&\leq -\mathbb{E}_{\boldsymbol{\lambda}_\mathrm{R} \sim p(\boldsymbol{\lambda}_\mathrm{R}), \boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R}), \boldsymbol{\lambda}'_\mathrm{R} \sim p(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})} [\log q(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})] \\
&= -\mathbb{E}_{\boldsymbol{\lambda}_\mathrm{R} \sim p(\boldsymbol{\lambda}_\mathrm{R}), \boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R})} [\log q(\boldsymbol{\lambda}_\mathrm{R}|\boldsymbol{x})] =: R_\mathrm{P}, \qquad (3)
\end{aligned}
$$

where $q(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})$ is an arbitrary conditional PDF. The equality holds if $q(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x}) = p(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})$. Therefore, assuming $q(\boldsymbol{\lambda}'_\mathrm{R}|\boldsymbol{x})$ in some parametric form, the left-hand side of (3) can be decreased by alternately decreasing R_P with respect to $(\boldsymbol{\phi}, \boldsymbol{\theta})$ and q. Specifically, for all $i \in \{1, \ldots, T\}$, we represent $q((\lambda'_\mathrm{R})_i|\boldsymbol{x})$ as the Laplace distribution with location parameter $(\hat{\lambda}_\mathrm{R})_i$ and scale parameter of one, where $\hat{\boldsymbol{\lambda}}_\mathrm{R} = \mathrm{P_{ext}}(\hat{\boldsymbol{\mu}}_\mathrm{R})$ is an output of an auxiliary neural network (i.e., F_0 extractor) $\mathrm{P_{ext}} : \mathbb{R}^{F \times T} \mapsto \mathbb{R}^T$ and $(\hat{\boldsymbol{\mu}}_\mathrm{R}, \hat{\boldsymbol{\sigma}}_\mathrm{R}) = \mathrm{DEC}(C, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R})$, and consider training its parameters $\boldsymbol{\psi}_\mathrm{P}$ along with $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$. Hence, $\mathrm{P_{ext}}$ is trained to estimate the log F_0 pattern from an input log mel-spectrogram.

Given $\boldsymbol{c}$ and $\boldsymbol{\lambda}_\mathrm{R}$, we also consider using the negative mutual information $\mathcal{I}_\mathrm{T}(\boldsymbol{\theta})$ between $\boldsymbol{x}$ and s_R as a training criterion. As above, the expectation of $\mathcal{I}_\mathrm{T}(\boldsymbol{\theta})$ except for a constant term over s_R can be upper bounded by $R_\mathrm{T} \coloneqq -\mathbb{E}_{s_\mathrm{R} \sim p(s_\mathrm{R}), \boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R}, s_\mathrm{R})} [\log r(s_\mathrm{R}|\boldsymbol{x})]$, where $r(s_\mathrm{R}|\boldsymbol{x})$ is an arbitrary categorical distribution and the exact bound is achieved when $r(s_\mathrm{R}|\boldsymbol{x}) = p(s_\mathrm{R}|\boldsymbol{x})$. Thus, it can be decreased by alternately decreasing R_T with respect to r and $(\boldsymbol{\phi}, \boldsymbol{\theta})$. Here, we assume $r(s_\mathrm{R}|\boldsymbol{x})$ to be a categorical distribution with each probability given as an output of an auxiliary neural network (i.e., speaker classifier) $\mathrm{CLS} : \mathbb{R}^{F \times T} \mapsto \mathbb{R}^{T_\mathrm{S}}$ [1], and consider training its parameters $\boldsymbol{\psi}_\mathrm{T}$ along with $\boldsymbol{\phi}$, $\boldsymbol{\theta}$, and $\boldsymbol{\psi}_\mathrm{P}$. Hence, CLS is trained to detect the speaker from an input log mel-spectrogram.

The criteria R_P and R_T are defined under specific $(\boldsymbol{c}, s_\mathrm{R})$ and $(\boldsymbol{c}, \boldsymbol{\lambda}_\mathrm{R})$, respectively. Since $\boldsymbol{c}$, s_R, and $\boldsymbol{\lambda}_\mathrm{R}$ are determined stochastically according to the training examples, the actual criteria used for training will be the expectations of R_P and R_T with respect to $\boldsymbol{c}$, s_R, and $\boldsymbol{\lambda}_\mathrm{R}$. Let $\mathcal{L}_\mathrm{P} \coloneqq \mathbb{E}_{\boldsymbol{x}' \sim p(\boldsymbol{x}'), \boldsymbol{c} \sim q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x}'), s_\mathrm{R} \sim p(s_\mathrm{R})} [R_\mathrm{P}]$ and $\mathcal{L}_\mathrm{T} \coloneqq \mathbb{E}_{\boldsymbol{x}' \sim p(\boldsymbol{x}'), \boldsymbol{c} \sim q_{\boldsymbol{\phi}}(\boldsymbol{c}|\boldsymbol{x}'), \boldsymbol{\lambda}_\mathrm{R} \sim p(\boldsymbol{\lambda}_\mathrm{R})} [R_\mathrm{T}]$, where $\boldsymbol{x}' \sim p(\boldsymbol{x}')$ indicates the log mel-spectrogram of a randomly drawn training sample. The process $\boldsymbol{\lambda}_\mathrm{R} \sim p(\boldsymbol{\lambda}_\mathrm{R})$ can be implemented as random resampling (RR), which converts an input log F_0 pattern $\boldsymbol{\lambda}$ into random one $\boldsymbol{\lambda}_\mathrm{R}$. In the experiment, we defined

[1] T_S is an arbitrary natural number. As shown in Fig. 1, CLS contains convolutional layers and thus T_S depends on T in the experiment.

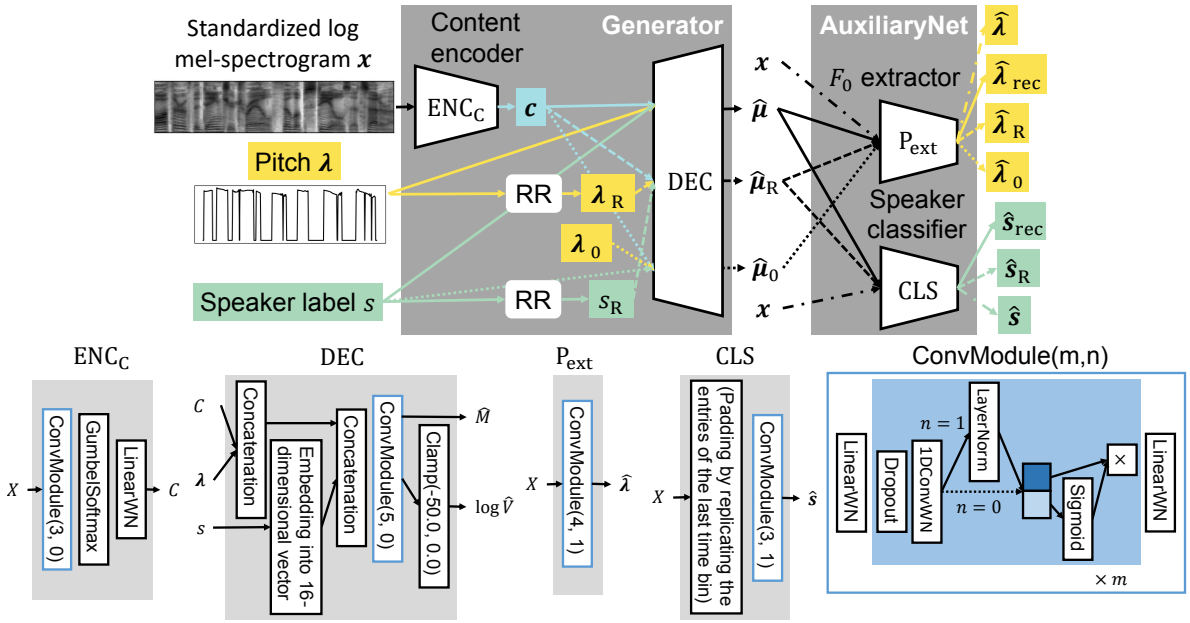

Fig. 1. The network architecture of the DisC-VC. "GumbelSoftmax" means sampling from the Gumbel-Softmax distribution [37]. "LinearWN" and "1DConvWN," respectively, are linear and 1D convolution layers with weight normalization [38] (i.e., the weight vectors are decoupled into their norms and directions). $\mathrm{Clamp}(a, b)$ is a function that clamps input into the range $[a, b]$ by setting the values less than a to a and by setting those more than b to b. "LayerNorm" means layer normalization [39] (i.e., normalization over the hidden units in a layer).

the RR of F_0 by $(\lambda_\mathrm{R})_i = \lambda_i + \beta$ with $\beta \sim \mathrm{Uniform}([0.3, 3))$, if $\lambda_i \neq 0$, and $(\lambda_\mathrm{R})_i = \lambda_i$, otherwise. We also defined the RR of speaker index by generating s_R from a discrete uniform distribution on $\{1, \ldots, S\}$. The idea of RR has also been adopted in SpeechFlow [19], however, there has been no consideration for the discrepancy between the specified F_0/timbre information and those of the conversion result.

The actual flow of computing $\mathcal{L}_\mathrm{P}$ and $\mathcal{L}_\mathrm{T}$ can be explained as follows. For each training sample $\boldsymbol{x}'$, the decoder generates $\boldsymbol{x}$ using $\boldsymbol{c} = \mathrm{ENC_C}(\boldsymbol{x}')$ along with $\boldsymbol{\lambda}_\mathrm{R}$ and s_R randomly drawn from predefined distributions $p(\boldsymbol{\lambda}_\mathrm{R})$ and $p(s_\mathrm{R})$, respectively. The auxiliary network then extracts $\hat{\boldsymbol{\lambda}}_\mathrm{R}$ and $\hat{\boldsymbol{s}}_\mathrm{R}$ from $\boldsymbol{x}$ and checks whether they are consistent with $\boldsymbol{\lambda}_\mathrm{R}$ and s_R. In addition, to better express unvoiced and voiced speech differently, we define $\mathcal{L}_{\mathrm{P}0}$ in a similar way as $\mathcal{L}_\mathrm{P}$ for a zero vector $\boldsymbol{\lambda}_0 \in \mathbb{R}^T$ and $\hat{\boldsymbol{\lambda}}_0 = \mathrm{P_{ext}}(\hat{\boldsymbol{\mu}}_0)$ as a training criterion, where $(\hat{\boldsymbol{\mu}}_0, \hat{\boldsymbol{\sigma}}_0) = \mathrm{DEC}(C, \boldsymbol{\lambda}_0, s)$. We also define $\mathcal{L}_{\mathrm{P}1}$ for $\boldsymbol{\lambda}$ and $\hat{\boldsymbol{\lambda}} = \mathrm{P_{ext}}(\boldsymbol{x})$, $\mathcal{L}_{\mathrm{P}2}$ for $\boldsymbol{\lambda}$ and $\hat{\boldsymbol{\lambda}}_\mathrm{rec} = \mathrm{P_{ext}}(\hat{\boldsymbol{\mu}})$, $\mathcal{L}_{\mathrm{T}1}$ for s and $\hat{\boldsymbol{s}} = \mathrm{CLS}(\boldsymbol{x})$, and $\mathcal{L}_{\mathrm{T}2}$ for s and $\hat{\boldsymbol{s}}_\mathrm{rec} = \mathrm{CLS}(\hat{\boldsymbol{\mu}})$.

We train the entire network to minimize $\mathcal{L} := \eta\mathcal{L}_\mathrm{like} + \eta_\mathrm{P}(\mathcal{L}_\mathrm{P} + \mathcal{L}_{\mathrm{P}0} + \mathcal{L}_{\mathrm{P}1} + \mathcal{L}_{\mathrm{P}2}) + \eta_\mathrm{T}(\mathcal{L}_\mathrm{T} + \frac{1}{2}\mathcal{L}_{\mathrm{T}1} + \frac{1}{2}\mathcal{L}_{\mathrm{T}2})$ based on back-propagation. In the experiment, we set $\eta = 1/FT$, $\eta_\mathrm{P} = 1/4T$, and $\eta_\mathrm{T} = 1/2T_\mathrm{S}$, and replaced expectation over $\boldsymbol{x}'$ in computing each loss with a sample mean of a given mini-batch, which consists of 16 randomly selected training samples. A training sample was defined as $\{(\boldsymbol{x}_s, \boldsymbol{\lambda}_s, s) | s = 1, \ldots, S\}$, where $\boldsymbol{x}_s$ and $\boldsymbol{\lambda}_s$ were a log mel-spectrogram and a log F_0 pattern of the sth speaker, respectively. It must be noted that the criterion $\mathcal{L}$ can be used not only for training the generator considered in this study, but also for training other existing generator networks that allow F_0/timbre conditioning (e.g., SpeechFlow [19]).

D. Conversion Process

By using the trained DisC model, we can apply the following types of conversion to a given test sample $(\boldsymbol{x}, \boldsymbol{\lambda}, s)$: (1) change log F_0 pattern by a given value $\beta \in \mathbb{R}$, (2) change log F_0 pattern from speaker s to $\check{s}_\mathrm{P}$, and (3) change timbre from speaker s to $\check{s}_\mathrm{T}$. By defining $\beta = 0$, $\check{s}_\mathrm{P} = s$, or $\check{s}_\mathrm{T} = s$, we can also perform each type of conversion individually.

