results Analysis

To explore the differences in the performance of image and embedding data, we used the open-source Plant Village dataset [15] that contains healthy and unhealthy images of leaves of various species and diseases. For this study, we selected 6 classes as seen training data, C and 1 class as unseen testing data U. Specifically, the 6 classes in our training data, C are *Peach bacterial spot*, *Peach healthy*, *Potato early blight*, *Tomato bacterial spot*, *Tomato early blight* and *Tomato healthy*. The unseen testing data is *Potato healthy*. We evaluate the quality of the generated images and embeddings via embedding space as well as utilising the plant and disease classifier described in Fig. 7.

A. Expt. 1: Analysis of the Classification Performance of the Image-Based Model

The first experiment involves exploring the performance of the deep learning models on unseen data with the aid of generated images. 2 sets of images would be prepared, 200 images of each class for the real dataset, and 200 images and 100 generated images via the CGAN per class for the real

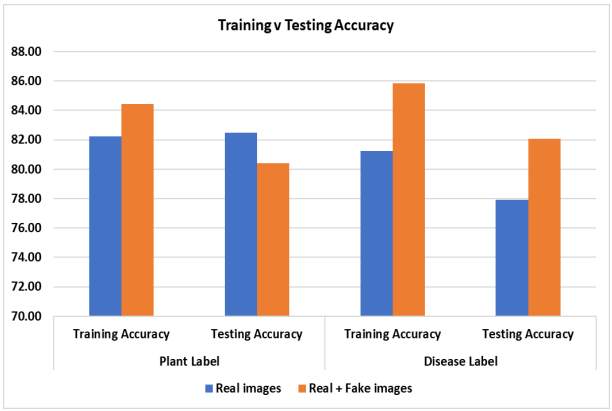

Fig. 9. Performance difference for training and testing accuracy of plant disease classifier on image data

and fake dataset. 2 pairs of models would be trained on each dataset, and then performance would be evaluated based on the accuracy of correctly identifying the plant and disease label of an unseen combination.

Fig. 8 shows that accuracy for identifying plant and disease for an unseen combination reduces with the introduction of generated images, however, the accuracy for the correct label was low to begin with. This may be due to the fact that, although the dataset included 3 different plant labels, analysis into the dataset shows that the distribution for plants is imbalanced. For instance, there are 3 classes with 'tomato' as the plant label, 2 for 'peach' and 1 for 'potato'. The ratio between tomato and potato sample sizes is 3 to 1, coupled with the fact that the leaves look visually similar, we believe the low accuracy of the unseen data may be attributed to this imbalance. Further evidence to this is revealed when the model wrongly predicts tomato with the highest confidence when testing with the unseen data.

We also attribute the reduction in accuracy to the quality of the images produced by the CGAN, which was trained on 2000 epochs. Various challenges arise when training GANs, especially when wanting to have it pick up on detailed features such as venation, particularly due to the limited resolution of the output image. Due to computational constraints, our initial dataset were images of size 256 by 256, but had to be resized to 128 by 128 and subsequently can produce only at 128 by 128. At a reduced size we suspect that finer details are hidden and removed and so the CGAN generates images that are not as detailed.

However, there was an increase in accuracy during training and testing evidenced in Fig. 9, which had increased performance when training on the real and fake dataset. This shows that the models are better fitted to seen classes, but are not sufficiently generalised to unseen data.

B. Expt. 2: Analysis of the Classification Performance of the Embedding-Based Model

Similar to experiment one, this experiment focuses on the performance via real and generated embeddings. The real

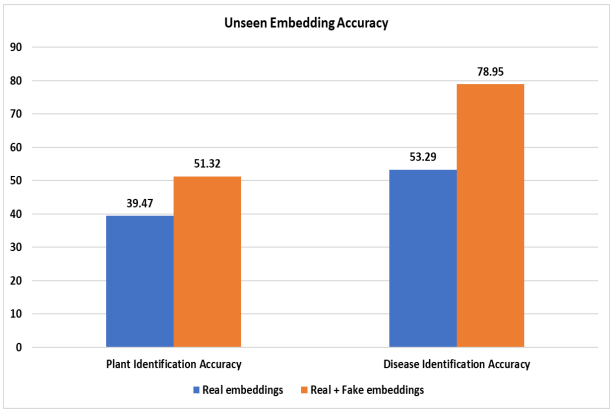

Fig. 10. Accuracy of identifying unseen plant label combination for real and real + fake embedding dataset

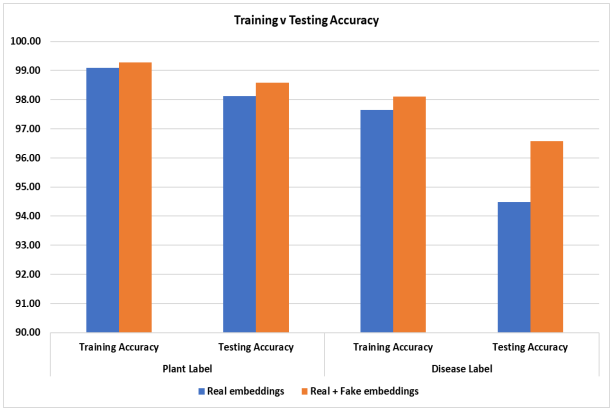

Fig. 11. Performance difference for training and testing accuracy of plant disease classifier on embedding data

dataset will consist of 200 embeddings per class and 200 real and 100 generated embeddings via CGAN for the real and fake dataset. The performance would also be tested on the same unseen combination, this time using unseen embeddings.

For our embedding CGAN, our results show a significant increase in performance when classifying an unseen combination of plant and disease, rising from 39.5% to 53.3% for plant accuracy and 51.3% to 79% for disease accuracy when trained on real embeddings and a combination of real and fake embeddings respectively, as shown in Fig. 10.

It also greatly improved training and testing accuracy on seen data, increasing for all values even when the baseline values were already more than 94% as shown in Fig. 11. We believe this is due to the way embeddings were extracted in the first place, capturing relevant information from each disease and plant species concept, encoding semantic and contextual details that could help CGAN better extract meaningful features.

We also found that training the embedding CGAN was significantly easier as compared to the image CGAN due to its smaller and simpler architecture as well as its lack of needing to extract features since it was already being fed extracted features. Thus, it made it easier for the generator to quickly

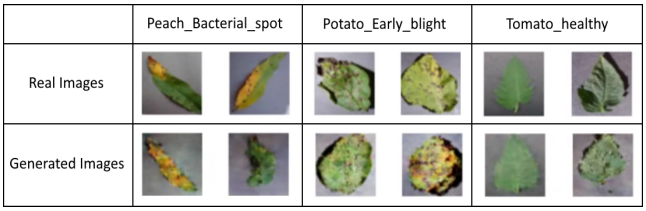

Fig. 12. Visual analysis of real images and generated images

catch on in 450 epochs in a short amount of time to be able to produce not only close to real embeddings, but also in variations as explored in the next section.

C. Expt. 3: Ablation Study on Embedding-Based CGAN Model Training with Increased Data, Including Synthetic Samples of Unseen Classes

Experiment 3 follows up the previous experiment by slightly modifying the embedding CGAN. Instead of taking in a single integer as the class, we decided to turn a class label into a two one hot vectors representing each part of the label which would then be concatenated together. For example, 'Tomato healthy' would have its one hot vector for 'tomato' being [1, 0, 0] and 'healthy' being [0, 1, 0]. The final class vector would then be [1, 0, 0, 0, 1, 0], which would be used as the class label for the generator. This approach allows us to generate unseen data by manipulating the input vectors. For this experiment, we generated 200 unseen embeddings and incorporated them into our pre-existing training dataset. The updated training dataset now comprises 200 real embeddings for each class along with the 200 previously generated unseen embeddings. Subsequently, we compared our findings with the experiment outlined in section IV-B.

Our findings indicate an accuracy of 52.6% for plant classification and 78.2% for disease classification, showcasing notable improvement in plant identification but limited progress in disease recognition. This discrepancy could be attributed to the fact that the generated embeddings are more proficient at capturing distinctive crop features compared to disease symptoms, as the differentiation of disease classes is highly dependent on the level of detail captured, making it a more difficult task.

D. Expt. 4: Qualitative Analysis

Experiment 4 explores the qualitative analysis of the generated images and embeddings against real images and embeddings respectively. Using t-sne analysis [21] to show the class-wise features in the embedding space we will explore the distribution and the separation of the features based on classes, real and fake data. We will also perform visual analysis on generated images discussing the differences between real and fake images.

Fig. 12 shows the real and generated data for 3 of the classes, and immediately we notice a lack of fine details in the generated images. Although low-level features are captured, such as the discolouration due to bacterial spot or early

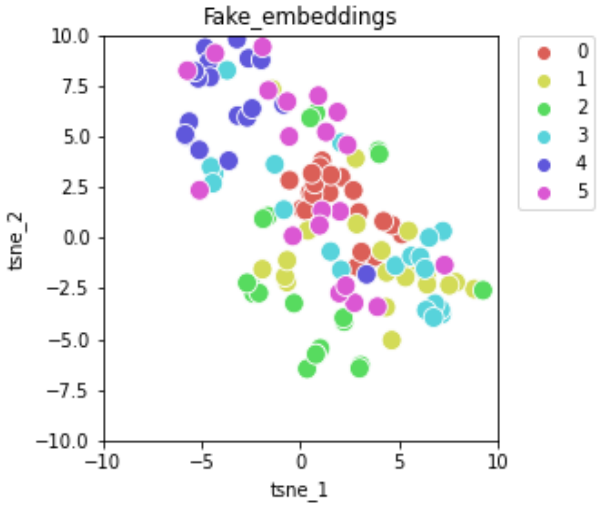

Fig. 13. T-SNE analysis in embedding space for generated images

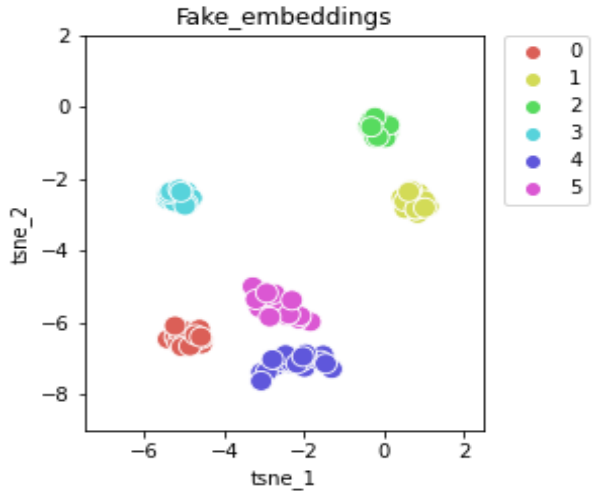

Fig. 14. T-SNE analysis in embedding space for generated embeddings

blight, higher level features such as the midrib or venation is not captured. it also has a tendency to confuse shadows as discoloration as evidenced in the second generated image for 'potato early blight'. The generated images are also blurry due to a lack of high-level features, and we suspect longer training times might alleviate this problem.

We built a feature extractor that utilised the MobileNetV2 model that was trained on real images and had its last layer removed to expose the features of shape 512. The generated images were then run through the feature extractor, and they were projected onto an embedding space in Fig. 13. The generated embeddings show almost no distinct clusters as compared to embedding clusters in Fig. 14. We again attribute this to not having enough high-level features for the classifier to accurately distinguish between the generated images. For fake embeddings, the projections look a lot more distinct for fake with 6 very obvious clusters being made with variations to show that the points, while similar enough to cluster, are not exact matches.

V. Conclusions

In this paper we investigated the capabilities of using CGANs to generate data, in terms of images and embeddings, to aid in the classification of unseen plant disease combinations. Our objective was to assess the effectiveness of CGAN-generated data in improving the performance of plant and disease classifiers, not only on seen data but also on previously unseen combinations, thereby enabling more accurate identification of unseen classes. We established that while image CGANs require more care and testing, embedding CGANs demonstrate a greater potential to aid in plant disease identification by being simpler, faster, and easier to train. By training plant and disease classifiers on both real and generated embeddings, we observed an increase in their overall performance for both seen and unseen combinations. This augmentation enabled the models to make more confident predictions on unseen combinations, resulting in enhanced plant and disease identification accuracy. In future work, we will incorporate semantic information, such as word embedding, to improve the learning of correlations between seen and unseen classes. By leveraging this additional contextual information, we anticipate further improvements in our model's performance.

***Abstract*—With research done to determine depression with different types of inputs, such as text, images, and mobile sensing, numerous distinct approaches have been devised and enhanced for identifying depression across diverse backgrounds. However, there is a significant lack of research in making use of only facial expressions to detect depression. Introducing such methods could be beneficial due to the large amount of research done to develop models capable of performing facial expression recognition. This project aims to utilize pre-existing facial expression models to determine depression based on the expression recognition capabilities, and to also determine the reliability and effectiveness of using only facial expression to detect depression. We have chosen to use EfficientNet, a state-of-the-art facial expression recognition model, to experiment with the different facial expressions that are shown based on images of clinically proven to be depressed patients. The findings from our work can further improve depression detection research, specifically focusing on making use of only information from shoulder up of patients, while also helping the community to improve mental health.**

I. Introduction

Depression is a mental illness that mainly affects mood, emotions, and behaviour. It usually results in sadness, despair, and the loss of interest in activities that once used to be enjoyable. It is currently one of the most common mental illnesses in the world, affecting an estimate of 3.8% of the population, and 5% of adults[1]. In addition, with the Covid-19 pandemic taking place for almost 2 years ever since December 2019, it has resulted in the worsening of depression, with an astounding 45% of infected patients having depression[2]. The increase in depression during the pandemic has resulted in doubling of individuals having suicidal thoughts, as compared to pre-pandemic[3]. There was also an upward trend of the number of suicide attempts during the Covid-19 period due to depression[3]. Despite how prevalent and devastating depression is today, many still are unaware of the symptoms of depression, and are also uninformed about how serious it is. This can result in depressed patients refrain from proactively seeking treatment. Furthermore, stigma surrounding depression can result in them to be afraid of judgement and discrimination and choose not to seek proper help and support. This issue is highly detrimental to society, and action needs to be taken to address it.

To date, various technologies have been proposed to create awareness and introduce intervention mechanisms to combat depression [4][5], from utilizing mobile applications for mobile health to electronic survey tools and screening assessments. With the rise of cloud-based collaborative video conferencing platforms such as Zoom or Microsoft teams due to the Covid-19 pandemic, patients with depression can seek treatment and care through such technologies. They can receive therapy from their therapists from what is usually known for their face-to-face practices. This is also known as teletherapy.

Some main teletherapy platforms include SimplePractice, TherapyNotes or BetterHelp, with main functions including HIPAA-compliant (The Health Insurance Portability and Accountability Act of 1996) video calls, appointment scheduling, secure messaging and recordings and providing different templates for presentation. With that, therapists can share content through different preferred presentation styles, while also having the ability to annotate for their patients to see. However, during a teletherapy session, therapists will have to juggle with many aspects of therapy, which includes providing a useful presentation, listening to what patients have to offer, as well as paying attention to patient's emotions, as well as non-verbal cues. Thus, there is a need for other forms of smart technology to be introduced to reduce the load of therapists in a tele-therapy setting.

A main communication type for video conferencing platforms would be the conversations that both parties will have through audio and chat. Work done by Deshpande, M. S.,& Rao, V. has utilized the emotion recognised from textual data to detect depression[6]. To the best of the author's understanding, work that utilises the emotion recognised from facial images or videos are underexplored to detect depression.

It is also known that video conferencing platforms have video as one of the main communication types, where both patients and therapists can see each other while communicating. It is common that most users use a webcam to stream their videos on conference calls. However, it is also common that most users will not be able to show their full body, usually only showing from the chest up, where the focus of the video is usually the face. While therapists are busy indulging in conversations with the patients, they may potentially overlook the expression of the subject, which may give insights to the engagement or feeling of the patient during the conversation. Thus, facial images can be an input used for therapists to determine how their patients are feeling and to potentially

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

make decisions that could help them or make them feel better.

Facial Expression Recognition using computer vision have also been researched and many state-of-the-art models have been created and collated due to the many challenges that have surfaced ever since 2011 [7], while also being a very prominent subject of discussion in the computer science field for almost 30 years [7]. Facial expression technology is nowhere new in Computer Vision and Artificial Intelligence but has not been utilized in depression detection. Thus, it would be beneficial to tap into such advanced systems and make use of them to aid in determining depression based on expressions. Therefore, it is essential to come up with an optimised solution for such technologies to aid therapists and medical professionals.

The contribution of this paper is two-fold:

1) The potential of using facial expressions as markers of depression is investigated.
2) Annotated images from videos from publicly available sources online.[1]

II. Related Work

The main bulk of related work will be split into 3 sections, works in teletherapy, facial expression recognition and depression detection.

A. Teletherapy

Teletherapy has surfaced ever since there was an option for therapists to have conversations with patients through the phone in the 1960s. It became increasingly popular, and even primary means of care for some individuals ever since the Covid-19 pandemic, with the main purpose to prevent the spread of the novel virus by discouraging face-to-face contact. There are a multitude of benefits and well as disadvantages of teletherapy. Having therapy online helps when patients have difficulties meeting therapists physically. There are many different factors that affect this, such as accessibility, where patients may be located a distance away from a suitable therapist. Other factors include anonymity, privacy as well as flexibility of time and space[8]. Most of the population now also has access to the internet and a smart device, while being proficient in using it, thus would also prefer attending therapy sessions through a phone or a computer.

However, not attending a therapy session physically has also resulted in certain problems, not just for the patients, but for therapists as well. Patients have reported that when comparing both types of therapy, some have felt that attending them online felt less engaging [9], some of them felt that their conversations are less private [9], or even issues with the internet or the hardware and software not being able to function as intended [9]. Therapists also felt that they are not able to pick up non-verbal cues while conducting sessions [9], while also struggling in certain moments to pick up markers of expressions, gestures, or postures [9][10]. Other therapists have also reported an increase in struggle to attune with their patients in an online setting, as compared to being in their office[9]. Thus, having external technologies can provide therapists with indicators of patient's mood, engagement and other non-verbal factors and fill in the gaps that teletherapy will not be able to achieve. With teletherapy on the rise, it is easier to obtain videos of teletherapy sessions as most video-telephony software provide a recording feature. While it is important to request for permission from all parties involved to ensure that data collection is ethical, this data collection is essential with the training and testing of models capable of depression detection.

B. Facial Expression Recognition

Facial expression analysis can be dated back many years, but the more prominent research done was by firstly Charles Darwin, where he explained and grouped facial expressions based on biological reasoning, which are making use of different muscle groups present on the face[11]. This is further researched by Ekman and Friesen, which they introduced the concept of the Facial Action Coding System[12]. The work done by these researchers has proved to be vital in the development of the first facial expression recognition models. These models make use of the facial action coding system to determine the different types of facial muscles used in the expression of facial expressions[12].

Facial features are another type of input that can be used to determine expressions in a person. This can include the eyes, lips, eyebrows, and cheeks[7]. There are also transient facial features, features that are not found in all people. This includes wrinkles and facial lines[7].

There are many types of facial expression recognition architectures present in the research field, including but not limited to: MobileNet[13], EfficientNet[14], ResNet[15]. These are computer vision models that can be used to train with annotated data, each with specialized methods to help with the development and training of deep learning models. These state-of-the-art models are also rather mature, thus the focus on this work is not to devise a new expression recognition model, but to utilize these pre-existing models.

There are also many datasets present due to the number of challenges present, with the more prominent ones being the EmotiW (Emotion Recognition in the Wild) challenge and AFEW (Acted Facial Expression in The Wild) challenge. AffectNet [16] is also another dataset used for emotion classification, where it consists of annotated images of people with their expressions. This manually annotated dataset is labelled with 7 different expressions, together with including valence and arousal of such expressions.

C. Depression Detection

Facial expressions can provide information about how one feels, and research has been done to prove that it can provide enough information with whether an individual is feeling depressed. Many studies have shown that the main parts of the face that can provide most of the information are usually the eyes and the mouth, where together with expressions, can help determine an emotion of a person[17][18]. Mehrabian, A.,

[1]Dataset will be made publicly available upon publication.

& Russell, J. A. did state that it is a lot more likely that one can determine emotions of someone else using facial expressions, as compared to using word of mouth[19]. This has resulted in more research done using facial features. Alghowinem, S., Goecke, R., Wagner, M., Parker, G., & Breakspear, M. have done research using specifically eye movement analysis to detect depression in individuals[18], while Wang, Q., Yang, H., & Yu, Y. uses the overall facial expression to analyse for depression detection as well [17]. Wang, Q., Yang, H., & Yu, Y. have decided to classify this issue as a binary problem (e.g., depressed/ not depressed) [17], while Alghowinem, S., Goecke, R., Wagner, M., Parker, G., & Breakspear, M. also classifies their models as binary [18].

Feature extraction for such research is more straightforward as it uses physical spots on the face to extract information. For instance, for eye movement analysis, features such as horizontal, vertical and eyelid movements can be extracted without much pre-processing needed [18]. However, normalisation is required as different people will have different eye sizes, and the eye sizes can also change depending on different factors like how far a person is located from the camera or the angle of the camera relative to the person. This similarly applies to any other frontal face features.

There are datasets present to help with depression detection. The more prominent ones would be the DAIC-WOZ dataset, which consists of annotated and transcribed audio recording, video recordings and questionnaire reports of clinically proven depressed patients. Another example dataset that is used for a challenge would be the SemEval-2018 dataset, which features a database of tweets from twitter and its multiple subtasks that determines the affectual state of the author based on their posted tweets. Most of these datasets do not make use of facial expressions to determine depressions, more frequently touching on speech and text as it has been proven to be highly accurate in detection. However, facial expressions are still indicators of depression, and thus should be considered while attempting to improve depression detection.

To date, there is research done to make use of facial expressions to determine depression [17][18]. Alghowinem, S., Goecke, R., Wagner, M., Parker, G., & Breakspear, M. have identified indicators of depression mainly using facial features and movement of facial features, however, there is little to no use of facial emotions to aid with their research. Alghowinem, S., Goecke, R., Wagner, M., Parker, G., & Breakspear, M. also investigated about how difference in emotions have led to no statistically significant differences in detecting depression, while Wang, Q., Yang, H., & Yu, Y. mentions about how cultural differences can result in different forms of depression. Since facial emotions are more universal and easier to understand for the average person, there is a need to utilize emotions to determine indicators of depression.

III. Methodology

A. Approach

To figure out which facial expressions a typical depressed person would evoke, as well as frequency of facial expressions

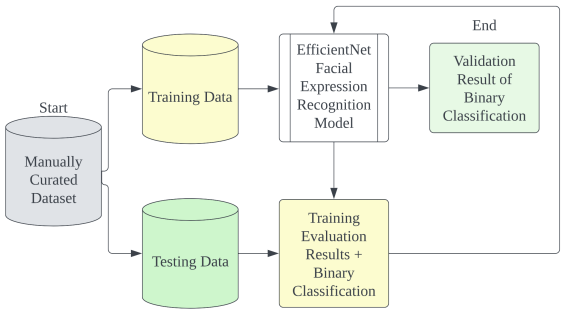

Fig. 1: Proposed Approach

used, it is necessary to collate existing data present online of images or videos of clinically proven depressed patients or make use of related datasets if present. It is mentioned in related work there is currently no such dataset present, thus the former option would be used. After collection of data, facial expression recognition models will be used to determine the expressions of the depressed patients. This is essential since expression recognition by other humans are highly inconsistent. After putting through a section images through the model, the results, which will be facial expressions, will be collected and presented in the results section. Results will be used to combine the 8 different classes of expressions into a binary classifier for depression. Then, determine how accurate the binary classifier is by testing on images of both depressed and non-depressed patients. The approach is also showcased in Figure 1.

B. Dataset

Images of depressed patients are collected from online sources, mainly making use of video clips of interviews or consultations of depressed patients, mainly from YouTube, with channels ranging from universities to individual channels that provide clips of interviews and consultations. For each clip of a specific person, to reduce randomness, 4 images will be taken from the video, focusing only on the face. These 4 images will be taken by splitting the video into 4 equal sections and selecting a specific timestamp. This first dataset will be for the training phase and will have around 100 images, representing 25 individuals. All the photos are extracted at points in the video where all their facial features are visible, where there is no obstruction or blocking of such to prevent any false detection or incorrect outcomes. The images are also cropped to ensure that the face is centered as well. An example of such an image is shown below in Figure 2, while Image II depicts annotated images by the expression recognition model. Figure 4 showcases the processing of an image in this research work.

For the testing phase, to test the reliability of the images taken, we will similarly be using interviews and consultations of depressed patients, but also include interviews with patients that are not depressed as well. This set of images will be around 100 images, split into half for depressed and not depressed.

Fig. 2: Pre-processed Image

Fig. 3: Annotated Image

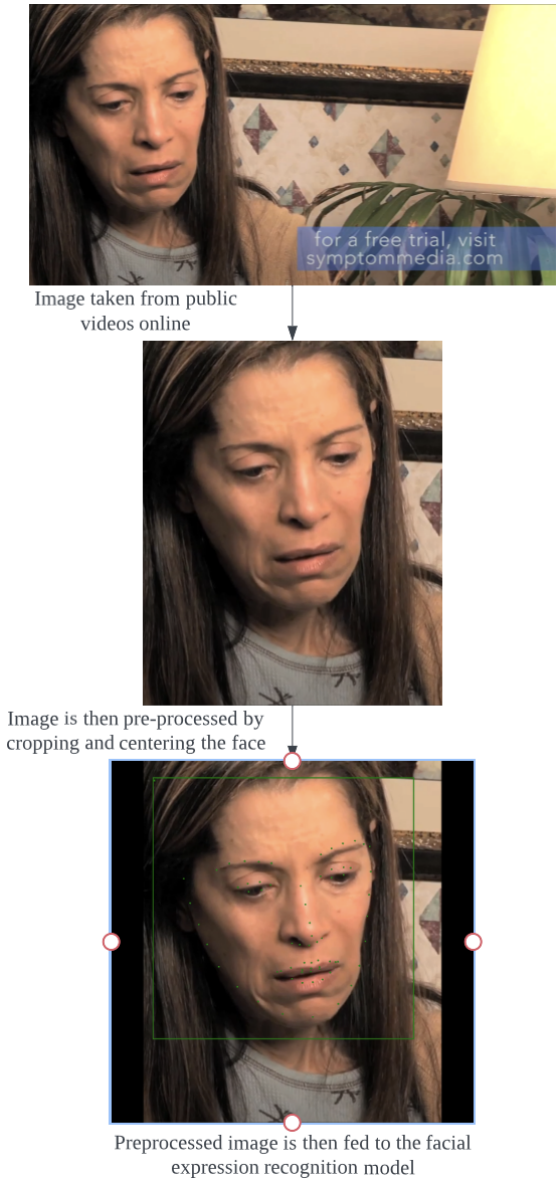

Fig. 4: Processing of Image

C. Model (EfficientNet Facial Expression Recognition)

A state-of-the-art facial expression recognition model will be used. Savchenko [20] has developed a facial expression and attributes recognition based on multi-task learning of lightweight neural networks. This model uses EfficientNet, which is known for their uniform scaling of dimensions using a user-specified compound coefficient[14]. This is because scaling up along single dimensions such as width, depth and resolution will saturate after reaching around 80%, as shown in equation (1)[14].

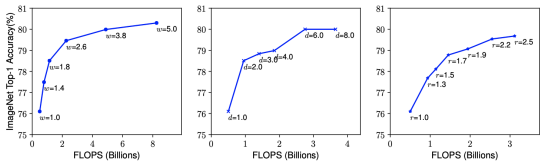

Fig. 5: Single Dimensional Scaling based on Width, Depth and Resolution respectively. Figure By: Tan, M. (2019, May 28). EfficientNet: Rethinking Model Scaling for Convolutional Neural Networks. arXiv.org. https://arxiv.org/abs/1905.11946v5

Research work done by Tan has observed that balancing network, width, depth, and resolution is an integral piece of scaling for ConvNet to help improve accuracy[14]. This is done via a scaling method with a constant ratio. The constant ratio is determined by the parameters in equation (1) below, which includes alpha, beta and gamma. The ratio is ensured in a way such that alpha times beta squared times gamma squared is approximated to 2, where alpha, beta and gamma is constrained to be more than or equal to 1[14].

$$\begin{aligned} depth : d &= \alpha_\phi \\ width : w &= \beta_\phi \\ resolution : r &= \gamma_\phi \\ ratio : \quad \alpha \cdot \beta^2 \cdot \gamma^2 &\approx 2 \\ \alpha \geq 1, \beta \geq 1, \gamma &\geq 1 \end{aligned} \tag{1}$$

With added robustness for facial extraction and alignment, it has resulted in higher accuracy numbers of 61.32% for 8 classes of expressions with the using of AffectNet dataset [20] as compared to other methods of less than 60%. This pipeline also has better performance compared to its peers.

IV. Experimental Results

A. First Experiment

The first experiment is to feed the training set of images of depressed patients to the model and obtain the images and the images' facial expression recognition results. The results are shown in Table I. Expression row represents the expression classifier associated with an image, and the count is the number of occurrences where an expression is detected. The model is highly consistent, with retraining of same images will result in similar outcomes.

Based on the results collected from the first experiment, 80% of the depressed patients are likely to evoke expressions that are sadness, surprise, disgust or neutral. Sadness is understandably the one with the highest count, as depression is

Model: EfficientNet

Expression	Sadness	Surprise	Disgust	Neutral
Count	24	22	17	19
Expression	Happiness	Contempt	Anger	Fear
Count	7	8	2	1

Table I: Results depicting expression detected by model

usually linked to having a despairing expression. Even though neutral may be classified under depressed, it is not surprising as there are studies proving that depression is linked to the lack of emotion, which results in a lack of expressions[21]. A split of classifiers can be done to turn 8 separate classifiers into one binary classifier capable of determining depression. The split will be determined based on the count from Table I, where sadness, surprise, disgust and neutral will be classified under depressed, and happiness, contempt, anger, and fear will be classified under non- depressed. The split is represented in Table II below.

Classifier	Expressions Involved
Depressed	Sadness, Surprise, Disgust, Neutral
Not Depressed	Happiness, Contempt, Anger, Fear

Table II: Classifier Grouping

B. Second Experiment

The second experiment is to test our classifier concluded earlier, by testing it against our testing dataset. To test out the classification, a confusion matrix will be used, as shown below in Table III. TP is the number of true positives that denotes depressed patients that predicted as depressed, TN is the number of true negatives that denotes non-depressed patients that are predicted as not depressed, FN is the number of false negatives that denotes depressed patients that are predicted as not depressed, FP is the number of false positives that denotes non-depressed patients. With the confusion matrix, we then calculate the accuracy, recall and precision in equations (2),(3) and (4). The purpose of using accuracy is to determine out of the binary classifier, how many of the test data is predicted correctly. The purpose of using recall is to determine out of all depressed patients, how many of them are predicted correctly. The purpose of using precision is to determine from all the patients that have been predicted as depressed, how many are depressed.

		Prediction	
		Depressed	Not Depressed
Actual	Depressed	True Positive (TP)	False Negative (FN)
	Not Depressed	False Positive (FP)	True Negative (TN)

Table III: Confusion Matrix

$$Accuracy(\%) = \frac{TP + TN}{TP + FN + FP + TN} \times 100 \quad (2)$$

$$Recall(\%) = \frac{TP}{TP + FN} \times 100 \quad (3)$$

$$Precision(\%) = \frac{TP}{TP + FP} \times 100 \quad (4)$$

After running our testing dataset through the same model again, this is the overall result for the confusion matrix in Table IV, while table V showcases the accuracy, recall and precision of the model to determine depression. From the results, it can be determined that our method of classification has around 59% accuracy based on the testing dataset, with 70% recall and 57.38% precision. With this result, the conclusion can be made that this classifier is able to detect depression in depressed individual 70% of the time, while the classifier can accurately predict depression about 57% of the time. One possible justification for the low precision could be due to the test data obtained from patient interviews and consultations not relating to depression. Patients in patient interviews usually express themselves negatively, as patients only attend consultations when they are feeling unwell. Other depression detection research such as eye movement analysis for depression detection by Alghowinem, S., Goecke, R., Wagner, M., Parker, G., & Breakspear, M. has about 60% recall accuracy[18], while Wang, Q., Yang, H., & Yu, Y. facial expression video analysis for depression detection has about 79% accuracy[17].

		Prediction	
		Depressed	Not Depressed
Actual	Depressed	35	15
	Not Depressed	26	24

Model	Results for detecting depression	
EfficientNet	Accuracy (%)	59
	Recall (%)	70
	Precision (%)	57.38

Table V: Results

C. Limitations

This method of determining expressions of depression in this research is very subjective since it is determined based on the results of the first experiment to craft a classifier for the second experiment. In addition, there are multiple studies online that concluded that depression varies from individual to individual. Some studies mentioned how depression is linked with reduced emotional exertion[21], while others discuss about how depression is linked to inconsistent emotion regulation[22]. Furthermore, other factors such as gender can also affect emotional language, where women tend to be more expressive with their emotions when depressed, while men are known to be less expressive[23]. This phenomenon is also largely affected by societal norms, family upbringing, or other potential mental issues[24]. With this in mind, there is a need in future work to utilise other expression features, with the

main aim targeting at micro-expressions, which current facial expression models are unable to achieve.

Also, the training and testing dataset might be too small since there are 8 different expressions associated with the expression recognition model, thus some of these expressions might have been overrepresented. However, there are a limited number of videos online that depict clinically proven depressed patients. To best improve this method, there is a need to create a new dataset from scratch. To improve the accuracy of this method, when time permits, the need for ablation studies on larger datasets is required to decide with classes more accurately constitutes depression.

D. Discussion and comparison of results with other related work

There are limited related work regarding solely on facial expression, with Wang, Yang and Yu[17] having research using it to detect depression in Chinese patients. Instead of using available data online, they have volunteered Chinese patients reacting to images, where they then use a camera to record facial expression. They followed up by using facial features points to track facial movement. While having a higher accuracy of around 79%, they have a more sophisticated methodology. They also do share a similar binary classification method instead of a scale to determine depression in users. This overall reduce the complicated process of depression detection, with less computation needed.

Looking at other widespread research in the depression detection field with other different inputs used for depression, multi-modality is another prospect that can further improve accuracy in such detection. An example would be research by Mohan et al. [25], where it focuses on using facial expression and sentiment analysis. This research uses more than facial expressions analysis, including sleep status as well as personality. Sentiment analysis uses user's provided texts to determine depressions through determining negative or positive sentiment. Together with sentiment analysis, the proposed method has seen around 73% accuracy.

V. Conclusions

In this paper, a state-of-the-art facial expression recognition model is used to determine expressions of depressed patients. Images of depressed patients are collected online through different video sources, and then fed through the model to determine patients' expressions. From the results, it is likely that depressed patients would usually show expressions of sadness, surprise, disgust and neutral. A binary classifier is then established and tested using the testing dataset, with the classifier having an accuracy of 60%. However, it is important to note that the datasets are small due to the lack of data present and could lead to bias. Another important thing to note is that based on the results, it is very difficult to only use facial expressions of depressed patients to determine depression, and other classifiers should be introduced and added to facial expressions to increase accuracy of model.

***Abstract*—Due to the limited tropical plant field photos but increasing digitized herbarium specimens, cross-domain plant identification has been employed to investigate the use of herbarium specimens on automated plant identification. However, the domain shift between herbarium and field images makes identifying plant species across these two domains challenging. One of the recent papers shows the superiority of triplet loss in preserving similarities between the crossed domains. Nevertheless, the impact of data deficiency on the performance of this triplet loss model has yet to be studied in depth in this field. Specifically, the transferability of the model features trained from limited cross-domain data to target images in the field domain. Therefore, this paper investigates the robustness of cross-domain plant features learned using this triplet loss metric learning approach compared to the supervised classification approach under general and few-shot experimental settings. Detailed experiments show that the triplet loss metric approach outperformed the supervised classification approach in the few-shot setting and achieved comparable results in the general experimental setting. In addition, the feature dictionary generation schemes composed of various herbarium field feature combinations we proposed boost our models' performance significantly compared to a single feature type dictionary strategy.**

I. Introduction

Over the last few years, we have seen tremendous progress in deep learning algorithms over automated plant identification [1]–[4]. However, these methods require much training data to achieve favorable results [5]. It is often difficult to obtain a balanced training dataset representing each class in a real-world scenario. Such is the case for automated plant identification of tropical species, where plant photographs are scarce. Meanwhile, herbarium images which are dried plant photographs, have been increasingly made available. In fact, the herbarium is one of the primary references for plant experts to identify samples collected in the field [6]. Therefore, cross-domain plant identification appears as one of the recent applications [7], [8] of machine learning and computer vision on digitized herbarium specimens.

Nonetheless, it remains challenging as there is a change in distribution (domain shift) in the training and test data. The training data consists of dried herbarium specimens, while the test data consists of live photographed plants and vice versa, which are highly morphologically different. Furthermore, the various available views or features representing a species in both domains are only partially present. They can be missing, especially for rare species which are difficult to photograph. In the cross-domain plant identification challenges, PlantCLEF 2020 [9] and 2021 [10], which is the largest benchmark in the field, we encoded the inadequacy of convolutional neural networks (CNNs) trained in the supervised and unsupervised manner. We learned that the triplet loss metric learning approach [11], [12] performed the best under the difficult test set with the least photographed species. Moreover, the triplet loss metric learning approach has shown supremacy over several plant diseases [13]–[15] studies.

However, the feasibility of the triplet loss model adaptable to limited training data in the context of the few-shot cross-domain plant identification configuration, has yet to be thoroughly explored. In addition, the triplet network's discriminative herbarium-field feature embedding space has yet to be investigated to produce a more generalized plant feature representation.

Therefore, in this paper, we exploit the robustness of the features learned by the triplet loss metric learning approach and compare its performance to that of the CNN trained with a general supervised recognition method in a few-shot configuration mimicking a realistic scenario. Specifically, we aim to determine the extent to which the methods can generalize to seen and unseen species when training data is limited. We also explore various feature dictionary generation strategies to improve the herbarium-field feature representations explicitly catered for our triplet network.

In short, this paper has two main contributions. First, we experimentally show that the triplet loss metric approach outperforms the traditional supervised classification approach in both seen and unseen classes in the cross-domain few-shot configuration. Second, we empirically studied and implemented various compositions of feature dictionaries from separate domain network streams (herbarium and field) to further encapsulate the representation of each species.

II. Methodology

A. Network Setup

The One-Streamed Mixed (OSM network) comprises a single classical CNN that receives both herbarium and field

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

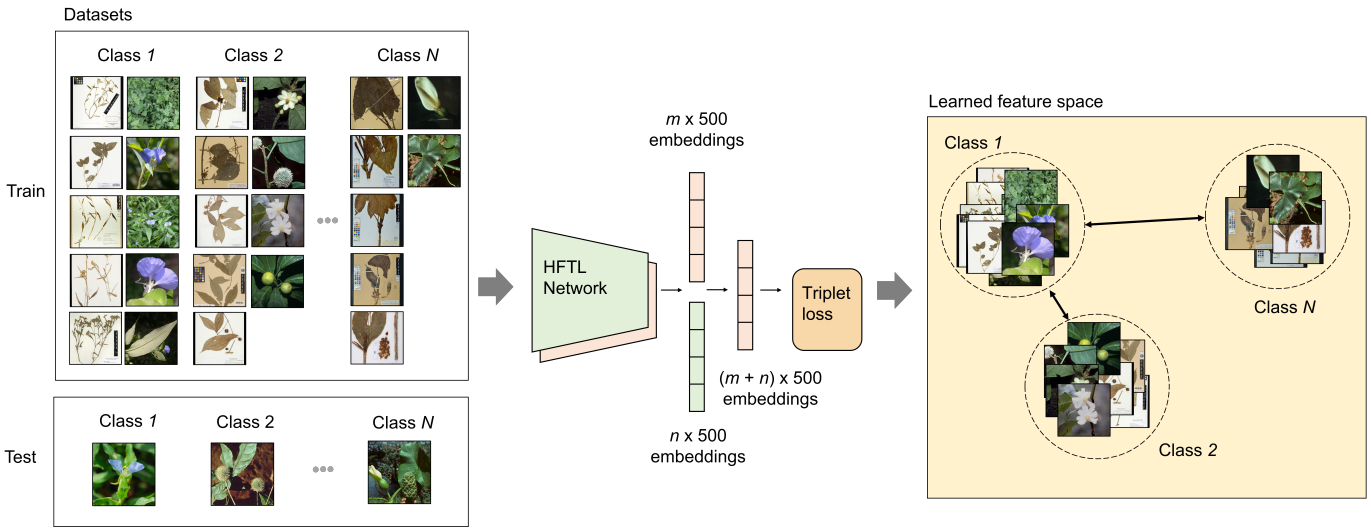

Fig. 1. Overview of the plant identification framework adopting the current state-of-the-art HFTL network to identify the imbalanced composition of herbarium and field images, producing a class discriminating feature space.

image inputs and is optimized by a softmax loss function. It serves as a benchmark.

The Herbarium-Field Triplet Loss (HFTL network) consists of two CNNs: herbarium CNN and field CNN, each receiving herbarium and field images as input, respectively, and each having an extractor layer. Fig. 1 shows the overview of the plant identification framework with the triplet network. The HFTL is optimized by a triplet loss function, and the network details can be found in [16]. Both OSM and HFTL networks use the same base CNN, which is Inception-ResNet-V2 [17]. However, they differ in their network compositions and training strategies.

B. Training Strategies

We initialized both OSM and HFTL networks on pre-trained ImageNet weights but trained HFTL networks in two stages, while OSM networks were in a single step. Since we designed our HFTL networks with two CNNs, the herbarium and field CNNs are each trained separately in the first stage. We then fine-tune the whole HFTL network with our training dataset in the second stage. In contrast, we directly train the OSM networks with our training datasets after initializing them with the pre-trained ImageNet weights. To reduce overfitting and improve generalization, we also apply data augmentation in all the training of the networks. We set up our experiments using the TensorFlow-Slim library with Tensorflow version 1.12.

C. Inference Method

Unlike conventional CNNs, where the classification layers are used to predict the class, deep metric learning models use its CNN (extractor layers) to generate discriminative features for classification. Similarly, we use the extractor layers of the HFTL and OSM networks to obtain the feature embeddings for identification. We do this by comparing the similarities between the extracted feature embeddings and a pre-saved

TABLE I
TRAINING PARAMETERS OF THE NETWORKS.

	OSM Network	HFTL Network
Batch size	128	128
Initial learning rate	0.0001	0.0001
Optimizer	Adam optimizer	Adam optimizer
Weight decay	0.00004	0.00004
Input image size	$299 \times 299 \times 3$	$299 \times 299 \times 3$
Loss function	Softmax cross entropy	Triplet loss

feature dictionary. We construct this pre-saved feature dictionary by assembling the average feature of each trained class from a set of training images. Before averaging each class feature, note that we also cropped each training image into ten variations: top-right, top-left, bottom-right, bottom-left, center and all five mentioned flipped horizontally to retain as much data. Consequently, we calculate the cosine similarity between the extracted feature and the feature dictionary to measure the feature similarities. It is then converted to probabilities using inverse distance weighting to rank the predictions via

$$P_i = \frac{(\frac{1}{d_i})}{\sum_k (\frac{1}{d_k^n})}, \tag{1}$$

where k and i represents the index of the class, d being the embedding distance, and n being the power in positive real number, which in our case is 5. We then use Mean Reciprocal Rank (MRR) score as an evaluation metric to measure the performance of our experiments. It is the average of the reciprocal ranks of the whole test set formulated as:

$$MRR = \frac{1}{\mid Q \mid} \sum_{i=1}^{|Q|} \frac{1}{rank_i}, \tag{2}$$

where $\mid Q \mid$ is the total plant occurrences, $rank_i$ is the predicted rank of the ground truth species for the ith plant

608-5	PlantCLEF 2021, PlantCLEF 2022	608	5,691

occurrence.

Feature Dictionary Generation Strategies. As opposed to traditional CNNs where a label is directly predicted, the triplet model relies on a discriminative embedding space for recognition. Therefore, a suitable feature dictionary is explored to boost the existing method. Our dictionary generation strategies include variations of the plant features to save (either the herbarium, field, or both) and the network used to obtain these features. Table II summarizes our feature dictionary generation scheme. *Feature type* indicates the feature to extract and save while *Feature extractor* denotes the network applied to generate these features. For HFTL network, the feature dictionary in method 1 is composed of herbarium features generated by its herbarium network. Method 2 dictionary is composed of herbarium and field features but generated by only its herbarium network. Method 3 dictionary is composed of either herbarium or field. Field features will be saved only if there are field samples available, otherwise herbarium features will be saved. Method 4 dictionary is composed of both herbarium and field. Unlike method 2, method 4 is generated by its herbarium and field networks respectively. These settings are similar for the OSM network. However, note that since OSM has only one stream, the feature extractor used is the same. Consequently, methods 2 and 4 are equivalent for the OSM network.

D. Datasets

We use the datasets from PlantCLEF 2021, PlantCLEF 2022, and our self-collected dataset from various reliable online queries to further analyze the impact of data scaling on model performance.

TABLE IV
DETAILS OF THE TEST DATASETS COMPRISING ONLY FIELD IMAGES.

Dataset	Source	# of species	# of images
Seen	PlantCLEF 2021	338	1,139
Unseen	Online queries	184	706

PlantCLEF 2021. This dataset is currently the largest benchmark dataset for cross-domain plant identification. It consists of 997 species represented by over 321,226 herbarium images and 5,824 field images. Note that only a subset of 435 species contains both herbarium and field training data, which we use for training. The dataset constructed from here is named "Initial" dataset in Table III.

PlantCLEF 2022. This dataset is currently the most extensive benchmark dataset for plant species identification. It consists of 80,000 species represented by four million field images. To build different dataset compositions with a varying number of training images compared to the initial cross-domain plant identification dataset, we exploit the PlantCLEF 2022 dataset. Specifically, we find that there are 185 shared species in PlantCLEF 2022, which corresponds to the 435 existing species in the PlantCLEF 2021 dataset. Here, we are able to build our "435" training set in Table III, accumulating up to 203,959 images from the "Initial" dataset. In addition, we also managed to find 173 additional species in this dataset that also exist in PlantCLEF 2021. Note that, these 173 species are species that contain herbarium images but no field images in PlantCLEF 2021. Therefore, we are able to generate our "608" training set in Table III, which increases the total number of images to 243,617.

Limited 5 training samples. To create a few-shot learning configuration, we construct two additional datasets with fixed limited five training samples. These are datasets "435-5" and "608-5" in Table III. As their name implies, "435-5" is the "435" dataset, but each species contains a maximum of five herbarium training samples and five field training samples. Similarly, "608-5" is the "608" dataset but with each species trained with a maximum of five herbarium samples and five field samples. We limit the number of samples to 5 for each class in order to test our hypothesis on the transferability of features across different domains using a triplet network, and to compare its performance with a supervised classification network.

Test sets. Our Seen test set is constructed from the PlantCLEF 2021 dataset. It is a set of 338 species from the 435 species that have both herbarium and field images. Meanwhile, our Unseen test set is generated from multiple online queries from sources such as GBIF and iNaturalist. Since we want this Unseen test set to contain species not in training, we collected 184 species neither from PlantCLEF 2021 nor 2022. Due to the difficulty of obtaining more field images, our test sets combined are only

focused on over 500 species as shown in Table IV.

III. EXPERIMENTS AND RESULTS

Our primary investigation concerns the study of few-shot learning and classical learning in cross-domain plant identification. Typically, CNNs perform poorly with inadequate training data and favorably otherwise. Therefore, these settings are studied to investigate if the HFTL network serves as a conventional OSM network benchmark.

A. Few-shot Setting

To exploit the capability of the models adaptable to the few shot setting, we train and compare the performance of several models on training sets with a fixed limited amount of images as mentioned in Sec. II-D. Table V and VI show the classification results on the seen and unseen test set respectively. We found that the metric learning approach (HFTL-435-5, HFTL-608-5) performed better than the traditional supervised approach (OSM-435-5, OSM-608-5) in both the seen and unseen test sets. We see a performance gap of over 15% from the metric learning approach against the classical supervised approach in the seen test set and up to 5% performance gap in the unseen test set. It confirms the superiority of triplet loss over traditional supervised methods in preserving similarities between cross-domains and the feasibility of the model adapting to limited training data.

B. Classical Setting

On the other hand, we also train and compare the performance of the models on a larger scale training data ("Initial", "435" and "608"). Note that these datasets do not have fixed limits on the number of images and may be imbalanced. Tables VII and VIII show their classification results on the seen and unseen test sets, respectively. Naturally, with the increase of training data, the performance of both approaches shows improvements. However, unlike the few-shot setting, we found that the metric learning approach (HFTL, HFTL-435, HFTL-608) performed better in the seen test set, but the traditional supervised method (OSM, OSM-435, OSM-608) performed better in the unseen test set. In the seen test set, we see a performance gap of approximately 30% from the metric learning approach, while a performance gap of approximately 10% achieved by the classical supervised method in the unseen test set. It shows the advantage of the metric learning approach in generalizing seen species and the classical supervised approach in generalizing unknown species better when there is sufficient training data. In addition, we find the increase in training classes for both approaches in the seen test set; specifically models OSM-608 and HFTL-608, does not significantly improve the performance as expected. It may be due to the fact that the seen test set is based on the 435 species and the reason why models trained with 435 species (OSM-435, HFTL-435) generalize best to this seen test set.

TABLE VII
RESULTS OF THE MODELS BASED ON CLASSICAL SETTING IN THE SEEN TEST SET.

HFTL-608	608	0.107	**0.1209**	0.1062	0.0888

C. Feature Generation Scheme

Regarding the various dictionary generation methods experimented on, we find that methods 1 and 2 work best under the unseen test set, while methods 3 and 4 work best under the seen test set. Since method 3 and 4 introduces field features to the feature dictionary, they help match the learned field embeddings of the seen species against the dictionary. In contrast, since there is no field training images for the unseen species, method 3 and 4 does not introduce useful field images to the class representations. Consequently, methods 1 and 2 are better representations of the unseen test set. These findings can be used to construct suitable feature dictionary for supervised

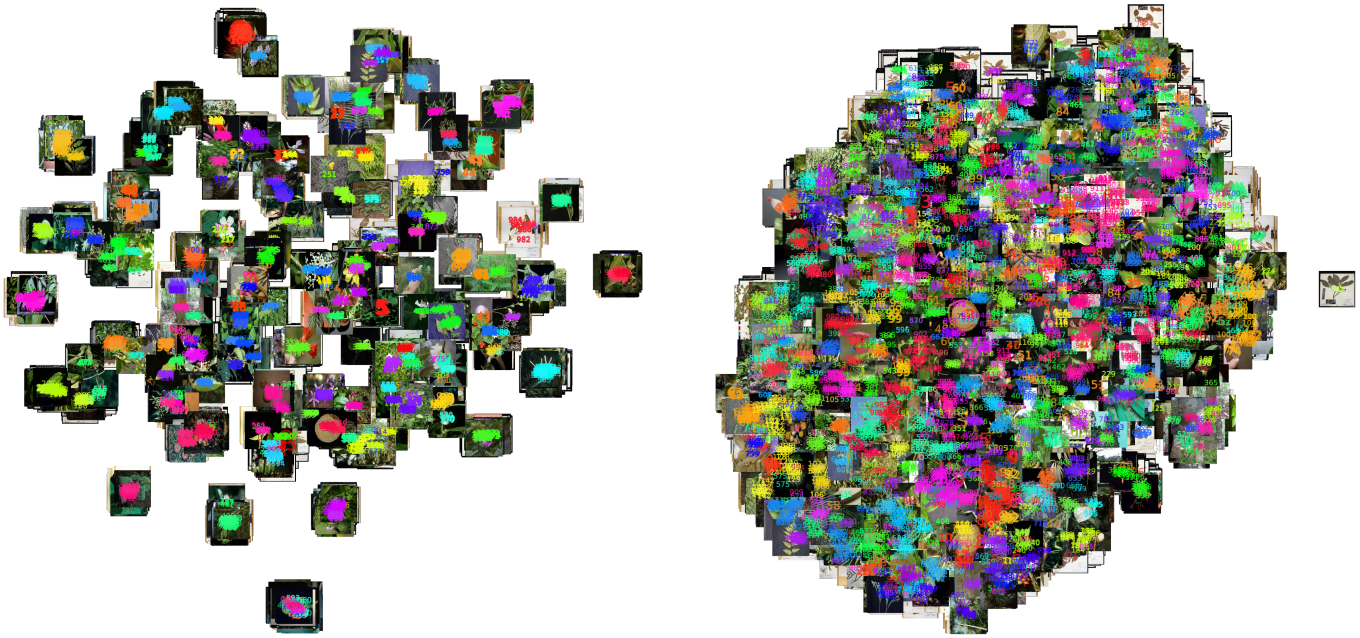

Fig. 2. T-SNE visualizations of 261 plant species and 4,402 images from the training dataset. (a) is generated from the few-shot HFTL-608-5 model. (b) is generated from the few-shot OSM-608-5 model.

and unsupervised cross-domain plant recognition whereby field features can be added to accommodate classification.

D. Visualizations

To visualize and compare the feature embeddings generated from the HFTL and OSM models, we use t-distributed Stochastic Neighbor Embedding (t-SNE) [18] to assess the performance of these models under few-show settings. t-SNE is a dimension reduction method that converts and visualizes high-dimensional data into a low two or three-dimensional space. Therefore, the feature embeddings generated can be represented and viewed in a two-dimensional image form. Fig. 2 presents the t-SNE visualizations showing 4,402 herbarium and field images (embeddings) of 261 species from the training dataset. We randomly selected two species from all the available family taxon to balance out the samples. In Fig. 2 , the images are accompanied by their respective species id. Each color represents a unique species id of the above mentioned 261 species. In addition, the images are grouped according to how similar their embeddings are to one another. The closer the images are stacked together, the more similar their embeddings are to one another. On the other hand, the further the images are from one another, the more different their embeddings are to one another.

Fig. 2 (a) is constructed from the HFTL-608-5 model, while Fig. 2 (b) is constructed from the OSM-608-5 model, in which both were trained under the few-shot settings. Similar to the results obtained in the experiments, HFTL-608-5 is better at distinguishing between species than OSM-608-5. As observed, the herbarium and field samples are better grouped according to their species in Fig. 2 (a) than in Fig. 2 (b). Based on the colored species ids, we can see that the HFTL-608-5 model is able to separate different species more clearly compared to the OSM-608-5.

In addition, we demonstrate the close-up t-SNE visualizations of a smaller training subset of 25 species and 392 images in Fig. 3. Unlike Fig. 2, the herbarium and field images are not computed to stack on top of one another to allow a clearer view. The close-up images' different border colors represent the different species. Meanwhile, the white numbered text in the close-up images represent the species id number. We randomly selected 25 species from 25 different family taxon to allow a clearer observation of the visualizations. Fig. 3 (a) is constructed from HFTL-608-5, while Fig. 3 (b) is constructed from OSM-608-5. Likewise, the HFTL-608-5 model shows better species recognition as the embeddings are well separated and clustered compared to OSM-608-5. Although the HFTL model can better recognize the plant species and give a distinct separation between different class embeddings, it is also noted that when the samples are very similar, the separation is weaker. It can be observed in the close-up samples with blue and yellow borders, which are visually similar. Consequently, we look forward to enhancing the maximization of the embedding distance between visually similar species for the triplet network by using their higher taxonomy classes to overcome this in future experiments.

IV. CONCLUSION

This work investigated and compared the feature generalization and transferability between the triplet network and the classical supervised learning network in this few-shot cross-domain plant identification. We found that the triplet network could learn more robust features despite a limited training sample and could further harness the similarity between different domains with our proposed feature generation scheme. This result is an important reference for researchers working in this field and a reliable reference for processing smaller plant data for practical applications. In future, we will extend the work to incorporate and exploit the potential power of the supervisory network to leverage this distance metric approach for better feature generalization to both seen and unseen data.

***Abstract*—This paper introduces a new lossless image compression method that aims to effectively utilize image correlations from two distinctive perspectives. Firstly, a hierarchical approach is employed to decompose the input image into subimages, and a new encoding order is designed for efficient subimage encoding. We enable the method to fully exploit the horizontal, vertical, and diagonal components of previously encoded subimages. Secondly, each subimage is further decomposed into low and high-frequency components, where the low-frequency components are first compressed. Then the low-frequency components are used as additional input for compressing the remaining high-frequency ones. In this scenario, the low-frequency ones serve as strong prior for encoding the higher frequencies. In addition to improving the compression performance, we make our method adapted to image sizes, specifically the performance differences depending on the input resolution, by introducing resolution-specific kernels. Experiments show that the proposed method achieves state-of-the-art performance for high and low-resolution benchmarks.**

I. Introduction

There have been some progresses in lossless image compression performances by using deep neural networks (DNNs) [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12]. Based on previous conventional non-learning methods (BPG, PNG, JPEG-LS, JPEG-XL) [13], [14], [15], [16] using the closed-loop pixel prediction, learning-based lossless compression methods [1], [2], [3], [4], [5], [6] replace the predictor with powerful DNNs to make a more precise prediction. These methods, which encode pixels one by one, are called autoregressive models. Early autoregressive methods such as PixelCNN [1], PixelCNN++ [2], and PixelRNN [4] predict the probability of an encoding pixel conditioned on all previous ones. However, these methods have two limitations. First, the inference time is impractical since they require neural network computations for the number of whole pixels. Next, these methods proceed in the raster scan order while there can be other orders that can exploit more correlated pixels.

To reduce the inference time, recent learning-based methods [3], [5], [6], [37] proceed with the encoding in the unit of subimages rather than individual pixels. For instance, MS-PixelCNN [3] divides the input into subimages and sequentially compresses them one by one. L3C [5] estimates the probability distribution starting from a uniform distribution and progressively upsamples to the final image. RC [6] divides the image into a lossy compressed image and its residuals, where the residuals are losslessly encoded. Although these methods achieve reasonable inference time, they demonstrate lower compression efficiency compared to start-of-the-art conventional methods, such as FLIF and JPEG-XL.

Furthermore, it is important to note that learning-based methods exhibit limited robustness to variations in image resolution. While these methods may demonstrate comparable performance when applied to high-resolution images (2K), their compression efficiency significantly deteriorates when dealing with low-resolution counterparts, such as 512×512. This decline in compression efficiency arises from the training bias of learning-based methods towards high-resolution images, which restricts their adaptability.

To address the robustness of encoding performance against image resolution variations, this paper presents a resolution-adaptive lossless compression scheme, based on our previous compression method using frequency decomposition network (LC-FDNet) [37]. The LC-FDNet provides state-of-the-art lossless compression performances by developing a hierarchical compression scheme that maximizes the correlation between previous and current subimages. The approach begins by decomposing the input into subimages based on spatial location and color channel. A hierarchical scheme is then employed to determine the compression order of these subimages, effectively utilizing the horizontal, vertical, and diagonal components for predicting the current encoding pixel. For each subimage, we further decompose it into low and high-frequency components to leverage a coarse-to-fine scheme. This is motivated by the observation that separate predictors are more effective for low and high-frequency regions, as high-frequency regions typically exhibit higher prediction errors. By compressing the low-frequency regions first and utilizing them as additional input for predicting the remaining high-frequency regions, we exploit the strong prior provided by the low-frequency regions. Moreover, the frequency decomposition process is designed to be image-specific, allowing the network to determine the optimal ratio of low and high-frequency regions for each image. On the basis of the LC-FDNet, this paper introduces a novel Resolution Refinement Block (RRB) to address the domain gap resulting from resolution variations across datasets. This block leverages image resolution information to dynamically generate resolution-specific convolution kernels. By applying these resolution-specific kernels to the intermediate features of the network, we enhance the network's

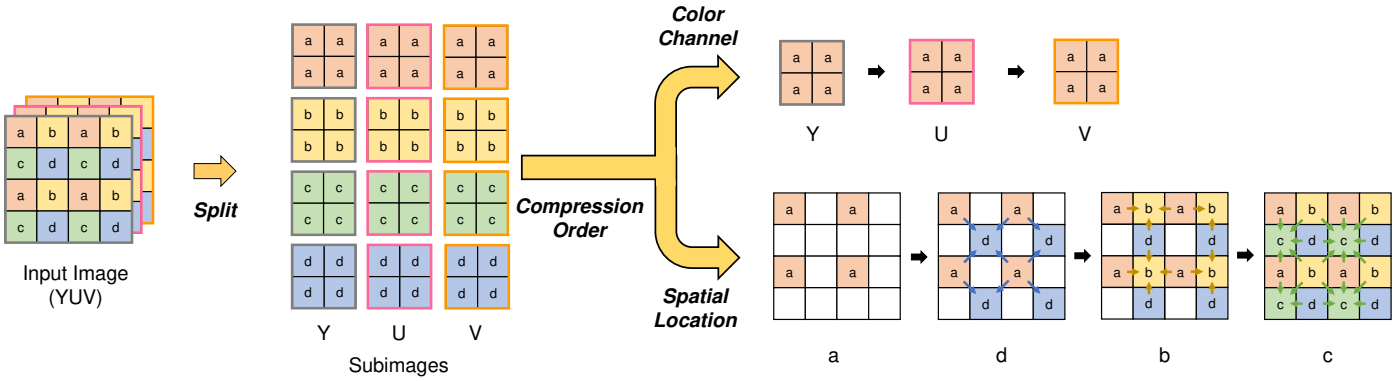

Fig. 1: Illustration of the overall compression scheme. We first split the input into 12 subimages (four for each channel) depending on spatial location and color channel, where the border color of a subimage represents the color channel. Then, we compress the subimages one by one, where the order of the compression is determined based on color channel and spatial location.

ability to handle image resolution dependencies and improve overall performance.

In summary, our method proceeds with the encoding in a coarse-to-fine manner in two aspects. First, we decompose an input image in a hierarchical fashion to maximally exploit the correlation between the decomposed subimages. Secondly, we decompose the subimages into low and high-frequency regions and use low-frequency components to compress the high-frequency ones better. Furthermore, we use image resolution as additional input to refine the intermediate features, which drives our network to be robust to image resolution. Experiments show that the proposed method achieves state-of-the-art performance for benchmark datasets with reasonable inference time.

II. Method

A. Overview

The framework of our method is illustrated in Fig. 1. We first convert an input RGB image $I \in \mathcal{R}^{H\times W\times 3}$ into a YUV through a reversible color transform [26], where H and W are the height and width of the image, respectively. Then, we split each of the YUV into 4 subimages, resulting in total of 12 subimages $x_{c,s} \in \mathcal{R}^{\frac{H}{2}\times\frac{W}{2}\times 1}$ based on the color channel and spatial location, where c is the channel index ($c \in \{Y, U, V\}$) and s is the spatial location index ($s \in \{a, b, c, d\}$). The subimages are compressed one by one, where the compression order of the subimages is designed to maximize the compression efficiency. The details of the spatial location index and compression order will be described in the next subsection. We intially compress 3 subimages $\{x_{Y,a}, x_{U,a}, x_{V,a}\}$ using a conventional compression algorithm. Then, the remaining subimages are sequentially compressed using learned networks, where the previously encoded subimages and the image resolution (HW) are given as input.

B. Compression Order

We decompose each color channel into 4 subimages indexed as a, b, c, d, which is shown in Fig. 1. The encoding of a subimage is conditioned on the previously encoded subimages. Specifically, for compressing the N-th subimage $y \in \mathcal{R}^{\frac{H}{2}\times\frac{W}{2}\times 1}$, our system takes as input the $N-1$ subimages that have already been encoded ($x_{in} \in \mathcal{R}^{\frac{H}{2}\times\frac{W}{2}\times(N-1)}$) along with the image resolution (HW). The set of previously encoded subimages (x_{in}) serves as strong prior for predicting and compressing the N-th subimage y, while the image resolution is utilized for refining the intermediate features. The correlation between the input subimages x_{in} and the N-th subimage y plays a crucial role in compression performance, as higher correlation leads to better estimation and enhanced compression efficiency. Therefore, arranging the subimages in an optimal order is essential to maximize correlation utilization.

We determine the order of the subimages by considering both color channel and spatial order. Regarding the color channel order, since Y contains more significant features than U and V, a natural choice is to compress them in the order of $Y \rightarrow U \rightarrow V$. Regarding the spatial order, MS-PixelCNN [3] uses a similar subimage splitting approach proceeding in the naive scan order of $a \rightarrow b \rightarrow c \rightarrow d$. We have observed that this order may not maximize the correlation between spatial locations. We observe that $a \rightarrow d$ maximizes the correlation compared to $a \rightarrow b$, where d fully exploits the information of a both horizontally and vertically, while b benefits from a but fails to utilize the vertical components fully. Based on this observation, we set the order as $a \rightarrow d \rightarrow b \rightarrow c$. In conclusion, we proceed with the compression of subimages in the order of $x_{Y,a} \rightarrow x_{U,a} \rightarrow x_{V,a} \rightarrow x_{Y,d} \rightarrow x_{U,d} \rightarrow \cdots \rightarrow x_{V,c}$, where we encode the initial subimages $x_{Y,a}, x_{U,a}, x_{V,a}$ using a conventional codec, such as JPEG-XL [16].

C. Architecture

This section presents the architecture of the proposed method illustrated in Fig. 2, which shows the process of compressing the N-th subimage y given the input x_{in} (concatenation of $N-1$ previously encoded subimages) and image resolution (HW). As shown in the figure, our method consists of the following steps: Backbone Network, Adaptive

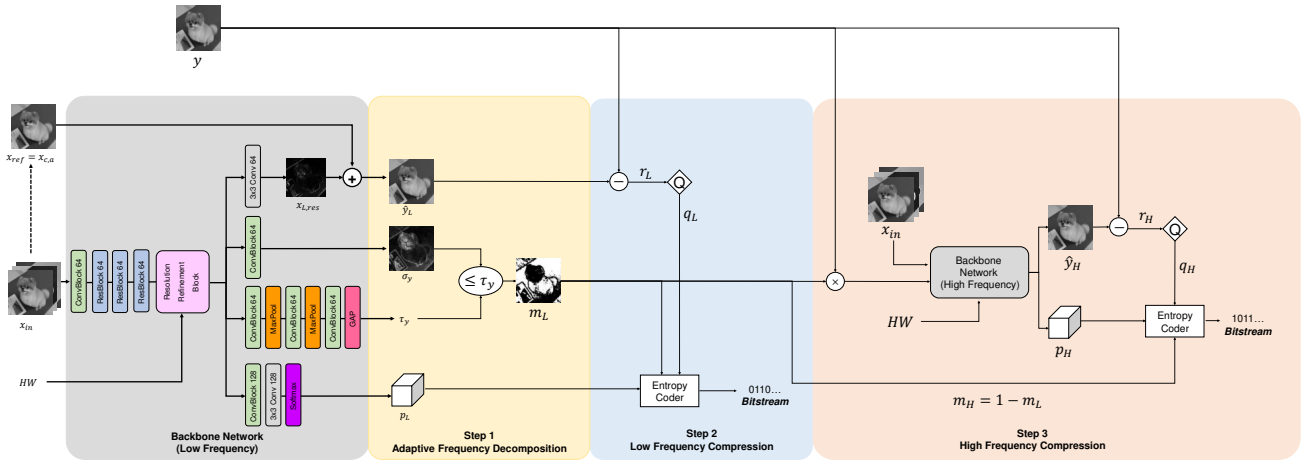

Fig. 2: The encoder architecture of the proposed method. In this figure, we consider the case of compressing $y = x_{Y,d}$ given $x_{in} = \{x_{Y,a}, x_{U,a}, x_{V,a}\}$. The input first goes through a backbone network (Fig. 3) that outputs several parameters and features for the next steps of encoding. Step 1, named adaptive frequency decomposition (AFD), receives the outputs from the backbone and determines whether each pixel belongs to either low or high-frequency regions. Then, Step 2 (low-frequency compression (LFC)) encodes the low-frequency region of the subimage y. The final Step 3 (high-frequency compression (HFC)) receives the encoded low-frequency region as additional input and compresses the remaining high-frequency region.

Frequency Decomposition (AFD), Low-Frequency Compression (LFC), and High-Frequency Compression (HFC). AFD decomposes the subimage by frequency, classifying each pixel into either low or high frequency. Then in LFC, only the low-frequency components are compressed. Finally, the remaining high-frequency components are compressed using the already encoded low-frequency region as additional input to the HFC. Throughout the paper, notations L and H denote low and high-frequency, respectively.

Initially, the already encoded subimages and the image resolution are fed to the backbone network and generates four intermediate outputs: 1) subimage prediction $\hat{y}_L$, 2) probability distribution p_L, 3) error variance map σ_y, and 4) error variance threshold τ_y. In the backbone, x_{in} first passes through one ConvBlock and three ResBlocks and generates an intermediate feature. The ConvBlock is composed of 3×3 convolution layer, Batch Normalization, and ReLU. The detailed architecture of the ResBlock is illustrated in Fig. 3. The intermediate feature is used to generate four outputs. However, we observe from experiments that the generated intermediate feature lacks the robustness to image resolutions.

Thus, we add a Resolution Refinement Block (RRB) (illustrated in Fig. 3) that explicitly uses the image resolution to refine the intermediate feature. We feed the information of image resolution as the number of pixels in the image *i.e.*, HW. In the RRB, we begin by applying positional embedding [43] to expand the dimensionality of the image resolution. Prior researches, such as in NeRF [44] have demonstrated that mapping the inputs to a higher dimensional space using high frequency functions can enhance the fitting of data with high-frequency variations. Afterwards, the embedding vector is passed through two MLPs to generate 3×3 convolution

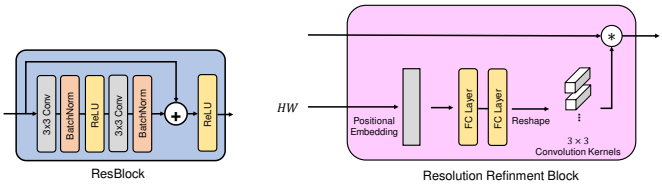

Fig. 3: Architecture of Backbone Network (Low Frequency)

kernels, which are then applied to the intermediate feature. If the channel dimension of the intermediate feature is C, then the output of the MLPs has a dimension of $3\times3\times C\times C$. The generated convolution kernels drive the intermediate feature to reflect the image resolution.

The refined feature is further processed through additional convolution layers to generate four outputs. Firstly, $\hat{y}_L \in \mathcal{R}^{\frac{H}{2}\times\frac{W}{2}\times1}$ represents the prediction of y, with better predictions resulting in more compact compression. Following the standard practice in lossless compression, we calculate the residual $r_L = \hat{y}_L - y$. As the residual is not in the form of integers, we quantize (round) it, denoting the quantized residual as q_L, which is then passed to the entropy coder.

Secondly, p_L is the estimated probability distribution of the quantized residual q_L. The probability distribution is directly estimated as the probability mass function (pmf), and thus the dimension of p_L is $\frac{H}{2}\times\frac{W}{2}\times K$, where K is 511 for the Y channel and 1021 for the U, V channels. To ensure that the probabilities sum up to 1, we apply the softmax operation to derive p_L.

For classifying each pixel as belonging to low or high-frequency regions, we introduce an error variance map $\sigma_y \in \mathcal{R}^{\frac{H}{2}\times\frac{W}{2}\times1}$, which is obtained through learning with an ap-

propriate loss function. The map intensity reflects the pixel's position in a high-frequency or low-frequency region, with higher intensity indicating a high-frequency pixel. To design the error variance map, we utilize the magnitude of the prediction error, and the loss function used for this purpose is defined as:

$$L_{ev} = \|\sigma_y - |y - \hat{y}_L|\|1. \tag{1}$$

Lastly, we learn a threshold $\tau_y \in \mathcal{R}$, which is applied to the error variance map to classify pixels as low or high-frequency regions. We have observed that the error variance heavily depends on the color channel, spatial location, and image characteristics. To adapt to different inputs, the network generates threshold values, with each subimage having its own threshold. In total, nine threshold values are generated.

Especially for the generation of the subimage prediction $\hat{y}_L$, we adopt a residual scheme. That is, instead of directly estimating the pixel value of the subimage y, the network estimates $x_{L,res}$, which is the difference between y and a reference image x_{ref} (set as $x_{c,a}$). For instance, in the case of compressing $y = x_{Y,d}$, the network sets $x_{Y,a}$ as offset and estimates the residual between $x_{Y,a}$ and $x_{Y,d}$. The final output $\hat{y}_L$ is derived as $x_{L,res} + x_{Y,a}$. In other words, the network estimates the residual with respect to x_{ref}. Since x_{ref} and y tend to have a high correlation, their difference usually has low variance, with the mean close to zero. This leads to stable training and performance enhancement.

After obtaining the above outputs, our method categorizes each pixel as either low or high-frequency in Step1 (AFD) of Fig. 2. With σ_y and τ_y in hand, this step generates a binary map as

$$m_L^i = \begin{cases} 1 & \text{if } \sigma_y^i \leq \tau_y \\ 0 & \text{else,} \end{cases} \tag{2}$$

indicating which components are considered by the LFC, where i denotes the pixel index.

Then, in the LFC (Step 2), we only compress the low-frequency components, specifically the pixels corresponding to $m_L^i = 1$. The quantized residual q_L is converted into bitstreams using the corresponding probability distribution p_L. We follow a low to high frequency compression order since the low-frequency region is more easily compressible. Given the input x_{in}, the compression efficiency in the low-frequency region is already optimized, and providing high-frequency components as additional input would only yield marginal performance enhancement. The significant gain in compression efficiency is achieved when the low-frequency components serve as an additional input for the high-frequency ones.

The HFC (Step 3) follows a similar pipeline to the LFC but introduces an additional input ($y \odot m_L$) alongside the inputs of the LFC (x_{in} and HW). The input $y \odot m_L$ represents the low-frequency components of the current subimage. In the HFC, these inputs are fed into the backbone network, which has the same architecture as the LFC but without the branches for deriving σ_y and τ_y. Consequently, we obtain two outputs: 1) $\hat{y}_H$, which represents the prediction of y in the high-frequency region, and 2) p_H, the probability distribution of the quantized residual q_H. The utilization of low-frequency components as a strong prior enables more accurate predictions in the high-frequency region.

Finally, $\hat{y}_H$ and p_H are fed into the entropy coder, allowing us to encode the high-frequency components, specifically the pixels where $m_L^i = 0$ or $m_H^i = 1 - m_L^i = 1$. The HFC can disregard the estimation of low-frequency components and solely focus on the high-frequency ones.

D. Loss Function

Our network is trained with the following losses. First is the reconstruction loss that derives the predicted subimage to match the ground truth. The reconstruction loss is defined as the L1 loss:

$$L_{rec} = m_L \cdot \|y - \hat{y}_L\|_1 + m_H \cdot \|y - \hat{y}_H\|_1. \tag{3}$$

We multiply the corresponding frequency mask to the reconstruction loss of LFC and HFC. By doing so, we ensure that only low-frequency components contribute to the reconstruction loss in LFC, while the high-frequency components contribute solely to the reconstruction loss in HFC.

Additionally, we incorporate the bitrate loss, which aims to minimize the cross-entropy between the true probability distribution of the quantized residual (p_{q_L}, p_{q_H}) and the estimated distributions (p_L, p_H) respectively. It is defined as

$$L_{br} = m_L \cdot \|-\log p_L(q_L)\|_1 + m_H \cdot \|-\log p_H(q_H)\|_1. \tag{4}$$

The bitrate loss encourages the model to accurately predict the probability distribution of the quantized residuals, thereby improving the overall compression performance. To restrict the contribution of each frequency component as in the reconstruction loss, we multiply the frequency masks to the corresponding reconstruction loss.

Altogether, we train our network with the loss:

$$L = L_{br} + \lambda_{rec} L_{rec} + \lambda_{ev} L_{ev} \tag{5}$$

where L_{ev} is the error variance loss mentioned in Eq. 1. λ_{ev} and λ_{rec} are the balancing hyperparmeters. In our experiments, we set both λ_{ev} and λ_{rec} as 1.

III. Experiments

A. Experiment Setup

Implementation Detail For the quantization of residuals r to q, we use the round function *i.e.*, $q = round(r)$. In this case, gradient-based optimization cannot be used since the derivative is zero except at integers. Thus, we approximate the round function as STE [38] *i.e.*, $q = r$ in the backward pass. Although other quantization approximation methods can also be applied, [39] has shown that various methods have a minor effect on the compression performance. In addition, deriving m_L with

TABLE I: Comparison of our method and other non-learning and learning-based codecs on high-resolution benchmark datasets. We measure the performances in bits per pixel (bpp). The difference in percentage to our method is highlighted in green.

Method	CLIC.m	CLIC.p	DIV2K

Ours	6.88	7.76	8.05

Eq. 2 introduces the same problem, where the derivative is zero except for the threshold. In this case, we approximate as $m_L = \text{sigmoid}(-(\sigma_y - \tau_y))$ in the backward pass. For the entropy coder, we employ "torchac," which is a fast arithmetic coding library for PyTorch developed by the authors of L3C [5].

Evaluation Dataset For the 2K high-resolution evaluation dataset, we use the following three benchmark datasets, CLIC.m, CLIC.p, and DIV2K. The CLIC mobile (CLIC.m) and CLIC professional (CLIC.p) are datasets released as part of the "Workshop and Challenge on Learned Image Compression" [28]. The CLIC.m consists of 61 evaluation images taken by mobile phones. The CLIC.p contains 41 evaluation images by DSLRs. The image resolutions in the CLIC datasets are mostly 2K, but some have low resolutions down to 512×384. The DIV2K [29] is a super-resolution dataset comprising 2K resolution high-quality images, where 100 images are provided for evaluation.

For the low-resolution evaluation dataset, the following three datasets are used: Kodak [41], McMaster [40], and Classic. Kodak contains 24 images with a resolution of 512×768. McMaster includes 18 images of size 500×500, which are cropped from high-resolution images. The Classic dataset consists of 12 popular images, which generally have a resolution of 512×512. For the Classic dataset, we use the following images: airplane, Barbara, coastguard, comic, flowers, goldhill, Lena, mandrill, monarch, pepper, ppt3, and zebra.

Training We train our network with the Flickr2k [32] dataset having 2,000 high-quality images. In addition, we use data augmentation by randomly downsampling the images by the ratios of 2, 3, and 4 for the robustness to resolution dependency. We randomly extract a patch of size 128×128 from the input image during training. Adam optimizer [33] is used for the training, with a batch size of 24 for 3,000 epochs. The learning rate is initially set as 1×10^{-3} and decays by a factor of 0.1 for every 1,000 epochs. The training takes 72 hours on a GeForce GTX 1080 Ti.

Evaluation We compare our method with learned and conventional non-learned compression algorithms. Specifically, the following conventional lossless image codecs are compared: PNG [14], JPEG-LS [15], JPEG2000 [34], WebP [36], BPG [13], LCIC [12], FLIF [27], and JPEG-XL [16]. As for the learned methods, L3C [5], RC [6], Near-Lossless [7], and LC-FDNet [37] are considered. L3C and RC are trained with Open Images dataset [42] consisting of 300,000 images, and Near-Lossless is trained with the DIV2K dataset. For the evaluation metric, *bits per pixel* (bpp) is used.

B. Compression Result

Results for High Resolution Images We present the comparison for 2K images in Table I, which shows that our method outperforms the conventional non-learning codecs and existing practical-time learned codecs. Compared to JPEG-XL, which yields better performance than all the traditional codecs and even better than some learning-based methods, our method shows 4.7%∼5.5% gains. In comparison to learning-based methods, our method shows superior performance against others. Note that our method demonstrates improved coding efficiency compared to LC-FDNet by 0.3%∼1.3%. In addition, it should be noted that in the case of CLIC.m, non-learning codecs such as FLIF and JPEG-XL also outperform existing learning-based methods. It can be interpreted that learning-based methods are difficult to be generalized to CLIC.m. Nevertheless, our method presents a 4.7% gain compared to JPEG-XL.

Results for Low Resolution Images We first show the compression results on the downsampled dataset and illustrate that our method is robust to image resolution. Then, we present the compression results when applied to the actual low-resolution dataset.

In Table II, we show the compression performance for the downsampled datasets. Specifically, we downsample the evaluation dataset of CLIC.m, CLIC.p, DIV2K by the ratios of 2, 3, and 4. We set JPEG-XL as the basis and address the percentage with respect to JPEG-XL. Comparing JPEG-XL and LC-FDNet, the performance gap generally decreases as the downsampling ratio increases, demonstrating that the LC-FDNet suffers from the domain gap in image resolutions.

TABLE II: Compression results for downsampled datasets. $\downarrow s$ denotes a downsampling ratio by s. LC-FDNet* indicates that the network is additionally trained with downsampled images. The difference in percentage is with respect to JPEG-XL.

(a) CLIC.m result

Method	CLIC.m	CLIC.m ↓2	CLIC.m ↓3	CLIC.m ↓4
JPEG-XL	7.20	9.55	10.32	10.93
LC-FDNet	6.90 +4.2%	9.22 +3.4%	9.94 +3.6%	10.53 +3.7%
LC-FDNet*	6.91 +4.0%	9.15 +4.1%	9.80 +5.0%	10.37 +5.1%
Ours	6.88 +4.4%	9.01 +5.7%	9.68 +6.2%	10.22 +6.5%

(b) CLIC.p result

Method	CLIC.p	CLIC.p ↓2	CLIC.p ↓3	CLIC.p ↓4
JPEG-XL	8.19	10.30	11.13	11.69
LC-FDNet	7.86 +4.0%	9.91 +3.8%	10.70 +3.9%	11.20 +4.2%
LC-FDNet*	7.82 +4.5%	9.74 +5.5%	10.59 +4.8%	11.02 +5.7%
Ours	7.76 +5.3%	9.64 +6.4%	10.36 +6.9%	10.82 +7.4%

(c) DIV2K result

Method	DIV2K	DIV2K ↓2	DIV2K ↓3	DIV2K ↓4
JPEG-XL	8.49	10.71	11.72	12.39
LC-FDNet	8.14 +4.2%	10.32 +3.6%	11.30 +3.6%	11.96 +3.5%
LC-FDNet*	8.11 +4.5%	10.22 +4.6%	11.13 +5.0%	11.72 +5.4%
Ours	8.05 +5.2%	10.03 +6.3%	10.93 +6.7%	11.52 +7.0%

TABLE III: Compression result on low-resolution dataset.

Method	Kodak	McMaster	Classic
PNG	13.05 +51.2%	13.97 +30.2%	14.35 +35.0%
JPEG-LS	9.48 +9.8%	12.68 +18.2%	13.59 +27.8%
JPEG2000	9.57 +10.9%	12.50 +16.5%	11.93 +12.2%
WebP	9.62 +11.5%	11.86 +10.5%	11.37 +7.0%
LCIC	8.86 +2.7%	12.30 +14.6%	11.92 +12.1%
FLIF	8.72 +1.0%	11.59 +8.0%	11.10 +4.4%
JPEG-XL	8.93 +3.5%	11.35 +5.8%	11.79 +10.9%
L3C	10.64 +23.3%	12.24 +14.1%	12.42 +16.8%
Near-Lossless	9.12 +5.7%	11.90 +10.9%	12.18 +14.6%
LC-FDNet	8.76 +1.5%	10.86 +1.2%	10.85 +2.1%
Ours	8.63	10.73	10.63

Since LC-FDNet is trained only with 2K resolution images, the performance decreases when the training and evaluation domain are not matched. For a fair comparison, we additionally train LC-FDNet with a downsampled version of FLICKR2K and denote it as LC-FDNet*, which shows somewhat larger performance gaps in the downsampled datasets compared to the original datasets. In the case of our method, we added Resolution Refinement Block (RRB), which utilizes image resolution to generate resolution-specific kernels. As a result, our method yields better compression efficiency compared to LC-FDNet*, especially for downsampled datasets where performance gaps up to 2.1% are achieved. In summary, adding downsampled images as an additional training dataset and RRB both have valid contributions, making the network robust to image resolution.

Table III exhibits the compression results on the actual low resolution dataset. It can be observed that our method achieves state-of-the-art performance for all three datasets. Note that learning-based methods such as L3C and Near-Lossless exhibit a large performance drop compared to conventional methods such as FLIF and JPEG-XL. It can be implied that learning-based methods typically suffer from generalization problems. On the other hand, our method outperforms FLIF and JPEG-XL, demonstrating steady performance over the image resolution changes.

TABLE IV: Ablation study of using difference components in RRB.

Method	DIV2K	DIV2K↓2	Kodak
Fully Connected Layer	8.10	10.21	8.78
One-hot Encoding	8.07	10.10	8.68
Positional Embedding	8.05	10.03	8.63

C. Ablation Study

In this section, we provide a motivation for our design choice to utilize positional embedding in the Resolution Refinement Block (RRB). We conduct an ablation study by substituting the positional embedding with fully connected layers or one-hot encoding to evaluate the impact of each components. For the one-hot encoding approach, we convert the input image resolution HW into a one-hot vector, where each class represents a specific downsampling ratio applied to a 2K resolution. The classes correspond to resolutions of 2K (2048×1080), 1K (1024×768), and so on. We use a total of four classes in this experiment.

Table. IV presents the results obtained using difference components for RRB across various datasets, ranging from high to low resolutions. The result demonstrates that positional embedding yields the best performance, validating our design choice. On the other hand, employing fully connect layers leads to the poorest performance, almost comparable to not using RRB at all. Although the MLP approach allows more flexibility, it fails to capture the relationship between image resolution and intermediate features. The one-hot encoding approach shows improved performance compared to the MLPs, yet it still falls short of positional embedding. In conclusion, the ablation study confirms that incorporating positional embedding to convey image resolution information is the optimal choice for our proposed method.