The target log F_0 pattern $\check{\boldsymbol{\lambda}} \in \mathbb{R}^T$ is defined as follows. Let $\mu_\mathrm{P}(s)$ and $\sigma_\mathrm{P}(s)$, respectively, be the sample mean and sample standard deviation of the log F_0 pattern (except for the zero entries) of the sth speaker in the training data set. For all $i \in \{1, \ldots, T\}$, we define $\check{\lambda}_i = [\sigma_\mathrm{P}(\check{s}_\mathrm{P})/\sigma_\mathrm{P}(s)][\lambda_i - \mu_\mathrm{P}(s)] + \mu_\mathrm{P}(\check{s}_\mathrm{P}) + \beta$, if $\lambda_i \neq 0$, and $\check{\lambda}_i = 0$, otherwise.

We obtain $(\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\sigma}}) = \mathrm{DEC}(\mathrm{ENC_C}(\boldsymbol{x}), \check{\boldsymbol{\lambda}}, \check{s}_\mathrm{T})$ and reconstruct a waveform from $\hat{\boldsymbol{\mu}}$ with a neural vocoder. In the experiment, we used Parallel WaveGAN [33].

III. Experiment

A. Experimental settings

By using the CMU Arctic speech databases [42], we trained the DisC model with the $1,000$ training samples per speaker for $5,000$ epochs, applied F_0 and/or timbre conversion to the 132 test samples per speaker, and compared the results with those obtained with the following baseline methods. The number of speakers was four in both the training and test data sets.

DisC-NoAux is DisC with no auxiliary network, and it is trained by minimizing $\mathcal{L}_\mathrm{like}$ in Section II-C1. ACVAE-C [17] is

the original ACVAE that takes MCCs as input and reconstructs a waveform from converted MCCs and F_0 pattern by using a WORLD vocoder [27]. ACVAE-S [29] is the extended ACVAE that takes mel-spectrogram as input and reconstructs a waveform from a converted mel-spectrogram by using a neural vocoder. For reference, we also used WORLD vocoder [27] itself for F_0-only conversion by using the MCCs of an input signal and $\check{\boldsymbol{\lambda}}$ given in Section II-D. We also tried F_0 and timbre conversion with BNE-Seq2seqMoL (BNE) [35] as an example of F_0-controllable methods. It must be noted that we cannot compare its result with those of the other methods as it is, since we used the pretrained synthesis model provided by the authors of [35], which was trained with a different data set than the CMU Arctic one.

To compare these methods, we tried **task P** to change log F_0 pattern by $\beta \in \{\log(1.5), -\log(1.5)\}$, **task T** to change timbre to that of a target speaker, and **task PT** to change both F_0 pattern and timbre to those of a target speaker. Since only simultaneous conversion of F_0 pattern and timbre is possible with ACVAE-S, we use the same results in tasks T and PT for this method. Before evaluation, we trimmed the leading and trailing silent sections of all the target and converted samples. In tasks T and PT, we tried all 12 patterns of combinations of source and target speakers.

B. Objective evaluation

To evaluate F_0 and timbre conversion performance, we adopted the F_0 error ΔF_0 (i.e., the root mean squared error between two log F_0 patterns) and the mel-cepstral distortion (MCD), respectively. Since target and converted speech signals are not necessarily aligned in the time direction, we first applied endpoint-free Dynamic Time Warping to a given pair of log F_0 patterns or MCCs and then computed ΔF_0 and the MCD with the optimally aligned sequences. For all the tasks, we computed ΔF_0 between the target log F_0 pattern $\check{\boldsymbol{\lambda}}$ and that of the converted speech. We evaluated the MCD between the samples before and after conversion for task P and those between the target and converted samples for tasks T and PT.

Tables I, II, and III show the results of tasks P, T, and PT, respectively. Table I shows that the timbre of the source speech was maintained more successfully with DisC than with DisC-NoAux in F_0-only conversion. In the same task, we also see that the F_0 conversion performance of DisC was better than that of DisC-NoAux. Tables II and III show that timbre conversion was more successfully done by DisC than by ACVAE-C, whereas F_0 conversion was more successfully done by DisC than by ACVAE-S (especially in timbre-only conversion task). ACVAE-C and -S achieved the best performance in terms of ΔF_0 and the MCD, respectively, however, they could not keep these criteria small at the same time.

C. Subjective evaluation

To conduct subjective evaluation, we randomly chose three test samples for each of the quality and timbre evaluations and for each setting (i.e., a combination of β, a source speaker, and a conversion method in task T and a combination of a source and target speakers and a conversion method in tasks T and PT). For timbre evaluation, we concatenated target and converted speech samples with a 1 s silent interval. We defined the target speech sample as a randomly selected one of the target speaker (i.e., the text content is not necessarily the same as that of the converted one). By considering the fact that we use the same result for tasks T and PT with regard to ACVAE-S, each of 15 listeners was presented 324 samples in each of quality and timbre evaluations.

We conducted a mean opinion score (MOS) test for sound quality, where each listener scores the sound quality of each sample by choosing one out of the five options, "1: Bad," "2: Poor," "3: Fair," "4: Good," and "5: Excellent." Timbre evaluation was done based on the ABX test for speaker similarity, where he/she chooses one out of the four options, "1: Different (sure)," "2: Different (not sure)," "3: Same (not sure)," and "4: Same (sure)," for each concatenated sample.

Tables IV and V, respectively, show the results of the quality and timbre evaluations. In task P, F_0 conversion by WORLD vocoder achieved the best sound quality, however, DisC could maintain the timbre of the source speaker the best. When converting only timbre (i.e., task T), neither DisC nor DisC-NoAux could achieve as high sound quality and timbre

TABLE I
MCD FROM A SOURCE SPEAKER AND F_0 ERROR ΔF_0 IN TASK P. THE VALUES BEFORE AND AFTER $\pm$, RESPECTIVELY, INDICATE THE MEAN AND THE STANDARD DEVIATION FOR ALL THE SETTINGS AND TEST SAMPLES.

	DisC	DisC-NoAux	(WORLD)
MCD	6.14 ± 0.37	6.33 ± 0.47	4.23 ± 1.11

ΔF_0	0.13 ± 0.11	0.14 ± 0.11	0.12 ± 0.10	0.14 ± 0.10	0.19 ± 0.13

TABLE IV
MOS FOR SOUND QUALITY. THE VALUES BEFORE AND AFTER $\pm$, RESPECTIVELY, INDICATE THE MEAN AND THE STANDARD DEVIATION FOR ALL THE LISTENERS, SETTINGS, AND SELECTED TEST SAMPLES.

Task	DisC	DisC-NoAux	WORLD	ACVAE-C	ACVAE-S
P	2.62 ± 1.05	2.42 ± 1.12	2.95 ± 1.17	–	–
T	2.57 ± 1.15	2.42 ± 1.19	–	2.24 ± 0.98	3.55 ± 0.94
PT	3.45 ± 0.91	3.77 ± 0.89	–	2.36 ± 1.04	3.55 ± 0.94

TABLE V
SCORE OF ABX TEST FOR TIMBRE SIMILARITY. EACH VALUE INDICATES SIMILARITY WITH SOURCE SPEAKERS FOR TASK P AND THAT WITH TARGET SPEAKERS FOR TASKS T AND PT.

Task	DisC	DisC-NoAux	WORLD	ACVAE-C	ACVAE-S
P	2.03 ± 0.83	1.85 ± 0.85	1.34 ± 0.59	–	–
T	2.06 ± 1.18	2.06 ± 1.10	–	1.59 ± 0.85	3.41 ± 0.69
PT	3.33 ± 0.80	3.37 ± 0.75	–	2.36 ± 0.88	3.41 ± 0.69

maintenance as ACVAE-S. However, by converting F_0 pattern and timbre simultaneously (i.e., task PT), they could achieve comparable performance to ACVAE-S. A possible reason for this would be that speaker identity strongly depends on the average fundamental frequency, as also pointed out in [43].

IV. Conclusion

We developed a new F_0-controllable VC method DisC that takes into account discrepancy between the target and generated F_0 patterns in the training process. In this paper, we assumed that the same set of speakers appears in training and test data sets. It would be important to extend DisC so that it can be applied to unseen speakers in the test phase. Another future direction would be to take into account other prosody information (e.g., rhythm and stress) as controllable features.

***Abstract*—This paper proposes a new application in speech communication using text-to-speech (TTS), and the goal is to enable dysarthria, articulation disorder, or persons who have difficulty in speaking to communicate anywhere and anytime using speech to express their thoughts and feelings. To achieve this goal, an input method is required. Thus, we propose a new text-entry method based on three concepts. First, from an easy-to-carry perspective, we used a wearable keyboard that inputs digits from 0 to 9 in decimal notation according to 10-finger movements. Second, from a no-training perspective, users input sentences in a way of touch typing using the wearable keyboard. Following this method, we obtained a sequence of numbers corresponding to the sentence. Third, a neural machine translation (NMT) method is applied to estimate texts from the sequence of numbers. The NMT was trained using two datasets; one is a Japanese-English parallel corpus containing 2.8 million pairs of sentences, which were extracted from TV and movie subtitles, while the other is a Japanese text dataset containing 32 million sentences, which were extracted from a question-and-answer platform. Using the model, phonemes and accent symbols were estimated from a sequence of numbers. Thus, the result accuracy in symbol levels was 91.48% and 43.45% of all the sentences were completely estimated with no errors. To subjectively evaluate feasibility of the NMT model, a two-person word association game was conducted; one gave hints using synthesized speech that is generated from symbols estimated by NMT, while the other guessed answers. As a result, 67.95% of all the quizzes were correctly answered, and experiment results show that the proposed method has the potential for dysarthria to communicate with TTS using a wearable keyboard.**

I. Introduction

The intelligibility and naturalness of text-to-speech (TTS) have greatly improved in recent years by employing deep neural networks, allowing its widespread use in commercial products, such as smart speakers (e.g., Amazon Echo and Google Home) and voice assistance applications (e.g., Apple Siri). A promising application area for TTS is to support speech communications for persons who have difficulty in speaking, such as dysarthria, and articulation disorder [1], [2]. TTS is useful for people who have problems with articulators, and many patients enjoy the benefits of conveying their intentions through TTS. However, the range of use is limited because sentences were input using a keyboard. In general, keyboards have a certain size and weight, so users cannot always input sentences anywhere and anytime, especially while walking. Therefore, to extend the availability and create a new application in speech communication using TTS, we propose a new text-entry method based on three concepts: (1) using a wearable keyboard, (2) touch typing, and (3) employing neural machine translation (NMT) method.

Fig. 1. A wearable keyboard TAP

As the wearable keyboard, as shown in Figure 1, we used TAP [3], which consists of 10 finger rings attached to sensors and Bluetooth. When a user wears TAP and types, the sensors detect an occurrence of finger's movements, encode on-off patterns of the occurrence, and send the code using Bluetooth. To avoid training for usage and the burden of remembering the code, we used the concept of touch typing. The QWERTY keyboard is familiar to most of today's computer users, and users remember the QWERTY layout allowing them to "touch type." We specified numbers 1–5 to the little, ring, middle, index, and thumb fingers of the left hand, respectively. Meanwhile, numbers 6–9 and 0 were specified to the thumb, index, middle, ring, and little fingers of the right hand, respectively. For touch typing, mapping was created between fingers and letters. In general, the mapping is ambiguous. For example, number 1, representing the little finger of the left hand, covers "q," "a," "z," and "1." Therefore, numbers 1, 4, and 3 may represent the words "are" or "ate." Following this method, we obtained a sequence of numbers corresponding to a sentence via the wearable keyboard. Then, NMT is trained and has shown powerful performance in mapping variable-length sequences into continuous vector representations [4], [5], [6], [7], [8], [9], [10], [11]. This paper aims to use the NMT method to estimate a sentence from an ambiguous input sequence of numbers.

The Japanese writing system has several types of characters, including Kanji and Kana characters. Notably, the Kanji characters have multiple corresponding pronunciations, which are determined by different contexts, showing that a Kanji character has several corresponding sequences of letters.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Moreover, the number of Kanji characters is more than 50,000. Therefore, sentence estimation from a sequence of numbers might be complicated. However, conventional Japanese TTS systems usually have a preprocessing module that estimates a sequence of phonemes and accent symbols from a sentence represented by Kanji and Kana characters. Because of the drawbacks of multiple pronunciations in Kanji and a large number of Kanji characters, it might be another choice to estimate a sequence of phonemes and accent symbols from a sequence of numbers. This point was also examined in this paper.

This paper is organized as follows: Section 2 mentions related works, Section 3 describes the outline of the proposed method, Section 4 explains the setup for conducting the evaluation experiments of the proposed method, Section 5 shows the objective experiment methods and evaluation results, Section 6 illustrates the subjective experiment methods and evaluation results, and Section 7 discusses the conclusions and proposes avenues for future work.

II. Related works

Text entry is a fundamental function essential not only for desktops and personal computers but also for mobile devices. The QWERTY keyboard is currently common to most computer users. Furthermore, soft QWERTY keyboards have become a popular text-entry method for smartphones. However, for wearable devices, such as smartwatches, soft QWERTY keyboards may be too large to be optimally displayed on touchscreens. Therefore, a remarkable challenge is encountered while trying to enter text on small-sized devices. An approach to solve the challenge involves two-step key selection methods [13], [14], [15], [16], [17]. Here, the QWERTY keyboards are divided into multiple sections. First, after a user selects a section, the section is displayed larger. Second, the user selects a desired character from the enlarged section. The biggest drawback of this approach is that the user must train for at least 10 hours to fully understand the system.

In terms of text-entry methods for ubiquitous computing, an eyes-free feature that enables users to input texts without looking at the keyboard is sometimes essential. This method is applied because, in a mobile scenario, users must pay visual attention to other tasks during text entry. Speech input is a promising candidate, but it has not been appropriate for every circumstance because of noisy environments and privacy reasons. Therefore, touch-based and eyes-free text-entry methods have been majorly used instead [13], [14], [19], [20], [21]. Since the minimum efforts of learning to type are one of the most essential requirements, the QWERTY layout has been used in many cases. The biggest drawback of this method is that the eyes-free touch system is inaccurate on a touch panel [18]. Thus, errors in text entry occur in most cases.

Within the existing study, [22] is the most essential work to ours, which eliminates the keyboard and replaces it with gloves sensing only the pressure of a depressed finger and not location. Since missing location information creates ambiguity

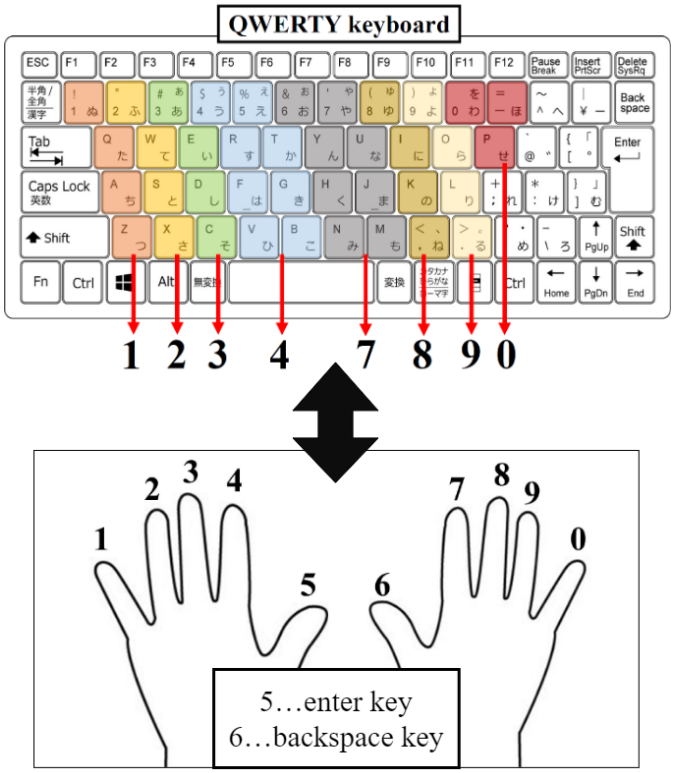

Fig. 2. The mapping between numbers and alphabets using a QWERTY keyboard

in the input stream, the researchers in the previous study attempted to estimate words based on lexical level matching and frequency-ranking estimation [22]. However, their vocabulary was small, and the execution of their study was limited. Thus, the proposed method includes the NMT. In terms of input devices, we will use a wearable QWERTY keyboard based on the "FingeRing" concept [23]. Examples of this method can be found in previous studies [24], [25], [3], [26].

III. Proposed Method

An NMT model is a neural network that directly predicts the conditional probability $p(Y|X)$ of translating a source sentence $X : x_1, \cdots, x_n$ into a target sentence $Y : y_1, \cdots, y_m$. Here, x_i or y_i represents a word. An NMT model consists of two components: (a) an encoder that computes a representation X for each source sentence, and (b) a decoder that generates a target word y_i at a single time. This process is formulated as

$$\log p(Y|X) = \sum_{j=1}^{m} \log p(y_j|y_{<j}, X). \quad (1)$$

In the proposed model, x_i is a number corresponding to a letter using a QWERTY keyboard layout. Figure 2 shows the mapping between the fingers and letters. Here, as special mappings, numbers 5 and 6 represent the enter key and the backspace key, respectively. As shown in Figure 2, the mapping is ambiguous. For example, the number 1 may represent either "q," "a," "z," or "1." However, the word "the" is uniquely mapped to number

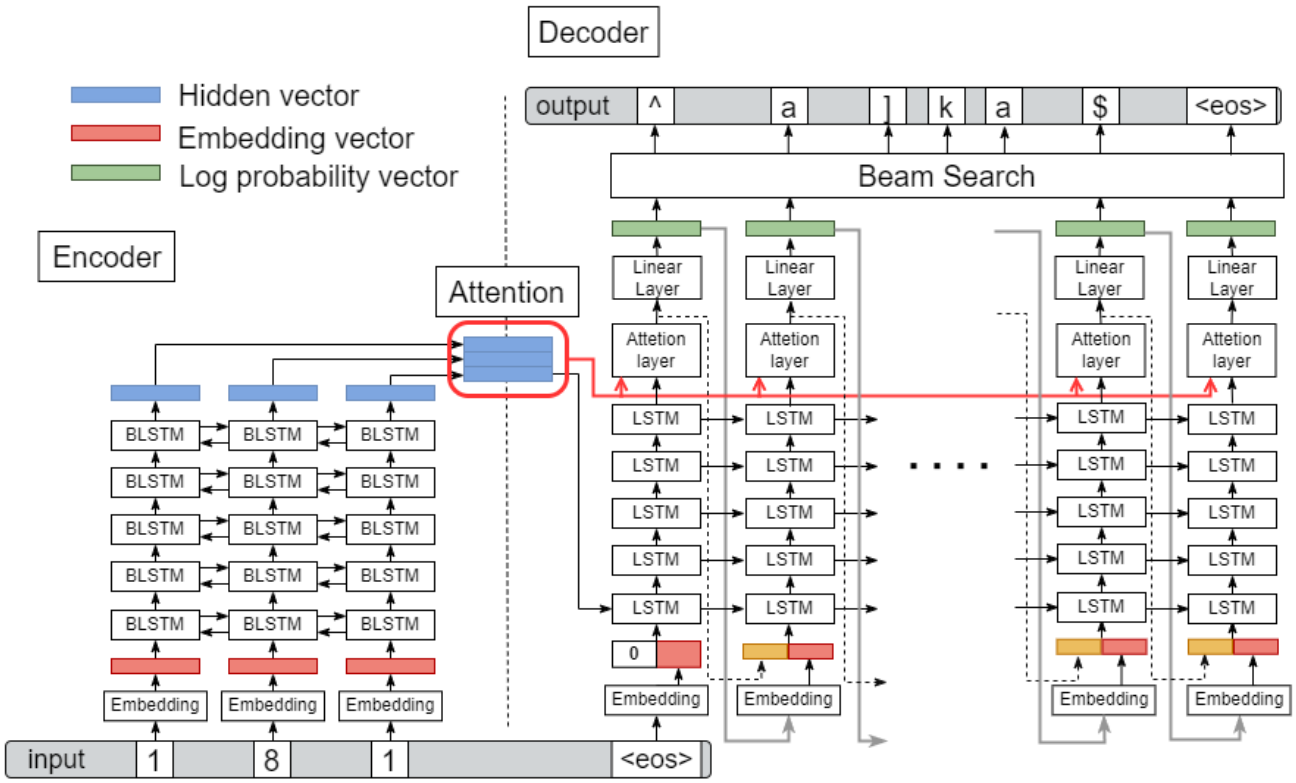

Fig. 3. An outline of the phoneme-based NMT model

473. To resolve such ambiguity, we used two types of NMT models. A character-based model estimates Japanese sentences including Kanji and Kana characters, while a phoneme-based model estimates a sequence of phonemes and accent symbols. Hence, y_i is either a Kanji and Kana character or a phoneme and accent symbol.

The text-entry problem is developed to estimate the sequence of output symbols $Y : y_1, \cdots, y_m$ from a sequence of numbers $X : x_1, \cdots, x_n$. The NMT model is trained sentence-by-sentence. For example, the number 21412871318418723833275 corresponds to the letter sequence of "watasihadaigakuseidesu ('I am a college student' in English)." The character- and phoneme-based models are expected to estimate "私は大学生です" and "ˆ w a [t a sh i w a # d a [i g a] k u s e e d e s u $," respectively. Here, ˆ, [,], #, $ shows the start of a sentence, F0-raise, F0-fall, accent phrase boundary, and end of the sentence, respectively.

Figure 3 shows an outline of the phoneme-based model. As shown in Figure 3, we used a stacking bidirectional long short-term memory (Bi-LSTM) for the encoder and a stacking LSTM for the decoder. In the encoder, each character is first represented by a 1-of-K representation, which is compressed by the embedding layer. The obtained hidden vector is inputted into the Bi-LSTM. The hidden vector becomes an input to the next layer's Bi-LSTM and is saved as an input to the attention mechanism [6]. Thus, it is essential to learn the context and alignment of characters by the attention mechanism because the proposed method has an ambiguity in the transformation. In the decoder, a character is estimated using both hidden vectors of the encoder and a character estimated in the previous time step.

IV. Experiment Data

To confirm the feasibility of the proposed method, experiments on two datasets were conducted. One is a Japanese-English parallel corpus (hereafter referred to as JESC) [28] containing 2.8 million pairs of sentences extracted from TV and movie subtitles. The other dataset is Yahoo! Chiebukuro data (version 3) [29] containing 32 million Japanese sentences. This corpus consists of sentences posted on a bulletin board system operated by Yahoo!

A. Dataset

1) Japanese-English Subtitle Corpus (JESC): JESC is a Japanese-English parallel corpus that consists of 2.8 million pairs of crawled TV and movie subtitles [28]. JESC consists mainly of short bursts of conversational dialog. The corpus contains a substantial number of colloquial expressions commonly found in spoken language. In this paper, we extracted and used the Japanese sentences from the paired dataset.

2) Yahoo! Chiebukuro data (version 3): Yahoo! Chiebukuro is a Japanese question-and-answer platform operated by Yahoo!. Users can post questions on various topics and receive

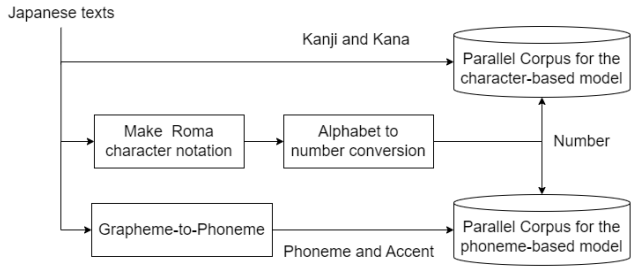

Fig. 4. Parallel corpus generation

responses from the community. The platform covers a wide range of topics, meaning that the corpus includes vocabulary on various topics, and the sentences in the corpus majorly consist of casual registers in written communication.

B. Parallel corpus construction for NMT training

A parallel corpus, which consists of pairs of characters sequences and corresponding numbers sequences, has been generated.

Figure 4 shows an outline to create a parallel corpus for sequences. First, morphological analysis is performed to assign Roman character notations to correspond to Kanji characters. Second, a number is generated by referring to a table that maps QWERTY keyboards to respective fingers corresponding to the keys at the time of touch typing. As a parallel corpus for the character-based model, the original Japanese sentences are paired with the generated number sequences. However, for the phoneme-based model, after generating a sequence of phonemes and accent symbols using the Grapheme-to-Phoneme function in ESPnet2 [30], the sequence is paired with the generated number sequences.

C. Experimental conditions

Table I shows the model configuration and training conditions. For the number of Kanji characters, all Kanji characters included in the training data were sorted in order of their appearance frequency. Then, the top 50,000 Kanji characters were selected. The 50,000-dimensional 1-of-K vectors representing the vocabularies are then embedded into 512 dimensions. These were later used as input to the Bi-LSTM.

V. Objective Evaluation

To evaluate the performance of the different kinds of output characters and the influence of the dataset size, we evaluated accuracy.

A. Configurations of Models

Four models were constructed for evaluation. Table II shows details of their training and evaluation data. Three models estimate the sequences of phonemes and accent symbols, and the other estimates sequences of Kanji and Kana characters. The models for the sequences of phonemes and accent symbols are distinguished by the training data. The datasets for Ph_JESC, Ph_Yahoo, and Ph_JESC+Yahoo are 2.7M, 32M, and 35M in size, respectively. Ja_JESC+Yahoo is trained on the same dataset as Ph_JESC+Yahoo.

TABLE I
Training conditions

Model	RNN-based encoder-decoder model
(Encoder)	-
RNN	Bi-LSTM
#layers	5 layers
#units	512 units in each layer
(Decoder)	-
RNN	LSTM
#layers	5 layers
#units of 1st layer	$1024 \rightarrow 512$
#units of 2nd–5th layers	$512 \rightarrow 512$
(Linear)	-
#units	$512 \rightarrow$ number of symbol types
activation function	Softmax
mini-batch	128 sentences
optimizer	Adam
loss function	Log-Softmax cross entropy

B. Evaluation Results

The models are evaluated by the accuracy of the estimated sentences. The evaluation indices are symbol and sentence accuracy. Symbol accuracy represents the percentage of estimated symbols that match symbols in reference sentences, while sentence accuracy indicates the percentage of estimated sentences that match the reference. For phonemes and accent symbols, the references are the sequences of phonemes and accent symbols generated by grapheme-to-phoneme. For Kanji and Kana characters, the references are original Japanese texts. Table III shows the experimental results.

In terms of output character types, phoneme and accent symbols are superior to Kanji characters in accuracy. The sentence accuracy of Ph_JESC+Yahoo is 12.15 points higher than that of the Ja_JESC+Yahoo. This shows that the sequences of phonemes and accent symbols are more suitable for estimation from ambiguous input than the sequences of Kanji and Kana characters.

Regarding the size of the training data, the symbol accuracy for Ph_JESC, Ph_Yahoo (32M), and Ph_JESC+Yahoo were 84.02%, 89.77%, and 91.48%, respectively. The symbol accuracy rate increases in proportion to the size of the training data. This shows that increasing the amount of data is effective in improving accuracy.