IV. Conclusion

We have presented a new resolution-adaptive lossless image compression method by adding a Resolution Refinement Block to our previous frequency decomposition network [35]. The overall compression scheme operates at the subimage level, aiming to maximize the correlation between consecutive subimages. Our approach carefully arranges the order of subimages to ensure that the current subimage fully utilizes the horizontal and vertical components of the previous subimages. To compress each subimage, we employ a coarse-to-fine strategy by decomposing it into low and high-frequency regions. The compression process begins with the compression of low-frequency components, which serve as strong priors

for compressing the high-frequency regions. The frequency decomposition method is adaptive to the specific characteristics of each image, enabling the derivation of an optimal ratio of low and high-frequency components. The Resolution Refinement Blocks generate resolution-specific kernels, enabling the network to be adaptive to image resolution variations. Experimental results demonstrate that our method achieves state-of-the-art performance across various datasets, independent of image resolutions.

***Abstract*—BRS is the first CNN-based interactive image segmentation algorithm to refine segmentation results based on a backpropagation scheme. In this paper, we give a detailed description of how BRS operates and demonstrate how to implement the algorithm. In BRS, user-provided clicks are first converted into interaction maps, which are then concatenated with the RGB image and provided as input to a segmentation network. In the test phase, performing the forward pass in the network generates an initial segmentation map. However, the user-annotated pixels may be mislabeled in the initial result. BRS refines this result by correcting the mislabeled pixels. We implement this BRS algorithm in PyTorch and publish the source codes. Moreover, we first show that BRS can reach the perfect IoU ratio of 1.0 in most cases and delineate objects more accurately than a variant of BRS, called f-BRS.**

I. Introduction

Interactive image segmentation is a task that enables users to segment objects of interest from the background. In this task, a target object is annotated interactively by a user in forms of either scribbles [1], [2], boxes [3]–[5], or clicks [6]–[8]. The user provides annotations until a desirable segmentation result is obtained. Interactive image segmentation allows users to select objects and delineate them easily, so it is useful in many applications such as image editing and medical image analysis. Recently, with the development of deep-learning-based algorithms for dense prediction tasks, demands for annotated data also have increased significantly. However, pixel-level annotations are costly due to their laborious and time-consuming traits. This labeling cost could be reduced by employing interactive image segmentation techniques.

Research on interactive image segmentation has been done since decades ago, and various approaches have been proposed to solve the problem. Recently, deep-learning-based methods [6]–[9] have begun to emerge for interactive segmentation. Xu *et al.* [6] first introduced deep learning into interactive segmentation. Adopting clicks as user annotations, they converted foreground and background clicks into interaction maps using the distance transform. They trained a CNN model, which takes the concatenation of the interaction maps and the RGB image as input. Since then, the idea of taking interaction maps as network input has become a conventional approach [7]–[9]. Although these interaction maps clearly represent the annotated labels in user-clicked locations, the output prediction may be inconsistent with the user-provided labels. In other words, the segmentation result of the CNN may have incorrect labels in user-clicked locations.

(a) Before BRS (b) After BRS

Fig. 1. (a) Before applying BRS, user-clicked pixels have incorrect labels in the segmentation result. Red and blue circles depict foreground and background clicks, respectively. (b) The mislabelled pixels within the gray ring are corrected after BRS.

Backpropagating refinement scheme (BRS) [7] is the first attempt to employ a backpropagating refinement strategy to address this issue. It enforces the network to yield correct labels in user-clicked locations, by modifying the input interaction maps, as illustrated in Fig. 1. Inspired by this research, subsequent methods [9], [10] have been developed; Sofiiuk *et al.* [9] and Lin *et al.* [10], respectively, proposed modifying intermediate feature maps of the segmentation networks, instead of input interaction maps.

In this paper, we focus on Jang *et al.*'s original BRS algorithm [7] and describe how to implement it. In [7], the codes were written in `Caffe`, which is now obsolete. Hence, we implement the algorithm in `PyTorch` and make the source codes publicly available at https://github.com/cwlee00/BRS-PyTorch. Also, we describe the different variations [7], [9], [10] of BRS comparatively using a unified set of notations. Finally, through experiments, we first show that the BRS algorithm can be used effectively for image segmentation, enabling maximum IoU ratios to even reach the perfect score of 1.0 in most cases.

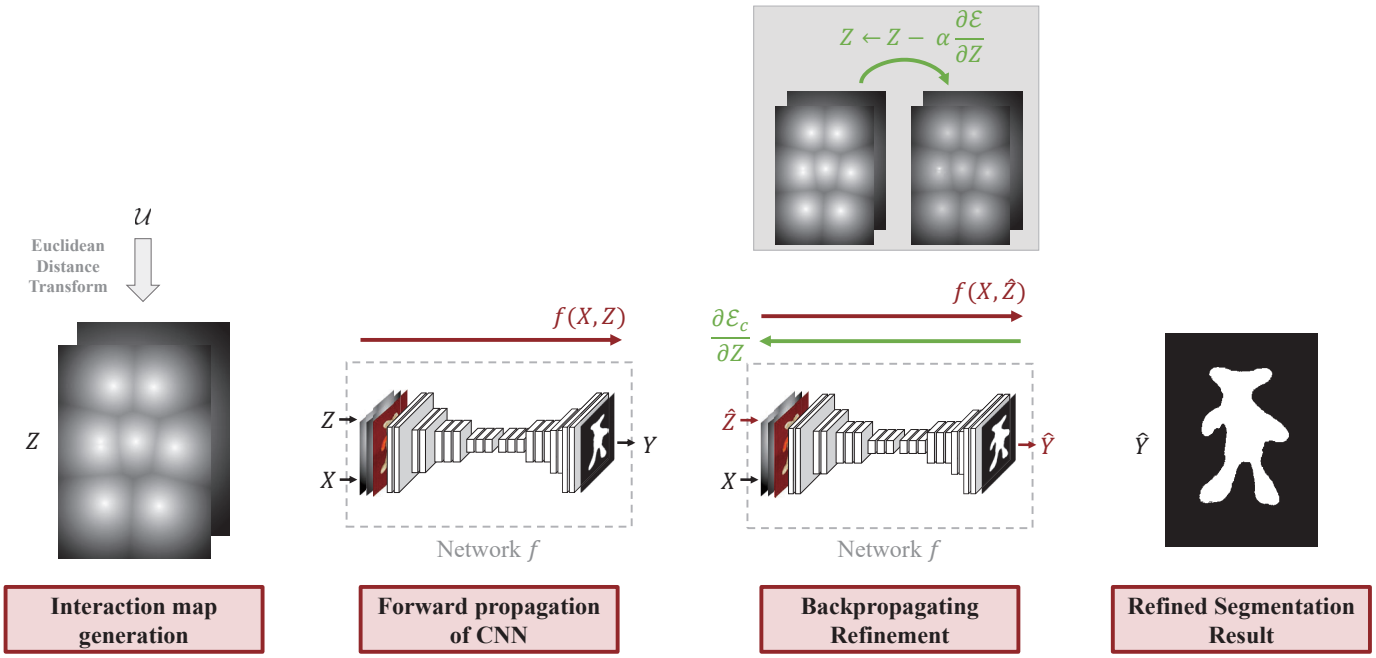

Fig. 2. Overview of the BRS algorithm.

II. Algorithms

A. BRS: Backpropgating Refinement Scheme

Fig. 2 shows an overview of the original BRS algorithm [7]. BRS allows a user to segment an object out by successively placing foreground and background clicks. Let $\mathcal{U}$ denote the set of user-provided clicks. Given $\mathcal{U}$, we first generate foreground and background interaction maps using the distance transform as in [6]. Each interaction map has the same height and width as the input image $X \in \mathbb{R}^{3\times H\times W}$. We stack the two maps into $Z \in \mathbb{R}^{2\times H\times W}$. We then feed the concatenation of X and Z into a CNN. Thresholding the output probability map of the CNN, we produce an initial segmentation map Y. Although the forward pass of the network usually provides a decent segmentation quality, it is still possible that the clicked pixels have incorrect labels as illustrated in Fig. 1. BRS aims to achieve more accurate segmentation by correcting these mislabeled pixels. More specifically, rather than fine-tuning the entire network to yield better segmentation results, BRS adjusts the interaction maps so that the output predictions are consistent with the input clicks.

Let us define notations for describing the BRS algorithm. The entire network can be represented by the composite function

$$f = f^R \circ f^{R-1} \circ \cdots \circ f^2 \circ f^1 \tag{1}$$

where f^r is the rth layer in the network, $r = 1, 2, \ldots, R$. Let y^r denote the response of layer r, and let θ^r be the set of parameters in layer r. Then, y^r can be written as

$$y^r = f^r(y^{r-1}; \theta^r). \tag{2}$$

Hence, y^0 and y^R are the input and output of the network. Since the input is the concatenation of X and Z, we have

$$y^0 = X \oplus Z. \tag{3}$$

The goal of BRS is to assign correct labels at user-annotated pixels by optimizing the input interaction maps. The optimization is done to minimize the energy function, given by

$$\mathcal{E}(Z) = \mathcal{E}_{\mathrm{C}}(Z) + \lambda \mathcal{E}_{\mathrm{I}}(Z) \tag{4}$$

where $\mathcal{E}_{\mathrm{C}}(Z)$ is the corrective energy, $\mathcal{E}_{\mathrm{I}}(Z)$ is the inertial energy, and λ is a weight. First, the corrective energy enforces the network output to yield correct labels in user-annotated locations, which is defined as

$$\mathcal{E}_{\mathrm{C}}(Z) = \sum_{\mathbf{u}\in\mathcal{U}} \left(l(\mathbf{u}) - y^R(\mathbf{u})\right)^2 \tag{5}$$

where $l(\mathbf{u})$ denotes a user-annotated binary label: 1 for foreground and 0 for background. Second, to prevent excessive perturbations of the interaction maps, we also minimize the inertial energy

$$\mathcal{E}_{\mathrm{I}}(Z) = \sum_{\mathbf{x}\in\mathcal{N}} \left(Z(\mathbf{x}) - Z_{\mathrm{init}}(\mathbf{x})\right)^2 \tag{6}$$

where Z_{init} is the initial interaction map before the modification, and $\mathcal{N}$ is the set of coordinates in the interaction maps.

As shown in Fig. 2, to perform BRS, we should compute the gradient of the energy function,

$$\frac{\partial \mathcal{E}}{\partial Z} = \frac{\partial \mathcal{E}_{\mathrm{C}}}{\partial Z} + \lambda \frac{\partial \mathcal{E}_{\mathrm{I}}}{\partial Z}. \tag{7}$$

The gradient $\frac{\partial \mathcal{E}_{\text{C}}}{\partial Z}$ of the corrective energy can be obtained via backpropagation. First, we compute the gradient of $\mathcal{E}_{\text{C}}$ with respect to the output segmentation map y^R,

$$\frac{\partial \mathcal{E}_{\text{C}}}{\partial y^R} = -2 \times \sum_{\mathbf{u} \in \mathcal{U}} \big(l(\mathbf{u}) - y^R(\mathbf{u})\big). \tag{8}$$

Then, by differentiating y^r in (2) with respect to the input y^{r-1}, we compose the derivative matrix $\frac{\partial y^r}{\partial y^{r-1}}$ or the transposed Jacobian matrix $(J_y^r)^T$ at layer r by

$$\frac{\partial y^r}{\partial y^{r-1}} = (J_y^r)^T = \begin{bmatrix} \frac{\partial y_1^r}{\partial y_1^{r-1}} & \cdots & \frac{\partial y_{k_r}^r}{\partial y_1^{r-1}} \\ \vdots & \ddots & \vdots \\ \frac{\partial y_1^r}{\partial y_{k_{r-1}}^{r-1}} & \cdots & \frac{\partial y_{k_r}^r}{\partial y_{k_{r-1}}^{r-1}} \end{bmatrix} \tag{9}$$

where k_r is the number of activations at layer r. Using the Jacobian matrix, we perform backpropagation by

$$\frac{\partial \mathcal{E}_{\text{C}}}{\partial y^r} = (J_y^{r+1})^T \frac{\partial \mathcal{E}_{\text{C}}}{\partial y^{r+1}}. \tag{10}$$

We begin the backpropagation by computing the gradient $\frac{\partial \mathcal{E}_{\text{C}}}{\partial y^R}$ in (8) at the last layer of the network. Then, we compute the gradient $\frac{\partial \mathcal{E}_{\text{C}}}{\partial y^r}$ in (10) recursively from $r = R-1$ to 0. As a result, we obtain $\frac{\partial \mathcal{E}_{\text{C}}}{\partial y^0}$. Finally, as y^0 is the concatenation of X and Z in (3), we can easily obtain $\frac{\partial \mathcal{E}_{\text{C}}}{\partial Z}$ from $\frac{\partial \mathcal{E}_{\text{C}}}{\partial y^0}$.

Also, we compute the gradient of the inertial energy by

$$\frac{\partial \mathcal{E}_{\text{I}}}{\partial Z} = 2 \times \sum_{\mathbf{x} \in \mathcal{N}} (Z(\mathbf{x}) - Z_{\text{init}}(\mathbf{x})). \tag{11}$$

Then, via the gradient descent

$$Z \leftarrow Z - \alpha \frac{\partial \mathcal{E}}{\partial Z}, \tag{12}$$

we can optimize the interaction maps until mislabeled pixels are corrected. We use the L-BFGS algorithm [11] to conduct the gradient descent. Fig. 2 includes an example of how BRS modifies the initial interaction map and improves the segmentation results.

B. f-BRS: Feature Backpropgating Refinement Scheme

With the use of backpropagation, BRS shows great improvement in segmentation results. However, Sofiiuk *et al.* [9] points out its drawback in terms of computational speed. Since BRS should optimize input interaction maps, it needs to run both foreground and background passes through the entire network. To alleviate this problem, they propose optimizing intermediate features in the network instead of interaction maps. Their f-BRS algorithm results in a faster speed, for it computes gradients through only a small part of the network.

They introduce a set of auxiliary parameters P to modify an intermediate feature layer y^m of the network. Let G be the modifying function for y^m. Then, the modified y^m can be written as $G(y^m, P)$. Note that the network output y^R is a function of y^m. Thus, after the modification, y^R is given by

$$y^R = f^R \circ f^{R-1} \circ \cdots \circ f^{m+1}(G(y^m, P); \theta^{m+1}). \tag{13}$$

Then, instead of (6), the inertial energy is reformulated as

$$\mathcal{E}_{\text{I}}(P) = \sum_{p \in P} \|p - p_{\text{init}}\|^2. \tag{14}$$

For auxiliary parameters P, Sofiiuk *et al.* [9] suggest using scale and bias terms. Suppose $y^m \in \mathbb{R}^{c_m \times h_m \times w_m}$, where c_m, h_m, and w_m are the number of channels, height, and width of the intermediate feature map y^m. Also, let $s \in \mathbb{R}^{c_m}$ and $b \in \mathbb{R}^{c_m}$ denote the scale and bias vectors. Thus, $P = \{s, b\}$. In f-BRS, the intermediate feature map y^m is modified by

$$G_{\text{f-BRS}}(y^m, P) = s \dot{\times} y^m + b \dot{\times} o \tag{15}$$

where $\dot{\times}$ denotes channel-wise multiplication, and o is the constant map whose all element is 1. Initially, they set $s = \mathbf{1}$ and $b = \mathbf{0}$ to ensure that there is no modification, *i.e.* $G_{\text{f-BRS}}(y^m, P) = y^m$. By controlling the scale and bias vectors, they attempt to obtain segmentation results that better align with user clicks.

To optimize each parameter $p \in P$, the following gradient should be computed:

$$\frac{\partial \mathcal{E}}{\partial p} = \frac{\partial \mathcal{E}_{\text{C}}}{\partial p} + \lambda \frac{\partial \mathcal{E}_{\text{I}}}{\partial p} \tag{16}$$

$$= \frac{\partial y^m}{\partial p} \times \frac{\partial \mathcal{E}_{\text{C}}}{\partial y^m} + \lambda \frac{\partial \mathcal{E}_{\text{I}}}{\partial p}. \tag{17}$$

Note that $\frac{\partial \mathcal{E}_{\text{C}}}{\partial y^m}$ in (17) can be computed by employing the backward recursion in (10). Compared to the original BRS, we see that the backward operation needs to be performed only to the intermediate layer y^m, rather than to the input layer y^0, which results in faster computation.

C. g-BRS: Generalized Backpropgating Refinement Scheme

The auxiliary vectors s and b in (15) in f-BRS are spatially invariant, *i.e.* oblivious to the position in an image. Therefore, adjusting these parameters tends to cause only global changes in the output and may not enable local refinement. To address this issue, Lin *et al.* [10] propose auxiliary parameters for both global and local refinement. They introduce three re-parameterization methods.

First, they introduce the method of adding an additional bias map $b_m \in \mathbb{R}^{h_m \times w_m}$ before applying channel-wise scale and bias. They channel-wise scale b_m using $w_c \in \mathbb{R}^{c_m}$, which allows each channel of b_m to shift differently. In this approach, the intermediate feature map is modified to

$$G_{\text{g-BRS1}}(y^m, P) = s \dot{\times} (y^m + w_c \dot{\times} b_m) + b \dot{\times} o. \tag{18}$$

Thus, the set of auxiliary parameters is $P = \{s, b, w_c, b_m\}$.

Second, they also suggest modifying y^m as follows:

$$g_1(y^m) = s \dot{\times} y^m + b \dot{\times} o, \tag{19}$$

$$g_2(y^m) = y^m + w_c \dot{\times} b_m, \tag{20}$$

$$G_{\text{g-BRS2}}(y^m, P) = w \cdot g_1(y^m) + (1 - w) \cdot g_2(y^m), \tag{21}$$

where $P = \{s, b, w_c, b_m, w\}$. Since g_1 in (19) enables global modification and g_2 in (20) allows local modification, fusing these two with a learnable weight $w \in [0, 1]$ regulates the trade-off between global and localized changes.

Third, they introduce another re-parameterization method using a 1×1 convolutional layer,

$$G_{\text{g-BRS3}}(y^m, P) = \phi(y^m + 10w_c \dot{\times} b_m) + b \dot{\times} o \tag{22}$$

where $P = \{b, b_m, w_c, \phi\}$, and ϕ denotes the 1×1 convolution with $c_m \times c_m$ parameters. Note that in `PyTorch` the second term $b \dot{\times} o$ in (22) can be implemented as biases in the 1×1 convolution layer ϕ.

For all three re-parameterization methods, the auxiliary parameters in P are optimized via gradient descent using the gradient computation in (16).

III. Implementation Details

Let us describe in detail how to implement the original BRS algorithm, which is summarized in **Algorithm 1**. First, in line 1, we transform the given set $\mathcal{U}$ of user-provided clicks into interaction maps Z using the Euclidean distance transform (EDT). In other words, interaction maps are obtained by computing the distance of each pixel to the nearest foreground and background clicks. The maximum distance in Z is set to 255 for efficient data storage. Then, in line 2, we feed the input image X and the interaction maps Z into the network f to get a probability map of the target object. We obtain the segmentation result Y by thresholding this probability map. The threshold value is 0.5, so each pixel is determined as foreground if its probability is higher than 0.5, and background otherwise.

Since the goal of BRS is to correct mislabeled pixels, BRS is activated when any clicked pixel has a wrong label. Line 3 shows the condition for activating BRS. Y_{u_i,v_i} is the output label at the ith click location (u_i, v_i), and l_i is the ith click label. Thus, if $l_i = 1$ and $Y_{u_i,v_i} = 0$, or if $l_i = 0$ and $Y_{u_i,v_i} = 1$ for any i, we refine Z by performing BRS.

Lines 4∼8 in **Algorithm 1** show the process of refining Z using backpropagation. We first formulate the energy function to be minimized in lines 3∼6. Then, we optimize the interaction maps according to the gradient of the energy function. Therefore, we should compute $\frac{\partial \mathcal{E}}{\partial Z}$ through backpropagation as described in Section II-A. To compute this gradient, we use the built-in differentiation engine in `Pytorch`. Then, we apply the L-BFGS algorithm [11] to optimize the interaction maps Z using gradient descent. To this end, we use the `fmin_lbfgs_b` function in the `scipy` library. Once the refined interaction map $\hat{Z}$ is obtained, we execute the forward pass again. Finally, we threshold the probability map yielded by the network to get a refined segmentation result $\hat{Y}$.

Algorithm 1 Procedure of proposed algorithm

Input: Input image X, user clicks $\mathcal{U}$

1: $Z \leftarrow \text{EDT}(\mathcal{U})$
2: $Y \leftarrow \text{Threshold}(f(X, Z))$
3: **if** $l_i \neq Y_{u_i,v_i}$ for any i **then**
4: $\quad \mathcal{E}_C \leftarrow \sum_i (l_i - f(X, Z)_{u_i,v_i})^2$ ▷ (5)
5: $\quad \mathcal{E}_I \leftarrow \sum_x (Z(x) - Z_{\text{init}}(x))^2$ ▷ (6)
6: $\quad \mathcal{E} \leftarrow \mathcal{E}_C + \lambda \mathcal{E}_I$ ▷ (4)
7: $\quad$ Compute $\frac{\partial \mathcal{E}}{\partial Z}$ ▷ (7)∼(11)
8: $\quad \hat{Z} \leftarrow \text{L-BFGS}(Z, \mathcal{E}, \frac{\partial \mathcal{E}}{\partial Z})$
9: $\quad \hat{Y} \leftarrow \text{Threshold}(f(X, Z))$
10: **end if**

Output: Refined segmentation result $\hat{Y}$

IV. Experimental Results

A. Training and Test Details

Training: We adopt the network architecture in [7] but take VGG-16 [12] as the backbone. We also do not make use of the fine decoder. For training, we use the SBD dataset [13]. We crop 400 x 400 patches randomly around each object instance and apply horizontal flips for data augmentation. To simulate user interactions, annotations are automatically generated as follows. Pixels in a ground-truth mask are set as foreground candidates, while those at least 5 and at most 40 pixels away from the mask boundary are set as background candidates. We randomly sample foreground and background clicks from these candidates. The numbers of foreground and background clicks are determined randomly within [1, 10] and [0, 10], respectively. We employ the cross-entropy loss between a ground-truth mask and its predicted probability map. We use the Adam optimizer with a learning rate of 10^{-4} and train the network for 20 epochs.

Evaluation: For evaluation, we use the GrabCut [5] and Berkeley [14] datasets. In interactive segmentation, the segmentation result varies depending on how a user places clicks. Thus, for reliable assessment, we use an automatic clicking strategy as done in [6], [8]. This clicking strategy is designed based on the assumption that a typical user would provide clicks near the centers of big erroneous regions.

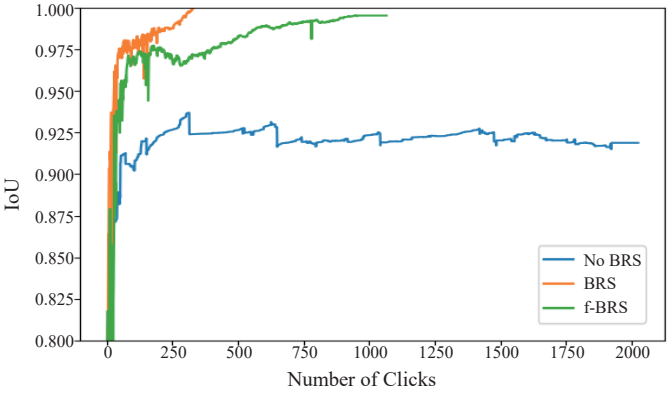

Fig. 3. IoU ratios according to the number of clicks for a sample image from the GrabCut dataset.

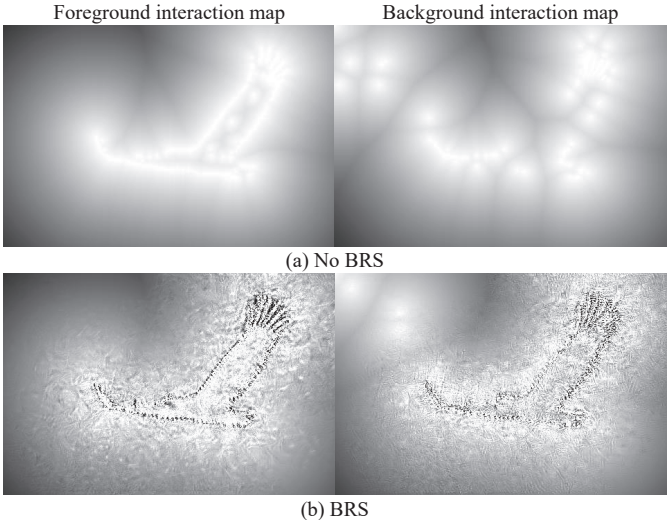
TABLE I
EVALUATION RESULTS ON THE GRABCUT AND BERKELEY DATASETS USING THE METRICS OF THE AVERAGE MAX IOU, NOF@99, NOF@100, AND THE AVERAGE RUNTIME TO PROCESS AN IMAGE.

Algorithm	GrabCut				Berkeley			
	Max IoU (↑)	NoF@99 (↓)	NoF@100 (↓)	Time (s)	Max IoU (↑)	NoF@99 (↓)	NoF@100 (↓)	Time (s)
No BRS	0.9604	44	50	**168.49**	0.9100	100	100	**139.90**
BRS	**0.9999**	**0**	**2**	366.42	**0.9998**	**0**	**63**	1340.84
f-BRS	0.9962	7	39	209.94	0.9807	68	99	388.07

B. Performance Assessment



Experimental Conditions: Existing methods for interactive image segmentation usually limit the maximum number of clicks to 20. In this work, we remove this constraint and explore whether increasing the number of clicks could improve segmentation results. Thus, for all the experiments below, we set the maximum number of clicks to be the total number of pixels composing the target instance. As exemplified in Fig. 3, when only the forward pass is executed, increasing the number of clicks does not necessarily lead to more accurate results. However, with the use of BRS, additional clicks enable the maximum IoU ratio to reach the perfect 1.0. As the upper bound for the number of clicks is very large, we set stopping conditions for clicks: When the algorithm reaches an IoU ratio of 1.0, we stop at that click. Also, when the IoU ratios are all the same for recent 100 clicks, we assume convergence and stop.

Performance Comparison: We assess different variations of BRS comparatively in terms of the average of the maximum IoU ratios achieved. We also report NoF@IoU indicating the number of images for which the algorithm fails to reach a certain IoU. We do not include results of g-BRS [10], as there are no source codes available for the algorithm. Thus, we compare the original BRS algorithm [7], f-BRS [9], with the case when no backpropagation is applied (*i.e.* when only the forward pass is executed). Table I compares the results.

We see that in terms of accuracy, BRS outperforms f-BRS. Applying BRS results in higher maximum IoU scores and fewer failure cases to reach a certain IoU. Also note that when no backpropagating refinement scheme is applied, the model cannot yield desired segmentation results. Qualitative comparisons are given in Fig. 6. In Table I, we also measure the average runtime to process an image. As compared with BRS, f-BRS is about 2∼4 times faster, thus f-BRS shows greater performance in terms of speed. However, it is inferior to the original BRS in terms of accuracy.

C. Analysis and More Results

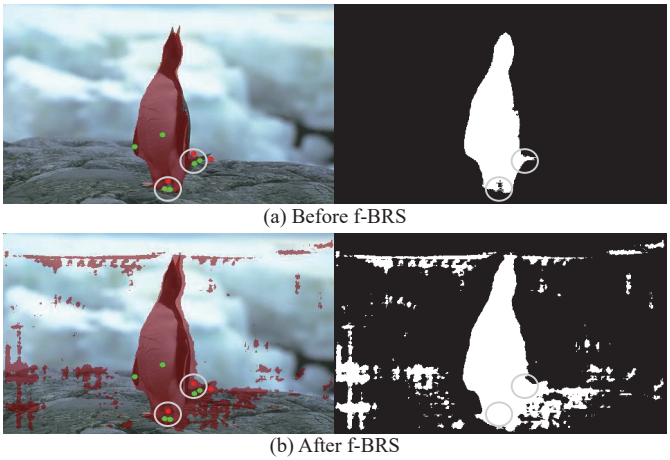


Fig. 4 visualizes examples of interaction maps. We see that the interaction maps using BRS contain much more information on elaborate details of the object. It is hard to find the details of the bird's wings in the interaction maps without BRS. This is one of the reasons why BRS yields a better segmentation mask than the algorithm that executes the forward pass only.

(a) No BRS

(b) BRS

Fig. 4. Visualization of interaction maps.

(a) Before f-BRS

(b) After f-BRS

Fig. 5. A failure case of f-BRS. Gray rings emphasize the regions where clicked pixels are corrected after f-BRS.

Also, we analyze why f-BRS is less accurate than BRS in some cases. We observed that f-BRS sometimes provides undesirable errors as in Fig. 5. In this example, although the labels of clicked pixels are corrected after f-BRS, many unwanted artifacts are generated in the background. This is because f-BRS optimizes intermediate feature maps of

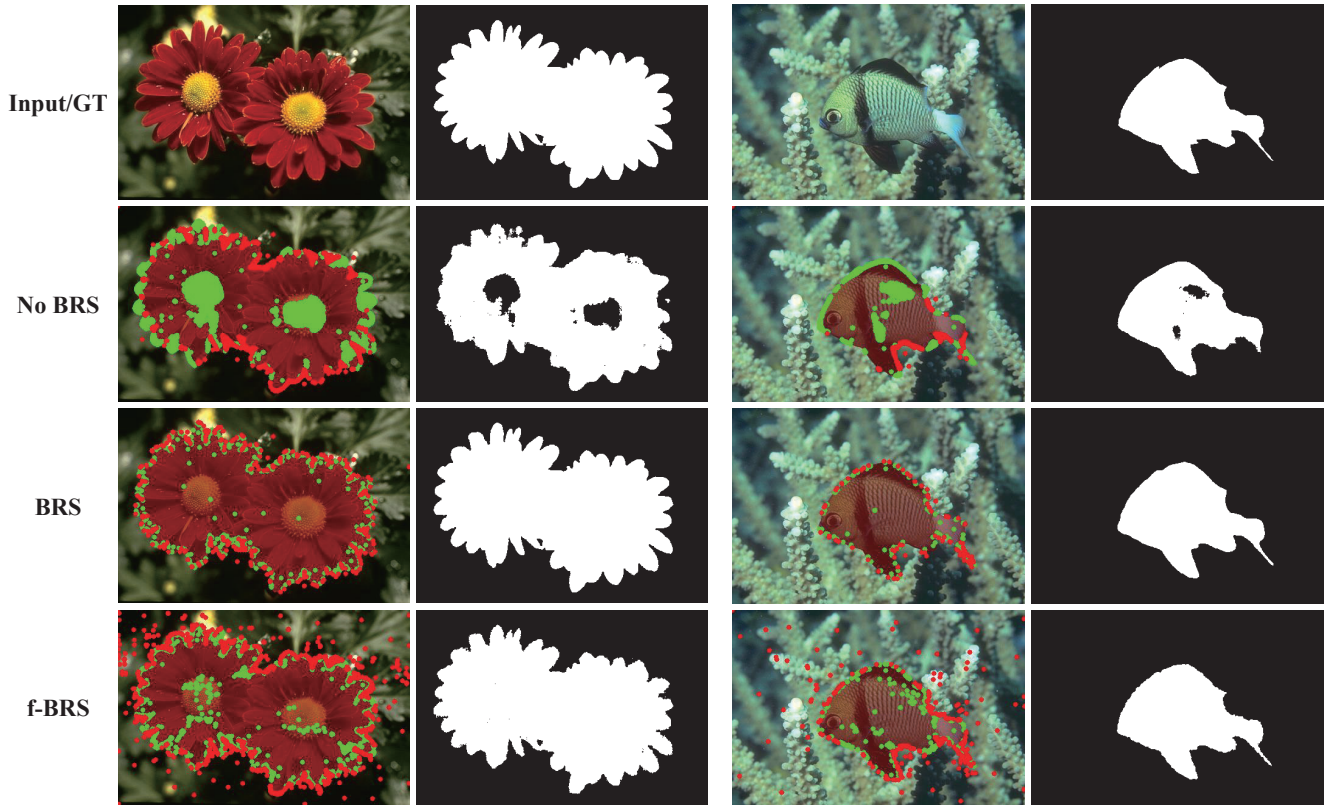

Fig. 6. Qualitative comparison of segmentation results. The left column shows an input image with clicks, while the right column shows the corresponding segmentation result. Foreground clicks are depicted by green circles, and background clicks by red circles.

the network via channel-wise operations. The channel-wise perturbations modify segmentation results globally. Consequently, along with the correction of clicked pixels, there are many changes in regions far from the clicks leading to errors. Therefore, f-BRS requires much more clicks and effort to correct such unwanted results. This also explains why f-BRS cannot reach the perfect IoU ratio of 1.0 in many cases in Table I.

V. Conclusions

In this paper, we provided a detailed description of the BRS algorithm and demonstrated how to implement the algorithm. In BRS, interaction maps are optimized to enforce output predictions to be consistent with user annotations. We implemented this BRS algorithm in PyTorch and made the source codes publicly available. Also, we described different variants of BRS comparatively using a unified set of notations, and showed that the original BRS algorithm can be used to segment out objects more accurately than f-BRS does.

***Abstract*—Implicit neural representation for video (INRV) utilizes a neural network to represent a video without relying on an explicit pixel-wise representation of RGB values, and, therefore an INRV-based video coding method aims to compress a neural network and transmit its parameters through a bit-stream. In this paper, we propose a novel rate-distortion (R-D) optimized INRV-based video coding method through a progressive feature extraction module (PFEM). The PFEM consists of a series of residual blocks (RBs) that can progressively control the quality of the reconstruction, by searching the optimal network architecture. By increasing the number of RBs, the quality of a reconstruction frame is improved. However, the quality comes at the expense of overheads in transmission. In the proposed method, the number of the RBs are decided to provide the best trade-off between the frame quality and bits. Our decision model is based upon the R-D theory. Experimental results demonstrated that the proposed method provides a superior coding gain to the conventional video coding standards.**

I. Introduction

As the volume of video data rapidly increases, extensive studies on video compression are conducted for efficient storage and transmission of visual data. Although conventional video codecs such as H.264/AVC [1] and H.265/HEVC [2] have been widely used in mobile devices and streaming services, the handcrafted features in the coding methods would limit compression efficiency. There have been many attempts to improve compression efficiency, by replacing conventional compression pipelines with neural networks [3]–[9]. However, these methods used large-scaled neural networks, incurring significant computational complexity and challenges in training.

Implicit neural representation for video (INRV) [10]–[13] has gained significant attention for video coding to address the problems of the conventional approaches. INRV utilizes a neural network to represent a video without relying on an explicit pixel-wise representation of RGB values. Therefore, the INRV-based video coding approach compresses a neural network and its parameters and transmits them through a bit-stream. In an encoder side, a network is configured to fit video data with spatial and temporal positional embedding [10]. In a decoder side, a network is reconstructed to produce an RGB value with the spatial and temporal indices of a frame as input.

Early INRV studies tried to embed all the (x, y, t) positions of a video sequence [14]–[16]. However, the model complexity has been substantially increased. In recent, NeRV [10] proposed an image-wise neural representation model, in which a frame was reconstructed using only the temporal index t instead of using all the temporal and spatial pixel indexes as input. The NeRV decoder was designed to reconstruct a video frame from the temporal embedding, and, thus it substantially reduced computational complexity. More recently, CNeRV [11] and HNeRV [12] used content-adaptive embedding to improve the quality of a reconstructed video, while keeping the same complexity. The decoder used a series of convolution layers to keep the high fidelity of video frames.

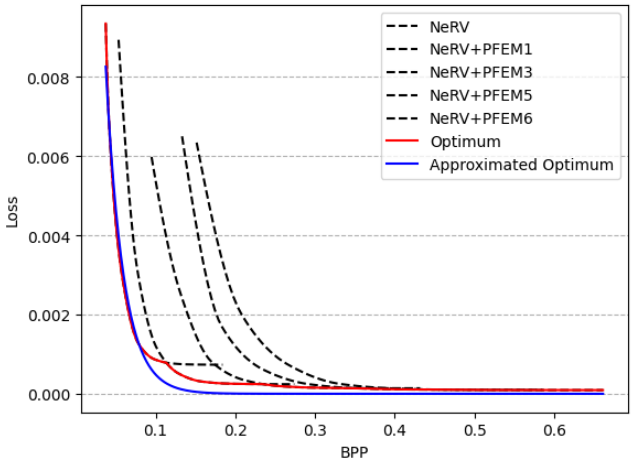

Fig. 1. Dotted graphs represent the R-D performance according to the number of RBs in the PFEM. The red graph represents the optimal R-D curve to achieve the best trade-off between frame quality and bits.

In this paper, we propose a rate-distortion (R-D) optimized INRV-based video coding method through a progressive feature extraction module (PFEM). The PFEM consists of a series of residual blocks (RBs) that can be adaptively configured to provide the best R-D performance. Fig. 1 displays the intuition of the proposed method. By increasing the number of RBs, the quality of a reconstruction frame is improved due to increasing representation capability of the INRV. However, the capability comes at the expense of overheads in transmission. In the proposed method, the number of the RBs are decided to provide the best trade-off between the frame quality and bits used to transmit a network architecture. Our decision model is based upon the R-D theory [17] and improves coding performance over the conventional video coding standards.

II. Related Works

A. Implicit Neural Representation for Video Compression

The INRVs have been demonstrated as powerful yet compact parameterized representations for 2D and 3D video data, in which a neural function maps spatial and temporal coordinates to density or RGB values [18]–[24]. The INRVs are actively used for various image processing and computer vision tasks, including video compression [10]–[13], 3D novel view synthesis [18], [19], video generation [25], and video pre/post-processing techniques [20]–[24] such as video interpolation and super-resolution.

Most of the INRV methods used three steps in their pipelines, including an input embedding, video overfit, and model compression. The NeRV applied a positional encoding (PE) with high-frequency variations as an embedding function to memorize the spatial coordinates in high-dimensional embedding space and avoid poor representation [10]. The network architecture utilized several multi-layer perceptrons (MLPs) and convolution layers to fit a target video content. MLPs consumed a large number of network parameters to directly output pixel values. Thus, they proposed a NeRV block with convolutions and PixelShuffle [26] for upscaling to save the parameters. In model compression, they applied a model pruning, model quantization, and entropy coding.

Various NeRV-like methods have been proposed for video coding. D-NeRV [23] was designed to effectively encode large-scale and diverse videos. It reduced memorization complexity among subsequent video frames, by providing clip-specific visual content and global temporal dependency information. In addition, task-oriented flow was predicted and used instead of directly predicting raw pixel values, thereby reducing complexity by preventing memorization of the same pixel values in different frames. HNeRV [12] proposed a hybrid INRV model that provided visual prior for better reconstruction and compression performance by using tiny content-adaptive frame embedding as inputs of a learned neural decoder. It was used as visual priors and increased the efficiency of the model, while keeping the same amount of information about the target visual data. The methods used pruning, quantization, and entropy encoding for model compression[12], [23]. E-NeRV [13] disentangled spatial and temporal contexts in the INRV to improve coding performance.

B. Neural Network Compression (NNC)

Neural network compression (NNC) is the process of reducing the size or complexity of a neural network model, while avoiding significant loss in performance. There are several methods commonly used for NNC, including pruning [27], quantization [28], and low-rank factorization [29].

Pruning is used to build a compact network with a less number of parameters [27], [30]. The pruning process eliminates the connections or weights with small magnitudes, while giving a minimal impact on the efficiency of the network. Quantization [28], [31] is used to lower the precision of the weights. Low-rank factorization algorithms approximate the weight matrices of a neural network into a more lightweight form and allow for more effective computations.

III. Proposed Method

A. Overview

We propose an improved INRV-based video coding method with an R-D optimization of a target neural network, based on the NeRV [10]. Most of the INRV-based video coding methods are built on a reconstruction module to fit video data to network parameters and recover the original spatial dimension in the output. We use the conventional INRV pipeline as a baseline, as shown in Fig. 2. It uses a PE, MLPs, and upscaling modules (UM) for the reconstruction. The MLP uses two linear layers.

The UMs are used to recover the dimension of the extracted features to the original dimension, consisting of five upscaling modules. The network parameters are quantized and encoded through an entropy coding.

This paper develops a novel R-D optimization technique that progressively controls the quality of the reconstruction, by searching the optimal network architecture, in addition to the conventional compression pipeline. For this purpose, a PFEM is incorporated into the baseline. The PFEM consists of a stack of RBs. When the depth of a model increases with the number of RBs, the representation capability improves. However, this causes a problem that the size of the model becomes large. In the proposed method, the quality is controlled through the number of RBs in the PFEM, because the RBs directly control the quality of the output frame and require more bits in transmission, as shown in Fig. 3.

B. Progressive Feature Extraction Module (PFEM)

The PFEM uses the stack of RBs consisting of two 3×3 convolution layers, as shown in Fig. 2. The RBs have been widely used for the tasks of image reconstruction and restoration. By using the RB, the gradient loss problem is mitigated with skip connections, by allowing the gradient to bypass a specific layer. In addition, by reducing the duplication of model representation with such skip connections, although the size of a target model decreases with model compression, the representation capability can be maximally maintained.

The PFEM is placed between the upscaling process in Fig. 2. The upscaled features are used as the input of the PFEM so that the spatial information of the features can be learned effectively. Through this, the baseline can further utilize spatial information, although it used only a temporal index as input. By placing the PFEM in the middle of the upscaling process, the size of the model is effectively adjusted by passing the features to the reconstruction process.

Fig. 3 displays the R-D performance with respect to the number of RB. As the number of RBs increases, the number of parameters increases, improving both peak signal-to-noise ratio (PSNR) and multi-scale structural similarity index (MS-SSIM). In addition, it can be seen that the rate increases as the number of parameters increases.

C. Optimal PFEM Selection

The number of the RBs consisting of PFEM is chosen with R-D optimization. To this aim, we define a Lagrangian cost J, defined as,

$$J(n) = D(n) + \lambda R(n), \tag{1}$$

where n is the number of the RBs, D is the distortion, and R is the bit-rates. λ is the Lagrangian multiplier. In our experiments, λ is set up as follows:

$$\lambda = \alpha \cdot 2^{\beta \times R}, \tag{2}$$

where α is 8.5, and β is -96.8, which are obtained empirically.

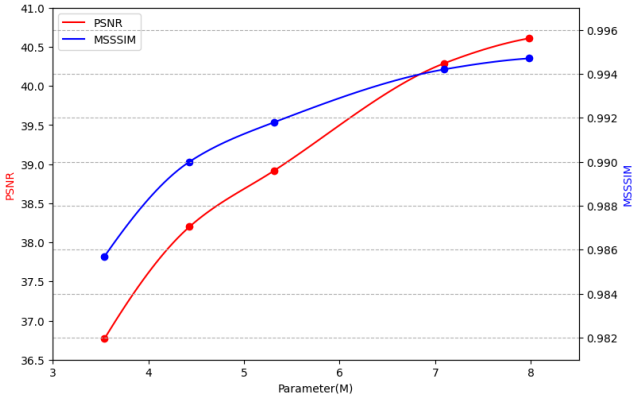

Fig. 3. The quality of the reconstructed frame in terms of PSNR and MS-SSIM and increment of bit-rates according to the number of RBs in the PFEM.