For phonemes and accent symbols, the accuracy for just phonemes symbols is higher than that for both phonemes and accent symbols in all models. The symbol and sentence accuracy for phonemes symbols are on average 1.07 and 5.02 points higher than for both phonemes and accent symbols, respectively. This shows that estimating accent symbols is more difficult than estimating phonemes.

TABLE II
TRAINING AND EVALUATION DATA FOR THE NMT MODELS

Model name	Type of output symbols	Dataset	Number of sentences		
			Training	Validation	Test
Ph_JESC	phoneme and accent	JESC	2.7M	2000	2000
Ph_Yahoo	phoneme and accent	Yahoo	32M	2000	2000

C. Analysis of Estimated Errors

Table IV shows the estimated sentences for the test data. The sentences shown in the table are not complete, but rather part of them. Words written in red indicate errors. From the table, we categorize these errors into three types.

The first-type of error is due to word conflicts. As mentioned in the section III, a numbers sequence can correspond to more than one word. For example, in the estimated 1, "tabete (eating)" is estimated from 414347 although "barete (exposing)" is correct. Since the two words are completely different in meaning, this error could be resolved by considering the wider context of the conversation.

The second-type is an error in the estimation of accent symbols as shown in the estimated 2. The first cause is a selection of homonyms. Japanese words contain some homonyms with different accents. For example, we distinguish between bridges, chopsticks, and edges by differences in their accents. Context-aware NMT models could also improve the selection of homonyms. Another reason is that NMT models cause excess and deficiency of accent symbols. This error might be negligible in conversation since the intended sentences could be assumed even when they include incorrect accent symbols. The frequency of the second-type error can be observed in Table III. The category "all symbols" in Table 3 represents accuracy for both phonemes and accent symbols, whereas "phonemes" represents accuracy for phonemes only. Therefore, the differences between sentence accuracy for all symbols and that for phonemes indicate the percentage of sentences containing errors in phonemes. In the case of Ph_JESC+Yahoo, the difference is 5.9 points. According to detail analysis, the value means that there are 118 sentences with errors in phoneme estimation, which corresponds to 10.4% of the error sentences.

The third-type of error is the repetition of identical phrases as shown in the estimated 3. The phrase "waruiten" is generated repeatedly. This error occurs in a sentence in which similar phrases appear several times, attributing that NMT models focus on the same position repeatedly. Therefore, a new attention algorithm that prevents NMT from repeatedly focusing on the same position would be effective in reducing the third-type of error.

VI. SUBJECTIVE EVALUATION

To subjectively evaluate feasibility of the NMT model, we carried out conversational experiments. The participants performed a guessing game task in pairs using QWERTY keyboards instead of the wearable keyboards. In this experiment, we use the phoneme-based model for the translation from numbers to characters. The participants are four pairs of eight.

A. Experimental Procedures

Participants conducted the guessing task in pairs, one of them using the proposed system, while the other used his voice. The participant who used the proposed system is a speaker, and the other is a listener. The guessing task consisted of the following steps:

1) The speaker chooses an item from a set of items. Each set consists of three items that are familiar for all participants.
2) The speaker enters sentences that describe the characteristics of the item by touch typing.
3) The system synthesizes speech from the inferred sequence and plays it back in real-time.
4) The listener predicts the item based on the synthesized speech.
5) The speaker repeats steps 2-3 until the listener could speak out an answer.

Note that the listeners were allowed to respond only once to prevent random guesses. When the system made an estimation

TABLE V
AVERAGE ACCURACY OF NMT MODELS

	all symbols	phoneme only
accuracy per symbol	90.57 %	92.86 %
accuracy per sentence	50.00 %	53.85 %

error and synthesized speech different from that of the intended speaker, the speakers are permitted to enter sentences that state the same feature in different expressions.

Five trials were performed for each pair. In the experiment, the speakers touch-typed sentences using a QWERTY keyboard in Roman character notations, then the Roman character notations were converted to numbers sequences for the NMT. We recorded the sequences of the Roman character notations, the numbers sequences inputted to NMT, the estimated symbols, and the synthesized speech. In the evaluations, the Roman character notations were used as answers: what the speakers had tried to say.

B. Accuracy of estimated sentences

Table V shows the accuracy of the sequences estimated in the conversational experiment. The results showed the almost same tendencies with the results of Section V.

C. Evaluation by Comprehensibility

After each trial, we let the participants look back on the conversation. To indicate what the speaker had tried to say, we showed the participants the sentences in Roman character notations which the speaker input by keyboard. To evaluate comprehensibility, which is the extent to which a listener understands a speech produced by a speaker in the guessing tasks, we asked the listeners to recall the synthesized speech and evaluate its comprehensibility using three categories: understandable, not understandable but guessable, and unguessable. The evaluation was possible for listeners, because each trial took a short period of time; i.e., an average of 3.8 sentences were synthesized, and the evaluation was carried out just after each trial. For speakers, we showed both of the estimated symbols and input sentences in Roman character notations and asked them to evaluate their satisfaction with a corresponding estimated symbols using two categories: intended or unintended.

Figure 5-(a) shows the results for the listener and Figure 5-(b) for the speaker. For 5-(a), the total of understandable and guessable is 67.95%, meaning that the comprehensibility of the proposed method is 67.95%. By referring to Table V sentence accuracy is 17.95 points less than comprehension. This shows that an utterance can be understood in some cases even if it is not perfectly estimated. For example, three sentences contained only errors in accent symbols. The listeners evaluated all of these sentences as understandable. The speaker evaluations show that 60.26% of the synthesized speech is as intended. Moreover, 10.26% of the synthesized speech was evaluated as unintended because of typing errors.

Table VI shows the comprehensibility each pair. The comprehensibility of the best pair is 82.35%, while that of the

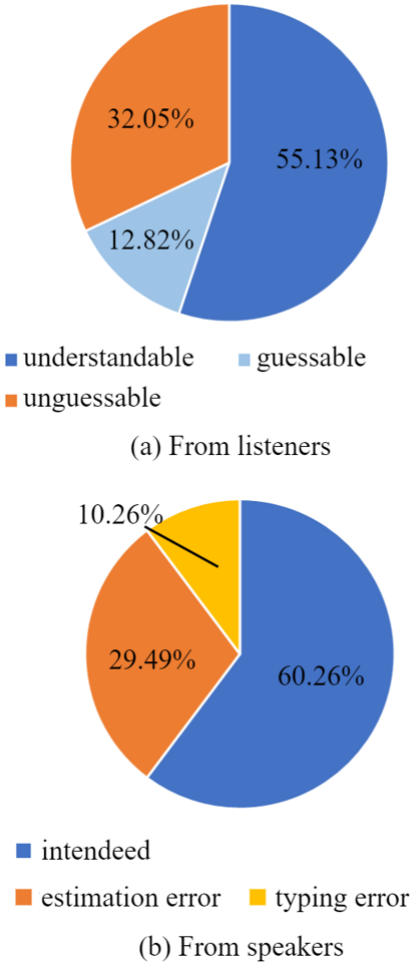

Fig. 5. The results for subjective evaluation

TABLE VI
COMPREHENSIBILITY FOR EACH GROUP

pair name	Comprehensibility
pair A	82.35%
pair B	50.00%
pair C	71.46%
pair D	68.18%

worst pair is 50.00%. This observation suggests that the comprehensibility depends on users. Among the speakers, the participant from pair A might be a quick learner. Actually, the accuracy of the estimation results depends on grammatical complexity and word difficulty. When an appropriate sentence is inputted into the NMT model, it has the potential to enhance the accuracy of the estimation. The speaker of the pair A might find the points during the experiments. These facts indicate that the comprehensibility is expected to increase as users get used to the proposed system.

VII. CONCLUSIONS

An NMT-text-entry method was applied in this paper using the QWERTY keyboard layout, and a digit from 0 to 9 in

decimal notation was inputted by fingers, resulting in an ambiguous input for alphabets. NMT, an attention-based encoder-decoder model, estimated a sentence from a sequence of numbers, and four NMT models were trained using two kinds of datasets. The experimental results revealed the following: (1) The most accurate model correctly estimates 91.48% of the characters in a sentence, (2) the performance of phoneme and accent symbols is better than the performance of the Kanji and Kana characters, and (3) the speech synthesized from estimated sequences conveys 67.95% of the sentences in a conversation. Thus, judging from the results, we can conclude that the proposed model has high potential as a text-entry method. Consequently, we plan to evaluate the proposed method using a wearable keyboard as an input device in the future. Furthermore, we need to investigate dealing with typing errors.

***Abstract*—The use of generated corrected accent speech with a learner's own voice holds potential for second language learners to enhance their pronunciation through self-imitation exercises. However, synthesizing speech with a corrected accent poses significant challenges, particularly due to the unavailability of data from the same speaker exhibiting both native and non-native accents. To address this, voice conversion (VC) and foreign accent correction (FAC) approaches have been explored. VC aims to transform the voice of a native speaker source while preserving linguistic content, whereas FAC targets accent conversion of a non-native source while retaining the speaker's voice. This study investigates the application of the MaskCycleGAN-VC model as an approach for generating corrected accent speech from native sources. The model is evaluated as it was originally proposed and with the adoption of speaker embeddings, speaker native language ID, conditioned discriminator, and accent loss. Objective and subjective metrics are assessed on English and Japanese corpora, and including speaker embedding, speaker native language ID, and conditioned discriminator showed improvements.**

I. Introduction

In order to learn a second language, students need to devote time outside of class to study [1]. In addition, many teachers focus on reading and writing skills, while neglecting the importance of speech in communication [2], [3]. In this context, computer-assisted language learning (CALL) systems appear as a solution applying computers in the language learning environment. However, most research works focus on teaching vocabulary, ignoring other skills, especially speech. Thus, it is worth exploring an automated method for evaluating the speech of non-native (L2) learners.

Given an L2 language learner, one approach is to synthesize speech with a native-like accent (L1) but transplant the L2 speaker's voice onto it, creating a "golden speaker". Since the only difference between the golden speaker and the L2 learner's own voice is the accent, the mispronunciations become more salient [4], enabling practice by self-imitation, i.e., the learner would be able to imitate their own voice, a pedagogically effective practice [5].

To achieve this type of feedback, two different tasks can be explored, the first one is voice conversion (VC) [6], and the second one is foreign accent conversion (FAC) [4]. In the VC task, the goal is to convert the speaker's voice while preserving linguistic content and speech style from the source audio. To generate self-imitation feedback for language learners with this approach, a native source audio is required for the conversion. On the other hand, FAC seeks to transform the features of an utterance that contribute to accent while maintaining those that carry the identity of the speaker [7], being able thus to reduce the foreign accent in the non-native speaker's speech. Since it is not feasible to have paired data from the same speaker with and without a native accent, generating self-imitation feedback without a native source audio becomes a more challenging task than traditional VC. In this work, some different works on VC and FAC will be briefly explained.

In order to generate a native accented reference for self-imitation, in this work the MaskCycleGAN-VC [8] model was explored with English and Japanese native and non-native data. This model was originally proposed and evaluated for VC task with native data only, which is different from converting voice with two different accents involved, after all, the non-native speaker is not guaranteed to produce correct phonemes in their speech. However, the proposed approach is capable of generating corrected accent audio with non-native speakers' voices, such as language learners. To try to improve the model conversion, some alterations to the original MaskCycleGAN-VC were explored. First, the incorporation of a speaker embedding and a speaker native language ID as conditional inputs to the generator, giving information related to the desired speaker voice and accent for the conversion. Then, in addition to the speaker embedding and native language ID for the generator, the discriminator was also conditioned to the desired accent with the speaker native language ID. Finally, an accent loss was also explored to encourage the generator to output the desired accent.

This paper is organized as follows. Section II briefly discusses different VC and FAC works. Section III describes the proposed methodology with MaskCycleGAN-VC. Section IV presents the results obtained with two different datasets and their discussion. Finally, conclusions and future work are drawn in Section V.

II. Related Work

Corrected accent speech for self-imitation can be achieved with two possible approaches. The first one is VC, in which the primary goal is to change the speaker identity of a given speech into another speaker, i.e., convert from an utterance

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

source speaker's voice onto a target speaker while preserving the linguistic content and the speech style from the source. With this approach, corrected accent speech can be synthesized by converting a native source utterance onto the voice of a non-native speaker, hence achieving native-accented speech with the voice of a non-native speaker. Applying different approaches and architectures, recent VC models can be trained without parallel data or text reference.

Sequence-to-sequence (seq2seq) models are one common approach for achieving VC. In general, those models consist of encoder and decoder modules, in which the first one extracts latent space representations from a given input, and the second one should be able to decode that representation into the desired output sequence. In many cases when parallel data is available, seq2seq models can be considered a state-of-art approach for sequence conversion [9]. For the VC task, they aim to disentangle the input into the speaker and linguistic information so that VC can be achieved by changing only the speaker information [9]–[11].

In [11], two encoders and one decoder are used for the conversion, with an additional encoder during the training step. The two encoders used during the conversion extract linguistic and speaker representations, and the additional encoder used during the training also extracts linguistic representation from phoneme transcriptions. In sequence, the decoder recovers acoustic features from those disentangled linguistic and speaker representations combined. The work [10] extracts bottleneck features (BNF) as a linguistic representation with a phoneme recognizer, and then combines that information with some speaker representation so that a seq2seq synthesis model can reconstruct the spectral features. To achieve normal speech to dysarthric speech conversion, [9] trains a many-to-one seq2seq model to convert normal speech into dysarthric speech, and subsequently applies a non-parallel frame-wise model to convert the identity to the desired normal speaker's voice.

Another approach is to use generative adversarial networks (GANs), such as in [8], [12], [13]. In general terms, GANs are composed of generator and discriminator networks, in which the first one is trained to generate data that resembles real data from noise input, and the second should distinguish whether the generated data looks real or not. For VC task, the generator is trained to convert the input speech speaker identity while the discriminator assesses if the generated data belongs to the real distribution.

In [12] a cycle-consistent adversarial network-based non-parallel VC model is proposed for mel-cepstrum conversion. This model is later improved in [13] by adopting a two-step adversarial loss and changing the generator and discriminator architectures. Then, for achieving mel spectrogram conversion, [8] proposes MaskCycleGAN-VC, which improves the previous model [13] by training the model with an auxiliary filling-in-frames task. In this task, a mask is applied to the input spectrogram so that the model is encouraged to learn time-frequency structures in a self-supervised manner. For the VC task, other approaches can also be found such as the flow-based VC model by [14], or the diffusion-based approach by [15], [16].

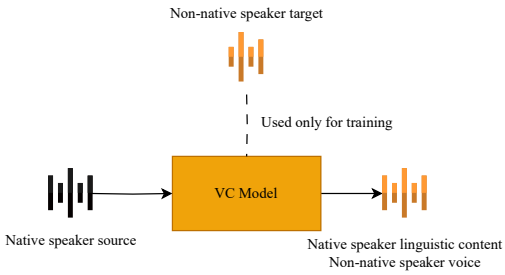

Fig. 1. Voice conversion scheme to generate feedback for self-imitation.

In the FAC approach, the desired input for the model is not a source native, but rather a non-native speaker. The goal is to convert the accent while preserving the voice. Since it seeks to not require a native reference for conversion, this task is more aligned with some practical implementations for feedback generation for learners, however, it is a more challenging task given that it is not feasible to have data from the same speaker with and without a native accent. Considering it is a harder task there are fewer works related to FAC.

Translator and synthesizer models are proposed in [17]. The first one translates BNF from an L2 speaker into L1, and the second converts the BNF into a mel spectrogram. On the other hand, [4] creates a "golden-speaker" utterance that is used for training a pronunciation correction model, so that in the inference it is capable of achieving FAC. Both of these works, incorporate seq2seq architecture models. Then, [18] propose a Tacotron-based text-to-speech model that is capable of synthesizing L2 speaker speech with corrected accent without parallel data in the training. In addition to those works, [19] trains a seq2seq conversion model that disentangles speaker identity and accent information, achieving a model capable of both VC and FAC between Chinese and Tianjin-accented Mandarin. In [20] VC model is used in order to synthesize a parallel dataset for FAC.

III. Methodology

This work proposes to apply the MaskCycleGAN-VC model for the conversion of a native source speaker's voice to a non-native target voice without altering the linguistic content, including pronunciation. This approach generates the corrected accent speech for self-imitation with the VC approach as in Fig. 1. A native source is used as input for the generation, and the non-native data is only needed for training the model. This approach differs from the FAC that takes as input non-native speech.

In addition to applying the MaskCycleGAN-VC model as it is, some alterations to the model were also explored and evaluated. Those alterations are as follows:

1) Applying a speaker embedding and speaker native language ID as conditional inputs to the generator.

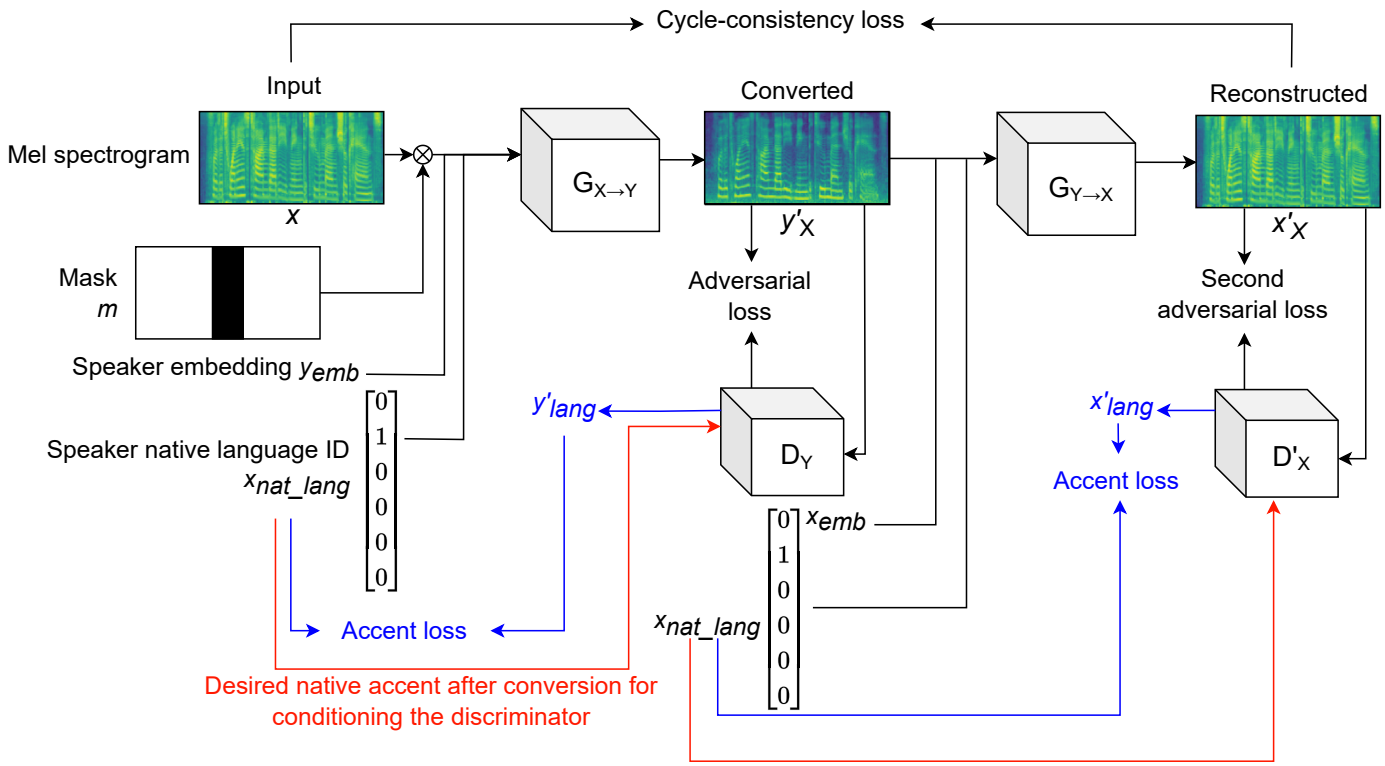

Fig. 2. Illustration of one training step from x to y (the step from y to x is ommited). Accent loss and discriminator are both depicted in the figure, but they are not applied simultaneously. For the accent loss, in addition to y' and x', the accent loss is also calculated in relation to the real input x in relation to both discriminators.

2) Conditioning the discriminator to the desired accent in addition to 1. The conditioning of the discriminator during training is illustrated in Fig. 2 in red.
3) Calculating an accent loss in relation to an additional classifier layer for the discriminator in addition to 1. The calculation of the accent loss during training is illustrated in Fig. 2 in blue.

A. MaskCycleGAN-VC

MaskCycleGAN-VC is a non-parallel cycle-consistent adversarial network-based voice conversion model [8]. It extends previously proposed cycle-consistent models works [12], [13] by adding an auxiliary filling-in-frames training task, outperforming them for pair-wise conversion of native speakers' mel spectrograms. In this auxiliary task, a mask is applied to the input mel spectrogram during training, therefore the generator should learn the time-frequency structures of a mel spectrogram in a self-supervised way. In comparison to the previous works, this addition enabled mel spectrogram conversion instead of mel cepstrum.

Different from the original work, in this work the model was applied to the voice conversion between a native speaker and a non-native speaker with the goal of generating corrected accent speech. Considering that non-native data presents different intonation and may not present all the correct phonemes from a native speaker, this task is expected to be harder than the native-to-native conversion. More details about the architecture of the MaskCycleGAN-VC model are presented in IV-B.

B. Speaker embedding and speaker native language ID

Speaker identity representations, such as speaker embeddings extracted from other models or simple speaker IDs, can be used as an additional input to the VC model in order to condition the speaker identity of the generated speech [4], [10], [11], [17], [19], [21]. In a similar way, adopting a class identification to condition the generator is also common for conditional GAN (CGAN) architectures [22].

In consideration of that, the adoption of a speaker embedding and a speaker native language ID as additional inputs to the generator was explored to condition the model generation to the desired speaker identity and accent, possibly increasing voice similarity and the output of native accented speech. Both are added to condition the input mel spectrogram after their dimensions are adjusted by a linear transformation.

C. Discriminator conditioning

For this alteration, the speaker embedding and speaker native language ID are still used as input to the generator. However, instead of conditioning only the generator, the native language ID of the desired accent is also used as an additional input to the discriminator. Similarly, the native language ID has its

dimensions adjusted by a linear transformation and is added to the discriminator input before its first layer.

By employing this, the discriminator is expected to judge if a given input belongs to the real distribution given the accent condition. This alteration is explored to try to achieve a better native-like accent after conversion since the discriminator could penalize generated data with the incorrect accent.

D. Accent loss based on speaker native language ID

For the MaskCycleGAN-VC [8] four different losses were originally calculated as presented below. For the total loss calculation, weight parameters $\lambda_{cyc} = 10$ and $\lambda_{id} = 5$ are applied to the cycle-consistency loss and identity-mapping loss consecutively.

1) Adversarial loss: ensures that the conversion results appear to be from the target speaker.
2) Cycle-consistency loss: checks if the results from the circular conversion are consistent, which assists the model training without parallel supervision.
3) Identity-mapping loss: encourages the input preservation.
4) Second adversarial loss: adds two additional discriminators and imposes the adversarial loss on the circular conversion results. In total, there are four discriminators in the model.

Given the incorporation of the speaker embedding and the speaker native language ID, for this alteration, an additional loss related to the native language of the accent is calculated. For this loss calculation, an additional fully-connected layer is added to the end of the discriminator as an additional classifier layer, so that the outputs from the discriminator are two, one judging whether the generated data resembles real data, and the other classifying its accent in relation to its native language, i.e., the speaker native language ID. For example, for a generated English sample, the discriminator could classify its native language as American, meaning it sounds native-like, or Chinese, meaning it does not sound native-like. For the sake of briefness, in this work this loss is abbreviated as accent loss.

In this work, the MaskCycleGAN-VC model is trained for converting from native speech to non-native speaker voice (X to Y), and also from non-native speech to native speaker voice (Y to X). Considering the first conversion, $X \rightarrow Y$, the generator $G_{X\rightarrow Y}$ converts from the native source acoustic features $\boldsymbol{x} \in X$ with native language $\boldsymbol{x_{nat_lang}}$ into the non-native target voice $\boldsymbol{y} \in Y$ maintaining the same $\boldsymbol{x_{nat_lang}}$ native accent. Then, D_Y predicts the native language accent for this $G_{X\rightarrow Y}(\boldsymbol{x}, \boldsymbol{x_{nat_lang}})$, and the difference between the predicted accent to the expected native accent $\boldsymbol{x_{nat_lang}}$ is calculated, as illustrated in (1). The $D_Y(*)[1]$ and $D_X(*)[1]$ in the next equations indicate that only one of the outputs of the discriminator is used for the calculation of this loss, the output related to classifying the accent.

$$\begin{gathered} \boldsymbol{y'_X} = G_{X\rightarrow Y}(\boldsymbol{x}, \boldsymbol{x_{nat_lang}}) \\ {\mathcal{L}_{acc}^{X\rightarrow Y}}_1 = \mathbb{E}_{x\sim P_X}\left[\left\|D_Y(\boldsymbol{y'_X})[1] - \boldsymbol{x_{acc}}\right\|_1\right] \end{gathered} \tag{1}$$

Considering the circular conversion, the previous output is used as input for the second generator, $G_{Y\rightarrow X}(\boldsymbol{y'_X}, \boldsymbol{x_{nat_lang}})$, and D'_X classifies its output native language accent for the second part of the accent loss, as in (2).

$$\begin{gathered} \boldsymbol{x'_X} = G_{Y\rightarrow X}(\boldsymbol{y'_X}, \boldsymbol{x_{nat_lang}}) \\ {\mathcal{L}_{acc}^{X\rightarrow Y}}_2 = \mathbb{E}_{x\sim P_X}\left[\left\|D_Y(\boldsymbol{x'_X})[1] - \boldsymbol{x_{nat_lang}}\right\|_1\right] \end{gathered} \tag{2}$$

Finally, the real data x is used as input for the discriminators D_X and D'_X to ensure both are being trained to identify correctly the native language accent. The outputs from both discriminators are compared to the real expected accent as in (3) and (4), and the final accent loss for the $X \rightarrow Y$ is defined as the sum of equations (1) to (4).

$${\mathcal{L}_{acc}^{X\rightarrow Y}}_3 = \mathbb{E}_{x\sim P_X}\left[\left\|D_X(\boldsymbol{x})[1] - \boldsymbol{x_{nat_lang}}\right\|_1\right] \tag{3}$$

$${\mathcal{L}_{acc}^{X\rightarrow Y}}_4 = \mathbb{E}_{x\sim P_X}\left[\left\|D'_X(\boldsymbol{x})[1] - \boldsymbol{x_{nat_lang}}\right\|_1\right] \tag{4}$$

The loss is also calculated for the conversion $Y \rightarrow X$, but instead of preserving the native accent $\boldsymbol{x_{nat_lang}}$, it seeks to preserve the accent from the native language of the speaker that is non-native $\boldsymbol{y_{nat_lang}}$. For this conversion, the equations are defined in (5) to (8):

$$\begin{gathered} \boldsymbol{x'_Y} = G_{Y\rightarrow X}(\boldsymbol{y}, \boldsymbol{y_{nat_lang}}) \\ {\mathcal{L}_{acc}^{Y\rightarrow X}}_1 = \mathbb{E}_{y\sim P_Y}\left[\left\|D_X(\boldsymbol{x'_Y})[1] - \boldsymbol{y_{nat_lang}}\right\|_1\right] \end{gathered} \tag{5}$$

$$\begin{gathered} \boldsymbol{y'_Y} = G_{X\rightarrow Y}(\boldsymbol{x'_Y}, \boldsymbol{y_{nat_lang}}) \\ {\mathcal{L}_{acc}^{Y\rightarrow X}}_2 = \mathbb{E}_{y\sim P_Y}\left[\left\|D_X(\boldsymbol{y'_Y})[1] - \boldsymbol{y_{nat_lang}}\right\|_1\right] \end{gathered} \tag{6}$$

$${\mathcal{L}_{acc}^{Y\rightarrow X}}_3 = \mathbb{E}_{y\sim P_Y}\left[\left\|D_Y(\boldsymbol{y})[1] - \boldsymbol{y_{nat_lang}}\right\|_1\right] \tag{7}$$

$${\mathcal{L}_{acc}^{Y\rightarrow X}}_4 = \mathbb{E}_{y\sim P_Y}\left[\left\|D'_Y(\boldsymbol{y})[1] - \boldsymbol{y_{nat_lang}}\right\|_1\right] \tag{8}$$

Finally, when the accent loss is calculated, the discriminator is not conditioned with the desired accent, as described previously in III-C, but the generator is conditioned to both speaker embedding and speaker native language ID.