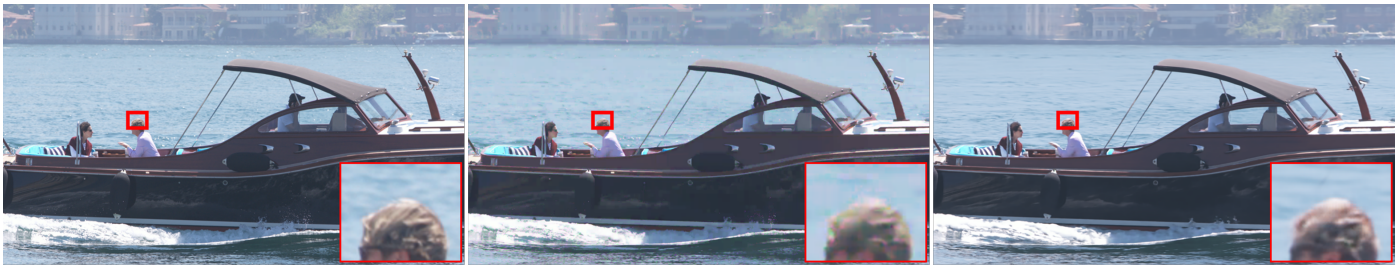
The optimal size is determined by minimizing J as follows:

$$n^* = \arg\min_{n \in N} J(n), \tag{3}$$

where n^* is the solution, and N is the set of the solutions. In the experiments, N is $\{12, 24, \cdots, 72\}$ with multiples of 12.

IV. EXPERIMENTAL RESULTS

A. Dataset and Experimental Setting



We conduct comparative experiments to evaluate the performance of the proposed method. We employ the conventional video codecs, H.264/AVC [1] and H.265/HEVC [2], and the baseline [10] for comparisons. We use "Big Buck Bunny", UVG [32], and DAVIS [33] dataset in the experiments.

Adam optimizer [34] is used to train the networks, and a learning rate is set to 0.0005 along with the cosine annealing learning rate scheduler. The number of training epochs was set to 1,000, and the batch size was set to 1.

B. Performance Evaluation

1) Quantitative evaluations: Table I displays a quantitative evaluation by calculating the Bjontegaard delta bit rate (BDBR) for each of NeRV and the proposed method, when H.264 is used as an anchor. The proposed method shows significantly improved coding performance as compared with NeRV for all the test sequences in the UVG dataset. Our method provides approximately 15.3% BD-rate reduction on average, as compared with H.264/AVC and 54.2% BD-rate reduction on average, as compared with NeRV as a baseline. Fig. 5 shows the R-D curves of H.265/HEVC, H.264/AVC, NeRV, and the proposed method (NeRV+PFEM). The proposed method provides a superior coding gain to the NeRV in all the ranges of the rates.

2) Qualitative evaluations: Fig. 4 shows the qualitative evaluation comparing H.264/AVC and the proposed method in the same bits per pixel (bpp) on "Yacht" test video sequence. The most left figure shows the ground truth. In the subjective comparisons, it was demonstrated that the proposed method maintains fine texture details after the compression.

V. CONCLUSIONS

In this paper, we proposed an implicit neural representation model for video compression with PFEM to improve the reconstruction quality while optimizing the trade-off between model size and compression performance. Also, by defining the equation for the R-D optimization with λ, we demonstrated the way to select the PFEM size according to the trade-off between model size and compression performance. In the experimental results, quantitative and qualitative results for video reconstruction have been enhanced.

***Abstract*—We propose a deep unrolling approach for underwater image enhancement using extreme channels prior. First, we formulate underwater image enhancement as a joint optimization problem that incorporates an underwater-related extreme channels prior and implicit regularization functions. Then, we solve the optimization problem iteratively and develop an unfolded deep neural network, where each block of the network represents an iteration in which the optimization variables and regularizers are updated using closed-form solutions and learned proximal operators, respectively. Experimental results demonstrate that the proposed algorithm outperforms state-of-the-art underwater image enhancement algorithms in both quantitative and qualitative comparisons.**

I. Introduction

Underwater image enhancement is an important preprocessing task for many applications in marine science and technology because the visual quality of captured underwater images degrades due to light absorption, refraction, and scattering. Therefore, underwater images exhibit low contrast, low brightness, blurry textures, and color distortion. To address this challenge, various underwater image enhancement algorithms have been developed, which can be broadly categorized into model- and learning-based approaches.

Earlier model-based approaches focused on directly enhancing the pixel intensities in underwater images without considering specific underwater imaging models [1]–[3]. However, these algorithms often lead to undesirable over- and under-enhancements, as they lack an understanding of the characteristics of underwater images. To overcome this limitation, researches have been made to formulate underwater image enhancement as an inverse problem by incorporating physics-based models. They employed image priors, *e.g.*, the dark channel [4], light attenuation [5], and hyper-Laplacian reflectance priors [6], to estimate the parameters for underwater imaging models. However, these approaches may be inaccurate due to manually designed priors.

Recently, significant advancements have been made in underwater image enhancement using deep learning techniques, *i.e.*, convolutional neural networks (CNNs) and generative adversarial networks (GANs). For example, Li [7] developed a baseline CNN for underwater image enhancement. Islam *et al.* [8] proposed a GAN-based algorithm to enhance underwater images in real-time using both paired and unpaired training. Liu *et al.* [9] proposed an object-guided twin-adversarial contrastive learning approach for enhancing underwater images. Although learning-based algorithms provide flexibility, adaptability, and efficient inference, their behaviors are difficult to analyze and interpret because of limited domain knowledge on to underwater images.

To overcome the limitations of both model- and learning-based approaches while leveraging their strengths, a model-based deep learning technique, which is known as algorithm unrolling, has recently been developed. Algorithm unrolling involves unfolding an iterative optimization algorithm into a series of layers within deep neural networks; each layer of the network corresponds to an iteration of the model-based iterative algorithm. Thus, algorithm unrolling can benefit from both approaches—interpretability from the model-based approach and data-driven adaptability from the deep learning-based approach. Because of this advantage, algorithm unrolling has recently been widely employed in various image processing and low-level computer vision tasks [10]–[12].

In this work, we propose an algorithm unrolling-based end-to-end underwater image enhancement algorithm using extreme channels prior. First, we formulate an inverse problem for underwater image enhancement as a joint optimization that incorporates physics-based constraints and underwater-related priors. In addition, we add implicit regularizers to capture prior knowledge of underwater images and compensate for modeling inaccuracies. To solve the optimization problem, we employ the augmented Lagrange multiplier (ALM) method, which divides the problem into subproblems that can be iteratively minimized. At each iteration, we update the optimization variables and regularizers using closed-form solutions and deep networks, respectively. Experimental results demonstrate that the proposed algorithm significantly outperforms state-of-the-art algorithms in both quantitative and qualitative comparisons.

II. Proposed Algorithm

A. Problem Formulation

The underwater image acquisition model is derived from the light transmission model, which is given by

$$\mathbf{I}(x) = \mathbf{J}(x)\mathbf{t}(x) + \mathbf{B}\left(1 - \mathbf{t}(x)\right), \tag{1}$$

where $\mathbf{I}$ and $\mathbf{J}$ denote the observed underwater and latent clean images, respectively; $\mathbf{t}$ and $\mathbf{B}$ are the transmission map and

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. 2022R1F1A1074402).

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

background light, respectively; x is the pixel location.

Given an observed underwater image $\mathbf{I}$, the underwater image enhancement task for restoring $\mathbf{J}$ is formulated as a joint optimization as

$$\min_{\mathbf{J},\mathbf{t},\mathbf{B}} \frac{1}{2}\|\mathbf{J}\mathbf{t}+\mathbf{B}(\mathbf{1}-\mathbf{t})-\mathbf{I}\|_2^2, \tag{2}$$

where $\mathbf{1}$ denotes a matrix of all ones, and the multiplication is element-wise. However, because the problem in (2) attempts to recover $\mathbf{J}$, $\mathbf{B}$, and $\mathbf{t}$ from a single input underwater image $\mathbf{I}$, it is highly ill-posed. Thus, it is essential to develop effective underwater-related priors that can constrain the inverse problem.

To this end, we first impose constraints on transmission map $\mathbf{t}$ and background light $\mathbf{B}$ based on the maximum attenuation model [13]. Then, the optimization problem in (2) becomes

$$\begin{aligned}\min_{\mathbf{t},\mathbf{B},\mathbf{J}} \frac{\lambda_1}{2}\|\mathbf{J}\mathbf{t}+\mathbf{B}(\mathbf{1}-\mathbf{t})-\mathbf{I}\|_2^2+\frac{\lambda_2}{2}\left\|\mathbf{t}-\tilde{\mathbf{t}}\right\| \\ +\frac{\lambda_3}{2}\|\mathbf{B}-\widetilde{\mathbf{B}}\|_2^2,\end{aligned} \tag{3}$$

where λ_1, λ_2, and λ_3 are the regularization parameters, and $\tilde{\mathbf{t}}$ and $\widetilde{\mathbf{B}}$ are the initial estimations of $\mathbf{t}$ and $\mathbf{B}$, respectively. We determine $\tilde{\mathbf{t}}$ and $\widetilde{\mathbf{B}}$ using the maximum attenuation model [13]. The optimal transmission map and background light are expected to be close to their initial estimations.

To improve the enhancement performance, we incorporate two extreme channels priors—the dark channel prior (DCP) [14] and bright channel prior (BCP) [15]—into (3) to better model the properties of natural clean images. In addition, we add two implicit regularization functions, $f(\cdot)$ and $g(\cdot)$, to capture the prior knowledge of clean image $\mathbf{J}$ and transmission map $\mathbf{t}$, respectively. Then, the optimization problem in (3) can be rewritten as

$$\begin{aligned}\min_{\mathbf{t},\mathbf{B},\mathbf{J}} \frac{\lambda_1}{2}\|\mathbf{J}\mathbf{t}+\mathbf{B}(\mathbf{1}-\mathbf{t})-\mathbf{I}\|_2^2+\frac{\lambda_2}{2}\left\|\mathbf{t}-\tilde{\mathbf{t}}\right\| \\ +\frac{\lambda_3}{2}\|\mathbf{B}-\widetilde{\mathbf{B}}\|_2^2+\lambda_4\|\mathcal{D}(\mathbf{J})\|_1 \\ +\lambda_5\|\mathbf{1}-\mathcal{B}(\mathbf{J})\|_1+f(\mathbf{J})+g(\mathbf{t}),\end{aligned} \tag{4}$$

where $\mathcal{D}(\mathbf{J})$ and $\mathcal{B}(\mathbf{J})$ denote the dark and bright channels of image $\mathbf{J}$, respectively, and λ_4 and λ_5 are the regularization parameters.

B. Optimization Algorithm

We employ the ALM method to solve the problem in (4). To this end, we first introduce auxiliary variables $\mathbf{P}$, $\mathbf{Q}$, $\mathbf{G}$, and $\mathbf{H}$ to split variables $\mathcal{D}(\mathbf{J})$, $\mathbf{1}-\mathcal{B}(\mathbf{J})$, $\mathbf{J}$, and $\mathbf{t}$, respectively. Then, the optimization problem in (4) can be reformulated as

$$\begin{aligned}\min_{\mathbf{t},\mathbf{B},\mathbf{J},\mathbf{P},\mathbf{Q},\mathbf{G},\mathbf{H}} \ & \frac{\lambda_1}{2}\|\mathbf{J}\mathbf{t}+\mathbf{B}(\mathbf{1}-\mathbf{t})-\mathbf{I}\|_2^2+\frac{\lambda_2}{2}\left\|\mathbf{t}-\tilde{\mathbf{t}}\right\| \\ & +\frac{\lambda_3}{2}\|\mathbf{B}-\widetilde{\mathbf{B}}\|_2^2+\lambda_4\|\mathbf{P}\|_1+\lambda_5\|\mathbf{Q}\|_1 \\ & +f(\mathbf{G})+g(\mathbf{H}) \\ \text{subject to} \ & \mathbf{P}=\mathcal{D}(\mathbf{J}),\ \mathbf{Q}=\mathbf{1}-\mathcal{B}(\mathbf{J}), \\ & \mathbf{G}=\mathbf{J},\ \mathbf{H}=\mathbf{t}.\end{aligned} \tag{5}$$

Next, we define the augmented Lagrangian function for (5) as

$$\begin{aligned}&\mathcal{L}(\mathbf{B},\mathbf{t},\mathbf{J},\mathbf{P},\mathbf{Q},\mathbf{G},\mathbf{H},\mathbf{\Gamma},\mathbf{\Upsilon})=\frac{\lambda_1}{2}\|\mathbf{J}\mathbf{t}+\mathbf{B}(\mathbf{1}-\mathbf{t})-\mathbf{I}\|_2^2 \\ &+\frac{\lambda_2}{2}\left\|\mathbf{t}-\tilde{\mathbf{t}}\right\|+\frac{\lambda_3}{2}\|\mathbf{B}-\widetilde{\mathbf{B}}\|_2^2+\lambda_4\|\mathbf{P}\|_1+\frac{\gamma_1}{2}\|\mathbf{P}-\mathcal{D}(\mathbf{J})\|_2^2 \\ &+\lambda_5\|\mathbf{Q}\|_1+\frac{\gamma_2}{2}\|\mathbf{Q}-(\mathbf{1}-\mathcal{B}(\mathbf{J}))\|_2^2+f(\mathbf{G})+g(\mathbf{H}) \\ &+\frac{\gamma_3}{2}\|\mathbf{G}-\mathbf{J}\|_2^2+\langle\mathbf{\Gamma},\mathbf{J}-\mathbf{G}\rangle+\frac{\gamma_4}{2}\|\mathbf{H}-\mathbf{t}\|_2^2+\langle\mathbf{\Upsilon},\mathbf{t}-\mathbf{H}\rangle,\end{aligned} \tag{6}$$

where $\gamma_1,\cdots,\gamma_4$ denote the penalty parameters, and $\mathbf{\Upsilon}$ and $\mathbf{\Gamma}$ are the Lagrange multiplier matrices.

The solutions to the optimization problem in (5) can be obtained by minimizing the function in (6). To this end, we employ the alternating direction method of multipliers [16], which splits the optimization into subproblems and solves them iteratively and individually. We describe how each optimal solution is obtained at each iteration k.

B- and t-subproblems: Given $\mathbf{J}_k$ and $\mathbf{t}_k$ at the k-th iteration, $\mathbf{B}_{k+1}$ and $\mathbf{t}_{k+1}$ are obtained by

$$\mathbf{B}_{k+1}=\arg\min_{\mathbf{B}} \frac{\lambda_1}{2}\|\mathbf{J}_k\mathbf{t}_k+\mathbf{B}(\mathbf{1}-\mathbf{t}_k)-\mathbf{I}\|_2^2+\frac{\lambda_3}{2}\|\mathbf{B}-\widetilde{\mathbf{B}}\|_2^2, \tag{7}$$

$$\begin{aligned}\mathbf{t}_{k+1}=\arg\min_{\mathbf{t}} \frac{\lambda_1}{2}\|\mathbf{J}_k\mathbf{t}+\mathbf{B}_{k+1}(\mathbf{1}-\mathbf{t})-\mathbf{I}\|_2^2+\frac{\lambda_2}{2}\|\mathbf{t}-\tilde{\mathbf{t}}\|_2^2, \\ +\frac{\gamma_4}{2}\|\mathbf{t}-\mathbf{H}_k+\gamma_4^{-1}\mathbf{\Upsilon}_k\|_2^2,\end{aligned} \tag{8}$$

respectively. As both subproblems in (7) and (8) are quadratic problems, their closed-form solutions are readily available.

J-, P-, and Q-subproblems: Next, the solutions for the extreme channel priors $\mathbf{J},\mathbf{P}$, and $\mathbf{Q}$ are obtained by solving

$$\begin{aligned}\min_{\mathbf{J},\mathbf{P},\mathbf{Q}} \frac{\lambda_1}{2}\|\mathbf{J}\mathbf{t}+\mathbf{B}(\mathbf{1}-\mathbf{t})-\mathbf{I}\|_2^2+\lambda_4\|\mathbf{P}\|_1+\frac{\gamma_1}{2}\|\mathbf{P}-\mathcal{D}(\mathbf{J})\|_2^2 \\ +\lambda_5\|\mathbf{Q}\|_1+\frac{\gamma_2}{2}\|\mathbf{Q}-(\mathbf{1}-\mathcal{B}(\mathbf{J}))\|_2^2 \\ +\frac{\gamma_3}{2}\|\mathbf{J}-\mathbf{G}+\gamma_3^{-1}\mathbf{\Gamma}_{k-1}\|_2^2.\end{aligned} \tag{9}$$

We iteratively solve the optimization in (9) by employing a linear mapping of pixels to their dark channel [15].

G- and H-subproblems: We employ deep networks G-Net and H-Net to adaptively learn the physics-based priors associated with explicit regularization functions $f(\cdot)$ and $g(\cdot)$. Specifically, $\mathbf{G}$ and $\mathbf{H}$ are updated as

$$\begin{aligned}\mathbf{G}_{k+1}&=\arg\min_{\mathbf{G}} \frac{\gamma_3}{2}\|\mathbf{G}-(\mathbf{J}_{k+1}+\gamma_3{}^{-1}\mathbf{\Gamma}_k)\|_2^2+f(\mathbf{G}) \\ &=\text{G-Net}_k(\mathbf{J}_{k+1}+\gamma_3^{-1}\mathbf{\Gamma}_k),\end{aligned} \tag{10}$$

$$\begin{aligned}\mathbf{H}_{k+1}&=\arg\min_{\mathbf{H}} \frac{\gamma_4}{2}\|\mathbf{H}-(\mathbf{t}_k+\gamma_4{}^{-1}\mathbf{\Upsilon}_{k-1})\|_2^2+g(\mathbf{H}) \\ &=\text{H-Net}_k(\mathbf{t}_{k+1}+\gamma_4^{-1}\mathbf{\Upsilon}_k).\end{aligned} \tag{11}$$

Finally, the Lagrange multiplier matrices are updated as

$$\mathbf{\Gamma}_{k+1}=\mathbf{\Gamma}_k+\gamma_3(\mathbf{J}_{k+1}-\mathbf{G}_{k+1}), \tag{12}$$

$$\mathbf{\Upsilon}_{k+1}=\mathbf{\Upsilon}_k+\gamma_4(\mathbf{t}_{k+1}-\mathbf{H}_{k+1}). \tag{13}$$

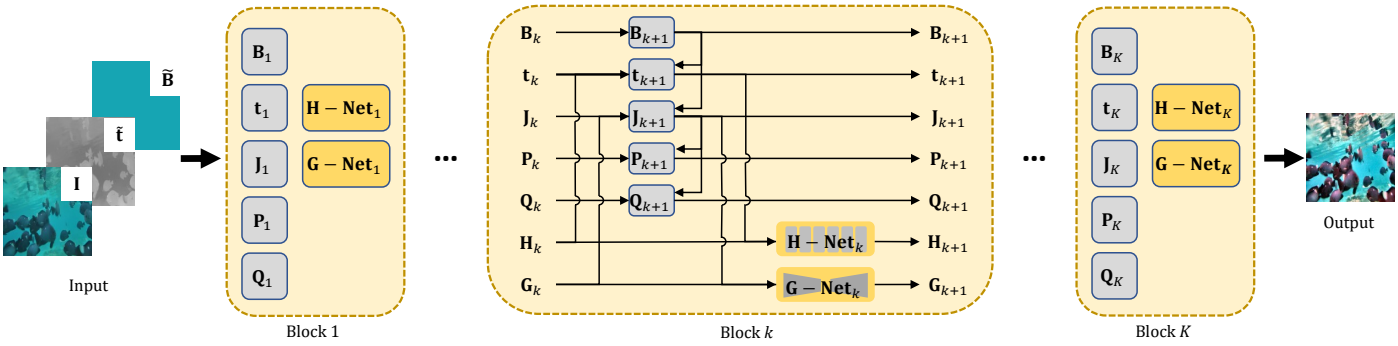

Fig. 1. Overview of the proposed algorithm, which is composed of K blocks.

C. Unrolled Network

We adopt the algorithm unrolling strategy to design an unfolded deep network for the proposed iterative optimization algorithm. Fig. 1 shows the architecture of the proposed deep unfolded network. The network takes underwater image $\mathbf{I}$, initial transmission map $\tilde{\mathbf{t}}$, and initial background light $\widetilde{\mathbf{B}}$ as inputs and processes them through K blocks; each block corresponds to an iteration of the iterative optimization algorithm.

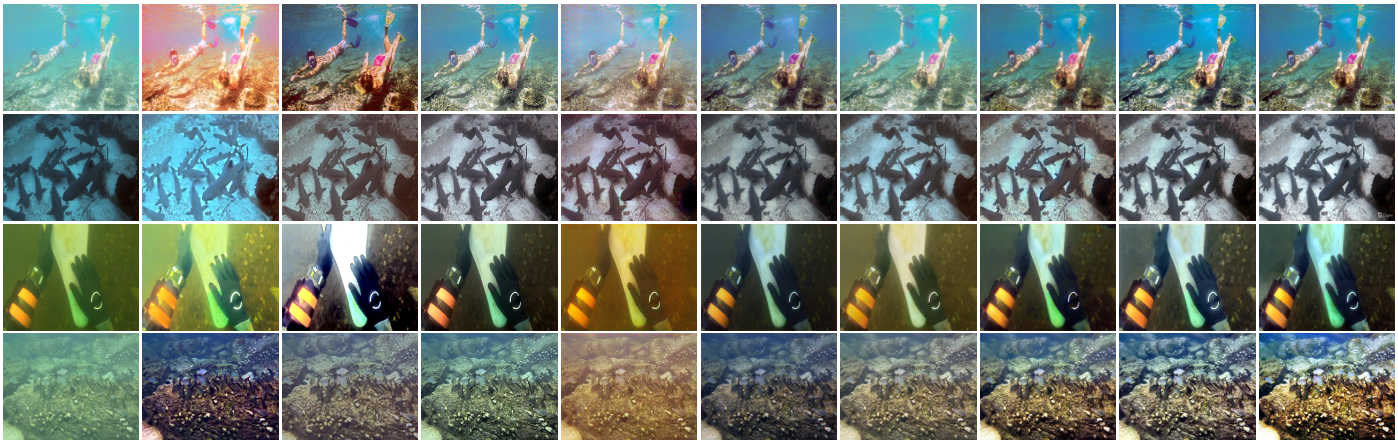
At each block k, optimization variables $\mathbf{B}$, $\mathbf{J}$, $\mathbf{t}$, $\mathbf{P}$, and $\mathbf{Q}$ are updated using closed-form solutions, and regularization variables $\mathbf{G}$ and $\mathbf{H}$ are updated using two specific CNNs: G-Net$_k$ and H-Net$_k$. We employ an informative proximal mapping module (IPMM) [18] and a residual dense network (RDN) [19] for G-Net$_k$ and H-Net$_k$. This process is repeated until the final block K, where the enhanced image $\widehat{\mathbf{J}}$ is obtained as the network output.

D. Training

We train the proposed algorithm using the l_1-norm between the ground-truth image $\mathbf{J}_{\text{gt}}$ and an enhanced image $\widehat{\mathbf{J}}$, which is defined as

$$L = \|\widehat{\mathbf{J}} - \mathbf{J}_{gt}\|_1. \tag{14}$$

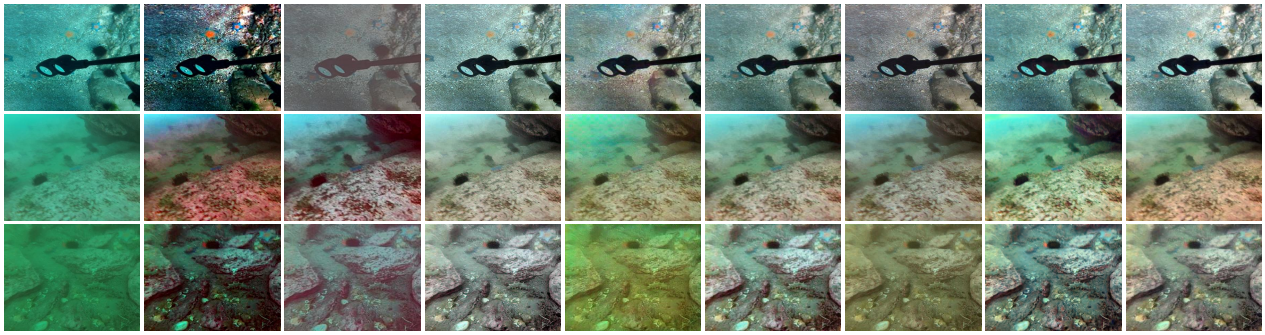
We use the Adam optimizer with parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$, and set the initial learning rate to 10^{-4}. The number of blocks, K, is fixed to 5 in all experiments. We set the regularization parameters, λ_1, λ_2, λ_3, λ_4, and λ_5, in (6) to 1.0, 0.7, 0.3, 0.5, and 0.5, respectively, whereas the penalty parameters, $\gamma_1, \ldots, \gamma_4$, are all learned from the training data.



Training dataset: We randomly selected 800 image pairs from the UIEB dataset [7], and the remaining 90 image pairs were used as the test set.

III. EXPERIMENTAL RESULTS

A. Quantitative and Qualitative Comparison



We compare the performance of the proposed algorithm with those the of state-of-the-art algorithms—GDCP [4], HLRP [6], MLLE [5], FUnIE-GAN [8], Water-Net [7], Ucolor [17], and TACL [9]. We use 90 image pairs from the UIEB dataset and 300 referenceless images from the UCCS dataset [20]. We use six quality metrics: PSNR, SSIM, LPIPS [21], UCIQE [22], NIQE [23], and BRISQUE [24]. PSNR, SSIM, and LPIPS are full-reference metrics, whereas UCIQE, NIQE, and BRISQUE are no-reference metrics. Higher PSNR, SSIM, and UCIQE scores indicate better performance, whereas lower NIQE, LPIPS, and BRISQUE scores imply better performance.

Table I quantitatively compares the underwater image enhancement performance. The proposed algorithm achieves the highest scores for PSNR, SSIM, LPIPS, and NIQE and provides comparable UCIQE and BRISQUE scores on the UIEB dataset. For example, the proposed algorithm yields 1.02 dB and 0.0514 higher PSNR and SSIM scores than the second-best TACL and Ucolor, respectively. In addition, the proposed algorithm achieves the second-best scores for the no-

reference metrics, UCIQE and NIQE, on the UCCS dataset. This indicates that the proposed algorithm is effective in producing visually appealing and high-quality images consistent with human perception.

Figs. 2 and 3 compare the enhancement results of each algorithm on the UIEB and UCCS datasets, respectively. In Figs. 2(b), (c), and (d), GDCP, HLRP, and MLLE, respectively, fail to recover the colors of the objects accurately, *e.g.*, the first and third rows. Funie-GAN [8] in Fig. 2(e) generates severe color distortions, significantly altering the visual characteristics of the images. In Figs. 2(f) and (g), Water-Net and Ucolor, respectively, provide blurry and low-contrast results with unnatural color tones. In contrast, both TACL and the proposed algorithm in Figs. 2(h) and (i), respectively, provide restored images closest to the ground-truths in Fig. 2(j) without visible color changes. Furthermore, Fig. 3 confirms the effectiveness of the proposed algorithm in enhancing real-world underwater images, producing more natural-looking results than the conventional algorithms.

B. Effectiveness of Extreme Channels Prior

We analyze the effectiveness of DCP and BCP using the UCCS dataset by training the proposed network under different settings. Table II compares the enhancement performance. The proposed algorithm with both DCP and BCP yields higher NIQE and BRISQUE scores than the models with only either DCP or BCP. This implies that both DCP and BCP can improve the enhancement performance.

TABLE II
EFFECTS OF THE EXTREME CHANNELS PRIOR ON ENHANCEMENT PERFORMANCE.

BCP	DCP	UCIQE	NIQE(↓)	BRISQUE(↓)
	✓	**0.5625**	4.3243	21.37
✓		0.5580	4.2300	21.18
✓	✓	0.5610	**4.1928**	**21.05**

IV. CONCLUSIONS

We developed an unfolding approach for underwater image enhancement. We first formulated a joint optimization problem that incorporates physics-based constraints, underwater-related priors, and implicit regularizers. Then, we iteratively solved this problem using the ALM method. Next, we unfolded the iterative algorithm into a series of blocks in a deep network, in which the optimization variables and regularizers are updated using closed-form solutions and neural networks, respectively. Experimental results demonstrated that the proposed algorithm provides superior enhancement performance to state-of-the-art algorithms.

***Abstract*—In this paper, we propose a novel approach for low-light image enhancement via distillation of NIR-to-RGB conversion network's knowledge. NIR images contain abundant detail information that is independent of lighting conditions. We leverage the knowledge of the NIR-to-RGB conversion network, which effectively preserves detail information from NIR while generating accurate colors, as it shares similarities with low-light image enhancement. By using the rich detail information provided by the NIR-to-RGB conversion for low-light image enhancement, we are able to reduce color distortion and noise while preserving detail information. Our experimental results show the superior performance of our proposed network.**

I. Introduction

When a digital image is acquired, it can be lack of lighting due to low-light environments, performance limitations of photography equipment and its improper settings. Low-light images contain low contrast, massive noise, and significant degradation of detail information, leading to a significant decrease in visibility. Consequently, they diminish the performance of various computer vision techniques designed for normal light conditions, making it difficult to apply those techniques. Therefore, enhancing low-light images is crucial for applying various computer vision techniques such as object and motion recognition in nighttime environments, and 24-hour surveillance.

Near-Infrared (NIR) images are commonly captured in the wavelength range of 700nm to 1000nm as a single-channel representation. Unlike RGB images, they preserve detail and texture well in even low-light environments, making them suitable for various nighttime computer vision applications. However, due to the lack of color information in NIR images, they appear unnatural to human visibility and it is challenging to directly apply them to existing various computer vision tasks. In recent years, NIR colorization research that converts NIR images into RGB has been actively conducted [1]–[3]. It is a challenging task that is involved in generating color information not present in the NIR images.

In this paper, we propose a novel technique to enhance low-light images by leveraging knowledge distillation from an NIR-to-RGB conversion network. The knowledge from the NIR colorization network is distilled to the low-light image enhancement network via the student-teacher model. The proposed method is based on the idea that the NIR-to-RGB conversion network extracts structural information from an NIR images and additionally estimates colors to generate an RGB image. This restoration process is similar to the low-light image enhancement in term of detail and color estimation.

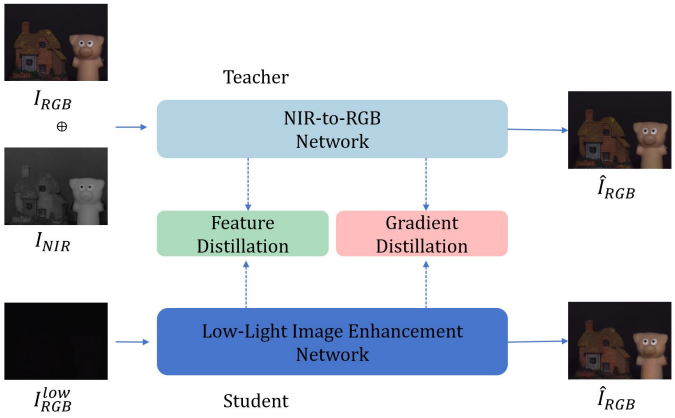

Fig. 1. Concept diagram of the proposed method

Fig. 1 illustrates the concept of the proposed technique which is to distill the knowledge from the NIR-to-RGB conversion network to the low-light image enhancement network in the student-teacher model. The key process in the NIR colorization task is to restore image details and colors, and it is similar to the restoration process in the low-light enhancement task. This observation motivates us to add the NIR input to the conventional student-teacher model for low-light enhancement. Additionally, we introduce a gradient distillation loss to effectively transfer texture information from the teacher network. A dataset with a pair of RGB and NIR images was built, and it was used for evaluating the proposed method. Experimental results show the superior performance of the proposed method.

II. Related Work

In recent years, significant advancements have been made in low-light image enhancement techniques. Many of the low-light image enhancement studies are being conducted based on the Retinex theory [4]. It states that an image can be decomposed into illumination and reflectance components. LIME [5] estimated illumination component only which is just fused with reflectance component. Retinex-Net [6] is a deep network-based method, which consists of image decomposition, illumination enhancement and denoising to the reflectance. KinD [7] and KinD++ [8] use sub-networks for each component

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

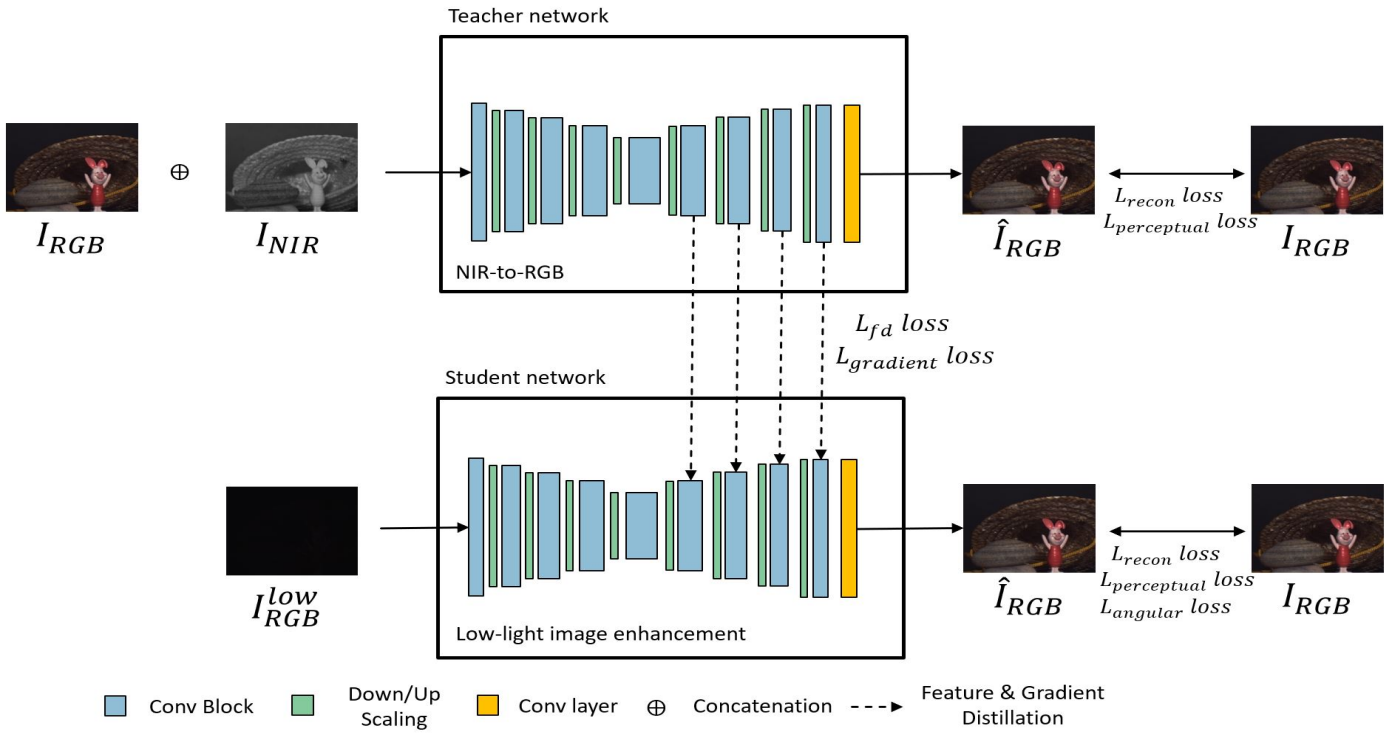

Fig. 2. The overall architecture of the proposed network

after decomposing an image to improve both the reflectance and illumination components. [9] attempts to further enhance low-light images by dual-teacher knowledge distillation. SNR-aware [10] utilizes the correlation between signal and noise to compute attention for patch-based enhancement of the low-light. [11] and [12] leverage the characteristics of near-infrared images that retain rich detail information even in extremely low-light conditions. These techniques have shown promising results and further research is being actively conducted.

III. The Proposed Method

A. Knowledge Distillation

Knowledge distillation [13] is a deep learning model that transfers knowledge from a teacher network to a student network. The student network can effectively learn the feature maps transferred by the teacher network, resulting in the improved performance. We further enhance the performance of a low-light image enhancement network through knowledge distillation of NIR-to-RGB conversion network. The proposed network utilizes two types of knowledge distillation techniques: feature distillation and gradient distillation. Through feature distillation, the overall detail information in the feature maps of the teacher network is learned, while the addition of gradient distillation enables the student network to learn more clear texture information, resulting in the enhanced textures in the generated images.

B. NIR colorization

Near-Infrared (NIR) images preserve abundant detail and texture information well in even low-light environments. Therefore, they have been popularly studied in various night-time computer vision tasks. NIR colorization is a task to aim at generating colorful RGB images, preserving rich details from NIR and restoring colors that appear natural to human visibility. This task is quite challenging as it is involved in generating color information that is not present in the original NIR images. This paper proposes a novel deep network that adopts the NIR-to-RGB conversion network as a teacher.

C. The Proposed Network

Fig. 2 illustrates the architecture of the proposed network which consists of a teacher network for NIR-to-RGB conversion, a student network for low-light image enhancement, and knowledge distillation between the teacher and the student. The teacher network takes both RGB and NIR images as inputs in order to accurately learn NIR colorization, unlike the conventional NIR colorization task which accepts RGB only. It learns the relationship between RGB and NIR images to generate color information resembling the real scene and to learn rich detail information present in NIR images. The teacher network is pre-trained and then, the student is learned while the learned teacher is kept fixed. The student network takes low-light image as input. It learns the relationship between different lighting images and generates normal-light images with rich colors and details close to ground truth images. Both

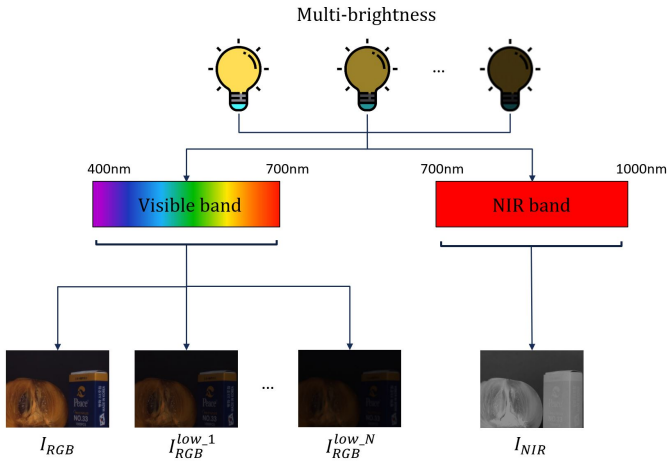

Fig. 3. Constructing dataset under different lighting conditions

the teacher and student networks follow the structure of U-Net [14].

The network for NIR-to-RGB conversion aims to preserve the rich structural and detail information of NIR images while generating realistic colors. The purpose of the network for enhancing low-light images is also to restore detail information by removing noise and generate realistic colors. Based on the idea that the objectives of both tasks are similar, we propose a technique to distill knowledge between the two networks. By distilling the rich details from NIR images in the teacher network, the student can remove noises and enhance detail regions in the low-light images. Similarly, by distilling the abundant color information from RGB images, it can suppress color distortion and improve color restoration capability. The improvement effects of the student network, such as noise reduction, detail enhancement, and color restoration for low-light images, are demonstrated in experimental results.

D. Loss function

The loss function of the proposed network consists of a reconstruction loss, a perceptual loss, an angular loss, a feature distillation loss, and a gradient distillation loss.

The reconstruction loss is to minimize the pixel value difference and is defined as follows:

$$L_{recon} = \|\hat{I}_{RGB} - I_{RGB}\|_1 \tag{1}$$

where $\hat{I}_{RGB}$ and I_{RGB} represent the RGB image generated by the network and the corresponding ground truth image, respectively.

The perceptual loss is to preserve high-level content information and generate more natural-looking images. It is defined as follows:

$$L_{perceptual} = \sum_{layer} |VGG(\hat{I}_{RGB}) - VGG(I_{RGB})|_{layer} \tag{2}$$

The above loss function calculates the difference in feature maps by layer using a pretrained VGG network.

The angular loss is aims to generate more natural colors by employing the Angular error [15], which quantifies the color restoration quality. It is defined as follows:

$$L_{angular} = arccos(\frac{\hat{I}_{RGB} \cdot I_{RGB}}{\|\hat{I}_{RGB}\|\|I_{RGB}\|}) \tag{3}$$

The feature distillation loss is used to train the student network to have similar feature maps to the teacher network. It is defined as follows:

$$L_{fd} = \sum_{layer} \|\alpha(F^S) - F^T\|^2_{layer} \tag{4}$$

where α represents the meta network and is used to reduce the difference in feature maps, effectively facilitating the learning of information from the teacher network.

The gradient distillation loss is used for the student network to learn texture information from the feature maps of the teacher network. It is defined as follows:

$$L_{gradient} = \sum_{layer} \|\nabla F^S - \nabla F^T\|^2_{layer} \tag{5}$$

where ∇ represents the first-order differential operator that includes ∇_x(in the horizontal direction) and ∇_y(in the vertical direction).

The loss function $L_{teacher}$ for the teacher network is defined as follows:

$$L_{teacher} = L_{recon} + L_{perceptual} \tag{6}$$

The loss function $L_{student}$ for the student network is defined as follows:

$$\begin{aligned} L_{student} =& L_{recon} + L_{perceptual} + \lambda_1 L_{angular} \\ &+ \lambda_2 L_{fd} + \lambda_3 L_{gradient} \end{aligned} \tag{7}$$

where λ_1, λ_2 and λ_3 represent hyperparameters.

IV. Experimental Result

A. Dataset

The dataset used for the evaluation of the proposed method consists of pairs of RGB and NIR images. It was created by controlling the intensity of the light to generate five levels of low-light conditions, ranging from approximately 0.1 Lux to 6 Lux. A total of 180 scenes were included in the training dataset, with a total of 900 images across different lighting conditions. The test dataset includes 20 scenes, with a total of 100 images across different lighting conditions. The RGB and NIR images were simultaneously captured for various scenes with multiple objects in a darkroom environment using a 4-channel camera, specifically the JAI's AD-130 GE. The camera captures the reflected light in a single channel format across all NIR wavelength bands.

B. Performance Evaluation

For the experiments, the hyperparameters λ_1, λ_2 and λ_3 were set to 0.1, 1, and 1, respectively. To evaluate the results of the low-light image enhancement experiments, both quantitative and qualitative evaluations were conducted. Fig. 4 shows the results of the qualitative evaluation. In Fig. 4, Retinex-Net [6] shows very poor performance with inadequate color improvement in the extremely low-light image. KinD [7] appears highly blurred, indicating the loss of detail information. KinD++ [8] shows improved detail information but exhibits darker restored colors compared to the actual ones and suffers from noises. SNR-Aware [10] exhibits unnatural color restoration and noise occurrence. Our result has less noise, preserves details, and produces more realistic colors and achieves superior performance compared to the existing methods. In Table I, all metrics related to structural and color information indicate the superior performance of the proposed method.

C. Ablation study

To evaluate the performance of the proposed teacher network, we conducted a couple of ablation studies such as 'without the teacher', 'without NIR in the teacher', and 'without gradient distillation'. In Fig. 5, (b) represents the case without the teacher network. It is observed that the color distortion and detail loss occurred in the carrot and lemon regions. This demonstrates that the knowledge of a teacher network that converts NIR-to-RGB reduces color distortion and conveys rich detail information. (c) shows the case where the NIR image is removed from the teacher network. It generates colors different from the actual ones and the seed parts of the kiwi and carrot were blurred, resulting in insufficient details. It is demonstrated that the NIR input enhances the restoration ability of detail information and color. (d) represents the case where gradient distillation is removed. Although there was an improvement in detail using the NIR image, the texture visual quality in the lemon and carrot part is insufficient. This indicates that gradient distillation effectively transfers texture information. In Table II, the evaluation of only the student network reveals that the NIR-to-RGB teacher network significantly enhances low-light enhancement performance. The absence of NIR in the teacher's input leads to a decrease in all metrics, indicating that the teacher network effectively utilizes details and structural information from the NIR. Additionally, gradient distillation further conveys the texture information, contributing to the overall improvement of low-light enhancement performance.

V. CONCLUSIONS

Low-light images suffer from a large amount of noise, and the loss of structure detail and color information, leading to a significant decrease in visibility. Therefore, low-light image enhancement techniques are essential in computer vision tasks. In this paper, we proposed a deep learning network that improves low-light images through knowledge distillation from the NIR-to-RGB network. The proposed method is designed based on the idea that low-light image enhancement and NIR-to-RGB conversion share similar objectives such as restoration of image details and color information. By leveraging the rich details of the network that converts NIR to RGB, the proposed method reduces noise and color distortion in low-light images and enhances color restoration capability. Quantitative and

qualitative evaluations of the experimental results demonstrate the superior performance of the proposed method.

***Abstract* — Estimating 3D human pose from a single RGB image is still challenging in computer vision. Driven by multi-view approach, we propose a model to estimate multiple virtual-view skeletons from a single real-view image which are then fused to derive the final 3D human skeleton. Our network is composed of two stages. The first-stage is a two-streams network, where a Real-Net stream predicts 2D image coordinates and relative depth for each joint from the real-view image and a Virtual-Net stream predicts the relative depths in virtual viewpoints for the same joints. Our second-stage network consists of depth-denoising module and fusion network, where the outputs of the first-stage network are concatenated, depth-denoised, and converted into the predicted 3D human skeleton. The experimental results show that our technique has achieved a performance of MPJPE=47.48 mm, which is comparable to other state-of-the-art methods based on a much longer image sequence (9~243 frames).**

I. INTRODUCTION

Extracting 3D human skeleton (or, the pose) from a single RGB image is challenging in computer vision, which draws many researchers' attention to focus on it. In recent years, 2D and 3D human skeletons have been used in numerous applications in order to achieve the goals of behavior analysis in video surveillance [2], action recognition [1], virtual/ augmented reality (VR/AR), human-computer interaction (HCI), human robot collaboration (HRC) [3], and elderly caring.

3D human skeleton sequence is one kind of input that are crucial to the achievement of action recognition. The recognition accuracy rely on how well the 3D human skeletons are estimated, in other words, the more precise the 3D human skeleton is, the more accuracy the action will be recognized.

For 3D human skeleton estimation, several types of input have been proposed and used, such as single monocular RGB image [4-5], multi-views RGB image [6, 7], RGB image sequence [8, 23] and RGBD images [9]. Among these kinds of inputs, RGB image sequence and multi-view RGB images gained more attention due to their more abundant information as input and the predicted accuracy is higher than monocular single view input. Nevertheless, single image input approach is still popular even their performance is lower compared to multi-view and monocular sequence approaches. This is because single image input has the advantages of a reduced or least amount of hardware or device required, i.e., being cost effective when applying to the real life. On the contrary, sequence image input will certainly increase the software/hardware design complexity, while multi-view image input approach can be only applied to specific scenarios (e.g., athlete training, film production), where multiple cameras from different viewpoints are available.

By surveying numerous papers, it was observed that the accuracy of 3D human skeleton estimation from multi-views [7, 10] is significantly higher than that from single-view [4, 5], due to the fact that multi-view input will provide more useful information that could be incorporated into a neural network model for generating a 3D human skeleton of great precision. To make a compromise, we would like to propose a new method which makes a compromise between the single-view and the multi-views approaches.

The contributions of our work are summarized as follows:

- Our method requires only a single-view RGB image as the input and predicts 2D skeletons and multiple depth information from different virtual viewpoints, which are then fused and used as the input of a fusion network to

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

regress the final 3D human skeleton.

- Our two-stream network predicting multiple depths in several virtual viewpoints is simple and effective.
- A depth-denoising algorithm was adopted in the training procedure, thus reducing the noise effect in following inferences.
- According to the experiments, it was shown that our algorithm provides a substantial improvement compared to the baseline method and even outperforms some methods based on input image sequence.

II. Related Work

A. Single-view methods

Sun et al. [11] proposed a method to predict 3D human pose from a single view input by predicting 3D heatmaps directly first and then apply integral operation (*soft-argmax*) on those heatmaps to obtain 3D joints location. They proposed this method to overcome the problem of non-differentiable post-processing and quantization error of heatmap. To overcome depth ambiguity, some researchers [12, 13] proposed a two-stage approach to predict 2D joints with or without relative depths (e.g., the densely-generated limb depth map [13]) first and then feed them into 2D-to-3D lifting network to estimate 3D skeleton. In [12], a simple method was proposed to lift the detected 2D joints to 3D space by introducing the algorithm of Part-Centric Heatmap Triplets (HEMlets), where three joint-heatmaps were used to represent the relative depth information of the end-joints for each skeletal body part. The outputs of HEMlets are then fused by up-sampling the features and sent to a regression network for estimating the 3D skeleton.

B. Multi-views methods

Since the information from a single monocular RGB image is limited in resolving inherent depth ambiguity, recent researches focus on utilizing information from multiple synchronized cameras to solve this problem. Iskakov et al. [7] proposed to learn differentiable algebraic triangulation and perform a volumetric aggregation of 2D feature maps produced by a 2D backbone. However, their proposed volumetric approach is computationally demanding. In order to avoid intensive computations caused by volumetric grids, Remelli et al. [14] proposed to fuse input images into a unified latent representation of pose via 3D geometry. On the other hand, Qiu et al. [6] presented an approach to predict 2D skeletons from multiple views and then used recursive Pictorial Structure Model (PSM) to recover 3D pose. Different from these methods that require multi-view images as input (hence surrounding in-ward cameras) to predict 3D skeleton, our method requires only single-view image as input (hence, a single camera).

III. Our Method

A. Two-Stage and Two-Streams Network Architecture

In this section, we provide the detailed design of our proposed method. An illustration of the geometry for multiple virtual-viewpoints is presented in Fig. 1, where a real camera and N virtual cameras from different viewpoints surrounding the human are indicated. All the $N+1$ cameras are arranged to viewpoints rotating around the z-axis of the coordinate system.

Hopefully, the goal of our design is to predict all 3D human skeletons in varying viewpoints from a single real RGB image as the input. Instead, we predict, as tradition, the 2D skeleton in the real viewpoint, together with the joint depths (relative to a root joint) along the y-axis of each camera coordinate system. Due to the lack of multi-view image information, joint depths in virtual viewpoints are embedded into the 2D joints of the real viewpoint. Hence, a total of real-view 2D skeleton and all-view joint depths can be predicted. This concept is illustrated in the architecture of Fig. 2, where a two-stage network is presented. In the first stage (Fig. 2(a)), it is composed of a two-streams network, the Real-Net stream and the Virtual-Net stream.

Real-Net is designed to predict the 2D skeletal joint and its relative depths in the real viewpoint v_0, denoted as $(\hat{u}_{v_0}, \hat{v}_{v_0}, \hat{d}_{v_0})$ (the joint index is ignored here), where the relative depth is measured with respect to a root joint (Pelvis). It outputs multiple 3D heatmaps $(J \times 64 \times 64 \times 64)$, J=18 is the number of skeletal joints in our model. Each 3D heatmap is used to predict the u, v, and d components, each of which is quantized into 64 levels for speed and memory consideration. 2D joints and their relative depth values can be obtained by applying *soft-argmax* operation on each 3D heatmaps.

The main goal of Virtual-Net is to estimate joints' relative depths $\{\hat{d}_{v_n}\}_{n=1}^{N}$ in the virtual viewpoints v_n. However, they must be embedded in the corresponding joint $(\hat{u}_{v_0}, \hat{v}_{v_0})$ of the real-view 2D skeleton to form $(\hat{u}_{v_0}, \hat{v}_{v_0}, \hat{d}_{v_n}), n = 1, \dots, N$. This network contains two outputs: (1) a set of 2D heatmaps (64×64×18×N) for predicting $(\hat{u}_{v_0}, \hat{v}_{v_0})$ and (2) a set of depth maps (64×18×N) for predicting $\{\hat{d}_{v_n}\}_{n=1}^{N}$. The 2D heatmaps are applied with *soft-argmax* operation to obtain 2D skeletal joints $(\hat{u}_{v_0}, \hat{v}_{v_0})$, as in the Real-Net, while joint depth values $\{\hat{d}_{v_n}\}_{n=1}^{N}$ predicted in the depth maps could be extracted under the guidance of the output $\hat{u}_{v_0}$ from the Real-Net (by using each joint number as row index and each predicted $\hat{u}_{v_0}$ from the Real-Net stream as the column index). In this paper, we

choose ResNeXt-50 as the backbone of both Real-Net and Virtual-Net.

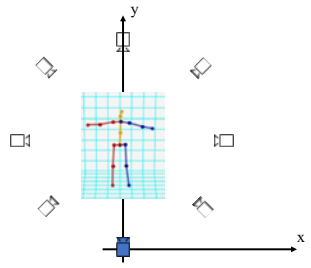

Fig. 1 Geometry of multiple virtual viewpoints (1 real camera (blue one) and N-1 virtual cameras) for human skeleton estimation.

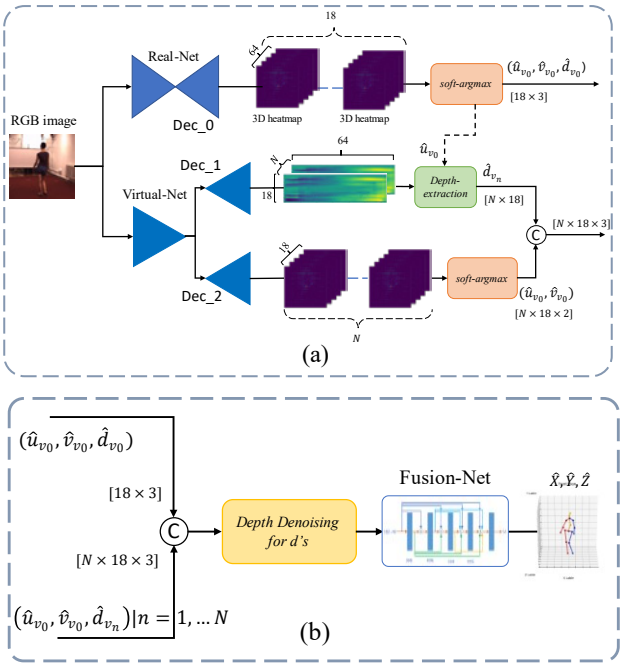

Fig. 2 Architecture design of our proposed approach. (a) 1st stage network. (b) 2nd stage network composed of depth-denoising and fusion-net modules. © is a concatenation operator.

In our design, the N+1 2D skeletons predicted from the Real-Net and Virtual-Net are expected to be the same and hence the two networks could be trained using the same ground truth from the real viewpoint. On the other hand, ground truth of depths in virtual viewpoints can be derived by geometrically rotating the real-view human skeleton for network training.

The second-stage network (Fig. 2(b)) consists of a depth-denoising module and a Fusion-Net which accepts N+1 concatenated 2D skeletons (with denoised depth values) as input and outputs the final 3D skeleton. The "depth denoising" is to disturb the predicted depths by adding Gaussian noises so that the network can have better robustness in test/inference. Our Fusion-Net is constructed by using a dense-connected structure of FC (fully connected) layers as in DenseNets [15] and using PReLU as the activation function.

B. Data Preprocessing and Depth Denoising

Normalization is a standard procedure as data pre-processing, without distorting or information loss, to transform data to have a common range of values. In ground truth preparation for the 1st stage network, the pelvis joint is chosen as the root for calculating the relative depth of each joint, which accompanies with the joint's 2D joint coordinates, are each quantized to a range of [0, 63] (i.e., the size of the 3D heatmap). For the 2nd stage network, ground truth of the 3D coordinates for each joint are normalized to be in the range of [-1, 1].

To derive ground truths of joint depths in virtual viewpoints, 3D skeletons in virtual-views should be generated. Let $S_r^j = (X_r^j, Y_r^j, Z_r^j, 1)$ be a given 3D joint from the real-view, and $S_{v_n}^j = (X_{v_n}^j, Y_{v_n}^j, Z_{v_n}^j, 1)$ is the 3D skeleton in virtual-view v_i. To obtain $S_{v_i}^j$, the equation below is used:

$$S_{v_n}^j = [R|T]S_r^j \tag{1}$$

where j represents the joint index, and R and T are the 3×3 rotation and 3×1 translation matrices (geometrical transformation from the real to the virtual camera v_n). From $S_{v_n}^j$, we can derive the joint depth $d_{v_n}^j$ by subtracting the Z coordinate of the root joint from $Z_{v_n}^j$.

Gaussian noise is commonly used in denoising [24]. Depth denoising module is designed by simply generating a Gaussian noise and add to the predicted depths from the first-stage network. It is represented as follow:

$$\tilde{d}_{v_n}^j = \hat{d}_{v_n}^j + N(\mu, \sigma^2) \tag{2}$$

where $N(\mu, \sigma^2)$ stands for the normally distributed noise generated at a mean μ and a variance σ^2, $\hat{d}_{v_n}^j$ is the predicted depth value for the j-th joint in virtual viewpoint v_n, and $\tilde{d}_{v_n}^j$ is the denoised depth value. Notice that denoising is only performed in training and will be ignored in testing phase.

C. Loss Functions

In the first-stage network, Real-Net is trained by using the Mean Absolute Error (MAE) for the predicted 2D joints and their associated relative depths by:

$$L_{real-net} = \sum_{j=1}^{J} |\hat{s}^j - s^j| \tag{3}$$

where $\hat{s}^j = (\hat{u}^j, \hat{v}^j, \hat{d}^j)$ stands for the predicted 2D coordinate and relative depth, and $s^j = (u^j, v^j, d^j)$ is the ground truth and j is the joint index.

The loss function for training the Virtual-Net is composed of 2D joint loss and relative depth value loss:

$$L_{virtual-net} = \alpha \cdot L_{2D} + \beta \cdot L_{depth} \quad (4)$$

where α and β are hyper-parameters and

$$L_{2D} = \sum_{n=1}^{N} \sum_{j=1}^{J} |\hat{p}_{v_n}^j - p_{v_0}^j| \quad (5)$$

$$L_{depth} = \frac{1}{N.J} \sum_{n=1}^{N} \sum_{j=1}^{J} |\hat{d}_{v_n}^j - d_{v_n}^j| \quad (6)$$

where j is the joint index, $\hat{p}_{v_n}^j = (\hat{u}_{v_n}^j, \hat{v}_{v_n}^j)$ is the predicted 2D coordinates for the j-th joint in virtual viewpoint v_n and $p_{v_0}^j = (u_{v_0}^j, v_{v_0}^j)$ is the ground truth, $\hat{d}_{v_n}^j$ is the predicted relative depth in virtual viewpoint v_n where n is the virtual view index and $d_{v_n}^j$ is its corresponding ground truth.

In the second-stage network, the loss function is composed of 3D joint position loss and bone vector loss, as below:

$$L_{fusion} = \lambda_{bone} \, . \, L_{bone} + \lambda_{joint} \, . L_{joint} \quad (7)$$

where

$$L_{joint} = \sum_{j=1}^{J} smoothL1(\hat{S}^j, S^j) \quad (8)$$

$$L_{bone} = \sum_{k=1}^{K} smoothL1(\hat{B}^k, B^k) \quad (9)$$

where $smoothL1$ is the smooth L1 loss function, $\hat{S}^j$ and S^j are predicted and ground-truth 3D coordinates for joint j, respectively; $\hat{B}^k$ and B^k are the predicted and ground-truth bone vector for k-th bone, respectively; λ_{bone} and λ_{joint} are scalers for bone vector loss and joint position loss, respectively. In this paper, bones consist of some selected virtual bones [23] and physical bones in human skeleton model.

IV. Experimental Results

A. Experimental Settings

In this paper, 3D skeletons in the virtual viewpoints are generated by arranging virtual cameras around the z-axis with equal angular intervals between them, as illustrated in Fig. 1.

Our proposed method is implemented using PyTorch platform. Our first-stage network is trained using initial learning rate of 0.001 and Adam optimizer, where Real-Net is trained for 50 epochs and Virtual-Net is trained for 100 epochs. For the second-stage network, it is trained for 250 epochs and optimized by using AdamW optimizer with an initial learning rate of 0.001. The other hyper-parameters are tuned as: $\alpha = 1$, $\beta = 1, \lambda_{bone}$=10, and $\lambda_{joint} = 1$.

Our first-stage network model is trained by using two popular datasets, Human3.6M [16] and MPII [17]. Adding MPII dataset in the first-stage training will make the models more robust and also applicable to the outdoor scenarios. In the second-stage training, we used only Human3.6M dataset. As in other references, we evaluate the accuracy of our proposed method by using two standard Protocols, Protocol #1 refers to Mean Per Joint Position Error (MPJPE) and Protocol #2 refers to P-MPJPE (MPJPE after performing rigid transformation via Procrustes Analysis). For Human3.6M dataset, 5 subjects (S1, S5, S6, S7, S8) are used for training and 2 subjects (S9, S11) are used for testing.

B. Ablation Study

To verify the impacts of multiple virtual viewpoints arrangement and depth denoising in the proposed method, we conduct ablation studies on different number N of virtual viewpoints and strength/ variance of Gaussian noise for depth denoising.

Table 1 shows the results of our method with different number of virtual viewpoints without depth denoising. It can be seen that when N is not zero, the MPJPE is decreased, meaning that the relative depths from virtual viewpoints help to lift the performance of the predicted 3D skeleton. It is also found that for N={1,2,3,7} the differences in MPJPE values are small, thus we select N={1,2,3} to further perform experiments on combinations of virtual cameras positioning. Finally, we found that when N=2 is used and the two virtual cameras are placed at an left-90 and right-90 degrees interval (i.e., the 2nd and 6-th clockwise positions starting from the real camera in Fig. 1), respectively, the best result can be achieved and denoted as (r, vv1, vv2) in Table 1.

To evaluate the performances of different depth denoising parameters, we choose the best virtual-view configuration N=2 (r, vv1, vv2) in Table 1 and apply the depth denoising to the real-view and virtual-view depths separately, as illustrated in Table 2, where σ_r and σ_v are the noise variances added to the joint depths predicted from the Real-Net and Virtual-Net, respectively. From the experiments, it is found that when $\sigma_r = 0.022$ and $\sigma_v = 0.01$, our proposed method achieves the best performance.

TABLE 1. Comparison of different number of virtual-views. This result is obtained without depth-denoising. (r, vv1, vv2) denotes real view, virtual views in a clockwise rotating angle around z-axis by 90- and 270-degree, respectively.

Number of virtual - views (N)	MPJPE (mm)	PA-MPJPE (mm)
0 (real view only)	50.6	38.1
1	49.2	37.5
2	49.2	37.6
3	49.2	37.7
4	49.3	37.8
5	49.3	37.6
6	49.3	37.6
7	49.2	37.7
8	50.0	38.3
9	49.3	37.7
10	49.3	37.7
2 (r, vv1, vv2)	**49.0**	**37.5**

TABLE 2. Comparison of different σ value for depth-denoising at the (r, vv1, vv2) configuration. σ_r: for real-view depth, σ_v: for virtual-view depths.

σ_r (noise on real)	σ_v (noise on virtual)	MPJPE (mm)	PA-MPJPE (mm)
0 (none)	0 (none)	49.00	37.49
0.022	0 (none)	47.52	37.22
0.022	0.001	47.60	37.17
0.022	0.005	47.50	**36.97**
0.022	0.010	**47.48**	37.50
0.022	0.015	47.78	37.30
0.022	0.020	47.81	37.12

C. Comparison with State-of-the-art Methods

Table 3 shows the comparison of proposed method with state-of-the-art methods on Human3.6M dataset. The T values indicate the number of consecutive frames used for 3D skeleton estimation. It can be seen that our proposed method (47.48mm in MPJPE and 37.5mm in PA-MPJPE) outperforms methods which also adopt a single image (T=1) as the input and achieves a comparable performance with respect to methods which adopt sequence images (T=9~243) as the input. For example, even there is a 2D pose refinement stage in [19], our method outperforms theirs by 1.7mm in MPJPE. Reference [20] proposed a PoseAug to adjust various geometry factors of a pose through differentiable operations, while our depth-denoising module designed by simply using Gaussian noise without any learned parameters can achieve a similar function and has a gain of 2.7mm in MPJPE.

In comparison to [18] and [23] which adopt a shorter length of sequence (*T*=9), our performance is inferior by only 1.7mm and 0.2mm in MPJPE, respectively. Actually, in practice viewpoint, adopting a long sequence of frames (e.g., up to *T*=96 [25] or even 243 [22]) as the input will face disadvantages of heavy network size, large memory requirement, and long delay in response time. On the other hand, our design adopting a single frame as the input not only results in a simplified system, but also achieves a quick response time and hence is a more cost-effective design. The qualitative results of our proposed method are illustrated in Fig. 3. Our network produces plausible 3D human skeleton which similar to the ground truth.

TABLE 3. Comparison of our result with other approaches under Protocol #1 (top) and Protocol #2 (bottom). (*T*: number of temporal frames used for estimation). **Bold**: best; <u>Underlined</u>: second best.

V. CONCLUSIONS

In this paper, we proposed a two-stage approach for 3D human skeleton estimation. In the first-stage, we proposed a two-streams network to learn joint depths in multiple viewpoints from a single RGB image, including one from real-view and *N* from virtual-views. In the second stage, we propose a simple yet effective method, named depth-denoising, to denoise the predicted depths from the first-stage network. Extensive experiments show that our techniques of fusion from multiple virtual viewpoints and depth denoising help to promote the overall performance. Our design has the advantages of low complexity and fast response time due to the use of a single image as the input. In the future work, the Fusion-Net can be re-designed to further promote the estimation accuracy.

***Abstract*—Hyperspectral change detection (HCD) has a profoundly impactful contribution to the remote sensing field, such as environmental monitoring, agriculture investigation, disaster assessment, and urban planning. Due to the large-scale data of hyperspectral images (HSIs), conventional regularizers needed in convex optimization (CO), which are typically mathematically sophisticated (e.g., total variation), could lead to a slow computational time. On the other hand, the lack of big data HSIs obstructs the application of deep learning (DE) methods to solve the challenging HCD problem. In this paper, we propose an HCD algorithm based on the CODE theory developed for hyperspectral inverse imaging problems and achieving small-data learning by combining CO and DE. In the proposed small-data learning HCD algorithm, a simple graph change detection network structure (SGCDNet) that learns deep features from limited labeled samples is sufficient. Then, a deep regularizer with a convex form is designed via the Q-quadratic norm function to extract useful information from the rough solution generated by SGCDNet and guide the convex data-fitting, designed with an area-control mechanism, to select a brilliant solution. The proposed convex formulation can be implemented by convex optimizers, such as the alternating direction method of multiplier (ADMM), to achieve high computational efficiency with convergence guaranteed. The real-data experiment shows the superiority of the proposed HCD algorithm.**

I. Introduction

Change detection (CD) is a technique to identify the changed areas among multi-temporal images, which makes significant contributions to environmental monitoring, agriculture investigation, disaster assessment, and urban planning [1]–[4]. Changed pixels of multi-temporal images typically come with material variations at the same position on different dates. Compared to conventional SAR and multispectral images, the high-resolution spectral information of hyperspectral images (HSIs) can provide endmember identifiability [5], [6], which promotes the development of HSIs in the CD field. In this paper, we aim to solve the highly challenging hyperspectral change detection (HCD) problem.

Traditional CD methods mainly focus on analyzing the pixel-level information of the multi-temporal images to detect the changed areas. For example. multivariate alteration detection (MAD), a transformation based on correlations analysis, analyzes the multi-temporal images at the pixel-level [7]. Change vector analysis (CVA) [8] determines the changed areas by investigating the change vector of the multi-temporal images with the intensity of the change vector representing the change probability. In [9], a CD method first adopts principal component analysis (PCA) to learn information from non-overlapping blocks of multi-temporal images, then detect the changed pixels using k-means [10]. In order to enhance the accuracy, HSIs have been adopted for the CD task in recent years. Thanks to the abundant spectral bands of the HSIs, advanced models that developed to fully exploit the spectral information achieve highly precise detection in HCD problems. For example, the HCD algorithm in [11] detects the change map by analyzing the difference of the abundance maps of the bi-temporal HSIs generated by the sparse unmixing model. PTCD exploits the local similarity using a non-overlapping patch strategy followed by the tucker decomposition eliminating the influence of the HSIs, and a detector is designed to generate the change map [12].

Recently, convex optimization (CO), widely used in remote sensing imaging problems, has been adopted for multi-temporal satellite imaging CD. An unsupervised convex relaxation method, called CD-ADMM [13], explicitly defines a convex criterion for the CD problem. Therefore, the convex problem can be solved using the convex optimization solver, alternating direction method of multipliers (ADMM) [14], [15], with convergence guaranteed. Since the inverse problem of CD is ill-posed with non-unique solutions, regularization terms are necessary to mitigate the ill-posedness. However, conventional regularizers are unable to fit various scenarios and could come with time-consuming computing procedures. For example, CD-ADMM adopts the total variation (TV) regularization to preserve the piecewise smoothness of the output change map. When the changed pixels are scattered distribution, the performance of CD-ADMM could be significantly affected. Moreover, the large-scale data of HSIs causes a slow computational time when solving the proximal operator corresponding to the regularization term.

In recent years, deep learning (DE) has drawn attention

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

due to its ability to solve various computer vision tasks by learning deep features embedded in images. To solve HCD problems, convolutional neural network (CNN) structures have been designed to dig for the information and the relationship of the multi-temporal images. In the general end-to-end 2-D convolutional neural network (GETNET), cross-channel gradient information is extracted using a simple mixed-affinity matrix, then the CNN is proposed to generate the change map for the hyperspectral datasets [16]. A siamese 2-D CNN structure is designed in CSANet, which explores the spatial-spectral–temporal features embedded in the multi-temporal HSIs using attention modules [17]. HyperNet proposes a spatial-spectral attention module to investigate the spatial correlation and discriminative spectral features of multi-temporal HSIs [18]. Though DE-based methods have achieved state-of-the-art performance under sufficient training samples, the acquisition and labeling of HSIs are expensive and labor-consuming, making the applications of DE-based algorithms impracticable.

In light of this, we propose an HCD algorithm by introducing a small data-learning theory blending the advantages of CO and DE, called CODE, which has been designed for solving hyperspectral inverse imaging problems and has successfully tackled the highly challenging hyperspectral inpainting problem [19]. As aforementioned, the regularization term in CO could lead to math-heavy optimization procedures, while DE typically relies on big data to learn sufficient information to fit the problem. The CODE theory combines CO and DE to create a learning framework suitable for small data scenarios. Specifically, a simple network structure trained by small data generates a rough solution. Then, the simple convex criterion of the inverse problem obtains the final output by leveraging the deep features embedded in the rough estimate. In the proposed method, a simple graph change detection network (SGCDNet) based on graph neural network (GNN) learns deep features with limited training samples and generates a roughly estimated detection map. Note that an unadorned network structure is sufficient for the CODE theory. Then the convex criterion designed for small-data learning HCD detects the change map with an area-control mechanism controlling the changed area and a simple convex deep regularizer designed via the $\boldsymbol{Q}$-quadratic norm function extracting useful information from the rough output. Such an HCD criterion is implemented by ADMM to achieve a computationally efficient algorithm. The experimental results show the superiority of the proposed HCD method.

Notations: $\mathbb{R}^{m\times n}$ is the set of all the $m \times n$ real-valued matrices. $\mathbb{R}^n$ denotes the n-dimensional Euclidean space. $\|\cdot\|_p$ and $\|\cdot\|_F$ denote the p-norm and Frobenius norm, respectively. $\mathbf{1}$ is the all-one vector with dimension specified in the subscript. vec$(\boldsymbol{M})$ is the vectorization of matrix $\boldsymbol{M}$. $[\boldsymbol{v}]_i$ is the ith entry of vector $\boldsymbol{v}$. $[\boldsymbol{M}]_{(i,j)}$ denotes the (i,j)th entry of matrix $\boldsymbol{M}$. Diag$(\boldsymbol{v})$ denotes the diagonal matrix whose ith diagonal entry is $[\boldsymbol{v}]_i$. diag$(\boldsymbol{M})$ denotes the column vector whose ith entry is $[\boldsymbol{M}]_{(i,i)}$. conv is the convex hull [15]. $\mathcal{I}_Y$ denotes $\{1,\ldots,Y\}$ for any given positive integer Y. $\odot$ denotes the Hadamard product.

II. Proposed method

A. Convex HCD Criterion with Area-Control Mechanism

Let $\boldsymbol{X}_1 \in \mathbb{R}^{M\times L_1 L_2}$ and $\boldsymbol{X}_2 \in \mathbb{R}^{M\times L_1 L_2}$ be the HSIs covering the same area acquired at different dates, with M hyperspectral bands and $L = L_1 \times L_2$ pixels. Since the properties of an unchanged location across different dates should be similar, the distance between the unchanged pixels of the bi-temporal HSIs $\boldsymbol{X}_1$ and $\boldsymbol{X}_2$ is assumed to be small based on the different image (DI) analysis [9]. Then, the criterion of the HCD problem generating the change map $\boldsymbol{Z} \in \mathbb{R}^{L_1\times L_2}$ can be formulated as

$$\min_{[Z]_{(i,j)}\in\{0,1\},\forall(i,j)} \Big\{ \big\|(\boldsymbol{X}_1-\boldsymbol{X}_2)\text{Diag}\left(\text{vec}(\mathbf{1}_{L_1}\mathbf{1}_{L_2}^T-\boldsymbol{Z})\right)\big\|_F^2 + \eta\mathbf{1}_{L_1}^T\boldsymbol{Z}\mathbf{1}_{L_2} + \lambda\text{REG}(\boldsymbol{Z})\Big\}. \quad (1)$$

The first and second terms are the data-fitting DF$(\cdot)$, minimizing the difference of the bi-temporal unchanged pixels and constraining the area of the changed pixels, respectively. The last term REG$(\cdot)$ is the regularizer describing the characteristic of the change map to mitigate the ill-posedness.

While the data-fitting domain in (1) introduces non-convexity, preventing from the adoption of highly robust convex solvers (e.g., ADMM) to implement the algorithm. A convex relaxation is needed to design a convex criterion with convergence guaranteed. Therefore, the constraint can be relaxed as $\boldsymbol{Z} \in \text{conv}\left\{\{0,1\}^{L_1\times L_2}\right\} = [0,1]^{L_1\times L_2}$, which is its convex hull, the continuous probability domain. Then the HCD criterion can be rewritten into a convex form as

$$\min_{\boldsymbol{z}\in[0,1]^L} \|(\boldsymbol{X}_1-\boldsymbol{X}_2)\text{Diag}\left(\mathbf{1}_L-\boldsymbol{z}\right)\|_F^2 + \eta\mathbf{1}_L^T\boldsymbol{z} + \lambda\text{REG}(\boldsymbol{Z}), \quad (2)$$

where $\boldsymbol{z} = \text{vec}(\boldsymbol{Z})$. Though the formulation of the HCD problem has been represented as a convex form, which can be solved by convex optimizers with convergence guaranteed, the large-scale optimization procedure with complex mathematics introduced by the conventional regularizers (e.g., TV) is still time-consuming.

B. Small-Data Learning Criterion via CODE Theory

In order to solve the HCD problem under a limited training sampling rate with high computational efficiency, CODE theory is introduced to rule out the sophisticated mathematics in the regularization design. CODE, recently developed for hyperspectral inverse imaging problems, judiciously avoids sophisticated mathematics by combining DE into CO criterion [19]. Specifically, a simple convex form regularizer is designed via $\boldsymbol{Q}$-quadratic norm utilizing deep information embedded in small training data extracted by a simple network structure. The general criterion of the CODE theory can be formulated as

$$\boldsymbol{z}^\star = \arg\min_{\boldsymbol{z}} \ \text{DF}(\boldsymbol{z}) + \frac{\lambda}{2}\|\boldsymbol{z}-\boldsymbol{z}_{\text{DE}}\|_{\boldsymbol{Q}}^2, \quad (3)$$

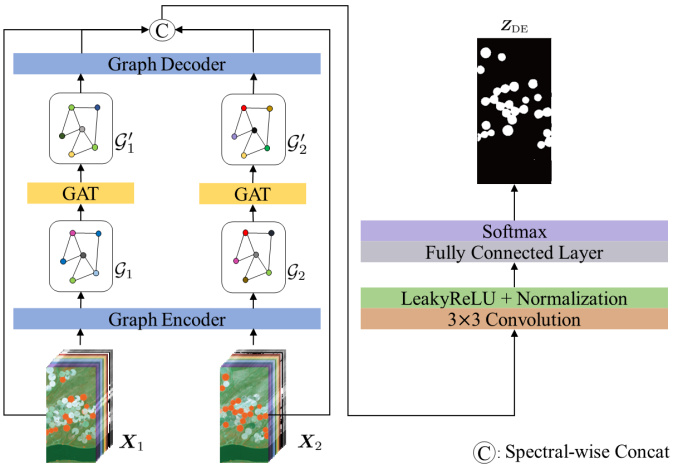

Fig. 1. Architecture of SGCDNet.

where the $\boldsymbol{Q}$-quadratic norm of the feature vector $\boldsymbol{v}$ is defined by $\|\boldsymbol{v}\|_{\boldsymbol{Q}}^2 := \boldsymbol{v}^T\boldsymbol{Q}\boldsymbol{v}$ [20]. Experiment evidence has suggested that the principal components analysis (PCA) is suitable for the design of the PSD matrix $\boldsymbol{Q}$ in $\|\cdot\|_{\boldsymbol{Q}}^2$ and has achieved state-of-the-art performance in the highly challenging hyperspectral inpainting problem [19]. For the HCD problem whose output is a gray-scale map, we design $\boldsymbol{Q}$ using the one-dimensional PCA, which is equivalent to the identity mapping $\boldsymbol{I}_L$. Then, the regularization term can be rewritten as

$$\text{REG}(\boldsymbol{z}) = \|\boldsymbol{z} - \boldsymbol{z}_{\text{DE}}\|_2^2. \tag{4}$$

Such a regularizer utilizes useful information in the training samples and guides the data-fitting DF$(\cdot)$ to select a suitable solution. To complete the small-data learning HCD algorithm based on the CODE theory, a simple graph change detection network (SGCDNet) is needed to be designed to acquire the rough solution $\boldsymbol{Z}_{\text{DE}}$, which will be detailed in Section II-C.

C. SGCDNet Design

As mentioned in Section II-B, a neural network is necessary for CODE theory to extract the deep information embedded in the labeled samples. To be more specific, we design a simple graph change detection network SGCDNet f_θ, where θ denotes the network parameters, to acquire the rough estimate $\boldsymbol{Z}_{\text{DE}} = f_\theta(\boldsymbol{X}_1, \boldsymbol{X}_2)$. By observation, the changed pixels tend to form small regions, which motivates us to study changed areas at the superpixel level. We believe that the relationship between the changed area and its neighbors will change when the region is changed across different dates. Therefore, the graph attention network (GAT) module [21], which automatically measures the importance of the neighboring superpixels by the attention mechanism, is adopted in SGCDNet.

The network structure of SGCDNet is shown in Fig. 1. In order to study at the superpixel level and reduce the data volume, the bi-temporal HSIs are firstly divided into superpixels by the simple linear iterative clustering (SLIC) method [22]. Linear discriminant analysis (LDA) [23] is applied to achieve dimension reduction before the superpixel segmentation. Then the graph $\mathcal{G}_i = (\mathcal{V}, \mathcal{E}),\ \forall i \in \mathcal{I}_2$, representing the bi-temporal HSIs, can be constructed by graph encoder [24], where $\mathcal{V}$ and $\mathcal{E}$ denote the nodes and edges, respectively. After constructing the graph, a single-head GAT layer [21] is adopted to extract the relationship between first-order neighborhood superpixels of $\mathcal{G}_1$ and $\mathcal{G}_2$. Then the feature graphs $\mathcal{G}_1'$ and $\mathcal{G}_2'$ are converted back to pixel level by graph decoder [24] and concatenated along the spectral dimension. To extract features at the pixel level, a convolution layer containing a 3×3 kernel with the Leaky Rectified Linear Unit (LeakyReLU) activation function is employed. Finally, the change map $\boldsymbol{Z}_{\text{DE}}$ is detected by a fully connected layer followed by a softmax function. The loss function of SGCDNet is designed based on cross-entropy, which is defined as

$$loss(\boldsymbol{Z}_{\text{GT}}, \boldsymbol{Z}_{\text{DE}}) = -\frac{1}{N}\sum_{i=1}^{N}\left([\boldsymbol{z}_{\text{GT}}]_i \log\left([\boldsymbol{z}_{\text{DE}}]_i\right)\right), \tag{5}$$

where N denotes the number of training pixels, and $[\boldsymbol{z}_{\text{GT}}]_i$ and $[\boldsymbol{z}_{\text{DE}}]_i$ represent the ith training pixels from the ground truth $\boldsymbol{Z}_{\text{GT}}$ and the network output $\boldsymbol{Z}_{\text{DE}}$, respectively.

D. Small-Data Learning HCD Algorithm and Implementation

By combining the convex deep regularizer (4) into the convex HCD criterion (2), the small-data learning HCD criterion can be written as

$$\min_{\boldsymbol{z}\in[0,1]^L} \|(\boldsymbol{X}_1 - \boldsymbol{X}_2)\text{Diag}\left(\boldsymbol{1}_L - \boldsymbol{z}\right)\|_F^2 + \eta\boldsymbol{1}_L^T\boldsymbol{z} + \lambda\|\boldsymbol{z} - \boldsymbol{z}_{\text{DE}}\|_2^2. \tag{6}$$

Note that both the data-fitting term and the regularization term are convex, leading to a convex criterion that can be solved by convex optimizers, e.g. ADMM. Then, we first define $\boldsymbol{Y} := \boldsymbol{X}_1 - \boldsymbol{X}_2 \equiv [\boldsymbol{y}^{(1)}, ..., \boldsymbol{y}^{(M)}]^T$, $\Psi := [\text{Diag}(\boldsymbol{y}^{(1)}), ..., \text{Diag}(\boldsymbol{y}^{(M)})]^T$, and $\psi := \text{diag}(\boldsymbol{Y}^T\boldsymbol{Y})$. The first term of criterion (6) can be rewritten as $\|(\boldsymbol{X}_1 - \boldsymbol{X}_2)\text{Diag}\left(\boldsymbol{1}_L - \boldsymbol{z}\right)\|_2^2 = \|\boldsymbol{Y}\|_F^2 + \|\Psi\boldsymbol{z}\|_2^2 - 2\psi^T\boldsymbol{z}$. To this end, we reformulate criterion (6) into general ADMM form as

$$\begin{aligned}&\min_{\boldsymbol{z}} \frac{1}{2}\|\Psi\boldsymbol{z}_1\|_2^2 + \left(\frac{\eta}{2}\boldsymbol{1}_L - \psi\right)^T\boldsymbol{z}_2 + \frac{\lambda}{2}\|\boldsymbol{z}_3 - \boldsymbol{z}_{\text{DE}}\|_2^2 + I_{\mathcal{Z}}(\boldsymbol{z}_4),\\ &\text{s.t. } \boldsymbol{z} = \boldsymbol{z}_i,\ i = 1, \ldots, 4,\end{aligned} \tag{7}$$

where the indicator function $I_{\mathcal{Z}}(\boldsymbol{z}_4)$ has value 0 if $\mathcal{Z} \in [0,1]^L$ (otherwise, ∞). Before solving criterion (7) via ADMM, we first write down the augmented lagrangian

$$\begin{aligned}&\mathcal{L}(\boldsymbol{z}, \{\boldsymbol{z}_i\}_{i=1}^4, \{\boldsymbol{d}\}_{i=1}^4)\\ &= \frac{1}{2}\|\Psi\boldsymbol{z}_1\|_2^2 + \left(\frac{\eta}{2}\boldsymbol{1}_L - \psi\right)^T\boldsymbol{z}_2 + \frac{\lambda}{2}\|\boldsymbol{z}_3 - \boldsymbol{z}_{\text{DE}}\|_2^2 + I_{\mathcal{Z}}(\boldsymbol{z}_4)\\ &+ \sum_{i=1}^{4}\frac{\mu}{2}\|\boldsymbol{z} - \boldsymbol{z}_i - \boldsymbol{d}_i\|_2^2,\end{aligned}$$

where $\mu > 0$ is the penalty parameter and $\boldsymbol{d}_i \in \mathbb{R}^L, \forall i \in \mathcal{I}_4$, are the scaled dual variable. Based on the ADMM theory [15],

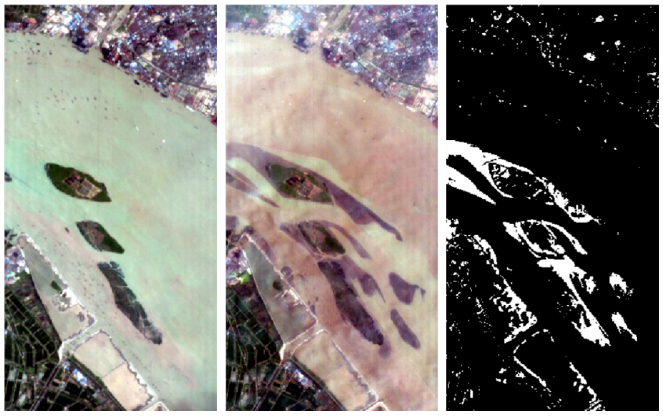
the global optimal solution $\boldsymbol{z}^\star$ can be obtained by iteratively updating the following subproblems until convergence:

$$\begin{aligned}\{\boldsymbol{z}_i^{q+1}\}_{i=1}^4 &= \arg\min_{\{\boldsymbol{z}_i\}} \mathcal{L}(\boldsymbol{z}^q, \{\boldsymbol{z}_i\}_{i=1}^4, \{\boldsymbol{d}^q\}_{i=1}^4),\\ \boldsymbol{z}^{q+1} &= \arg\min_{\boldsymbol{z}} \mathcal{L}(\boldsymbol{z}, \{\boldsymbol{z}_i^{q+1}\}_{i=1}^4, \{\boldsymbol{d}^q\}_{i=1}^4),\\ \boldsymbol{d}_i^{q+1} &= \boldsymbol{d}_i^q + \boldsymbol{z}_i^{q+1} - \boldsymbol{z}^{q+1},\ \forall i \in \mathcal{I}_4,\end{aligned}$$

where the subscript q is the iteration number. The closed-form solutions of the subproblems can be easily derived as

$$\begin{aligned}\boldsymbol{z}_1^{q+1} &= \mu[(\|\boldsymbol{y}_1\|_2^2+\mu)^{-1},\ldots,(\|\boldsymbol{y}_L\|_2^2+\mu)^{-1}]^T \odot (\boldsymbol{z}^q - \boldsymbol{d}_1^q),\\ \boldsymbol{z}_2^{q+1} &= \frac{1}{\mu}(\frac{\eta}{2}\mathbf{1}_L - \psi) + \boldsymbol{z}^q - \boldsymbol{d}_2^q,\\ \boldsymbol{z}_3^{q+1} &= \frac{1}{\mu}\boldsymbol{z}_{\mathrm{DE}} + \frac{1}{\lambda}(\boldsymbol{z}^q - \boldsymbol{d}_3^q),\\ [\boldsymbol{z}_4^{q+1}]_\ell &= \begin{cases} [\boldsymbol{z}^q - \boldsymbol{d}_4^q]_\ell, \text{ if } [\boldsymbol{z}^q - \boldsymbol{d}_4^q]_\ell \in [0,1],\\ 0, \text{ if } [\boldsymbol{z}^q - \boldsymbol{d}_4^q]_\ell < 0,\\ 1, \text{ otherwise,}\end{cases} \quad \forall \ell \in \mathcal{I}_L\ ,\\ \boldsymbol{z}^{q+1} &= \frac{1}{4}\sum_{i=1}^4 (\boldsymbol{z}_i^{q+1} + \boldsymbol{d}_i^q).\end{aligned}$$

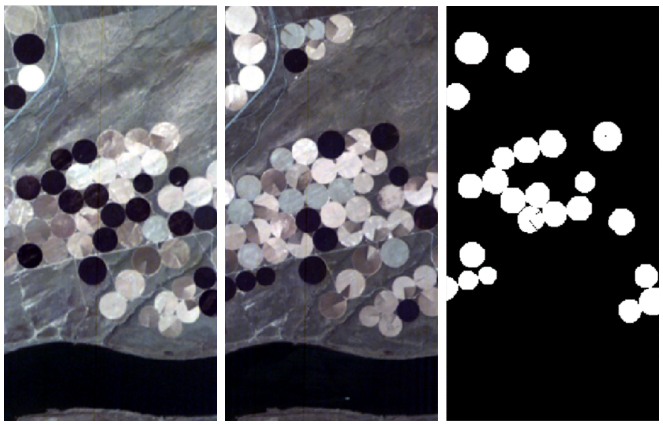
We have completed the proposed small-data learning hyperspectral change detection (SDL-HCD) algorithm, whose superiority will be experimentally demonstrated next in Section III.