IV. Experimental Results

A. Experimental Conditions

In this work, two experiments were conducted; English conversion and Japanese conversion. For native English conversion, we used the CMU-ARCTIC[1] [23] which consists of English native speakers (mostly Americans), and the L2-ARCTIC[2] [24] which consists of non-native English speakers with 6 different native languages. Both are composed of read speech from out-of-copyright texts from Project Gutenberg.

TABLE I
AMOUNT OF DATA PER SPEAKER FOR THE ENGLISH DATA.

Speaker	Gender	Native language	Train (min.)	Evaluate (min.)
clb	Female	US	51.39	12.76
rms	Male	US	52.75	13.35
lxc	Female	ZH	60	15.49
hqtv	Male	VN	55.05	13.93

TABLE II
AMOUNT OF DATA PER SPEAKER FOR THE JAPANESE DATA.

Speaker	Gender	Native language	Train (min.)	Evaluate (min.)
JJ_KYO_F01	Female	JP	6.85	0.73
JJ_KYO_M02	Male	JP	6.15	0.74
FJ_IWA_F03	Female	ZH	12.63	1.30
FJ_KYO_M03	Male	ZH	11.81	1.35

Since they have partially parallel data, those datasets are commonly used in conversion tasks with foreign-accented speech, such as in [4], [17], [18]. Considering that different speakers may read the same text, the data used for training is not totally non-parallel, but data used in the training for one speaker is selected so as to not be present in the evaluation. In this experiment 2 native and 2 non-native speakers were selected, and their amount of data used for training and evaluation is presented in Table I.

For native Japanese conversion, we used the UME-JRF[3] [25] dataset. This dataset is also composed of read speech, but the amount of data available per speaker is considerably shorter. In the same way as the datasets for English, the data used for training is not completely unparallel, but samples used for training are not present in the evaluation. Again, 4 speakers were selected, and their corresponding amount of data used for training and evaluation is present in Table II.

For both language experiments, models were trained for pair-wise conversion between the same genders and different genders, i.e., female-female, male-male, female-male, and male-female. The audio data were sampled at 16kHz, and 80-dimensional log mel spectrogram with a window length of 1024 and hop length of 256 samples were extracted according to the original MaskCycleGAN-VC [8]. For the English experiments, the model was trained for 50 epochs with batch size of 1, and for the Japanese experiments, the model was trained for 100 epochs with batch size of 1. In order to synthesize a waveform from the converted mel spectrograms, the HiFi-GAN [26] vocoder was fine-tuned for the selected speakers using the same data used in the conversion model training.

Furthermore, the speaker embeddings, for the altered MaskCycleGAN-VC, were extracted with the Resemblyzer[4]. The embeddings are 256-length vector representations for the speakers. As for the native language ID, it is a one-hot representation of an ID associated with the accent of the speaker. The speaker embedding of the target speaker and the native language ID of the source speaker (desired accent) are both added as input to the generator.

B. Model Configuration

The MaskCycleGAN-VC model is composed of two generators and four discriminators. The generator structure is composed of two 2D convolutions for downsampling, six residual blocks with 1D convolutions, and two 2D convolutions for upsampling, following the structure of the 2-1-2D CNN [13]. As for the discriminator, it follows the structure from PatchGAN [27], which consists of four 2D convolution layers for downsampling.

For the generator, both downsample and upsample layers have a factor of 2 and kernel sizes of 5x5, for the residual blocks the kernel size is 1x3 and 256 channels. For the discriminator, the first three downsample layers have a scale factor of 2 and kernel sizes of 3x3, but the last downsample has a scale factor of 1 and kernel size of 1x10. Finally, 1x1 convolution was applied before and after reshaping the feature map [13] for both the generator and discriminator.

C. Evaluation Metrics

For the evaluation of each model, 3 objective metrics and 3 subjective metrics were evaluated. The objective metrics were the mel-cepstral distortion (MCD), root of mean square errors of F_0 (F0 RMSE), word error rate (WER), and character error rate (CER). MCD goal is to assess the spectral conversion, F0 RMSE the fundamental frequency conversion, and the WER or CER tries to assess the intelligibility to some extent. For both WER and CER, two ESPnet[5] [28] pre-trained ASR models were utilized. WER is evaluated only for the English language with a transformer-based ASR model trained on LibriSpeech[6], meanwhile, since the division of a sentence into words is less clear in Japanese, CER is calculated for the Japanese language with a conformer-based ASR model trained on LaboroTVSpeech[7].

For the subjective evaluation, experiments were conducted with 14 English speakers and 10 Japanese speakers. For both languages, the calculated metrics were naturalness, native-likeness, and voice similarity. For both naturalness and native-likeness, the participants listened to converted audio and were asked to evaluate it from 1 to 5. In terms of naturalness 1 is equivalent to bad, and 5 to excellent. For native-likeness, 1 is equivalent to heavily foreign-accented and 5 to native-like pronunciation. In the voice similarity experiment, the participants listened to 3 audios: 1 converted, 1 from the source speaker, and 1 from the target speaker. In sequence, they were asked to choose which one the converted one had the voice more similar to. The results for voice similarity are expressed in the percentage of participants who chose that the converted audio is more similar to the target.

NON-ALTERED MODEL OBJECTIVE EVALUATION FOR ENGLISH CONVERSION PER SPEAKERS PAIRS.

Conversion pair	MCD (↓)	F0 RMSE (↓)	WER (↓)
Native Female to Non-native Female	8.79	32.35	6.2
Native Male to Non-native Male	10.12	73.34	15.1
Native Female to Non-native Male	11.20	34.77	10.3
Native Male to Non-native Female	9.34	88.35	14.9

TABLE IV
ALTERED MODEL OBJECTIVE EVALUATION FOR ENGLISH CONVERSION FOR ALL THE FOUR SPEAKERS PAIRS.

Model version	MCD (↓)	F0 RMSE (↓)	WER (↓)
No alterations	**9.86**	57.20	**11.6**
Speaker native language ID + Speaker embedding	9.88	57.11	12.3
Speaker native language ID + Speaker embedding + Conditioned discriminator	10.88	**56.78**	14.8
Speaker native language ID + Speaker embedding + Accent loss	11.14	60.49	34.2

TABLE V
NATURALNESS AND NATIVE-LIKENESS FOR ENGLISH CONVERSION FOR ALL THE FOUR SPEAKERS PAIRS WITH 95% CONFIDENCE INTERVALS.

Model version	Naturalness	Native-likeness
No alterations	**3.37** $\pm$ 0.22	2.67 $\pm$ 0.23
Speaker native language ID + Speaker embedding	3.21 $\pm$ 0.25	2.63 $\pm$ 0.25
Speaker native language ID + Speaker embedding + Conditioned discriminator	3.13 $\pm$ 0.23	**2.76** $\pm$ 0.24
Speaker native language ID + Speaker embedding + Accent loss	2.6 $\pm$ 0.27	2.29 $\pm$ 0.25

TABLE VI
VOICE SIMILARITY FOR ENGLISH CONVERSION FOR ALL THE FOUR SPEAKERS PAIRS WITH 95% CONFIDENCE INTERVALS.

Model version	Similarity to target
No alterations	0.56 $\pm$ 0.12
Speaker native language ID + Speaker embedding	0.54 $\pm$ 0.13
Speaker native language ID + Speaker embedding + Conditioned discriminator	0.56 $\pm$ 0.12
Speaker native language ID + Speaker embedding + Accent loss	**0.58** $\pm$ 0.12

D. English Conversion

1) Objective evaluation: The objective evaluation results obtained for the English data are summarized in Table III and Table IV. Table III presents the results for each conversion pair trained with the non-altered MaskCycleGAN-VC model, while Table IV shows the overall results for the different alterations tested with the MaskCycleGAN-VC model.

As it can be observed from Table III, the female-female conversion has the lowest values within all the pairs. Moreover, the conversions with native male source yield the highest F0 RMSE and WER values. Then, from Table IV, the adoption of speaker embedding, speaker native language ID, and discriminator conditioning, resulted in a slight decrease in the F0 RMSE, but most alterations did not improve the other two metrics.

2) Subjective evaluation: The subjective evaluation for English language data is presented in Table V and Table VI. From Table V it is possible to observe that the increase in the accent reduction (higher native-likeness), does not follow an increase in naturalness. In fact, the highest naturalness observed was with the non-altered MaskCycleGAN-VC model, while the highest native-likeness was observed when adopting speaker embedding, speaker native language ID, and conditioned discriminator. In terms of voice similarity, the proposed alterations did not present any improvement.

E. Japanese Conversion

1) Objective evaluation: In the same manner as for the English language results, for the Japanese data, the objective evaluation results are summarized in Table VII and Table VIII. As it can be observed from Table VII the female-female conversion has the lowest values for F0 RMSE and CER, but not for MCD. The conversions with native male sources yield the highest CER values. Then, from Table VIII, the adoption of speaker embedding, native language ID, and discriminator conditioning, resulted in a decrease for all three metrics, indicating its potential for improving the conversion between Japanese native and non-native speakers. The adoption of speaker embedding and native language ID also brings some improvement to MCD and WER.

TABLE VII
NON-ALTERED MODEL OBJECTIVE EVALUATION FOR JAPANESE CONVERSION PER SPEAKERS PAIRS.

Conversion pair	MCD (↓)	F0 RMSE (↓)	CER (↓)
Native Female to Non-native Female	9.82	35.84	32.8
Native Male to Non-native Male	8.44	45.53	43.2
Native Female to Non-native Male	8.21	111.33	34.4
Native Male to Non-native Female	11.7	89.78	56.9

TABLE VIII
ALTERED MODEL OBJECTIVE EVALUATION FOR JAPANESE CONVERSION FOR ALL THE FOUR SPEAKERS PAIRS.

Model version	MCD (↓)	F0 RMSE (↓)	CER (↓)
No alterations	9.54	70.62	41.8
Speaker native language ID + Speaker embedding	9.43	71.25	36.8
Speaker native language ID + Speaker embedding + Conditioned discriminator	**9.02**	**67.88**	**35.4**
Speaker native language ID + Speaker embedding + Accent loss	12.36	83.40	64.8

TABLE IX
NATURALNESS AND NATIVE-LIKENESS FOR JAPANESE CONVERSION FOR ALL THE FOUR SPEAKERS PAIRS WITH 95% CONFIDENCE INTERVALS.

Model version	Naturalness	Native-likeness
No alterations	2.44 ± 0.23	2.94 ± 0.27
Speaker native language ID + Speaker embedding	**2.7** ± 0.27	3.05 ± 0.28
Speaker native language ID + Speaker embedding + Conditioned discriminator	2.56 ± 0.23	**3.11** ± 0.25
Speaker native language ID + Speaker embedding + Accent loss	1.56 ± 0.19	1.94 ± 0.26

TABLE X
VOICE SIMILARITY FOR JAPANESE CONVERSION FOR ALL THE FOUR SPEAKERS PAIRS WITH 95% CONFIDENCE INTERVALS.

Model version	Similarity to target
No alterations	0.51 ± 0.15
Speaker native language ID + Speaker embedding	**0.64** ± 0.13
Speaker native language ID + Speaker embedding + Conditioned discriminator	0.35 ± 0.18
Speaker native language ID + Speaker embedding + Accent loss	0.36 ± 0.17

2) Subjective evaluation: The subjective evaluation for Japanese language data is presented in Table IX and Table X. In the same way, as for the English data, the highest native-likeness was observed when adopting speaker embedding, native language ID, and conditioned discriminator. For the Japanese data, the naturalness presents a slight increase in naturalness as well. In terms of voice similarity, only the adoption of speaker embedding and native language ID was able to bring some minor improvement, but the approach with the greater accent correction presented the worst voice similarity.