III. Experimental results

A. Experimental Setting

In this section, we compare the proposed SDL-HCD with benchmark HCD methods, including MAD [7], PCTD [12], CD-ADMM [13], CSANet [17], and HyperNet [18]. Due to the lack of labeled HSIs, the experiment conducted on real hyperspectral datasets under a limited labeled rate condition set as 0.1% demonstrates the performance of the HCD algorithms in a practical scenario. For MAD, PCTD, CD-ADMM, HyperNet, and the proposed SDL-HCD, the final output binary change map is generated by the k-means classifier. The penalty parameter μ is set as 0.001 in this paper; note that if $\mu > 0$, the convergence of the algorithm is theoretically guaranteed, which only affects the convergence speed without changing the performance. The parameters η and λ, which govern the strength of regularization, are subjected to experimentation across a spectrum of values $\{10^n \mid n = -2, -1, 0, 1, 2, 3\}$. For the real-data experiment in this paper, the parameter set $(\eta, \lambda) = (100, 100)$ is cherry-picked from this testing phase due to its stable performance across diverse datasets. The superpixel scale, which controls the number of superpixels, is set as 60 for SGCDNet. SGCDNet is trained using Adam optimizer [25] with an initial learning rate of 0.0001, a decay of 0.9 every 10 epochs, and the number of epochs set to 450.



B. Datasets Description

In this paper, two widely used hyperspectral datasets, both containing two aligned bi-temporal HSIs and a ground-truth map marking the changed pixels and unchanged pixels with 1 and 0, respectively, are selected to investigate the efficacy of the HCD methods.

Fig. 3. Pseudo-color illustrations of the Hermiston dataset. (a) HSI acquired on May 1st, 2004. (b) HSI acquired on May 8th, 2007. (c) Ground-truth change map.

- The River dataset with a dimension of $L = 463 \times 241$ pixels and 242 spectral bands, ranging from 350 to 2580 nm, was captured by the Hyperion sensor over Jiangsu province, China, on May 3rd, 2013, and December 31st, 2013, respectively [16]. After removing low-quality bands, 128 high SNR bands are used in this paper. The main change area is focus on substance in the river. The pseudo-color images of the bi-temporal HSIs and the ground-truth map are shown in Fig. 2.
- The Hermiston dataset with a dimension of $L = 390 \times 200$ pixels and 242 spectral bands, ranging from 350 to 2580 nm, was captured by the Hyperion sensor over Hermiston city in Umatilla County, on May 1st, 2004, and May 8th, 2007, respectively [12]. After removing low-quality bands, 154 high SNR bands are used in this paper. The changed areas of this dataset are primarily rural change, including crops, soil, and water. The pseudo-color images of the bi-temporal HSIs and the ground-truth map are shown in Fig. 3.

C. Quantitative Assessment

To fairly compare the performance of the HCD methods, three representative quantitative assessments, i.e., overall accuracy (OA), kappa coefficient κ, and F1-score (F1), are adopted. Before introducing the quantitative indices, we first define TP, FP, TN, and, FN standing for true positives, false positives, true negatives, and false negatives, respectively. OA is the total accuracy of all the classified pixels and can be represented as

$$\mathrm{OA} = \frac{\mathrm{TP} + \mathrm{TN}}{\mathrm{TP} + \mathrm{TN} + \mathrm{FP} + \mathrm{FN}}.$$

Kappa coefficient κ is widely used to measure the classification results, which takes into account the inter-rater reliability, and provides a more robust evaluation than OA. We first define the hypothetical probability of chance agreement P_e as

$$\mathrm{P}_e = \frac{(\mathrm{TP} + \mathrm{FP})(\mathrm{TP} + \mathrm{FN}) + (\mathrm{FN} + \mathrm{TN})(\mathrm{FP} + \mathrm{TN})}{(\mathrm{TP} + \mathrm{TN} + \mathrm{FP} + \mathrm{FN})^2}.$$

Then, κ can be written as

$$\kappa = \frac{\mathrm{OA} - \mathrm{P}_e}{1 - \mathrm{P}_e}.$$

F1 is a widely used metric combining precision and recall indicators. The precision indicator is the ability of the algorithm to correctly identify positive pixels out of all predicted positive pixels, which can be defined as

$$\text{precision} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP}}.$$

On the other hand, the recall indicator is the ability of the algorithm to correctly identify positive pixels out of all actual positive pixels, and can be defined as

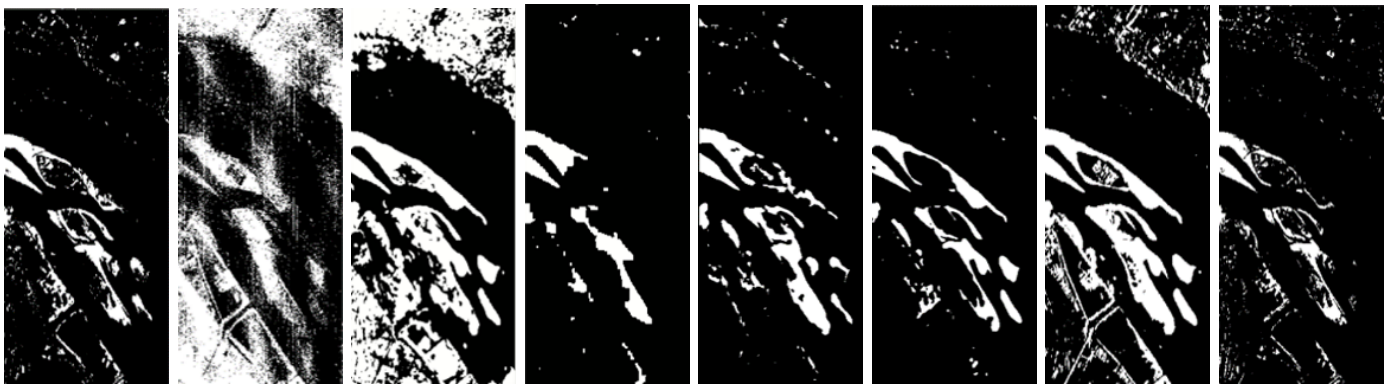
$$\text{recall} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}}.$$

F1-score is the harmonic mean of Pr and Re, particularly useful when dealing with imbalanced datasets, and can be written as

$$\mathrm{F1} = 2 \times \frac{\text{precision} \times \text{recall}}{\text{precision} + \text{recall}}.$$

Computational time (measured in seconds) is used to measure the computational efficiency. In this paper, all the experiments are conducted on the computer facility equipped with NVIDIA RTX 3090 GPU, AMD Ryzen 9 5950X CPU with 3.40-GHz speed, and 24-GB random access memory. All the DE-based algorithms are implemented on Python 3.10.9 and PyTorch 2.0.0. On the other hand, mathematical-based algorithms are performed on MATLAB R2023a.

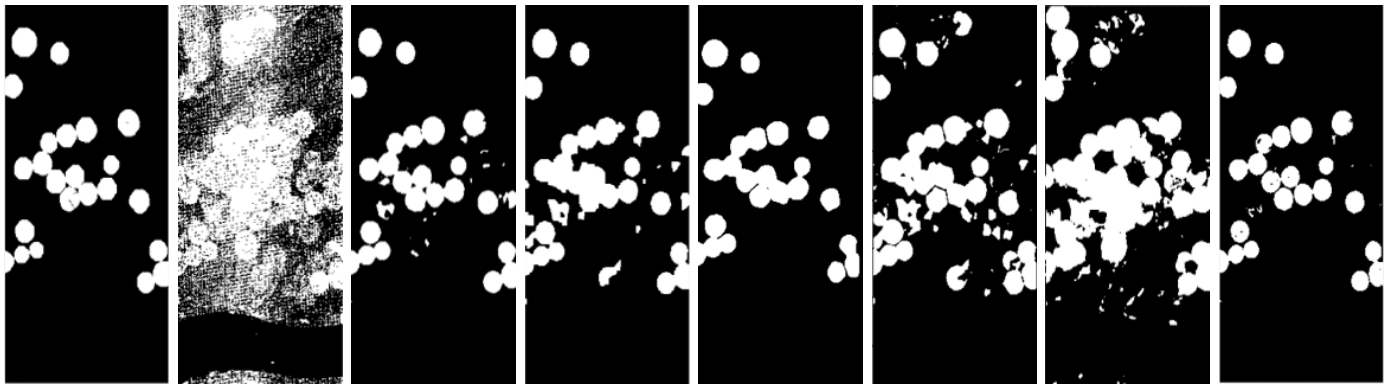
D. HCD Performance Under Limited Labeled Samples



Although DE-based algorithms trained by sufficient data have demonstrated their effectiveness in HSI imaging tasks, acquiring hyperspectral big data is very costly in practice, promoting the development of small-data learning and unsupervised learning. In light of this, we investigate the capability of the HCD algorithms, including unsupervised, self-supervised, and semi-supervised ones, under a limited sampling ratio scenario.

TABLE I
Quantitative comparison on the River hyperspectral datasets.

Method	OA↑	κ ↑	F1↑	time (sec.)
MAD	0.636	0.126	0.251	0.75
PCTD	0.709	0.263	0.367	240.05
CD-ADMM	0.950	0.637	0.663	411.90
CSANet	0.938	0.594	0.626	96.27
HyperNet	0.933	0.587	0.623	40.05
SGCDNet	0.815	0.365	0.446	33.67
SDL-HCD	**0.966**	**0.789**	**0.808**	34.12



1) Experiment on the River Dataset: The output binary change maps of the HCD algorithms are shown in Fig. 4, and the quantitative comparison is shown in Table I. As shown in Fig. 4(b), MAD is able to detect the changed pixels in the center of the river; however, there are too many false positives, especially at the river bank. MAD only relies on correlation analysis and does not make use of advanced spectral and spatial characteristics. This false-positives phenomenon also happens in Fig. 4(c), the change map of PCTD, which uses tucker decomposition as a high-order principle component analysis (PCA) to eliminate spectral variations between unchanged pixels. In the detection process, the tensor-based algorithm PCTD comes with a slow computational time, as shown in Table I. The CO-based algorithm CD-ADMM is able to avoid false positives at the river bank and detect most of the changed pixels, while the details of the changed regions on the river bank are lost, which is illustrated in Fig. 4(d). The performance is also reflected in the quantitative indices shown in Table I, achieving the second on all three indicators. However, the TV regularizer in CD-ADMM not only reduces the capacity to detect scattered distributed changed pixels but causes a time-consuming computational procedure, especially in handling the large-scale hyperspectral optimization problem. Though under the situation of limited training samples, DE-based algorithms are able to generate finer details of changed areas, thanks to the ability to learn deep features from labeled data. CSANet and HyperNet have decent performance, but the details are not well-detected due to the lack of training samples, as shown in Table I and Figs. 4(e) and (f). Both CSANet and HyperNet exploit spectral and spatial attention of the bi-temporal HSIs; however, CSANet further utilizes temporal attention to focus on the temporal variations, leading to a more precise detection than HyperNet. The change map of the simple network structure SGCDNet is shown in Fig. 4(g). SFGCDNet can detect the approximate changed regions but loses the details of the change map, owing to its simple structure. Though the output of SGCDNet is a rough solution, SDL-HCD can still utilize the useful information embedded in the rough estimate and achieve state-of-the-art performance, as shown in Table I. Note that the additional computational time brings by the optimization procedure of SDL-HCD is within one second, thanks to the judicious design of the deep regularization with a simple convex form.

2) Experiment on the Hermiston Dataset: The output binary change maps of the HCD algorithms are shown in Fig. 5, and

(a) (b) (c) (d) (e) (f) (g) (h)

Fig. 4. Change detection results of the CD algorithms on the River dataset. (a) Ground Truth. (b) MAD. (c) PCTD. (d) CD-ADMM. (e) CSANet. (f) HyperNet. (g) SGCDNet. (h) SDL-HCD.

(a) (b) (c) (d) (e) (f) (g) (h)

Fig. 5. Change detection results of the CD algorithms on the Hermiston dataset. (a) Ground Truth. (b) MAD. (c) PCTD. (d) CD-ADMM. (e) CSANet. (f) HyperNet. (g) SGCDNet. (h) SDL-HCD.

TABLE II
Quantitative comparison on the Hermiston hyperspectral datasets.

Method	OA↑	κ ↑	F1↑	time (sec.)
MAD	0.609	0.215	0.375	0.61
PCTD	0.976	0.897	0.911	100.89
CD-ADMM	0.960	0.838	0.861	143.82
CSANet	0.980	0.915	**0.927**	84.37
HyperNet	0.893	0.638	0.697	25.99
SGCDNet	0.927	0.736	0.776	23.45
SDL-HCD	**0.982**	**0.916**	**0.927**	23.76

the quantitative comparison is shown in Table II. MAD tends to generate massive false positives despite the computational time being fast, as shown in Fig. 4(b). CD-ADMM and PCTD both detect most of the changed pixels, while the false detection of CD-ADMM is a little more than PCTD in the center region of the image, as shown in Figs. 4(c) and (d). The piecewise smoothness promotion in CD-ADMM may lead to the unclearly separated edges of changed and unchanged regions, and cause a computational time about six times more than the proposed SDL-HCD, as demonstrated in Table II. As shown in Fig. 5(e), CSANet can detect the changed areas with the only defect that the boundary of the changed region is unclear. HyperNet generates false positives, as illustrated in Fig. 5(f), mainly due to the self-supervised training scheme. As shown in Fig. 5(g), there are massive false positives in the change map of SGCDNet, leading to lower κ and F1 values. SDL-HCD successfully extracts useful information from the rough estimate produced by SGCDNet and achieves state-of-the-art with a computational time about four times quicker than CSANet.

IV. Conclusions

In this paper, we propose a small-data learning algorithm with an area-control mechanism to solve the HCD problem, lacking big data in practical scenarios, by introducing the small-data learning CODE theory [19], which has been applied to highly challenging hyperspectral inverse problems, such as hyperspectral inpainting. A simple graph learning network SGCDNet, which can learn information from limited labeled samples using just a low inference time, is proposed based on the nature of CODE theory that a simple network structure is sufficient to guide the convex criterion to select a brilliant solution. Then, a simple convex deep regularizer, judiciously designed based on the $\boldsymbol{Q}$-quadratic norm function, trickly rules out the large-scale optimization procedure commonly coming with the traditional regularization term (e.g., TV) and successfully distills useful information from the roughly estimated solution generated by SGCDNet. Thanks to the

simple mathematical convex criterion, SDL-HCD can be implemented by the well-known convex solver ADMM to achieve a high computational algorithm. The proposed SDL-HCD outperforms benchmark methods in real-data experiments and shows its efficacy under a limited labeled sampling rate.

ACKNOWLEDGMENT

This study was supported partly by the EINSTEIN Program of National Science and Technology Council (NSTC), Taiwan, under Grant MOST 111-2636-E-006-028; and partly by the Emerging Young Scholar Program of NSTC, Taiwan, under Grant NSTC 112-2628-E-006-017. ***Abstract*—We propose an efficient Neural Architecture Search (NAS) method, named Zero-DNAS, for object detection tasks capable of discovering a suitable architecture under given memory and FLOPs constraints. NAS aims to explore the search space automatically to discover the best-performing network architectures for a given task. However, NAS is resource-consuming and usually requires hundreds of hours of GPU computations to discover a neural network architecture with good performance. Especially for more extensive and complex computer vision tasks such as object detection, the computing time and memory when conducting NAS would increase dramatically. Practically, the conventional sampling-based NAS methods do not guarantee the best possible solutions, whereas differentiable methods require substantial memory resources, making it challenging to apply in macro search space settings. In comparison, we propose a differentiable NAS paradigm with zero-cost proxy metrics and aims to determine the architecture within the constraints of memory and FLOPS. The experiments on object detection datasets show that our proposed algorithm can discover more accurate and faster architectures in a heavy macro search space in less than 2 NVIDIA 2080TI GPU hours.**

I. Introduction

With the rapid progress in deep learning, numerous neural network architectures are required to satisfy particular demands in terms of performance and efficiency. Under the settings of a specific task, Neural Architecture Search (NAS) can relieve researchers from the complexities of architectural design by automatically exploring the search space to discover the best-performing network architecture. The solutions found must also be compact enough for practical scenarios, such as self-driving cars or other tracking[1][2] algorithms that require real-time inference on edge devices under hardware constraints. Hence, NAS algorithms must be hardware-aware and capable of searching for network architectures based on specific targets (i.e., hardware constraints), such as the number of floating-point operations per second (FLOPS) and the number of network parameters.

In addition, NAS is a computationally demanding technique that may require thousands of hours of GPU computations to discover a compact and objective neural network architecture. With recent advances in the NAS field, the time required for performing a search has been significantly reduced. One-shot sampling-based methods, such as [3]–[5], have substantially accelerated the NAS process by sharing weights across multiple candidates and avoiding training every architecture from scratch. However, such sampling-based algorithms still need to be faster and may lead to discovering suboptimal architectures because they treat NAS as a black-box optimization problem over a discrete sample domain, requiring numerous architecture evaluations to generate a solution.

Some studies propose differential NAS (DNAS)[6], [7] formulating the search problem in differentiabl way. Continuous relaxation of the search space allows gradient descent-based architecture discovery, reducing search time while maintaining performance. However, DNAS's fixed cell structure across all layers may not be optimal due to varied layer impacts[8]. Moreover, DNAS is usually unsuitable for a macro-architecture search space like FBNet[9] because parallel feature processing at every layer consumes considerable memory resources and substantially restricts its utility.

Recently, pruning at initialization techniques[10]merged into NAS, leading to new research field in NAS, Zero-Cost Proxies. Despite mathematical advances[11][12]. most focus on small spaces and simple tasks[10][13], and didn't prove the effectiveness on large search space and complex task like object detection.

This paper addresses the crucial and challenging task of developing an efficient and reliable NAS algorithm, specifically designed for demanding tasks such as object detection. Our proposed method builds upon the differentiable NAS paradigm, offering significant enhancements. Firstly, we incorporate zero-cost proxy performance metrics into a differentiable NAS algorithm, thereby eliminating the need for expensive network training. This design opens up the possibility for differentiable NAS to be applied in large macro-architecture search spaces, resulting in a greatly accelerated search process. Furthermore, we introduce a mechanism to meet user-defined computational and memory constraints, ensuring the discovered architecture is tailored to specific requirements. Lastly, we propose a novel layer-depth regulation strategy, forcing the algorithm to discover architectures that provide higher inference speeds.

The primary contributions of this work can be summarized

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

as follows:

- We introduce a novel zero-cost Differentiable Neural Architecture Search algorithm (Zero-DNAS), which is capable of efficiently discovering architectures for object detection tasks while keeping search time and memory consumption minimal. The resulting architectures exhibit superior performance and high inference speed.
- Zero-DNAS is specifically designed to satisfy the user-defined parameters and FLOPS constraints, ensuring the discovery of the most accurate model tailored to individual needs.
- We also propose a layer-depth constraint to ensure the final discovered architecture provides a rapid inference speed. Our findings indicate that maintaining a low layer count helps to discover faster models.

II. Related Work

This section discusses sampling-based search algorithms that treat the exploration procedure as a black-box optimization task over a discrete space. Moreover, we also detail differentiable solutions that address the search problem in a differentiable way using gradient descent. Also, we review the NAS algorithms specifically designed to handle object detection tasks.

A. Sampling-based search

In early Neural Architecture Search (NAS) studies like Zoph et al.[14], Reinforcement Learning (RL) methods were used with a recurrent neural network (RNN) controller for sampling and training candidate architectures. However, this approach proved computationally expensive and time-consuming due to training numerous candidate networks from scratch.

Efficient Neural Architecture Search (ENAS) [3] introduced a weight-sharing mechanism. The RL controller samples a candidate network, inheriting weights from a pre-existing larger network (supernet). After training the candidate network, weights and validation accuracy update the supernet's weights and RL controller.

However, ENAS[3] faces a weight coadaptation problem, leading to suboptimal results. To address this, SPOS[4] suggested a uniform sampling training procedure to replace the RL controller. Additionally, AttentiveNAS[15] improved the sampling procedure by considering the Pareto front of subnetwork performance. Notably, search algorithms in [4][15] use evolution algorithms, adding a stage to the overall architecture search process.

For enhanced efficiency in searching, Cream[16] proposed prioritized paths based on subnetwork accuracy during training. Real-time prioritization, considering performance and complexity, eliminates the need for complex RL or evolutionary searches.

B. Differentiable search

Contrary to traditional methods that approach architecture search as a non-differentiable problem involving a discrete search space, DNAS-based methods offer an innovative approach by framing the search process as a continuous, differentiable optimization problem. A pioneer work in this area, DARTS[6], utilized the concept of continuous relaxation to represent architectural configurations, thus enabling the application of gradient descent techniques for architecture search. However, DARTS[6] represents its architectures at the cell level and utilizes complex directed acyclic graphs for representation. Despite the flexibility, it has been shown to lead to efficiency issues[9]. Also, this cell-level structure tends to neglect the possibility of varied structures at different network depths.

In a different approach, Wu et al. [9] designed a layer-wise search space that incorporates a pre-determined macro-architecture. Here, each layer has the freedom to select distinct blocks, whose types are determined dynamically during the search process. This flexible architecture setup is advantageous for the discovery of more precise models. However, despite the impressive performance of DNAS methods in classification tasks, they still require training the network parameters, which is time-consuming, memory-inefficient, and challenging to apply in more complex tasks such as object detection.

C. Object detection NAS

Most NAS methods primarily focus on architecture design for image classification and directly apply the discovered configurations as backbones for object detection. However, this approach can lead to suboptimal outcomes due to a task gap. Recently, a subset of Neural Architecture Search (NAS) methods targeting object detection architectures has emerged, including [17][18][19][20][21]. These methods harness object detection loss to identify superior architectures, but they are computationally demanding, relying on powerful GPUs with substantial memory to complete the search.

OPANAS[17]proposes a complex feature pyramid network (FPN) search space involving a densely connected directed acyclic graph representing diverse FPN structures. However, the intricate FPN structure is unsuitable for real-time applications. NAS-FCOS[18] aims to discover architectures for FPNs and detection heads, inspired by the anchor-free object detector FCOS[22] using an RL paradigm.

In contrast, DetNAS[19] employs a sampling-based training and evolution algorithm to search for the detection backbone. Although both methods[18][19] achieve high accuracy, their focus is limited to specific parts of the detection module.

SM-NAS[20] strives to identify efficient module combinations and modular-level architectures for object detection. This method covers multiple stages in the object detection pipeline, including the backbone, feature fusion neck, RPN, and detection head. The authors introduce a two-stage structural-to-modular strategy to optimize module combinations and architecture.

III. Proposed Method

This section offers an in-depth explanation of our proposed search algorithm. We begin by defining the problem

TABLE I: The candidate configurations of each block within the proposed ScaledYOLOv4 [23] and YOLOv5 [24] search spaces. Each "backbone" CSP block (or C3 block for YOLOv5) has 12 distinct choices and each "neck" CSP2 block has 4 variations for choosing. Note that YOLOv4-CSP large is used to search for larger and accurate model while YOLOv4-CSP small is for smaller and compact model. Please refer to Fig. 2 for a detailed explanation of the channel split (γ) and depth (d).

Model part	Block type	YOLOv4-CSP large		YOLOv4-CSP small		YOLOv5	
		γ	d	γ	d	γ	d
Backbone	CSP/C3	0.25	2	0.25	0	0.25	0
Backbone		0.25	4	0.25	2	0.25	3
Backbone		0.25	6	0.25	4	0.25	6
Backbone		0.25	8	0.25	6	0.25	9
Backbone		0.50	2	0.50	0	0.50	0
Backbone		0.50	4	0.50	2	0.50	3
Backbone		0.50	6	0.50	4	0.50	6
Backbone		0.50	8	0.50	6	0.50	9
Backbone		0.75	2	0.75	0	0.75	0
Backbone		0.75	4	0.75	2	0.75	3
Backbone		0.75	6	0.75	4	0.75	6
Backbone		0.75	8	0.75	6	0.75	9
Neck	CSP2/C3	0.50	2	0.50	2	0.50	0
Neck		0.50	4	0.50	4	0.50	3
Neck		0.50	6	0.50	6	0.50	6
Neck		0.50	8	0.50	8	0.50	9

setting. Subsequently, we present the structure search space, encompassing the macro-architecture and the possible block configurations. After that, we detail the search process in our proposed Zero-DNAS algorithm. Lastly, we elaborate on the hardware constraints and our newly proposed depth-aware loss.

A. Problem definition

The overall objective of the classical NAS problem is formulated as follows:

$$\min_{\alpha \in A} \min_{w_\alpha} L(\alpha, w_\alpha) \tag{1}$$

where A is a search space and α is an architecture candidate from the search space. The goal is to determine an architecture α that yields the best performance after training its weights w_α. In most cases, the main bottleneck in computation time and memory capacity is the inner part of network weight training; hence, the focus is on optimizing this part of the problem. To validate these ideas, we designed a search space, which is introduced in the following subsection.

B. Search space

Besides the cell-level search spaces [26], [27], this work employs a layer-wise search space with a predetermined macro-architecture. This architecture is segmented into stages, with each stage aligning with a layer. We demonstrate our algorithm's versatility and draw on prior handcrafted models by independently crafting search spaces for ScaledYOLOv4[23] and YOLOv5[24].

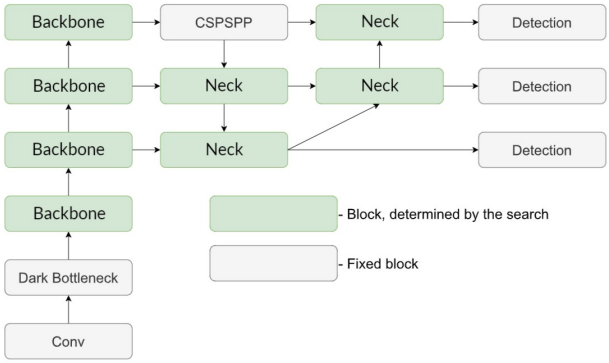

Fig. 1: The layer-wise macro-architecture search space for ScaledYOLOv4 [23], where NAS determines the design of the eight searchable (highlighted in green) blocks. Each block (also known as a layer or stage) is optimized to find a suitable network configuration from the available candidate sets. Refer to Fig. 2 for a detailed structure of the searchable block.

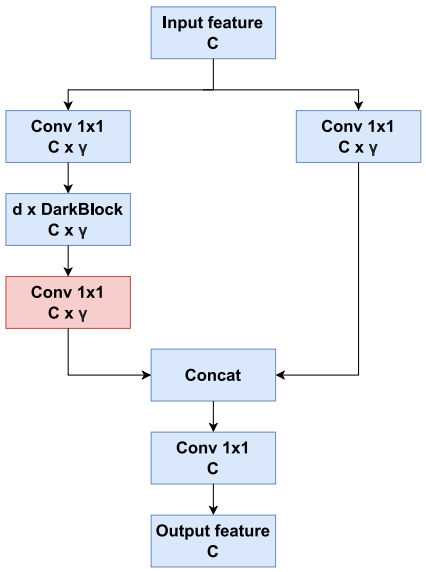

Fig. 2: The illustration of the CSP structure used in ScaledYOLOv4 search space. Here, C is the channel number, while γ is the reduction ratio of the channel for two parallel branches. Also, d determines the number of Darknet53 [25] modules used to extract more informative features. Note that the C3 block used in the YOLOv5 search space has a similar structure, except it does not include the module depicted in red.

Fig.1 introduces the ScaledYOLOv4[23] macro-architecture search space. YOLOv5[24] macro-architecture isn't depicted due to space limits, but both have 8 searchable stages (4 for backbone and 4 for neck blocks). Our algorithm seeks the optimal block structure in each green stage, while the gray stages remains fixed. The structure of the green block with adjustable parameters is shown in Fig. 2. As outlined in Table I, each backbone block offers 12 candidate configurations, and each neck block has 4 choices. The proposed object detector architecture search space comprises 8 layers, each selecting

a candidate block. This yields approximately $5 \cdot 10^6$ possible architectures (i.e., $12^4 \cdot 4^4$) for both ScaledYOLOv4[23] and YOLOv5[24] search spaces, making architecture optimization extremely demanding.

C. Search procedure

1) Preliminary of DNAS: We adopt a DNAS approach to solve Eq. (1). At each layer, a block b_l is independently sampled from a set of candidate blocks $b_{l,i}$ according to the probability $P_{\theta_l}(b_l = b_{l,i})$ (which we aims to optimize). The probability of sampling a complete architecture α can be computed as

$$P_\theta(\alpha) = \prod_l P_{\theta_l}(b_l = b_{l,i}). \tag{2}$$

To make the procedure differentiable, we use Gumbel softmax[28], introducing Gumbel random noise $g_{l,i}$ to $\theta_{l,i}$. θ represents an architecture importance matrix, $\theta_{l,i}$ signifies the importance of choosing the ith block at layer l, and τ controls Gumbel softmax softness. Throughout training, τ decreases to reach a one-hot value (selecting one configuration per block). $P_{\theta_l}(b_l = b_{l,i})$ is denoted $m_{l,i}$ in Eq. (3) for symbol simplification.

$$\begin{aligned} P_{\theta_l}(b_l = b_{l,i}) = m_{l,i} &= \text{GumbelSoftmax}(\theta_l) \\ &= \frac{\exp\left[(\theta_{l,i} + g_{l,i})/\tau\right]}{\sum_i \exp\left[(\theta_{l,i} + g_{l,i})/\tau\right]}. \end{aligned} \tag{3}$$

To facilitate forward and backward propagation of DNAS (Fig. 3), DNAS generates the feature map, x_{l+1}, for layer $l+1$ by summing weighted feature maps from different candidate blocks $b_{l,i}(x_l)$. This can be represented as:

$$x_{l+1} = \sum_i m_{l,i} \cdot b_{l,i}(x_l). \tag{4}$$

With these modifications, the DNAS problem is relaxed to learn the probability distribution P_θ of the block importance parameter θ and the network parameters w_α in the supernet (which combines all block configurations), aiming to minimize expected loss. This leads to an optimization problem formulated in the following:

$$\min_\theta \min_{w_\alpha} E_{\alpha \sim P_\theta} L(\alpha, w_\alpha). \tag{5}$$

However, the training procedure to determine network weights (w_α) is time-consuming and limits the size of candidate pools in DNAS methods. Also, in DNAS settings, all candidate blocks are trained simultaneously, making it require substantial memory resources and infeasible on a typical GPU device.

2) Zero-DNAS algorithm: To mitigate the issues of training time and memory consumption, we propose an innovative solution to the problem defined in (5). We score each block configuration within the supernet using a zero-cost metric, WOT (WithOut Training) [29]. Intuitively, a superior network architecture for downstream tasks should effectively differentiate between two different input images, even when using randomly assigned network weights. Under the assumption, WOT assesses the similarity between the activation outputs of a **randomly initialized** network subjected to varying inputs.

By integrating WOT into the DNAS process, we establish our Zero-DNAS algorithm which eliminates the costly inner optimization (i.e., finding the optimized w_α) and substantially reduce the search time and memory cost. Compared to the original NAS problem (equation (1)), after employing the WOT metric, our new optimization objective aims to learn the distribution of the architecture importance parameters(P_θ) and maximize the following expected score:

$$\max_\theta E_{\alpha \sim P_\theta} WOT(\alpha) \tag{6}$$

The WOT metric for each possible block wot_l, i is computed at the network initialization stage and requires only one forward propagation pass through the randomly initialized network. Thus, our method makes the search space for DNAS more flexible and allows the use of larger block configuration pools.

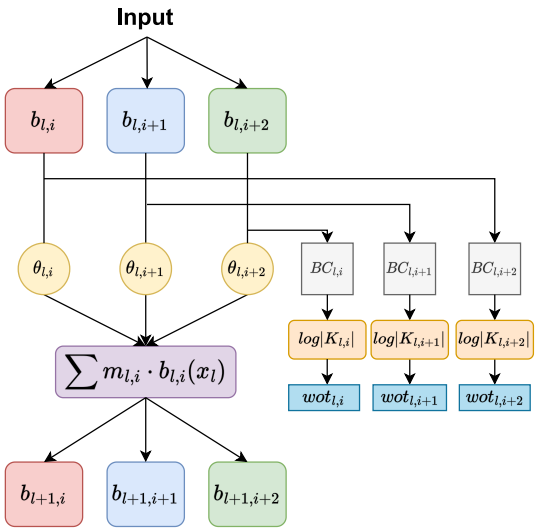

Fig. 3: The illustration of the block score $wot_{l,i}$ computation. First, activation patterns from a block $b_{l,i}$ are represented as binary codes ($BC_{l,i}$). Then, the correlation matrix ($K_{l,i}$) is formed based on the Huffman distances between the binary codes. Ultimately, the $wot_{l,i}$ is computed by taking the logarithm of the derivative of $K_{l,i}$.

At the beginning of the search procedure, we set all architecture importance parameters (i.e., θ) the same for every block. Next, we performed one forward pass through the supernet, computed the block WOT score $wot_{l,i}$ for every $b_{l,i}$ (Fig. 3) and stored them in a look-up table. Specifically, to compute $wot_{l,i}$, we binarize block activation outputs of k input images into k long binary vectors. Next, we build a $k \times k$ correlation matrix, $K_{l,i}$, for each block by calculating the Hamming distances among those binary vectors. The lower the correlation of the matrix, the better the performance of a candidate architecture is expected. Thus, $wot_{l,i}$ is computed by taking the logarithm of the derivative of $K_{l,i}$. Finally, the

WOT metric of the whole supernet is formulated as follows:

$$WOT(\alpha) = \sum_{l}\sum_{i} m_{l,i} \cdot wot_{l,i}$$
$$\text{where} \quad wot_{l,i} = log|K_{l,i}|. \tag{7}$$

Finally, the importance parameter $\theta_{l,i}$ is updated by backward propagation using the gradient of $WOT(\alpha)$ w.r.t $\theta_{l,i}$, which flows through the $m_{l,i}$ continuous variable in (3).

D. Hardware constraints

The optimization of Eq. (6) focuses solely on accuracy. However, the complexity of the searched architecture must also align with the target device. Thus, we introduced two terms to align the search algorithm with specified hardware constraints. We employed FLOPS count for computation cost and parameter count for memory footprint. The FLOPS loss is formulated by using mean squared error (MSE):

$$L_{flops}(\alpha) = (f_t - \log(f(\alpha)^{\beta}))^2 \tag{8}$$

where f_t is the specified target FLOPS, $f(\alpha)$ denotes the overall FLOPS of the model, and β is a hyper-parameter.

Similarly, the parameter loss term is computed as follows:

$$L_{params}(\alpha) = (p_t - \log(p(\alpha)^{\lambda}))^2 \tag{9}$$

where p_t corresponds to the target parameter number, $p(\alpha)$ represents the overall number of parameters, and λ is a hyper-parameter. Here, $f(\alpha)$ and $p(\alpha)$ are computed as

$$f(\alpha) = \sum_{l}\sum_{i} m_{l,i} \cdot f_{l,i} \tag{10}$$

$$p(\alpha) = \sum_{l}\sum_{i} m_{l,i} \cdot p_{l,i} \tag{11}$$

, where the precomputed $p_{l,i}$ and $f_{l,i}$ correspond to the parameters and FLOPS of a block $b_{l,i}$, respectively.

E. Depth-aware loss

Although the number of FLOPS correlates with model efficiency, architectures with fewer FLOPS don't always equate to faster inference speed. We find shallow and wide models are usually faster than their deeper and narrower counterparts. Thereby, we incorporate the following depth-aware loss into the optimization procedure to favor computationally efficient designs.

$$L_{depth}(\alpha) = \sum_{l}\sum_{i} d(\alpha) \cdot \omega \tag{12}$$

$$d(\alpha) = \sum_{l}\sum_{i} m_{l,i} \cdot d_{l,i} \tag{13}$$

where ω is a hyper-parameter to control this term's influence, $d_{l,i}$ denotes the depth of i^th candidates block in l^th layer.

In the end, the final loss function for optimization takes the following form:

$$L(\alpha) = -WOT(a) \cdot \psi + L_{flops}(\alpha) + L_{params}(\alpha) + L_{depth}(\alpha). \tag{14}$$

Also, the original objective function in (6) is replaced by the constraint-aware optimization problem, defined as

$$\min_{\theta} E_{\alpha \sim P_\theta} L(\alpha). \tag{15}$$

Algorithm 1 outlines the step-by-step search process. The searching algorithm takes the following items as the inputs: (a) the target/hardware constraints for FLOPS (f_t) and parameters (p_t), (b) the pre-defined searching space defining the number of searchable layers and the candidate network blocks for each layer, and (c) the pre-calculated metrics dictionary, $dict = (F_s, P_s, D_s, W_s) = (\{f_{l,i}\}, \{p_{l,i}\}, \{d_{l,i}\}, \{wot_{l,i}\})$, including the cost sets from the FLOPS constraints, the parameter constraints, the depth constraints, and the WOT values. It finally outputs the most fitting neural architecture as a result.

During the search process, the metrics for the whole supernet are computed (lines 4–8 of Algorithm 1). Next, the overall loss is calculated (lines 9–13 of Algorithm 1), and updating architecture importance parameters θ (line 14). Finally, the best architecture is acquired by sampling the blocks at every layer according to the θ distribution (line 18).

Algorithm 1 The proposed architecture search

Input: Target constraints: f_t, p_t; Pre-defined Searching Space: (l, i) indicates the ith candidate network block in the lth layer; Initialize equal importance θ for all candidate blocks; Pre-calculated Metrics dictionary: $dict = (F_s, P_s, D_s, W_s) = (\{f_{l,i}\}, \{p_{l,i}\}, \{d_{l,i}\}, \{wot_{l,i}\})$; Temperature τ;

IV. Experimental Results

This section demonstrates the experimental results and compares the proposed method with previous NAS algorithms under different object detection architectures. The detection

performance is evaluated using multiple datasets, which are described in the first subsection. Next, we provide details about the evaluation metrics used in the experiments and the comparison. Following that, we present the implementation details for the search method and hyper-parameters used in the experiments. Finally, we showcase the comparison results and ablation studies, demonstrating that the proposed method can discover hardware-aware architectures using significantly less GPU time and memory resources.

A. Datasets & evaluation metrics

To prove these concepts, we conducted experiments on two benchmark datasets for object detection tasks: "Common Objects in Context (MSCOCO)" and "VOC". The MSCOCO dataset includes images of various scenes containing 80 classes of objects in their natural environments. Overall, it consists of 118,000 images in the training set and 20,000 images for testing. The VOC dataset with 20 classes, includes 5,000 images for the training and testing set respectively.

To evaluate the proposed algorithm and compare it with other approaches, we utilized the overall search time to assess the efficiency of NAS methods. Additionally, we employed mean average precision (AP) and average precision at $IoU = 50$ (AP50) to measure the detection performance. To estimate the efficiency of a network architecture, we calculated three metrics: (a) the number of FLOPS for evaluating computational cost, (b) the number of parameters for memory-cost evaluation, and (c) the number of frames per second (FPS) that the model can process, serving as a metric for inference speed.

B. Implementation details

For Zero-DNAS implementation, we used these hyper-parameters: $\beta = 0.01$, $\gamma = 0.03$, $\psi = 0.01$, $\omega = 0.005$, $\tau = 3$, and a τ decay of 0.065. During the search process, the Mish and Swish activations were substituted with ReLU to compute the score, as this has a minimal impact on network representation power [30]. The search ran for 40 epochs, 2,880 iterations per epoch, with τ decreasing every epoch.