F. Discussion

Although the MaskCycleGAN-VC model was not originally proposed for conversion between native-nonnative speech, it is still capable of achieving the conversion, but not as well as between two native speakers. Some tentative changes were experimented with, and from the results, it is possible to observe that the adoption of speaker embedding, native language ID, and conditioned discriminator was the model alteration that rose the most improvement, although not for all cases.

Moreover, the adoption of an accent loss proved to worsen the non-altered model for most cases. Since the models were trained for pair-wise conversion, it is not surprising that the actual improvement was slim to non-existing, after all, in a pair-wise conversion the speaker and accent information are always the same, and there is not much gain of information from a speaker embedding or a speaker native language ID.

Overall, even though it was trained for more epochs, the results for Japanese data were worse, as was expected since the amount of data available was smaller. However, conducting experiments with another language besides English is important from a practical perspective.

V. CONCLUSIONS

This work presented the results of applying the MaskCycleGAN-VC model in the task of converting from a native source speaker voice to a non-native target speaker. This model was trained pair-wise for four different pairs, with two different languages, English and Japanese. In addition to the direct application of the models, some alterations to the model were also proposed. Those results can be divided into objective and subjective evaluation, and the metrics calculated were the MCD, F0 RMSE, CER/WER, naturalness, native-likeness, and voice similarity.

Although originally tested only on the native-to-native conversion, the model still is capable of performing VC, but with more limited performance. According to the experimental results, the inclusion of speaker embedding, native language ID, and conditioned discriminator led to improvements in some cases. However, the adoption of an accent loss did not yield positive results. It is supposed that since the models were trained for pair-wise conversion, the benefits of speaker embedding and native language ID were limited, as they provide little additional information when the speaker and accent remain constant.

For future works, exchanging the pair-wise frame of MaskCycleGAN-VC into a many-many conversion can be interesting. Furthermore, experiments with different types of models should also be conducted, especially focusing on experiments with different languages. Finally, trying to apply the VC approach to generate data for training a FAC model is also a work of interest as in [20].

***Abstract*—Previous studies found that speech uttered by professional announcers is more intelligible than that by non-experts in noisy environments. On the basis of this finding, we developed a voice-conversion (VC) system to mimic professional announcers' voices by modifying the speaker embedding of non-expert speech. The results from our experiments to evaluate this system indicated that intelligibility increased significantly with this system. In this paper, to discuss what physical features correlate to the intelligibility, the following two issues are investigated by analyzing this system: (1) whether speech intelligibility can be changed gradually even by shifting one PCA (principal component analysis) component of the speaker embedding of the above VC system and (2) what physical features are changed when the PCA component is shifted, we retrained the VC system with a larger amount of training data. Comparing the speech intelligibility and candidate features that were changed with the shift of one axis of PCA, we found that spectral tilt, spectral plateau, and cepstral peak prominence are strongly correlated with intelligibility.**

Keywords: spectral tilt, spectral plateau, cepstral peak prominence, PCA, STOI, voice conversion

I. Introduction

Speech intelligibility is important in providing general information such as the arrival/departure time of trains and flights; driving instructions, nearby gas stations, and parking lots. It is especially important in announcing emergency situations such as fires, earthquakes, and landslides; as well as guiding people to safety. Making speech more intelligible is specifically challenging in noisy and reverberant environments such as airport/train stations, kitchens, and shower rooms. It is even more difficult when listeners are elderly with or without hearing impairments.

The easiest and most natural response to the challenges is turning up the volume of playback devices; however, increasing the volume is not equivalent to increasing the intelligibility of speech. A person can involuntarily increase the intelligibility of his/her speech in noisy places, known as the Lombard effect [1]. But increasing the volume of playback devices does not have such effect. Various approaches have been proposed to increase speech intelligibility in noisy environments without increasing the total power of speech. These include modification of spectral properties [2]–[4], dynamic range compression [5]–[7], modification of speech modulation spectrum [8], [9], and time-scale modification [10], [11].

Several studies have found that voice-related professions, e.g., professional announcers, voice actors, and singers, can produce speech that is clearer and easier to hear than non-professional people [12], [13]. Other studies have shown that the speech by professional announcers can maintain intelligibility better than that by non-experts in very noisy environments [14]. Inspired by this phenomenon, a previous study [15] developed an end-to-end deep neural network (DNN) based voice conversion (VC) system that mimicked the speaking style of professional announcers to increase speech intelligibility of non-expert people.

As reported in the previous study [15], by analyzing the principal component analysis (PCA) of speaker embedding in the proposed VC system, the first PCA component was found to be related to gender difference and the second PCA component of speaker embedding captured the difference between non-expert speakers and professional announcers. This is advantageous as a non-expert voice can be converted to have the voice style of a professional announcer only by changing the second PCA component of a speaker embedding. Since professional announcers' voices are more intelligible even in a noisy environment, it is expected that the second PCA component can be used to increase the intelligibility of non-expert voices. To clarify this point, the authors [15] proposed replacing the second PCA component of a non-expert speaker embeddings with the average value calculated from the second principal component of all male professional announcers. The obtained speaker embedding was then used to synthesize converted stimuli.

Experimental results [15] from objective measurements and subjective evaluation of the converted stimuli confirmed that adapting to an announcer's voice can increase the intelligibility of a non-expert speaker's voice. By modifying the second PCA component of speaker embedding, we can manually control the announcer speaking style, hence increase the intelligibility of speech in a noisy environment without completely changing speaker individuality. Statistical analysis also showed that modifying the second PCA component yields the highest performance. These results suggest that the second PCA com-

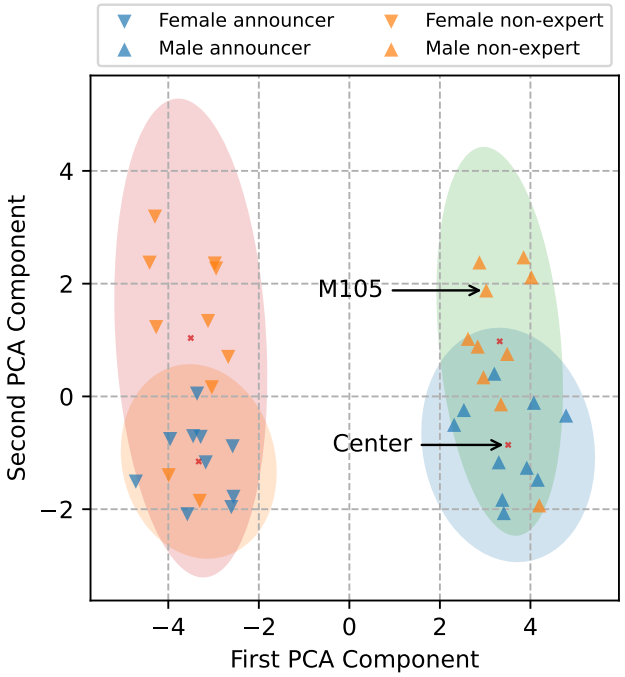

Fig. 1. Speaker embeddings in PCA domain

ponent is related to the intelligibility of speech.

However, the DNN-based VC system is a black box; it is unknown what happens that improves the intelligibility of speech when the second PCA component is swapped. It is also unclear whether speech intelligibility can be changed gradually by shifting only the second PCA component. This paper analyzes speaker embeddings in the system [15] that is thought to be a black box in a DNN-based VC for improving speech intelligibility and discusses physical cues for improving intelligibility. More specifically, we retrain the above VC system with a larger amount of training data and use it to control the second PCA component. We then study the subsequent effects on physical properties and intelligibility of speech and present two discussion points:

- Whether speech intelligibility can be changed gradually even by shifting one PCA component of the speaker embedding.
- What physical features are changed when the PCA component is shifted.

Possible candidates of physical correlates are spectral tilt and plateau and cepstral peak prominence (CPP).

II. Voice-conversion system

A. Training voice-conversion system

StarGANv2-VC [16] is one of the most effective VC systems. On the basis of this system, the authors [15] proposed a method for converting the voice of a non-expert speaker to that of a professional announcer to increase speech intelligibility. Their goal was to increase the effectiveness of StarGANv2-VC by adding automatic speech recognition to the discriminator module. They also used a Parallel WaveGAN [17] vocoder to generate converted speech utterances from the corresponding converted mel-spectrograms.

We retrained the above VC system with a larger amount of training data to discuss the properties of the PCA second component of the speaker embedding related to expert versus non-expert speakers. More specifically, the training data consist of utterances from 20 professional announcers from the ATR dataset A-set and 20 non-expert speakers from the ATR dataset C-set [18]. All the utterances are pre-processed by resampling to 24 kHz, removing leading and trailing silence; and they are combined to 5-second chunks. There are total 29,956 utterances, in which 500 utterances are used for validation. The 80-band log-mel spectrogram with band-limited frequency range (0 to 8 kHz) is extracted using short-time Fourier transform. The window length and frame shift are set to 1024 and 256, respectively.

We follow the training strategy described in the above studies [15], [16] with the same objective functions and hyper-parameters. We then used the style encoder of our retrained system to generate the PCA of the speaker embeddings for non-experts and professional announcers to verify that the second PCA component is related to expert and non-expert speakers.

Figure 1 shows the visualization of the first two PCA components of the speaker embedding. It can be seen that the first PCA component is related to gender with female and male speakers distributed on the left and right. The second PCA component is related to expert and non-expert speakers. The clusters of female/male professional announcers are compact and those of non-expert speakers are wide on the second PCA component. This phenomenon suggests that the professional announcers can control the configurations of their voice organs and high intelligible speech is the result of such effort, resulting that the variance of their voices are smaller than those of non-expert speakers.

B. Shifting second PCA component

We referred to the second PCA component of a non-expert speaker (M105 in the ATR dataset C-set) as the source and average value of the second PCA component of ten professional male announcers in the ATR dataset A-set as the Center. The PCA components of M105 and the Center are visualized in Fig. 1. Let d be the distance between the PCA values (the second PCA component) of the source and Center. We calculated three checkpoints, i.e., C1 $= 0.25d$, C2 $= 0.5d$ and C3 $= 0.75d$ from the source, respectively. For example, assuming that the second PCA components of the source and Center were vectors: $\mathbf{a}$ and $\mathbf{b}$; the checkpoints were calculated as: C1 $= 0.25d = (1-0.25)\times\mathbf{a}+0.25\times\mathbf{b}$, C2 $= 0.5d = (1-0.5)\times\mathbf{a}+0.5\times\mathbf{b}$, and C3 $= 0.75d = (1-0.75)\times\mathbf{a}+0.75\times\mathbf{b}$.

With our retrained voice-conversion system, we first calculated the PCA components for a non-expert speaker and all ten male professional announcers. We then calculated the Center by taking the average of the second PCA components corresponding to the professional announcers and calculated

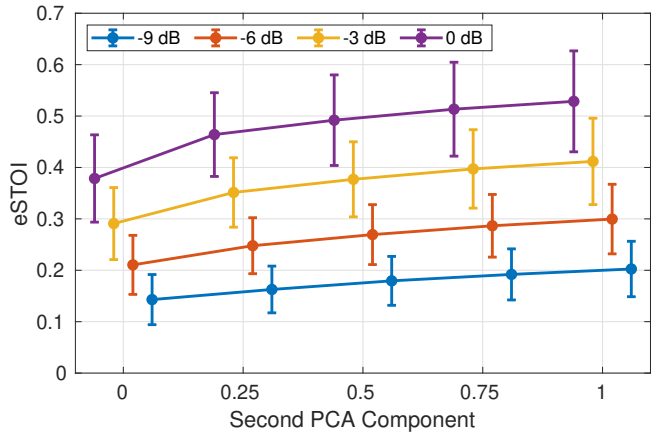

Fig. 2. eSTOI scores at four levels of noise (-9, -6, -3, 0 dB). On the horizontal axis, 0 denotes the source and 1 is the Center. 0.25, 0.5 and 0.75 are the checkpoints, C1, C2, and C3, respectively.

the distance between the second PCA components of the non-expert speaker and the Center as d. We then used d to calculate the PCA values for checkpoints C1, C2, and C3 accordingly. Finally, in turns, we replaced the second PCA component of the non-expert speaker embedding with the PCA values of C1, C2, C3, and Center and used our retrained voice-conversion system to produce the converted speech stimuli.

III. Second PCA Component and Intelligibility in Noise

The first discussion point is investigated in this section. We conducted an experiment to gain insights about the correlation between the second PCA component and speech intelligibility. The consistency of the correlation was also examined in various levels of noise.

We selected 520 Japanese words, each containing 1 to 4 morae, from the ATR dataset A-set and ATR dataset C-set as the clean stimuli for conversion-target and source speakers. All speech waveforms were pre-processed to a 16-kHz sampling rate with a single channel. We followed the instructions in [15] and used 16 kHz here instead of 24 kHz as described in Section II. There were 6 types of speech stimuli in the experiments: S_N is the natural speech of a non-professional speaker, collected from speaker M105 in the C-set; S_A is the natural speech of professional announcers, collected from 20 male and female speakers in the A-set; and S_1, S_2, S_3, and S_C are converted speech produced by shifting the second PCA components of speaker embedding of the source (M105) to checkpoint C1, C2, C3, and Center, respectively.

To create the noisy stimuli, we masked the clean stimuli with pink noise at four different signal-to-noise-ratio (SNR) levels: -9, -6, -3, and 0 dB. We calculated the root-mean-square of the speech signal only in the speech-presence region and scaled the noise signal to match the desired SNR level. The speech-presence region is derived from the text labels of the ATR dataset. To avoid the effect of different onset and offset timing between speech stimuli, the duration of each stimulus was adjusted to contain the same 200 ms of leading noise and 200 ms of trailing noise. Speech stimuli were gated with two raised cosine onset and offset windows of 40 ms to avoid overshoot distortion.