Next, we constructed model architectures based on the search results and trained them from scratch to estimate their final performance. Following the search phase, we conducted model training for 300 epochs using the stochastic gradient descent optimizer with a momentum of 0.937 and a learning rate of 0.01. Moreover, we followed a cosine annealing schedule and set the weight decay to 0.0005. The same data augmentation techniques employed in the ScaledYOLOv4 and YOLOv5 algorithms were applied to train models derived from various search spaces. For estimating model inference speeds, we executed the models on the NVIDIA 2080Ti GPU.

C. Results and Comparison

1) Comparison with the manually designed configurations: In this subsection, We compare our method with manual designs from ScaledYOLOv4 and YOLOv5. Table II shows better accuracy and latency of our discovered architectures on the VOC dataset. Notably, the Zero-DNAS architecture, discovered from the 'YOLOv4-CSP small' search space (as defined in Table I), demonstrates a 0.6 higher average precision (AP) and approximately a 32% faster inference compared to ScaledYOLOv4 [23]. Furthermore, Zero-DNAS-L (discovered from the "YOLOv4-CSP large" search space) achieves a 0.5 higher AP and approximately 48.64% faster inference compared to ScaledYOLOv4-P5 [23]. In the YOLOv5 space, v5-Zero-DNAS-L and v5-Zero-DNAS-M match accuracy with YOLOv5-L/M, but with significantly faster speeds. Notably, fairness ensured with similar FLOPS and parameters.

2) Comparison with other NAS algorithms: Next, we conduct comparisons with other sampling-based and differentiable NAS methods. As shown in Table III, Zero-DNAS outperforms other NAS methods. It significantly reduces the search time, outperforming recent methods by 60x, while achieving a more efficient and accurate model configuration. Furthermore, unlike the DNAS algorithms with macro-architecture search spaces such as FBNet [9], which encounter memory exhaustion in complex object detection tasks, our method successfully completes the search procedure.

We further compared the models discovered using the proposed Zero-DNAS method with other recent NAS-designed object detection architectures on the MSCOCO dataset. The results are presented in Table IV. Our algorithm excels in both time and GPU memory usage, operating 50x faster and utilizing 10x less GPU memory, all while maintaining high performance and efficiency in the resulting architecture.

3) Ablation study of hardware constraints: In this subsection, we analyze the impact of hardware constraints on the search procedure and the discovered architecture. Table V presents the effects of different losses on the search process and showcases the performance of the discovered architecture. The results indicate that the algorithm closely follows the chosen target constraints. Nevertheless, amalgamating the FLOPS, parameters, and depth losses offers greater control over the search process. When the depth constraint is removed, the algorithm tends to prioritize deeper networks at the cost of a drop in FPS. Similarly, relaxing the parameter constraint results in a higher AP but leads to a larger model size.

V. Conclusions

This work introduces an efficient and differentiable Neural Architecture Search (NAS) algorithm for object detection, capable of identifying precise and efficient architectures under specific hardware constraints in less than 2 hours. Utilizing standard GPUs, such as the NVIDIA 2080Ti, our method demonstrates the feasibility of conducting NAS for complex object detection tasks, providing an advantage over traditional DNAS methods that demand high-end GPUs. By leveraging a training-free metric (WOT) to score network initialization within a differentiable architecture search framework, we can discover highly accurate object detection models subjected to specific FLOPS and parameter requirements. Through the incorporation of a depth-aware loss, the proposed approach ensures enhanced inference speeds. The resulting object de-

TABLE II: The performance of architectures discovered in the ScaledYOLOv4 and YOLOv5 search spaces was evaluated on the VOC dataset using an NVIDIA 2080Ti device. For fair comparisons, the FLOPS and parameters of our models configurations were set to match the manually designed counterparts: ScaledYOLOv4-P5, ScaledYOLOv4, YOLOv5-L, and YOLOv5-M.

Model	AP50	AP	FLOPS	Target FLOPS	Parameters	Target Parameters	FPS

***Abstract* — Vehicle tracking has always been a vital aspect of modern transportation systems. This phenomenon has gained even more interest with the introduction of Advanced Driver Assistance Systems (ADAS) and Autonomous Vehicles. Most state-of-the-art (SOTA) vehicle trackers, and their enhanced versions, commonly rely on mathematical motion models (e.g., Kalman Filter) as the core information. However, these models may produce unreliable outputs, especially when objects exhibit complex motion patterns. Hence, we propose a reliable feature-based tracking framework that fully exploits distinct vehicle appearance and conduct a comparative analysis with classic motion-based trackers. Additionally, we revisit previously proposed track handling strategies to incorporate a specially designed track management system for feature-based tracking. The proposed method achieves the highest score on all selected multi-object-tracking (MOT) evaluation metrics compared to the current SOTA methods on the KITTI dataset. Notably, our approach experienced significantly low False Positive (FP) errors, ensuring its performance in minimizing unreliable information.**

I. INTRODUCTION

Multi-object tracking (MOT) has gained significant popularity in the field of computer vision, finding applications in various domains such as robotic perception, complex medical imaging, and surveillance management. In the context of Autonomous Vehicles and ADAS, object tracking plays a critical role. By continuously monitoring the positions and trajectories of vehicles, pedestrians, and other objects, the tracking framework provides essential information for autonomous systems to make decisions and take appropriate actions. It is a vital component that contributes to the perceptual aspects of autonomous vehicle systems, including navigation, path planning, and even the advanced Vehicle-to-Infrastructure (V2I) tasks related to traffic management.

Vehicle Tracking has been dominated by the tracking-by-detection (TBD) paradigm, which leverages the innovative performance of modern object detectors to enhance tracking accuracy. Specifically, TBD can be seen as a data association approach that aims to match the detections across frames in a sequence. Currently, two popular TBD methods are being extensively researched and developed: motion-based tracking and feature-based tracking.

Motion-based tracking has recently gained favor in TBD field. This approach heavily relies on mathematical motion models, specifically the Kalman Filter, to calculate motion cues such as velocity, direction, and acceleration. These cues are then used to predict the object's location within a frame. Despite its inability to accurately estimate object location, this method is popularly employed due to its computational efficiency and robust performance in the presence of noise, such as changes in lighting conditions or object appearance variations.

One example of a motion-based tracking method is SORT [1], which utilizes Kalman Filter to predict object's state and adopts the Intersection over Union (IoU) and Hungarian algorithm to associate tracks across a video sequence. Although SORT performs well in real-time scenarios, it faces challenges in efficiently tracking occluded objects, leading to a relatively high number of identity switches. Addressing the occlusion issue, DeepSORT [2] builds upon SORT and takes object appearance into account. It integrates a pre-trained Convolution Neural Network (CNN) into the association process and introduces a matching cascade mechanism that computes appearance similarities before employing IoU and Hungarian matching. DeepSORT demonstrates relatively low identity switches, showcasing its strong performance in

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

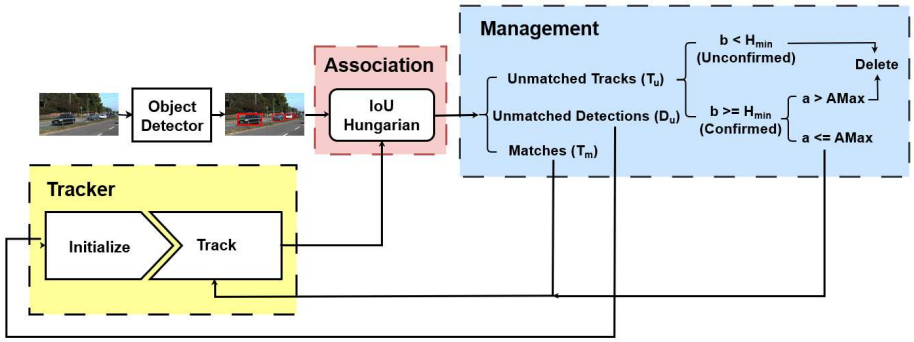

Fig. 1 System overview of proposed tracking framework

occlusion scenarios. Drawing upon the foundations laid by SORT and DeepSORT, several proposed approaches have been developed to overcome the remaining limitations, such as improving detection quality [3], handling non-linear motion [4], or addressing missing detection problems [5].

However, the heavy reliance on mathematical models introduces a level of unreliability to the output of trackers in ADAS. The assumptions made by these models often fail to accurately capture all the complex and diverse motions exhibited by on-road vehicles in real-world scenarios. For instance, situations of abnormal vehicle behaviors such as sudden lane change, hard braking, rapid acceleration as well as variation in camera motion contribute to the varied range of different vehicle motions that usually happen. Additionally, cameras in ADAS systems are not stationary but follow the vehicle, which creates additional challenges for motion-based tracking systems. Moreover, the appearance of on-road vehicles remains relatively consistent in terms of size, shape, color, and texture, and these characteristics do not undergo significant changes during tracking. Therefore, feature-based tracking can fully exploit these consistent appearance details and leverage them for accurate tracking.

In light of this, we propose a fully feature-based multi-object tracking framework that shifts the focus from mathematical models to leveraging the object appearance as the primary information for tracking. Our approach builds upon a previously proposed tracker [6] that analyzes rich vehicle features such as shapes, colors, or textures. By utilizing these insights, our framework can effectively handle complex real-world scenarios, including on-road objects' varied motion patterns or occlusions. To enhance the track management strategy, we also revisit SORT and incorporate an adaptive thresholding approach specifically designed for feature-based tracking. This approach aims to reduce the occurrence of common errors associated with feature-based vehicle tracking, such as out-of-frame handling, and feature loss. In summary, our contributions can be summarized as follows:

1. **A novel Feature-based tracking framework:** our proposed tracking framework fully exploits object appearance as tracking information, leading to reliable and accurate information.
2. **A Track Management System:** we revisit SORT [1] and design a track management system specialized for feature-based tracking.
3. **Adaptive Thresholding Approach:** we proposed an adaptive thresholding approach to handle the problems of feature-based trackers such as out-of-frame or feature loss scenarios.

II. Proposed Method

In this section, we present a novel vehicle tracking framework, as shown in Fig. 1, which incorporates an Object Detector, a Feature-based Tracker, a Data Association mechanism, and a Track Management strategy. Notably, we introduce adaptive thresholding approaches specifically designed for feature-based tracking methods. The following subsections provide a comprehensive description of these components, offering detailed insights into their methodologies.

A. Object Detector

Firstly, the accurate identification and precise localization of tracking targets in image sequences are crucial for achieving high-quality tracking performance. This object detection task (OD) plays a pivotal role in determining the overall accuracy and effectiveness of the tracking results. Furthermore, in ADAS applications, it is essential to meet strict processing time constraints. To meet these requirements, we evaluated several single-stage OD models from the YOLO family, known for their real-time capabilities, simplicity, and efficiency [7]. Among these models, YOLOv7 stood out due to its outstanding accuracy on the Microsoft COCO dataset [8], as shown in TABLE 1. Consequently, we have chosen YOLOv7 as our object detector to ensure accurate and efficient object detection,

thereby guaranteeing reliable tracking in ADAS systems. By leveraging the capabilities of YOLOv7, we aim to enhance the overall performance of our tracking framework and provide dependable object detection in real-time scenarios.

TABLE 1
COMPARISON OF BASELINE OBJECT DETECTORS [9]

Model	#Param. ↓	FLOPs↓	Size	AP^{val}↑	AP^{val}_{50}↑	AP^{val}_{75}↑
YOLOv4 [10]	64.4M	142.8G	640	49.7%	68.2%	54.3%

B. *Feature-based Tracker*

The primary objective of the tracker is to estimate the position of the object based on information from the previous frame. In this paper, we utilize the idea of DiMP-50 Tracker [6] to build our feature-based tracker. The tracker's workflow consists of two primary steps: Initialize and Track. In the following parts of this subsection, we delve into the methodology of these components, providing a detailed overview of their functioning. Moreover, an additional aspect of the tracker, which involves bounding box refinement using IoUNet prediction, will be described.

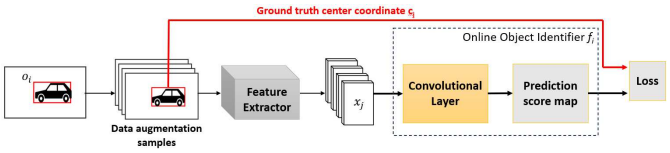

Fig. 2 Initialize component of tracker.

Initialize: The initialize step is responsible for establishing object identifiers when they first appear, as shown in Fig. 1, based on their characteristics. Fig. 2 illustrates the initialize process, the input to the component is an image containing information about a newly detected bounding box o_i, obtained from the object detector. Some data augmentation methods such as: translation, rotation, blur and dropout are then performed to create a set of augmented image samples that accounts for potential variations in object appearance. The Initialize process continues with feature extractor, here using ResNet-50, to create a set of deep feature maps x_j from the augmented image samples. The set is combined with associated bounding box centroid c_i to create a set of training samples, denoted as $S_{train} = \{(x_j, c_j\}_{j=1}^{n}$, the training samples are then used to train the online object identifier f_i, which consists of a single convolutional layer responsible for detecting the possibility of an input window containing an object.

The object identifier f_i is designed as a compact network that can be trained online for the purpose of being able to continuously and rapidly update changes in the object's appearance. It will be trained 10 epochs for the first frame, and then every 20 frames it will be trained 20 epochs on the updated training dataset S_{Train}. The object identifier is trained using the regularized loss is described in (1).

$$L = \frac{1}{|S_{Train}|} \sum_{(x,c)\in S_{Train}} \|r(f_\theta(x), c)\|^2 + \lambda\|\theta\|^2, \quad (1)$$

where, θ denotes the weight of the object identifier f and λ is the regularization factor. The function r captures the difference, or errors, between the predicted target confidence score $f_\theta(x)$ and the ground-truth bounding box centroid c at each spatial location. While r can be straightforwardly defined as the difference between the two inputs, to address the issue of data imbalance and enhance the model's emphasis on positive data, we opt to utilize a combination of least-squares

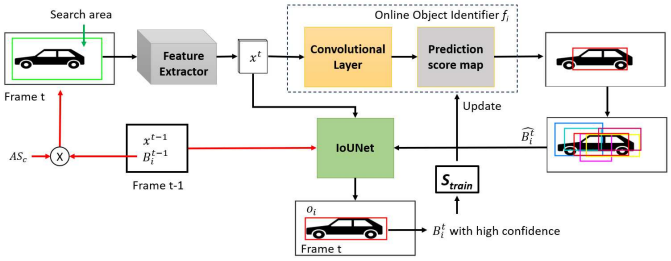

Fig. 3 Track component of tracker.

regression and hinge loss for r, as proposed in [6].

Track: After establishing initial information, the tracker proceeds to the next task of estimating object states in the subsequent frames, which is dealt with by the Track component. Fig. 3 describes the operational mechanism of the track component on the subsequent frames in a video sequence for an object o_i. To save processing time, the system will rely on the bounding box of the object in the previous frame B_i^{t-1} to determine the search area for the current frame t, and the feature x^t is only extracted in this search area. This area delimits the most probable position that the object exists in the current frame, enable the tracker concentrate only on the potential location of the object in the frame. Unlike in [6], where the search area is determined by multiplying B_i^{t-1} by a fixed scaling factor S_c, we will change S_c depending on the relative position of the object in previous frame as calculated in (2).

$$AS_c = \frac{min(d_x, d_y)}{D_{max}} S_c, \quad (2)$$

where, AS_c denotes adaptive search area scale, S_c represents the pre-defined default scaling factor, and d_x and d_y indicate the closest distances from the center of the bounding box in the previous frame to the edges of the input image, respectively. D_{max} signifies the maximum distance from the bounding box center to the image's edge. If the bounding box center in the

previous frame is closer to the vertical edge, D_{max} is calculated as half the image's width; otherwise, it is calculated as half the image's height. The adaptive search area scale dynamically adjusts the search area when the object approaches the image's edge, causing a partial disappearance and altering the object's appearance. By restricting the search area, the system focuses on the most relevant and reliable object features, enabling the tracker to adapt better to appearance changes and reduce false outputs.

Using the extracted features x^t, the online object identifier f_i is employed to generate a confidence score map across the entire search area. This map reflects the likelihood of the object's presence at different locations. The location with the highest score is chosen as the centroid of the object's bounding box in the current frame, representing the most probable location of the object. By combining this centroid with the width and height of the bounding box from the previous frame, a coarse estimation of the object o_i in current frame is obtained.

Although the tracking module performs well in determining the location of objects within the frame, its accuracy is limited as it relies on a coarse estimation derived solely from the size of the previous bounding box. To address this limitation, the IoUNet prediction approach, introduced in [13], is employed to refine and regress a more precise target box. As shown in Fig. 3, after obtaining a coarse estimation of the object's location in terms of the bounding box centroid together with the bounding box width and height from the previous frame, ten bounding box proposals, denoted as $\widehat{B_i^t}$, are generated by adding uniform noise, encompassing a range of potential object positions surrounding the coarse estimation. Using the extracted features x^{t-1} and bounding box B_i^{t-1} from previous frame, as well as current extracted features x^t, IoUNet predict IoU score for each proposal in $\widehat{B_i^t}$. The final estimation, B_i^t, is obtained by averaging of three proposals with the highest IoU score.

Furthermore, in order to maintain the object identifier's effectiveness, new training samples will be incorporated into the S_{train} dataset if they are predicted with a satisfactory level of confidence. To prevent an excessive increase in memory size, the oldest samples in S_{train} will be removed to make room for the new ones. This process ensures that the object identifier remains up to date and capable of accurately identifying objects.

C. Data Association Method

The core requirement of any tracking-by-detection method is the ability to assign detections to existing targets. In detail, produced output of the tracker, which includes bounding boxes of targets, is associated with measured bounding boxes given by an object detector. We tackle the assignment problem by using a similar approach to SORT [1], which employs Intersection over Union (IoU) and the Hungarian matching algorithm as shown in Fig. 1.

Given N detected boxes (D) from the object detector and M generated track boxes (T) from the tracker, the IoU distance between each detected box and all generated boxes resulting in cost matrix, $mIoU\ (D,T)$, as described in (3):

$$mIoU(D,T) = \begin{bmatrix} IoU(D_1,T_1) & \cdots & IoU(D_1,T_M) \\ \vdots & \ddots & \vdots \\ IoU(D_N,T_1) & \cdots & IoU(D_N,T_M) \end{bmatrix}, \quad (3)$$

where, IoU corresponds to the IoU score between chosen detected box D and generated box T is calculated as in (4).

$$IoU(D,T) = \frac{D \cap T}{D \cup T}. \quad (4)$$

Given the cost matrix $mIoU$, the Hungarian Algorithm [14] witnessed the final stage of the assignment process resulting in three possible outputs, namely matches (T_m), unmatched tracks (T_u), and unmatched detections (D_u) as shown in Fig. 1. Each T_m represents the pairings of D and T that are matched with the highest IoU score. T_u indicates tracks that have an overlap less than a predefined IoU_{min} threshold and, similarly, D_u refers to unmatched detections, which correspond to detections of new objects.

D. Track Management

Dealing with the set of T_m, T_u, and D_u, our framework employs a modified version of track handling approach as in [1], [2], as shown in Fig. 1. Additionally, we also propose an adaptive thresholding method designed for the proposed system, which can also be used for other feature-based trackers.

Track Initialization and Rejection: New tracks are initialized when there exists a set of unmatched detection D_u, each element in D_u will be initialized as new track T with the associated parameter $(c, \gamma, h, a, b, S_c)$ that contains bounding box center position c, aspect ratio γ, height h followed by the track management parameters such as track age a, track hit b, and predefined search area scale S_c.

After initialization, each T undergoes data association for detected boxes in the subsequent frame. The counter b is incremented following a successful association. In contrast, for every unsuccessful association of tracks, a and S_c are incremented to accommodate potential object re-entry and are reset to the initial value if any track subsequently rematches with a detected box. Any track with the related a that exceeds a maximum age threshold $AMax$ is considered to have

permanently left the frame and is therefore rejected. Unlike SORT and DeepSORT, which rely on a fixed age threshold, we propose to use an adaptive thresholding approach specifically designed for feature-based trackers, aiming to minimize associated errors. The $AMax$ is defined similarly to AS_c as described in (2). By employing the Adaptive Maximum Age mechanism, when a vehicle's trajectory starts to extend beyond the frame boundaries, $AMax$ gradually diminishes, facilitating the quick deletion of these tracks. This adaptive approach ensures that the tracker effectively handles objects that move out of the frame, enhancing overall tracking performance.

Track Confirm Mechanism: In tracking applications, scenarios when objects only appear in a few initial frames, should also be considered. Therefore, as described in [2], tracks at creation are considered to be tentative during their first H_{min} frames and is confirmed after consecutive successful associations. During H_{min}, tentative tracks will be deleted right after an unsuccessful association. By requiring consecutive matches, this method helps minimize related errors caused by false or short-lived detections.

III. Experimental Results

In this section, we presented an in-depth analysis of tracking evaluation and performance comparison to assess the performance of the proposed tracking framework compared to existing methods on the KITTI Object Tracking Benchmark [15]. For evaluation, the proposed method is tested on a chosen set of sequences specialized for vehicle tracking. For comparison, we executed the proposed tracking framework as well as reproduced results from DeepSORT [2] and SORT [1] using the same detection input, the results are evaluated on different selected metrics. Furthermore, performance analysis and ablation studies are accomplished for deeper insight.

A. Dataset

Our tracking framework is evaluated on KITTI Object Tracking Benchmark [15], a popular dataset utilized for many tasks in Autonomous Vehicle applications. The dataset incorporates data from various sensors including Color and Greyscale Cameras, a Laser Scanner, and GPS/IMU navigation systems. KITTI Image Dataset comprises a total of 21 Training and 29 Testing sequences, all captured at a common frame rate of 10 FPS using vehicle-mounted color cameras positioned at a height of 1.65 meters above the ground.

While the KITTI Dataset can be used for tracking applications on either vehicles or pedestrians, our framework specifically focuses on vehicle tracking. Consequently, a total of nine sequences, primarily composed of on-road vehicles, are selected for evaluation. These chosen sequences cover a diverse range of on-road scenarios spanning from highways to urban areas for a realistic evaluation of the framework's performance.

B. Evaluation Metrics

We use the metrics MOTA, HOTA, and IDF1 [16]–[18] to evaluate our tracking performance, with each metric providing different criteria for tracking performance assessment.

MOTA [16] measures the tracking performance at the detection level by calculating the matching between each ground-truth detection $(gtDet)$ and predicted detection $(prDet)$. From that approach, the number of matched pair of $gtDet$ and $prDet$ is regarded as True Positive (TP). The number of times a $prDet$ is unmatched results in the number False Positive (FP) while the number missed $gtDet$ corresponds to False Negative (FN). Moreover, association performance in MOTA is measured with the concept of Identity Switch $(IDSW)$, an $IDSW$ is counted when objects unexpectedly swap their identity during tracking. The final score of MOTA is calculated as in (5).

$$MOTA = 1 - \frac{|FP| + |FN| + |IDSW|}{|gtDet|}. \quad (5)$$

On the other hand, IDF1 [18] acquires tracking errors at the association level by measuring bijective matching between sets of ground-truth trajectories $(gtTraj)$ and prediction trajectories $(prTraj)$. Matching between each $gtTraj$ and $prTraj$ results in ID-True Positive $(IDTP)$. The counts of ID-False Negative $(IDFN)$ and ID-False Positive $(IDFP)$ represent the counts of remaining unmatched $gtDet$ and $prDet$, respectively. Final IDF1 score is calculated as in (6).

$$IDF1 = \frac{|IDTP|}{|IDTP| + 0.5|IDFN| + 0.5|IDFP|}. \quad (6)$$

HOTA [17] is a recently proposed metric that, unlike MOTA and IDF1, considers errors at both mentioned levels. This metric balances the effects of detection and association errors on tracking performance. At the detection level, HOTA acquires the instances of FN, FP, and TP in a similar way to MOTA to calculate Detection Accuracy $(DetA)$. Additionally, by using the method of matching the set of ground-truth Identity $(gtID)$ with prediction Identity $(prID)$ over a set of TPs, HOTA proposed an association-level evaluation that acquires True Positive Association (TPA), False Negative Association (FNA), and False Positive Association (FPA), these three concepts are used to measure Association Accuracy

($AssA$). As a result, the HOTA score over different localization thresholds (0.05 to 0.95 in 0.05 intervals) is calculated as in (7).

$$HOTA = \int_0^1 HOTA_\alpha \, d\alpha \approx \frac{1}{19} \sum_{\substack{\alpha=0.05 \\ \alpha+=0.05}} HOTA_\alpha \,, \quad (7)$$

where, $HOTA_\alpha$, calculated in (8), is the HOTA score over an α, which is the geometric mean of $DetA$ and $AssA$ over α.

$$HOTA_\alpha = \sqrt{DetA_\alpha \cdot AssA_\alpha}, \quad (8)$$

where, $DetA_\alpha$ and $AssA_\alpha$ are $DetA$ and $AssA$ calculated with localization threshold α as in (9) and (10).

$$DetA_\alpha = \frac{|TP|}{|TP| + |FN| + |FP|}, \quad (9)$$

$$AssA_\alpha = \frac{1}{|TP|} \sum_{c \in TP} \frac{|TPA|}{|TPA| + |FNA| + |FPA|} . \quad (10)$$

Note that the concepts of TP, FN, FP, TPA, FNA and FPA in (9) and (10) are calculated for a particular value of α. However, for clarity, the subscript is omitted.

C. Results

For comparison, we also reproduced two popular motion-based tracking methods that employ similar association strategies as our proposed method, namely DeepSORT [2] and SORT [1].

TABLE 2 and TABLE 3 illustrate the results of our evaluation on MOTA and IDF1 metrics, respectively. It is evident that our method notably improved tracking performance in the overall MOTA score. In detail, our method ranked first in FN and FP, surpassing the second-best method (SORT) with a slight reduction in FN and a complete out-performance in FP (from 775 to 465). The proposed method also secured the top position on other associated parameters, which are Mostly Track Ratio (MT), Mostly Lost Ratio (ML), and Tracking Precision (MOTP). Similarly, at the association level, the proposed method is dominant in IDF1 due to the relatively low IDFP value in comparison two other methods.

TABLE 2
EVALUATION RESULTS OF THREE METHODS ON MOTA METRIC.

	MOTA↑	MOTP↑	MT↑	ML↓	FN↓	FP↓	IDSW↓	Frag↓
SORT [1]	66.9	75.5	45.2	11.5	2928	775	153	202
DeepSORT [2]	63.3	74.7	44.9	12.5	2970	1169	**137**	**178**
Proposed	**70.1**	**80.5**	**48**	**10**	**2868**	**465**	152	211

TABLE 3
EVALUATION RESULTS OF THREE METHODS ON IDF1 METRIC.

	IDF1↑	IDTP↑	IDFN↓	IDFP↓
SORT [1]	70.52	7449	4190	2037
DeepSORT [2]	74.23	7971	3668	1867
Proposed	**76.68**	**8004**	**3635**	**1232**

To conclude, those mentioned enhancements prove the accuracy and reliability of our approach, the results on HOTA metrics (TABLE 4), additionally, contribute to this fact as the corresponding performance in both detection (*DetA)* and association (*AssA)* is leading in comparison with either SORT or DeepSORT.

TABLE 4
EVALUATION RESULTS OF THREE METHODS ON HOTA METRIC.

	HOTA↑	DetA↑	AssA↑
SORT [1]	54.65	53.85	56.62

Proposed	**60.77**	**58.42**	**63.84**

D. Ablation Studies

TABLE 5 summarizes the comparison of the proposed method on different improvement proposals, we compare our baseline method with two other ones with strategy improvements, namely Proposedv1 and Proposedv2.

Proposedv1 updated the Baseline method with Adaptive Maximum Age Threshold (AMax), resulting in a reduction in IDSW (-185) and Frag (Fragmentation) (-23). This approach also demonstrates the best performance in overall HOTA and MOTA scores. Here, the tendency indicates that the proposed method benefits considerably from AMax mechanism.

On the other hand, Proposedv2 integrated Adaptive Search Scale (ASc) and Track Confirm Mechanism (Cfm). ASc is implemented to minimize errors that may arise when objects tend to move out of frame, potentially resulting in feature loss and causing confusion for the tracker. The track confirm mechanism, on the other hand, is used to minimize errors for scenarios when tracks only appear for a few initial frames. By applying these two strategies, Proposedv2 significantly reduced *IDSW* and *Frag* errors, and achieved the highest association-level score (IDF1). Still, the improvement in IDF1(+0.04) compared to Proposedv1 is not considered significant, and there is a slight decrease in the overall HOTA and MOTA scores. This trend can be attributed to the fact that Proposedv2 focuses only on, as much as possible, reducing errors caused by objective uncertainties.

TABLE 5
ABLATION STUDY ON HOTA, MOTA, IDF1 FOR VARIOUS STRATEGIES: ADAPTIVE MAXIMUM AGE (**AMax**), ADAPTIVE SEARCH SCALE (**ASc**), TRACK CONFIRM (**Cfm**).

	AMax	*ASc*	*Cfm*	HOTA↑	IDF1↑	MOTA↑	IDSW↓	Frag↓
Baseline	-	-	-	58.21	71.68	69.71	396	294
Proposedv1	✓	-	-	**61.77**	76.64	**71.24**	211	271
Proposedv2	✓	✓	✓	60.77	**76.68**	70.06	**152**	**211**

E. Limitations

Although the proposed method has successfully witnessed improvements in accuracy and reliability, it still exhibits a certain limitation. The concern is that performance in IDSW

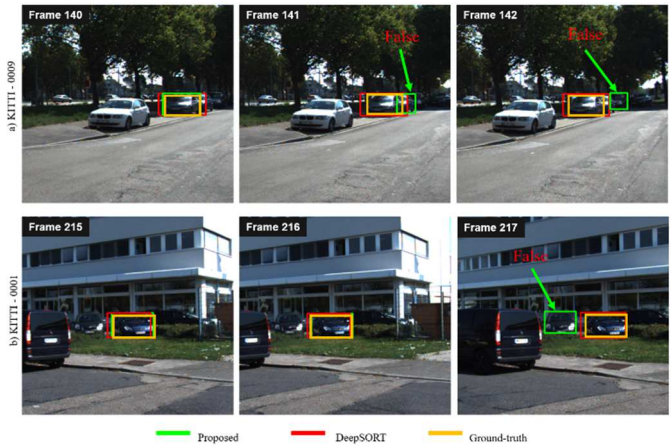

Fig. 4 Types of false output generated by Proposed method

and Frag is still poor compared to previous methods (especially DeepSORT). We consider this to be a distinctive issue in feature-based tracking, particularly evident in crowded scenarios, where uncertainties in object searching are relatively high. For example, Fig. 4 illustrates a situation in which vehicles are in close proximity and have identical appearances. The proposed method struggles to differentiate between the objects, leading to uncertain and incorrect outputs. In contrast, DeepSORT effectively handles the situation by leveraging the accurate predictions generated by the Kalman Filter. These findings highlight that future developments should focus on enhancing the proposed method's capability to predict object states in crowded environment.

IV. Conclusions

In this paper, we have introduced a novel feature-based tracking framework that leverages appearance information to enhance tracking performance. We have also presented a new track management system and an adaptive thresholding approach. These techniques have been specifically designed to address the requirements of vehicle tracking in ADAS applications. Through extensive evaluation on the well-established KITTI benchmark, our proposed method has demonstrated its effectiveness by surpassing existing approaches in terms of tracking accuracy and robustness. A series of ablation studies were conducted to further emphasize the advantages of the integrated track management system and adaptive thresholding approach. Overall, our findings underscore the importance of considering appearance information and implementing advanced track management strategies in feature-based tracking. This paper contributes to the existing body of knowledge in the field of vehicle tracking and provides valuable insights for future developments in ADAS applications.

***Abstract* —** Images captured under low-light conditions often suffer from overall darkness and poor visual quality. In this study, we propose a light-weight zero-reference image enhancement method to improve the visual quality of low-light images. The proposed method is composed of some parts: image partition, transformation map estimation, and pixel value adjustment. To achieve transformation map estimation, a light-weight network, CSPDCE-Net, is developed. For performance evaluation, two image datasets, SICE and LOL, are selected here. For visual quality, the average PSNR and SSIM of the proposed method can achieve 17.01dB and 0.71, respectively. Compared with the existing methods, the proposed method can achieve better performance in terms of PSNR and SSIM. The experimental results show that the proposed method not only can process low-light images well but also is superior to some existing methods.

I. INTRODUCTION

With the rapid development of computer vision technology, digital image processing systems have been widely applied in various fields such as video surveillance, industrial production, and intelligent transportation. However, during the image acquisition process, the lighting conditions of images often vary, such as sunny, cloudy, rainy, and nighttime scenarios. However, images captured under poor lighting conditions, such as nighttime or cloudy conditions, may have poor visual quality. The image captured in relatively low-light environments is commonly referred to as a low-light image [1][2]. Figure 1 shows two low-light images. As shown in Fig. 1, it is quite difficult to recognize the image content by humans. This means that it would be more difficult for an intelligent system to detect and recognize human faces or license plates in low-light images. Therefore, improving the visual quality of low-light images plays a crucial role in many computer vision applications [2].

(a) (b)

Fig. 1 Examples of low-light images.

In fact, there are some traditional image enhancement techniques to deal with low-light images. For example, many histogram-based methods had been developed [14]. The basic concept of histogram-based methods is to modify pixel values to increase the contrast of input images. Recently, there are advancements in low-light image enhancement techniques developed based on deep convolutional neural networks (CNNs) [3]. However, most supervised-learning-based CNN-based image enhancement methods require a large amount of image pairs, i.e., low-light and normal-light images. In fact, capturing simultaneously both low-light and normal-light images in the same scene or synthesizing image pairs is an immense challenge. To overcome the constraint, several unsupervised deep learning methods have been proposed [4,5,6,7]. For example, the unsupervised-learning-based methods was developed based on a generative adversarial network and Retinex model [6]. In [6], a two-layer decomposition network decomposes a low-light image into an illumination map and a reflection map. Then, the Retinex model with correction coefficients is exploited to obtain the enhanced images. However, unpaired low/normal-light images are necessary for model training in [6]. The requirement makes the existing method infeasible.

To avoid the requirement of paired/unpaired low/normal-

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

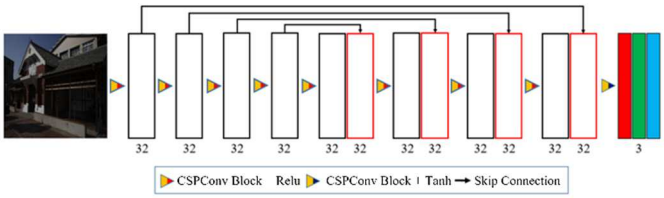
light images, an unsupervised-learning-based method was devised in [8]. The existing method called Zero-DCE [8] is designed to estimate the mapping function for modifying pixel values. The main feature of Zero-DCE is that paired or unpaired images are not needed for model training. On the other hand, some real applications such as video surveillance, intelligent factory, and autonomous driving, require intelligent image processing systems deployed in mobile or embedded devices. Therefore, this motivates us to develop a light-weight zero-reference network to deal with low-light images.

The rest of this paper is organized as follows. In Section II, we describe the proposed light-weight image enhancement method. Experimental results are shown in Section III. Section IV contains the conclusion.

II. PROPOSED METHOD

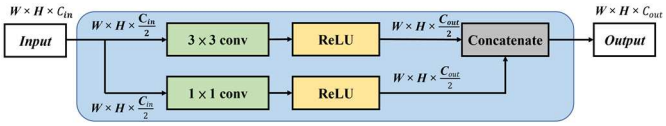
Image enhancement can be considered as the problem of finding an appropriate mapping function between input pixel values and the output results. In recent years, many low-light image enhancement methods have been developed based on deep neural networks such as U-Net [9] and its variants to produce visually improved results. However, these existing methods often have a large number of model parameters and computational requirements and then make them inappropriate to run on edge devices [10].

In fact, it is an important issue that a network should be light-weight to process low-light images due to limited storage and computational power of embedded/edge devices in existing applications. However, the existing methods may suffer from the issue of limited storage and computational power. Unlike U-Net, DCE-Net [11] does not adopt the down-sampling operation to reduce the size of feature maps for computing a suitable transformation function. Unfortunately, this leads to the need of more memory and computational complexity for processing these feature maps and then makes DCE-Net unsuitable for embedded/edge devices.



To effectively address the above issues, we propose a new light-weight image enhancement method to deal with low-light images. The proposed method is composed of three parts: image partition, transformation map estimation, and pixel value adjustment. In order to reduce the memory usage during runtime, the proposed method splits the input image into four regions. After image partition, the proposed network, CSPDCE-Net, is used to estimate the transformation map for these regions. Finally, pixel values in each region are adjusted based on the estimated transformation map to obtain the enhanced image. We elaborate each part in the following.

A. *Image partition*



To reduce the memory requirement during model execution, this study divides the input low-light image into four equal parts, denoted as I_1^O, I_2^O, I_3^O, and I_4^O, before feeding them into the CSPDCE-Net for transformation map estimation. Each part is separately processed by the CSPDCE-Net, resulting in transformation parameter maps $\mathcal{A}_1$, $\mathcal{A}_2$ $\mathcal{A}_3$, and $\mathcal{A}_4$. Finally, these individual maps are merged to obtain the combined transformation parameter map $\mathcal{A}$ for pixel value adjustment. It is expected that this approach would reduce the memory usage during the subsequent transformation map estimation.

B. *Transformation map estimation*

To estimate the transformation map for each region, a light-weight network, CSPDCE-Net, is proposed. Similar to DCE-Net, the architecture of the proposed CSPDCE-Net model is shown in Fig. 2(a). As shown in Fig. 2(a), similar to DCE-Net, CSPDCE-Net consists of some convolutional layers. However, the main difference between DCE-Net and CSPDCE-Net is that each 3×3 convolutional layer in DCE-Net is replaced with a CSPConv Block, forming a new model architecture called CSPDCE-Net. In addition, the main concept of CSPNet is adopted to establish CSPDCE-Net in this study.

(a)

(b)

Fig. 2 CSPDCE-Net architecture: (a) CSPDCE-Net and (b) proposed CSPConv block.

As shown in Fig. 2(b), the input of a CSPConv block is divided into two parts. The two Conv1×1 layers are used to divide the input feature maps into two parts. In Fig. 2(b), C_{in} and C_{out} represent the number of the input and output channels in a CSPConv block, respectively. In one part, the 3×3 convolutional layer is performed by using depth-wise convolution. Since only a half of input feature maps are

processed by the 3×3 convolution, it is expected that the computational complexity of the proposed method can be reduced. Then the two parts are concatenated as the output in a CSPConv block. It is expected that the CSPDCE-Net can learn the transformation map after network training with a suitable loss function.

C. *Pixel value adjustment*

After generating the transformation map by using CSPDCE-Net, the next step is to adjust pixel values of the low-light images. This means that the visual quality of a low-light image can be improved based on the estimated transformation map. Therefore, the pixel value adjustment function $LE_n(\mathrm{x})$ is described as follows:

$$LE_n(x) = LE_{n-1}(x) + \mathcal{A}(x)LE_{n-1}(x)\big(1 - LE_{n-1}(x)\big) \qquad (1)$$

where x represents the input, $\mathcal{A}$ represents the transformation map estimated by CSPDCE-Net, and $LE_{n-1}(x)$ represents the result. The iteration is performed for a total of 8 times.

D. *Network training*

One key issue is to suitably estimate the transformation map for pixel value adjustment. To obtain a trained network for transformation map estimation, we adopted an unsupervised training framework using multiple exposures and low-light images. The proposed framework of network training is illustrated in Fig. 3. The following describes how the model is trained and the design of the loss functions.

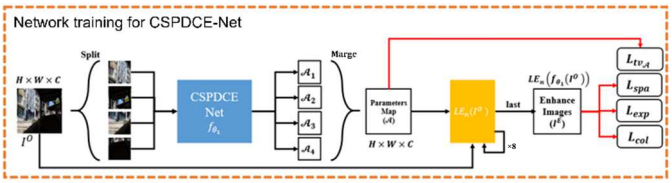


Fig. 3 Illustration of the network training for CSPDCE-Net.

Similar to Zero-DCE [8], the loss function used in the training process considers four characteristics:

1. Spatial Consistency
2. Exposure Control
3. Color Constancy
4. Illumination Smoothness

Spatial Consistency Loss (L_{spa})

The spatial consistency loss L_{spa} promotes spatial consistency in the enhanced images by preserving the differences between neighboring regions of the input image and its enhanced version. The loss L_{spa} is defined below:

$$L_{spa} = \frac{1}{K}\sum_{i=1}^{K}\sum_{j\in\alpha(i)}\big(\big|\big(I_i^E - I_j^E\big)\big| - \big|\big(I_i^O - I_j^O\big)\big|\big)^2, \qquad (2)$$

where K represents the number of local regions, $\alpha(i)$ denotes the four neighboring regions (up, down, left, right) centered around region i, and $|\cdot|$ represents the L_1 norm. I^E and I^O represent the average intensity values of the local regions in the enhanced and input images, respectively.

Exposure Control Loss (L_{exp})

To adjust the exposure level of the image, this study utilizes the exposure control loss (ECL) L_{exp} [8] to regulate the exposure level. The ECL is used to measure the distance between the average intensity values of local regions and the desired exposure level E. The loss L_{exp} is expressed below:

$$L_{exp} = \frac{1}{M}\sum_{k=1}^{M}\big|I_k^E - E\big|, \qquad (3)$$

where M means the number of non-overlapping local regions with a size of 16×16, the average intensity value of local regions in the enhanced image is denoted as I_k^E.

Color Constancy Loss (L_{col})

According to the gray world color constancy assumption [11], the average color of each sensor channel in the entire image is gray. In this study, color constancy loss [8] is utilized to correct potential color deviations in the enhanced image and establish relationships between the three color channels. The color constancy loss L_{col} can be expressed below:

$$L_{col} = \sum_{\forall(p\ ,\ q)\in\varepsilon}(I_p^E - I_q^E)^2, \varepsilon = \{(R,G),(R,B),(G,B)\} \qquad (4)$$

where I_p^E and I_q^E are the average intensity values of channels p and q in the enhanced image, and R, G, and B are the color channels of I^E.

Illumination Smoothness Loss ($L_{tv_{\mathcal{A}}}$)

To maintain smoothness among neighboring pixels, this study utilizes illumination smoothness loss to constrain the transformation map $\mathcal{A}$ and prevent excessive variations in illumination between adjacent pixels. The illumination smoothness loss $L_{tv_{\mathcal{A}}}$ is defined as follows:

$$L_{tv_{\mathcal{A}}} = \frac{1}{N}\sum_{n=1}^{N}\sum_{c\in\beta}\big(|\nabla_x\mathcal{A}_n^c| + |\nabla_y\mathcal{A}_n^c|\big)^2, \beta = \{R,G,B\} \qquad (5)$$

where N denotes the number of iterations, ∇x and ∇y denote the horizontal and vertical gradient operations.

Total Loss

According to Eqs. (2)-(5), the total loss can be expressed

as follows:

$$L_{total} = \omega_{spa}L_{spa} + \omega_{exp}L_{exp} + \omega_{col}L_{col} + \omega_{tv_A}L_{tv_A} \quad (6)$$

where the weights, ω_{spa}, ω_{exp}, ω_{col}, and ω_{tv_A}, are used to balance these losses.

III. EXPERIMENTAL RESULTS

To evaluate the performance of the proposed method, some image datasets, SICE and LOL, are selected here. The SICE Dataset is used for model training. The SICE Dataset consists of 589 high-resolution images and their corresponding multiple exposure versions, so there are a total of 4,413 images. The multiple exposure versions are illustrated in Fig. 4. In addition, to evaluate image visual quality, we consider the performance index, Peak Signal-to-Noise Ratio (PSNR) [12] and Structural Similarity Index (SSIM) [13].

Fig. 4 Examples of the SICE Multiple Exposure Image Dataset.

A. Performance of visual quality

Two low-light images are selected for visual quality evaluation. Fig. 5 shows two low-light images and the corresponding results. Fig. 5(a) are test images and the image content is not clear and difficult to be recognized. Fig. 5(b) shows the proposed method enhanced results. Compared to Fig. 5(a), the visual quality of the enhanced images is better than that of test images. Compared to the proposed method, in Fig. 5(c1), the results of Zero-DCE show insufficient brightness recovery. In Fig. 5(d1), the images generated using HE exhibit a yellowish color bias, and the sky are not brightened. In Fig. 5(c2), the results of Zero-DCE and Fig. 5(d2), which is the result of HE, there is some noise in the night sky. The result shows that the proposed method can raise visual quality of low-light images and surpass other methods.

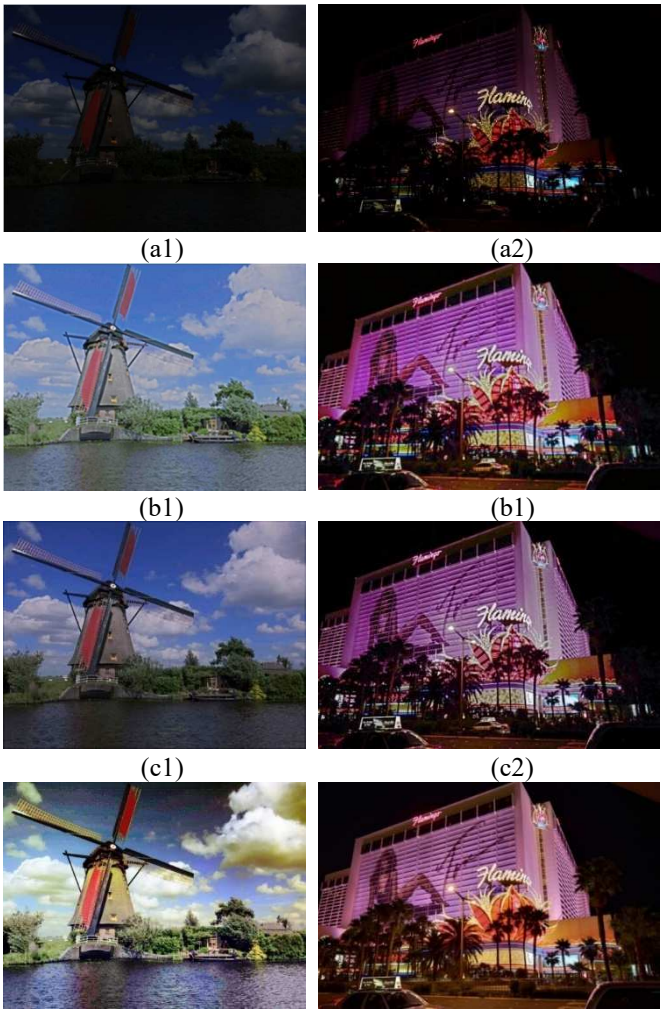

Fig. 5 Results of image enhancement: (a1)(a2) input images, (b1)(b2) proposed, (c1)(c2) Zero-DCE [8] and (d1)(d2) HE [14] .

B. Objective evaluation

Here we make a comparison with some existing methods [8] and [14]. As shown in Table I, the average PSNR and SSIM of the proposed method can achieve 17.01dB and 0.71, respectively. Compared with the existing methods [8] and [14], the proposed method can have better results in terms of PSNR and SSIM. In addition, the parameter size of the proposed is smaller than that of the existing method [8]. Therefore, the experimental results indicate that the proposed method is superior to the existing method [8].

Table I Quantitative comparison of existing method and the proposed CSPDCE-Net in terms of PSNR and SSIM for LOL Dataset

Method	SSIM	PSNR(dB)	Parameter(M)
Input	0.195	7.77	-
HE [14]	0.496	14.10	-
Zero-DCE [8]	0.532	16.88	0.07
CSPDCE-Net (Proposed)	0.71	17.01	0.04

IV. CONCLUSIONS

In this paper, we propose a light-weight zero-reference image enhancement method to improve the visual quality of low-light images. The proposed CSPDCE-Net is composed of several parts: image partition, transformation map estimation, and pixel value adjustment. To achieve transformation map estimation, a light-weight network, CSPDCE-Net is developed. To perform network training, an unsupervised learning approach is adopted.

To evaluate the performance of the proposed low-light image enhancement method, the LOL dataset was used for testing. Compared to the existing methods, the proposed CSPDCE-Net can achieve better performance in terms of PSNR and SSIM. The experimental results indicate that the CSPDCE-Net not only can process low-light images well but also is superior to the other methods.

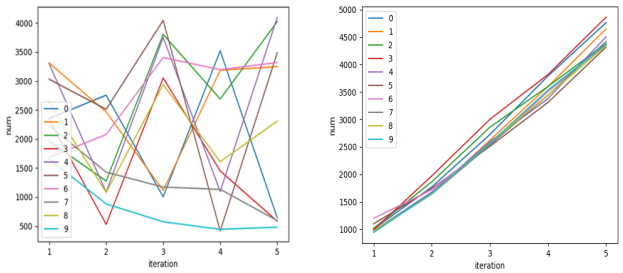
***Abstract*—In recent years, self-training has become more and more popular in model learning because it only requires a small amount of labeled data to reach high classification accuracy. Since the conventional self-training does not perform in a class-specific manner, class imbalance problem happens frequently as self-training tends to select more pseudo labeled samples from easy classes. It becomes even worse when training dataset is originally class-imbalanced. In this paper, classwise self-paced self-training is proposed to solve this problem. A classwise pseudo-labeling method ensures that sufficient data are selected for each class in a self-pace manner. To avoid increasing number of noisy samples, two indicators, confidence score and uncertainty score, are proposed based on dropout prediction for noisy label filtering. Experimental results demonstrate that the proposed method achieves very competitive performance on CIFAR-10 and ISIC2018 datasets. Keyword: Deep Learning, Image Classification, Semi-Supervised Learning, Self-Training**

I. Introduction

A. Introduction



Semi-supervised learning has attracted attention in recent years. Since supervised learning approaches require a large number of labeling data, total time of data acquisition and manual-labeling has also increased significantly. Semi-supervised learning effectively exploits unlabeled data to improve the accuracy of training models. Recent semi-supervised learning methods can be classified into two categories: self-training framework [1] and consistency regularization [7] [10][11][12].

In self-training, the model is initially trained with just a few labeled data. Then, the trained model is used to predict the pseudo-labels of unlabeled data. The set of unlabeled data with pseudo-labels is filtered based on the predicted confidence score by a given threshold. Lastly, the labeled data and the selected pseudo-labeled data are employed as the new training data to retrain the model. This loop repeats until the classifier can no longer find any more unlabeled data higher than the threshold or reach the maximum iteration number. Consistency regularization aims to train a model that is invariant to various data augmentations, such as weak augmentations or strong augmentations. Famous methods includes FixMatch [11] and its variant Flexmatch [12]. In this paper, we focus on the first category, self-training based methods.

Most self-training methods rely on a fixed threshold to select unlabeled data based on the confidence score. However, the selection of threshold is not straightforward. It does not take the easy/hard classes into account, and thus leads to the problem of class imbalance. Training samples of easy classes may have larger number higher than the threshold compared to those in the hard classes during the iteration of self-training.

In Fig. 1(a), the number of pseudo-labeled samples selected for each class (10 classes in total) is unstable in each iteration. It makes the model learning more concentrating on classes with more samples to reduce the total loss and neglects the training for classes with few training samples. This motivates us to proposed a mechanism for self-training to maintain stable and balanced growth of pseudo-labeling sample selection for each class, as depicted in Fig. 1(b).

To solve the class imbalance problem, classwise self-paced self-training is proposed. Rather than using a fixed global threshold, the selection of unlabeled data is performed dynamically within each class and ensures the amount of samples in each class. Two indicators, confidence and uncertainty score, are employed to avoid increasing number of noisy samples. The system framework is depicted in Fig. 2.

(a) Imbalanced self-training. (b) Proposed method.

Fig. 1. Number of pseudo-labeling samples selected for each category during each iteration. 0-9 refers to the class index. The number of pseudo-labeling samples selected for each class changes drastically in conventional self-training framework whereas it maintains stable growth by our method.

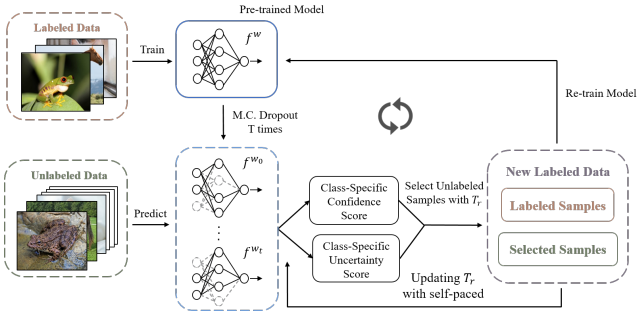

Fig. 2. System Framework

II. Related Work

A. Noisy Student

Xie et al. [6] [6] proposes a framework that combines knowledge distillation to improve self-training, which differs from self-training in that for each iteration of training, [6] uses a new and larger student model to The purpose of this is to allow the student model to have greater potential than the teacher model. In order to make the student model have better generalization ability, three kinds of noisy will be added in the training process of the student model: data augmentation, dropout, and stochastic depth. Raise the difficulty of student model learning, force the model to learn more generalized knowledge, beyond the teacher model.

B. Curriculum Labeling

Cascante-Bonilla, Paola, et al. [2] has improved the problem that the original selftraining method is not flexible enough when selecting unlabeled data. Inspired by curriculcum learning, let the model learn from simple samples first and then gradually progress to difficult samples. The model will have better judgment after learning simple samples, and the learning effect will be better when adding difficult samples than adding them at the beginning, which is a human-like learning method. This paper use extreme value theory as the core concept. They analyze the prediction distribution of unlabeled data and proposes Curriculum Labeling, which can effectively train the model in the self-training process and reduce the chance of false labeling. The implementation method is to sort the prediction results when selecting the unlabeled data stage, and then choose to select the data in a proportional way to join the next round of training.

C. Fixmatch

Sohn, Kihyuk, et al. [11] propose a semi-supervised learning method which based on both consistency regularization and pseudo-labeling. This method performs two types of Data augmentation on the input image simultaneously. 1) Weak augmentation :This is performed with operations such as flip and shift, and the result is used to generate a pseudo-label, which is used as a target for another type of augmentation. 2) Strong augmentation : Inspired by previous studies, this side uses more complex augmentation methods such as Cutout [13], CTAugment [14], and RandAugment [15], which usually result in a higher degree of image distortion. Unlabeled data enters the model judgment after weak-augmented, and gets prediction. If the prediction of this data is higher than the fix ed threshold 0.95, a pseudo-label will be given to the data. Then pass this data through strong-augmented and calculate cross entropy with pseudo-label.

D. Monte Carlo Dropout

For the same amount of data, we may train neural networks with different weights, but both can solve the problem. Gal, Yarin, and Zoubin Ghahramani. [5] study in detail the dropout layer in deep learning, interpreting it as the approximate bayesian inference in the deep gaussian process. This interpretation allows us to model the uncertainty in deep learning models through dropout and extract information from the discarded parts of the model. This paper studies in detail the nature of this uncertainty by combining bayesian models with deep learning models. Through a simple hands-on approach, model uncertainty can be estimated without additional complex computations, modifications to existing models, or sacrificing test accuracy.

III. Proposed Method

A. Confidence and Uncertainty Scores

In semi-supervised learning, only limited labeled samples are available. The classification model is usually pre-trained on ImageNet dataset. Then, label data of target dataset is employed to fine-tune the model. The model trained on labeled data is used to predict unlabeled data and assign pseudo-labels. Since the predictions may have a high bias during early iteration of model training, prediction with high confidence score can be incorrect. Two indicators: *confidence score* and *uncertainty score* are proposed to improve the accuracy of pseudo labels.

Define labeled data $D_L = \{(x_m, y_m) \mid m \in (1, \ldots, M)\}$. M is the number of labeled data. Unlabeled data $D_U = \{x_n \mid n \in (1, \ldots, N)\}$. N is the number of unlabeled data. Dropout is employed to filter noisy labels and reduce the bias for pseudo-label prediction. Dropout is applied during the inference stage while other parameters are frozen. As a result, multiple predictions can be made for each data sample. Denote q_θ^* the dropout layer. $\widehat{W}_t$ is the model weights by randomly discarding some weights through dropout layer. $t \in 1, \ldots, T$ is the index of forward passes. Define total T times forward pass through the network with dropout. The model weight $\widehat{W}_t$ can be defined as follows.

$$\widehat{W}_t = q_\theta^*(W) \tag{1}$$

W is the model weights before dropout layer.$\widehat{W}_t$ is different at each time, and so do the prediction result of times t as $y_t^* \in R^C$, and C is the total number of predicted class. y_t^* can be defined as follows.

$$y_* = \operatorname{softmax}\left(f^{W_t}(x)\right), \quad t \in 1, \ldots, T \tag{2}$$

By averaging the predictions y_t^* of T times, the prediction can be made with a lower bias. The maximum value of the average prediction vector y_t^* can be exploited as the *confidence score* P of this data sample.

$$P = \max\left(\frac{1}{T}\sum_{t=1}^{T} y_t^*\right) \tag{3}$$

The class index of the maximum value is then used as the pseudo-labels of data sample as follows.

$$\hat{y} = \underset{i}{\operatorname{argmax}}\left(\frac{1}{T}\sum_{t=1}^{T} y_t^*\right) \tag{4}$$

In addition, the variance of multiple dropout prediction is also meaningful. If the variance is high, it represents the prediction is diverse and highly uncertain. The pseudo-label can be potentially noisy. The variance for dropout predictions of T times can be calculated given the first prediction $\hat{y}$. The *uncertainty score* U can be defined as follows.

$$U = \operatorname{Var}\left(y^* \mid \hat{y}\right) \tag{5}$$

With these two indicators, noisy samples can be filtered out by keeping only samples with high confidence and low uncertainty scores.

B. Self-paced Classwise Sample Selection

In the framework of self-training, a critical issue is to select good and enough number of pseudo-labeled samples. However, maintaining quality and quantity are a trade-off problem. If the threshold is set too high, the number of selected samples can be relatively small and the training iterations will be long. In addition, it may tend to selection more samples from easy class and lead to class imbalance problem. On the contrary, if the threshold is set too low, many samples will be selected for training. The probability of incorrect pseudo-labeled sample will increase, and the quality of training data cannot be guaranteed. In addition, the fixed threshold relies empirically on experiments to find the better value and is not universal across datasets. In order to these problems, a self-paced classwise sample selection method is proposed via two indicators, confidence score and uncertainty score.

1) Self-Paced Samples Selection

Inspired by self-paced learning [16], our method calculates pseudo labels and examines samples in a fixed pace, which ensures that all samples can be seen at a fixed iteration to end the training. T_r represents the percentage of pseudo-labeled samples that should be added to training in current iteration. The initial value 100 represents that no pseudo-label sample is currently added. A hyperparameter T_{step} is defined to set the stepping percentile for thresholding after each iteration:

$$T_r -= T_{step} \tag{6}$$

In our experiments, T_{step} is set to 20. In each new iteration, (6) is executed until $T_r = 0$. That is, after all the pseudo-labeled data are examined to the training, the whole training process is finished.

2) Classwise Selection with Noisy Label Filtering

To ensure that sufficient data are sampled for each category, a class-specific sampling method is applied. However, the sampling thresholds in difficult classes are likely to be lower than that of the global selection method. Compared with a fixed yet higher threshold in the global selection method, classwise sampling method leads to higher probability of sampling more noisy labeled samples into the training. Therefore, a classwise sample selection method is proposed based on noisy label filtering is proposed.

Denote the confidence score P as $\{p_n : n \in 1, \ldots, N\}$, and uncertainty score U as $\{u_n : n \in (1, \ldots, N)\}$, where N is the number of unlabeled data. Split the confidence score P and uncertainty score U into subsets according to the pseudo-label $\hat{y}$ of each sample : $P = \{P_1 \cup P_2 \ldots \cup P_C\}$, $U = \{U_1 \cup U_2 \ldots \cup U_C\}$, where C is the number of classes in the dataset. As mentioned earlier, self-paced sample selection uses T_r to select a certain percentage of samples. The percentage is used to determine the class-specific threshold and filter samples. For each subset of confidence score P_c and uncertainty score U_c, threshold of cutting line is calculated respectively for P_c and U_c as follows.

$$T_p^c = \text{ Quantile } (P_c, T_r, descending = False) \tag{7}$$

$$T_u^c = \text{ Quantile } (U_c, T_r, descending = True) \tag{8}$$

The Quantile function first sorts the input in descending or ascending order based on parameter $descending$ is $True$ or $False$. The value of the T_r-th percentile is returned. For example, if the input set contains values of 1 to 10 and T_r is set to 80 (which means 80%), 8 is returned as threshold if $descending = False$. Only values larger than 8 will be chosen. On the other hand, Quantile function return 3 if $descending = True$ and 1 and 2 are selected. T_p^c and T_u^c represents the thresholds of the confidence and uncertainty score of class c. In each iteration, only samples above the confidence threshold and below the uncertainty threshold are selected into training in the next iteration.

C. Model Re-training

To avoid confirmation bias of model, re-initialing is adopted before new iteration rather than continuous fine-tuning the model. It reduces the impact of incorrect pseudo-labeled samples in the early training period. The process terminates when no more unlabeled data can be added into the model training. The complete algorithm is described in Algorithm 1.

IV. Experimental Results

Backbone model WideResNet-28-2[17] and ResNet-18[18] are used for CIFAR-10 and ISIC2018, respectively. Both of

them are pretrained on ImageNet. Fast Autoaugment[19] and Mixup[20] are employed as data augmentation methods during the model training. The dropout is set to 10.

A. Dataset

CIFAR-10[21] contains 60,000 32×32 color images in 10 classes. Each class has 6,000 images. 4,000 images are used as labeled data for training, 41,000 images as unlabeled data. The number of validation and test set is set to 5,000, and 10,000, respectively.

SVHN[22] is a Google Street View House Number classification dataset. There are 10 categories, representing numbers 0 to 9. In the experiment, the training set is divided into 1,000 labeled data and 71,257 unlabeled data, the validation set was 1,000, and the test set is 26,032 images.

ISIC2018[23] is a skin lesion dataset, containing 10,208 600×450 color images in 7 classes. 1,000 images are used as labeled data for training, and 8,500 images as unlabeled data. The validation set contains 515 images, and 193 in the test set.

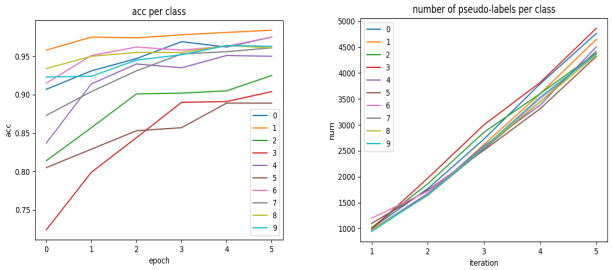
TABLE I
CLASSIFICATION ERROR ON CIFAR-10 DATASET.

Approach	Method	Error rate
Pseudo-Labeling	PL	17.78
	CL	5.62
	PL-CB	6.28
	UPS	6.42
	Ours	4.82

B. Experimental Results on CIFAR-10

1) Comparison with other method

Table I presents the classification error comparison with other methods on CIFAR-10 dataset. Recent pseudo-labeling methods have been chosen for comparison, including **PL** [1], **CL**, [2], **UPS** [3] and **PL-CB** [4]. The proposed method achieves the best results on CIFAR-10 dataset.



2) Visualization of Noisy Label Filtering

The visualization noisy label filtering is depicted in Fig. 4. The leftmost of each row is the predicted pseudo-label for that row of pictures. CNF on the right of the picture represents the confidence score, and the UNC is the uncertainty score. In this cases, the pseudo labels are incorrect but having high confidence score. Since their uncertainty score is higher than threshold, they are considered as noisy sample by our method.

Fig. 3(a) illustrates the test accuracy of each category at different iterations. Compared with Fig. **??** ,our method has a significant improvement in some categories. Fig. is a graph of the number of pseudo-labels for each category at different iterations. In the original method (Fig. 1.4), due to the use of strong augmentation such as Mixup, the number of pseudo-label data of each category is extremely unstable in different iterations, the changes are very drastic, and the difference between the number of data each class is very large. However, it can be seen from Fig. 5.4 that our method can effectively improve this problem. Even using the strong augmentation, it can maintain stable and balanced growth, and the difference between the number of the most and the least pseudo-labels in each class of the data witch at the last iteration does not exceed 1,000.

3) Ablation Study

Table II evaluates three components of our method. The baseline method PL uses a fixed threshold of 0.9 to select the pseudo-labeled data and achieves classification error of 17.78.

(a) Test Accuracy on CIFAR-10. (b) Number of the pseudo-labels.

Fig. 3. Visualization of the experiment result on CIFAR-10.

TABLE II
ABLATION STUDY ON CIFAR-10 DATASET.

Methods	Error rate
PL	17.78
PL + FA + Mixup	8.59
PL + FA + Mixup + NLF	8.18
PL + FA + Mixup + SP	5.13
PL + FA + Mixup + SP + NLF	4.78

TABLE III
CLASSIFICATION ERROR ON SHVN DATASET.

Approach	Method	Error rate
Pseudo-Labeling	PL	9.94
	CL	3.83
	Ours	3.77

After adding two data augmentation methods, Fast Autoaugment (FA) and Mixup, the error rate can be decreased to 8.59. Next, we evaluate the impact of noisy label filtering (NLF) and self-paced samples selection (SP), respectively. When including noisy label filtering and self-paced samples selection into self-training, the error rates can be further decreased to 8.18 and 5.13. Self-paced samples selection significantly reduces classification error than the other components. Finally, adding all the components together, it achieves the error rate of 4.78.

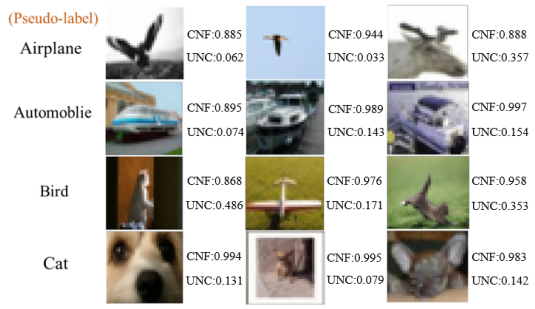
C. Experimental Results on SVHN

The test accuracy and the number of the pseudo-labels for each category are shown in Fig. 5(a) and Fig. 5(b). The biggest difference from the results in CIFAR-10 is that the SVHN dataset is not a category-average dataset.Owing to the proportional selection relationship, our method can adjust the amount of pseudo-label data for each category according to the distribution of the dataset. It allows for flexibility in the data set requirements, eliminating the need for category averages.

Table III shows the different pseudo-labeling-based methods experiment result on SVHN. Our method get an error rate of 3.77, that is superior to other proposed method.

D. Experimental Results on ISIC2018

Table IV presents the comparison with other methods on ISIC2018 dataset. Our method achieves classification error 26.43, which is very competitive to recent methods. Although



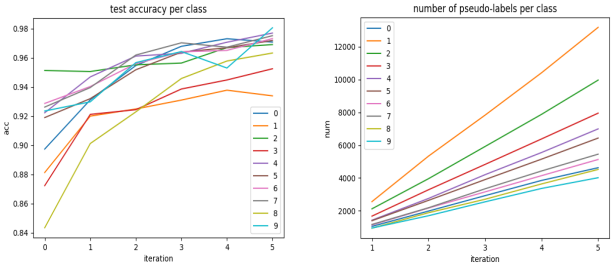


Fig. 4. Visualization of noisy pseudo-labeled sample filtering.

(a) Test Accuracy on SVHN. (b) Number of the pseudo-labels.

Fig. 5. Visualization of the experiment result on SVHN.

TABLE IV
CLASSIFICATION ERROR ON ISIC2018 DATASET.

Approach	Method	Error rate
Pseudo-Labeling	PL	36.27
	CL	32.13
	Ours	26.43

ISIC2018 is not a category-average dataset, the proposed method outperforms other methods.

V. CONCLUSION

A classwise self-paced method is proposed for self-training. Self-paced learning is employed to improve the selection of pseudo-labeled sample in self-training. This enable the model training from simple and reliable data first, and then gradually adding difficult data in to the training process. Dropout is exploited to evaluate data uncertainty. As a noisy label filtering, it helps pseudo-labeled sample selection be more accurate. In a class-specific selection fashion, these two methods can be combined to solve the class imbalance problem that is prone to occur frequently when self-training is applied. This also improves the accuracy of each category in the testing phase, and reduces the gap in accuracy between hard and easy categories. In the future, we hope that the concept of classwise self-paced samples selection can be combined with other semi-supervised learning methods, such as consistency regularization, to achieve higher classification accuracy.

CapFormer: A Space-Time Video Description Model using Joint-Attention Transformer

Mahamat Moussa, Chern Hong Lim and KokSheik Wong
School of Information Technology, Monash University Malaysia
E-mail: {mahamat.moussaabbasal, lim.chernhong, wong.koksheik}@monash.edu

***Abstract*—Transformers in video understanding are becoming popular due to the recent success of vision transformers. However, video transformers are still emerging and require various tricks to understand video tasks, such as action detection, classification, and description. The need for such tricks is due to videos' temporal and spatial space, which requires different techniques to understand the context better. The most critical component is the attention block, which gives different results if tackled differently. In video description techniques, the model designs are mainly complex due to the integration needed between visual and language contexts. In this work, we proposed a simple yet efficient video description model that relies entirely on an attention mechanism. The model uses a joint-attention mechanism to learn the spatial and temporal context of video frames with their description context. Surprisingly, this integration setting suggests a more straightforward way to achieve the same task achieved by complex networks, and thus, it is efficient in terms of training. To validate the design, we evaluated the proposed architecture on a large video description dataset (MSR-VTT) and compared its result with various works, and it showed promising results over other designs in terms of the ROUGE metric.**

I. Introduction

In recent years, many deep learning video understanding techniques have been developed to endow machines with the capability to understand the visual context at a high level [1]. Combining videos and natural language processing (NLP) has become a promising method in video description and video question answering (VQA) [2]. The success behind this combination is that video and NLP share similar high-level characteristics [3], as video and NLP are processed as a sequence of frames and sequence of words, respectively.

Previously, video description was achieved by combining multiple models such as convolutional neural networks (CNN), Recurrent Neural Networks (RNN), and Long-Short Term Memory (LSTM). The introduction of Vision Transformers (ViT) pushed progress positively by replacing CNN with Transformers. Furthermore, [3] introduced TimeSformer, a convolution-free network built on temporal and spatial self-attention transformer. The model extends the concept of ViT into video classification and achieves state-of-the-art performance [3]. ViT and TimeSformer have a similar architecture, demonstrating the effectiveness of simplified neural networks by utilizing attention mechanisms to achieve tasks that used to be done in complex ways. However, the works mentioned above consider only the video classification task, which is only halfway to describing a video. To achieve this feature, the model needs to integrate a language model to describe the content and events in the video. In this regard, the work of [3] is limited because the model is not designed to describe videos due to its architecture that consists of an encoder only, which is similar to [4].

Motivated by this, we introduce "CapFormer" a video description model using a joint-attention mechanism to learn the video features and their word embedding in a unified design. The architecture of CapFormer consists of two parts: 1) Encoder that uses divided self-attention over spatial (space) and temporal (time) mechanisms to learn spatial-temporal features from videos, and 2) Decoder that jointly learns the context of video concerning its word embedding in the description text. Such integration enables the model to generate a sentence that best describes the video content. CapFormer introduces a simplified concept to achieve a video description task entirely based on attention mechanism, unlike most video description networks that are complex in design or combine different networks [5], [6]. Our simplified design network shows its efficiency with various experiments by processing videos with higher frame rates and more extended duration with a good performance.

We evaluate our model on MSR-VTT [7] (a large video description dataset) and compare its performance against state-of-the-art video description methods. Results show that our model outperforms the conventional methods and transformer-based architecture that are complex in design.

II. Related Work

Many video understanding techniques have been developed based on transformer architecture. These techniques can be highlighted based on 1) Video attributes understanding techniques to perform detection, classification, and recognition and 2) Video attributes Integration with language to perform captioning, description, and question answering.

Video attributes understanding Attributes understanding in videos has been progressing since the introduction of vision transformer (ViT) by [4], which has contributed towards developing more video understanding models and frameworks that use transformers as main or part of their designs, achieving state-of-the-art performance in many visual understanding tasks due to its attention mechanism [8]. The work of video attribute understanding and learning covers various domains such as video understanding [9], video classification [3], action and activity recognition [10]–[12]. Although these works are

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

transformers-based, their designs are limited to attribute understanding only, facilitating and supporting visual understanding. Such design is mainly interested in the encoder part to perform classification or prediction.

Video attributes integration with language The video and language integration aims to understand video attributes and learn the contextual relationship between videos and their descriptions. Such concept enabled many applications in the video domain such as video description and captioning [13], [14], video question-answering [15]–[17], and video retrieval [18], [19] all based on transformers.

Regarding network design, integrating video and language requires different approaches than learning video attributes only. One common approach is to combine visual understanding networks such as CNN with transformers [20]. However, many recent approaches show that ViT can replace CNN to perform video learning tasks [3]. The focus then shifted to designing more efficient Video Transformer networks. These works include: Spare Transformers [21], Hierarchical Transforms [22], [23], Query-driven Transformers [24], [25], Local Transformers [26], Memory efficient Transformers [27], and more.

For instance, [22] proposed a multi-modal hierarchical temporal aware architecture that utilizes two encoders: one for video understanding and another for text. Their technique relies on extracting two views from the video, long view and short view, then learning the features of each and combining them to do cross-modal learning between text and video. Similarly, [23] adopted a design that uses two encoders to learn textual and visual data in a multi-modal design. Their design is based on pixel-level visual understanding, which neglects the local (within a frame) and global (among frames) context of the visual data, especially in long videos.

Another design that integrates language with video is the work by [24]. In their design, they use a transferable visual model from the natural language supervision approach by generating video captions using GPT-2, then query the result with ground truth description and perform video caption interaction between the ground truth description and the generated one. This work aims to contribute to text-video retrieval progress.

The common problem identified in these works is the complexity of design. Such complexity can be understood prior to transformers; however, with the presence of ViT, we aim to find a more straightforward and efficient solution to do the same task. We design our architecture to leverage the attention mechanism for the entire learning journey. We use the space-time technique to enable our model to learn the local and global context of the video and the relationship with their description words, making it a simple video description architecture that extends the attention over space, time, and word embedding.

III. CapFormer Development

Using a joint-attention mechanism, we put forward a video description model named CapFormer . Our model integrates an encoder for video understanding and a decoder for language generation to perform video description.

The model generates a sentence that describes the learned video features. In detail, the model takes a video clip X and its description T as input. The clip $X \in \mathbb{R}^{H\times W\times C\times N}$ has F frames of a dimension $H \times W$ pixels and C channels, where $C = 3$ denotes a color frame (RGB). The description T is a sentence consisting of i words, where each sentence is tokenized with a fixed-length vector L. The overall architecture of the model is illustrated in Fig. 1.

A. CapFormer Encoder

The encoder of CapFormer learns video representation features at a given time step (t). Each frame of X is divided into N non-overlap patches of size $P \times P$ as $N = HW/P^2$. These patches are flatten as vectors $\mathbf{x}_{(p,t)} \in \mathbb{R}^{3P^2}$ where $p = 1, \ldots, N$ denotes the spatial position and $t = 1, \ldots, F$ denotes the temporal position over frames. Each patch of $\mathbf{x}_{(p,t)}$ is mapped into an embedding vector $\mathbf{z}^{(0)}_{(p,t)} \in \mathbb{R}^D$ linearly using Learanble Matrix $(LM) \in \mathbb{R}^{D\times 3P^2}$ as given by (1).

$$\mathbf{z}^{(0)}_{(p,t)} = LM\mathbf{x}_{(p,t)} + \mathbf{e}^{pos}_{(p,t)} \tag{1}$$

The $\mathbf{e}^{pos}_{(p,t)} \in \mathbb{R}^D$ is the positional embedding for the spatial p and temporal t of each patch. The resulting linear embedding vector $\mathbf{z}^{(0)}_{(p,t)}$ represents the input to the encoder. At each patch p of each layer l of the encoder, a vector of query, key, and value is computed from $\mathbf{z}^{(\ell-1)}_{(p,t)}$ that is encoded by a previous block $\ell - 1$, as given by (2) where $\wp$ represents query (q), key (k), or value (v). The LN denotes layer normalization, a denotes a position through multiple attentions, and D_h indicates the latent dimension of each attention.

$$\wp^{(\ell,a)}_{(p,t)}\& = W^{(\ell,a)}_{\wp}\mathrm{LN}\left(\mathbf{z}^{(\ell-1)}_{(p,t)}\right) \in \mathbb{R}^{D_h} \tag{2}$$

Next, we compute the attention $\boldsymbol{\alpha}$ over the temporal and spatial position of X using (3) and apply softmax (SM). The $\measuredangle$ represents both temporal and spatial position but in a sequential process. First, the temporal attention is calculated (hence $\measuredangle$ = temporal), and then the spatial attention is calculated (hence $\measuredangle$ = spatial), and the En indicates the end of the current process.

$$\boldsymbol{\alpha}^{(\ell,a)\measuredangle}_{(p,t)} = \mathrm{SM}\left(\frac{\mathbf{q}^{(\ell,a)\top}_{(p,t)}}{\sqrt{D_h}} \cdot \left[\mathbf{k}^{(\ell,a)}_{(0,0)}\left\{\mathbf{k}^{(\ell,a)}_{(p,t')}\right\}_{\measuredangle'=1,\ldots,En}\right]\right) \tag{3}$$

After that, the final learned weights of X are computed by concatenating vectors of all attention heads $\mathcal{A}$ and perform a dot product on the weight matrix for the linear projection of the concatenated outputs W_O as in (4) then pass it through a multilayer perceptron (MLP) in (5) to obtain the resulting embedding $\mathbf{Z}$ of the learned video attributes, which will be passed to the bimodal block in the decoder as key, value.

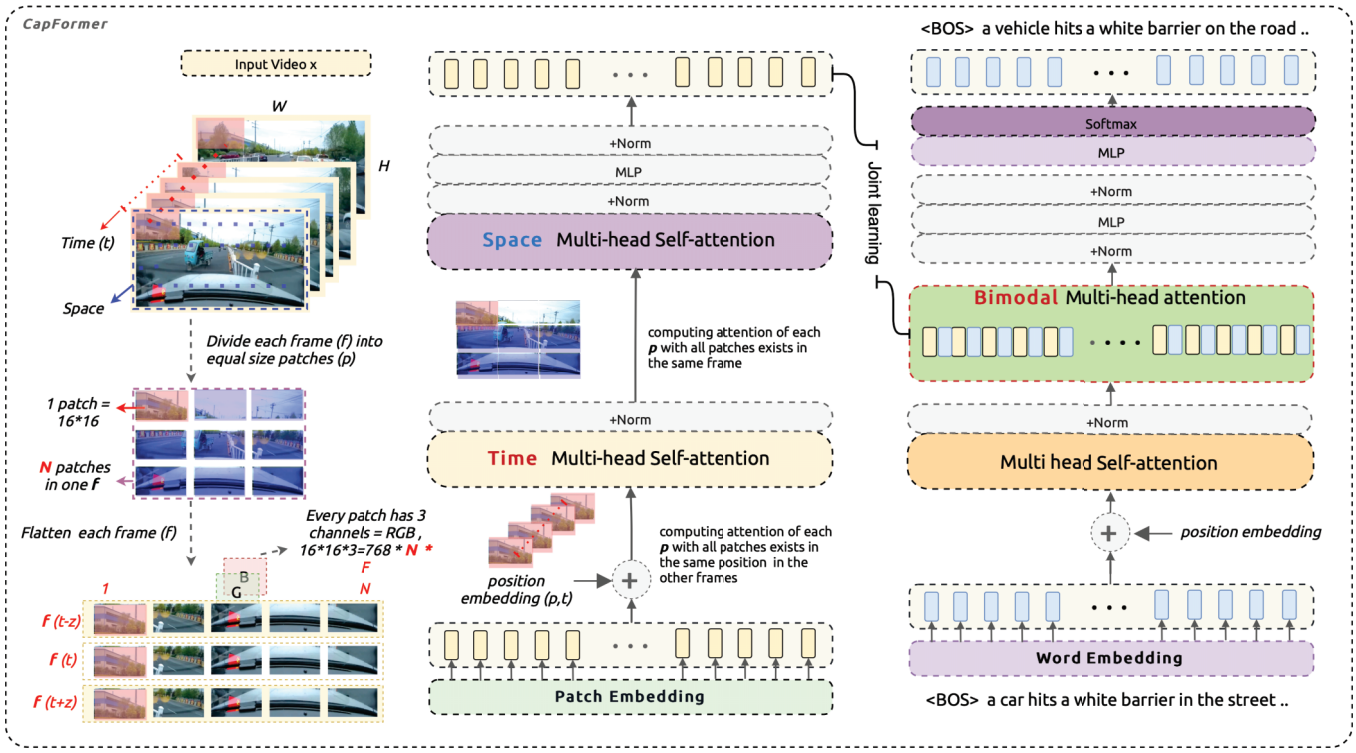

Fig. 1. The Architecture of CapFormer.

$$\mathbf{z'}^{(\ell)}_{(p,t)} = W_O \begin{bmatrix} \mathbf{s}^{(\ell,1)}_{(p,t)} \\ \vdots \\ \mathbf{s}^{(\ell,A)}_{(p,t)} \end{bmatrix} + \mathbf{z}^{(\ell-1)}_{(p,t)} \tag{4}$$

$$\mathbf{Z} = \mathrm{LN}\left(\mathrm{MLP}\left(\mathbf{z'}^{(\ell)}_{(p,t)}\right)\right) + \mathbf{z'}^{(\ell)}_{(p,t)} \tag{5}$$

B. CapFormer Decoder

The decoder of CapFormer takes the resulting embedding from (5) as key, value, and the description $\mathbf{T}$ that contains i words. The $\mathbf{T}$ is converted into a vector T_v consisting of i words, tokenized in a fixed-length vector using an embedding layer: $T_v = \{i_1, i_2, \ldots, i_C\}$ where i_C is the length of T_v as illustrated in figure 2.

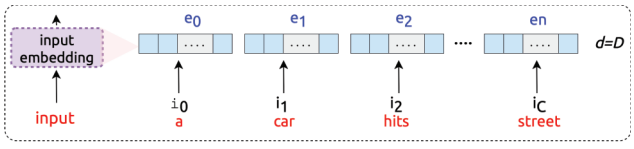

Fig. 2. Video description embedding illustration

The T_v is projected into a query (q), key (k), and value (v) to compute its self-attention At using (6).

$$At(q_i, k_j) = \left(\frac{q_i.k_j}{\sqrt{d_k}}\right) \tag{6}$$

Next is to obtain the computed attention weight AW using (7) which is then used to obtain the weighted sum. Finally, the attention heads are concatenated and linearly projected to obtain the final output query (q) = A_q as shown in (8), which is used as input for the bimodal block.

$$AW = \mathrm{SM}\left(At(q_i, k_1), At(q_i, k_2), \ldots, At(q_i, k_T)\right) \tag{7}$$

$$\mathbf{A_q} = W_O \begin{bmatrix} head_1 \\ \vdots \\ head_n \end{bmatrix} \tag{8}$$

Computing Joint-attention of X and T: The bimodal multi-head attention is the attention block where the interaction between the output of the encoder Z which is projected into key k_e and value v_e, and the output of the multi-head self-attention block of the decoder A_q occurs. Since the video description is generated token by token, the bimodal multi-head attention considers the temporal aspect of the decoder by concatenating the query vector at a time step $A_{q_{(t)}}$ in the decoder with the encoder's k_e and v_e as shown in (9),

$$Bimodal(A_{q_{(t)}}, k_e, v_e) = W_O \begin{bmatrix} head_1 \\ \vdots \\ head_h \end{bmatrix} \tag{9}$$

where the $head_n$ is defined in the Bimodal Scaled Dot Product Attention (BSA) function in (10), n denotes the

attention heads, while the full expression of BSA defined in (11).

$$head_n = BSA(A_{q_{(t)}}, k_e, v_e) \tag{10}$$

$$BSA(A_{q_{(t)}}, k_e, v_e) = SV\left(\frac{QK^T}{\sqrt{d_k}}\right)V. \tag{11}$$

Let us define the resulting attentive context vector of the bimodal from (9) as C_t for time step t; we use C_t as input to pass it through an MLP with the residual connections and then apply softmax function to generate the probability distribution P_t over the vocabulary vector at time step t until the stop token is generated. As a result, the complete sentence that describes the input video X is generated as shown in (12)

$$P_t = \mathrm{SM}\left(MLP(LN(C_t)) + C_t\right) \tag{12}$$

As a result, a full predicted sentence describing the video's learned attributes is generated.

IV. Experiments

We evaluated the proposed CapFormer model on a Large Video Description Dataset: MSR-VTT [7] to examine its performance compared to other models that use the same dataset for video description tasks. MSR-VTT consists of 10k video clips. We split the data as follows: 65% for training (viz., 6513 clips), 30% for testing (viz., 2990 clips), and 5% for validation (viz., 497 clips). Each clip has 20 sentences of description available.

Our model is configured with a stack of 12 encoder layers and six decoder layers. However, depending on the experiment, the number of layers could be changed empirically. We use a video of size $W \times H \times F = 224 \times 224 \times 8$, where each frame is divided into patches of 16×16 pixels. This results in 14×14 patches, each with a size of $16 \times 16 \times 3$ pixels.

A. Training and Hyperparameters

CapFormer is trained on an Advanced Computing Platform (HPC) powered by NVIDIA A100 GPU for 30 training epochs using the PyTorch framework.