To objectively measure the intelligibility of speech in noise and determine whether speech intelligibility is increased gradually by shifting values along the second PCA component, we calculate the extended Short Term Objective Intelligibility (eSTOI) of the speech stimuli at 4 SNR levels: -9, -6, -3 and 0 dB at 5 checkpoints (Source, C1, C2, C3, and Center) using pySTOI python package [19]. The clean speech by speaker M105 were used as the reference signals at checkpoint 0 and the clean-converted speech were used as the reference signals at other checkpoints for eSTOI calculation.

Figure 2 shows the experimental results. The vertical lines at each checkpoint correspond to the standard deviations of eSTOI scores. It appears that intelligibility was increased gradually when the second PCA component was shifted from source to checkpoints C1, C2, C3, and Center. The eSTOI scores were also consistent with various levels of noise. The results provide an important insight in that the intelligibility could be tuned adaptively to various levels of noise on the basis of the voice of an arbitrary person by shifting the second PCA component using our retrained system.

IV. Intelligibility and its Physical Correlates

A. Spectral tilt, spectral plateau, and intelligibility

Studies on laryngeal anomalies have found that breathiness is a prominent feature used for determining various pathological conditions [20]. Breathiness is a phenomenon caused by the incomplete closure of vocal fold. As a result, breathy voices are more difficult to hear (less intelligible) in noisy environments. Compared with normally phonated signals, breathy glottal signals have steeper downward spectral slopes, less energy in the high-frequency region, and are less periodic [21]. Several acoustical studies have reported correlations between spectral tilt (downward spectral slope), spectral plateau (energy in the high-frequency region); and breathiness ratings [22]. Based on these knowledge, we hypothesize that a speech signal that has a flatter spectral tilt and larger plateau energy could have higher intelligibility and vice versa.

Figure 3 (a) shows an example of the spectral tilt we calculated for this study. It is the frequency spectrum of the vowel /a/ with the spectral tilt presented as the red line. We used the label of the ATR dataset to extract a segment of vowel /a/. We then calculated the Fourier spectrum of the segment. Finally, we calculated the regression line of the spectrum between 300 and 4,000 Hz. We used the slope of the regression line as the spectral tilt. Figure 3 (b) shows an example of the spectral plateau. On the same spectrum shown in Fig. 3 (a), the spectral plateau is presented as the red line between 2,000 and 4,000 Hz. We subtracted the entire spectrum from its peak magnitude. We then calculated the average magnitude of the spectrum in the 2,000-4,000-Hz band. We used this average magnitude to represent the spectral plateau and compared it with the plateaux of other spectra.

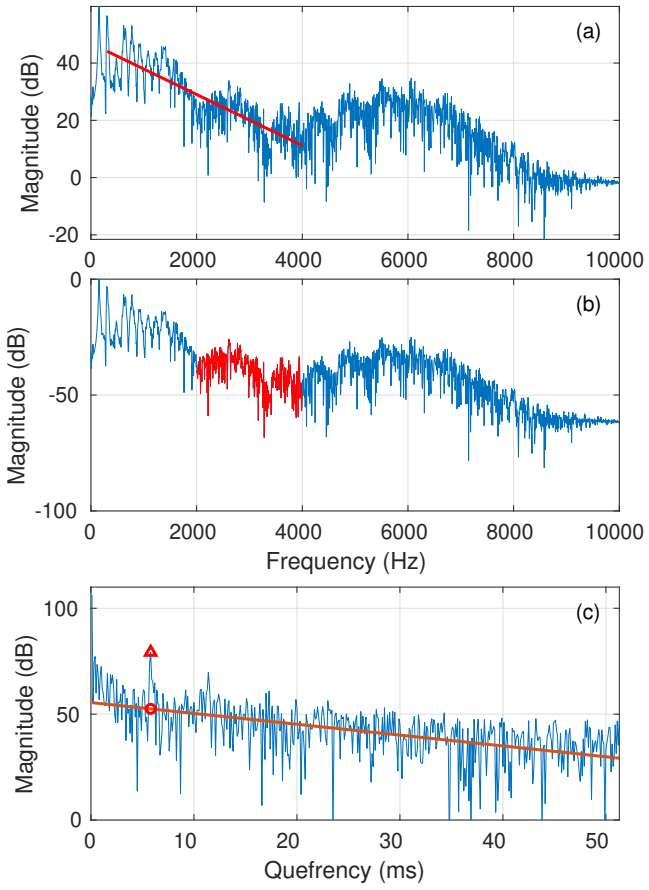

Fig. 3. Frequency spectrum and quefrency cepstrum of vowel /a/

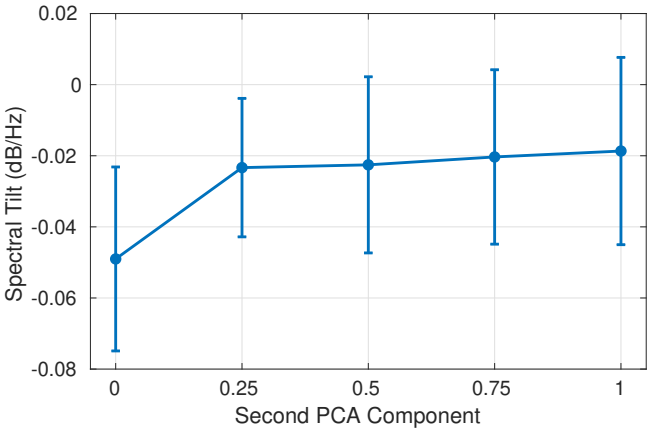

Fig. 4. Average spectral tilt and standard deviation of vowels /a/, /e/, /i/, /o/, /u/. On the horizontal axis, 0 denotes the source and 1 is the Center. 0.25, 0.5 and 0.75 are the checkpoints, C1, C2, and C3, respectively.

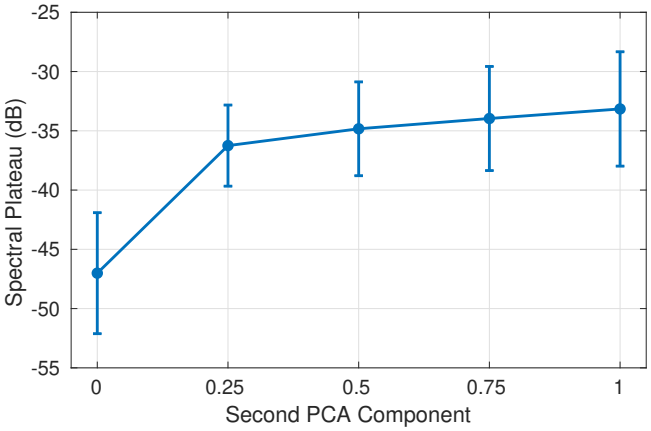

Fig. 5. Average spectral plateau and standard deviation of vowels /a/, /e/, /i/, /o/, /u/. On the horizontal axis, 0 denotes the source and 1 is the Center. 0.25, 0.5 and 0.75 are the checkpoints, C1, C2, and C3, respectively.

B. Periodicity, CPP, and intelligibility

A breathy voice is less periodic compared with a normal one and the quefrency domain is effective for analyzing signal periodicity. A crude explanation of the quefrency domain is that we treat the spectrum of a speech waveform as a signal and apply Fourier transform to it; the result is the cepstrum of the speech waveform in the quefrency domain. It can be observed that a highly periodic speech spectrum should result in clear harmonics in the quefrency domain; therefore, clearer cepstral peaks.

Several analyses have found a strong relation between the periodicity of a signal and its CPP [20], [23]. A CPP is the distance between the most prominent peak and the level of the cepstral background noise on the regression line immediately below the peak. Experimental results [20]–[23] indicated that the CPP of a breathy voice is significantly lower than that of a normal voice. In other words, a higher CPP level is an indicator of higher speech intelligibility. Figure 3 (c) shows an example of the CPP in the quefrency domain. It is the cepstrum of the vowel /a/ with its regression line and CPP shown as the red line and red triangle, respectively. We use the regression line of the cepstrum as the referenced background noise. The CPP is calculated as the difference in magnitude of the highest peak (the red triangle) and the red circle directly under it on the regression line.

C. Second PCA component, physical correlates, and intelligibility

Thus far, we have learned from the literature that a shallower spectral tilt, larger amount of energy of the spectral plateau, and higher CPP are associated with higher speech intelligibility. The next step is examining the correlation between the second PCA component and acoustical properties. We shifted the second PCA component, as described in Section II-B, and used our retrained voice conversion system to generate five types of stimuli. We then used the ATR dataset label to extract the vowel /a/, /e/, /i/, /o/, /u/ segments of five types of stimuli (S_N, S_1, S_2, S_3, and S_C). Finally, we used these segments to calculate spectral tilt, spectral plateau, and CPP.

The results of this experiment are shown in Figs. 4, 5, and 6. The vertical lines at each checkpoint correspond to the standard deviations of the averaged spectral tilts, spectral plateaux, and

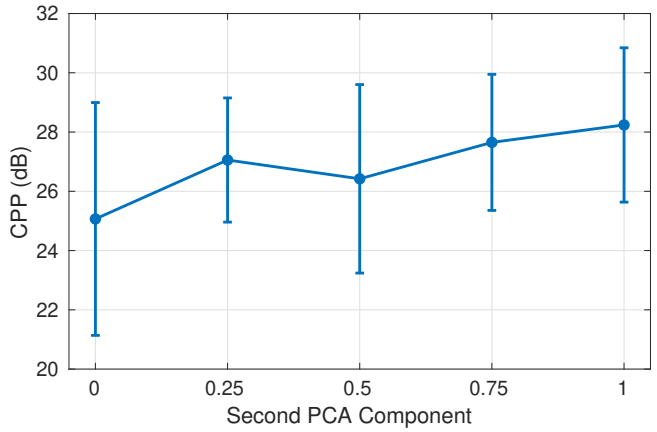

Fig. 6. Average cepstral peak prominence and standard deviation of /a/, /e/, /i/, /o/, /u/. On the horizontal axis, 0 denotes the source and 1 is the Center. 0.25, 0.5 and 0.75 are the checkpoints, C1, C2, and C3, respectively.

CPPs. It is known that a breathy voice (low intelligibility) has a steeper spectral slope (steeper tilt) and less energy in the high-frequency region (small or no plateau). It can be seen in Fig. 4 that the averaged slopes of the spectral tilts are reduced gradually from about -0.05 dB/Hz at checkpoint 0 to above -0.02 dB/Hz at the Center. Similarly, it appears in Fig. 5 that the average energy in the high-frequency regions (spectral plateaux) are rised from about -47 dB at checkpoint 0 to about -33 dB at the Center. Observing the experimental results visualized in Figs. 4, 5, and 2, there is a relation between the spectral tilt, spectral plateau, and intelligibility, i.e., the improvement of these physical properties is consistent with the improvement of speech intelligibility. More specifically, the non-expert speaker has the steepest spectral tilt and smallest spectral plateau, suggesting that the non-expert speaker has the lowest speech intelligibility. In contrast, the Center appears to have the shallowest spectral tilt and largest spectral plateau; therefore, it has the highest intelligibility. Between the non-expert speaker and Center, checkpoints C1, C2, and C3 have a small fluctuation; however, the overall trend is that the spectral tilts become shallower and spectral plateaux larger, indicating that the intelligibility becomes higher when the second PCA component is shifted from the non-expert speaker to checkpoints C1, C2, C3, and finally the Center.

It has been reported that the spectrum of a breathy voice (low intelligibility) is less periodic, and a less periodic spectrum results in a less prominent cepstral peak. It can be seen in Fig. 6 that the averaged cepstral peaks have become more prominent, rising from about 25 dB at checkpoint 0 to above 28 dB at the Center. Observing the experimental results visualized in Figs. 6 and 2, there is a relation between the CPP and intelligibility, i.e., the improvement of the CPP is consistent with the improvement of speech intelligibility. More specifically, the non-expert speaker has the lowest CPP; in other words, the speaker has the least speech intelligibility. The CPP values of other checkpoints are all larger than that of the non-expert. Although there is a small fluctuation, it appears that the CPP values becomes larger, indicating that the intelligibility becomes higher when the second PCA component is shifted from the non-expert speaker toward the Center.

The experimental results visualized in Fig. 2 show that speech intelligibility is increased gradually when the second PCA component is shifted gradually. The shift also produces enhancements of spectral tilt, spectral plateau, and CPP as shown in Figs. 4, 5, and 6, respectively. These results provide evidence that there is a correlation between the improvement of intelligibility and enhancement of physical properties of speech.

V. Conclusion

We presented two points of discussion for finding the correlations between the second PCA component, physical properties, and intelligibility of speech in order to learn why speech intelligibility can be increased by mimicking professional anouncers' voices using the end-to-end DNN-based VC system [15]. The first point is whether speech intelligibility can be changed gradually even by shifting one second PCA component of the speaker embedding and the second point is what physical features are changed when the second PCA component is shifted. To do so, we retrained the VC system [15] with a larger amount of training data. We then used our retrained system to shift the second PCA component of a non-expert speaker to those of checkpoints C1, C2, C3, and the Center. We used the eSTOI to evaluate the intelligibility of speech stimuli with four levels of noise (-9, -6, -3, and 0 dB) at five checkpoints. Experimental results confirm for the first point of discussion that speech intelligibility can be increased gradually by shifting the second principal component toward those of professional announcers.

We investigated why it is possible to increase speech intelligibility by using the second PCA component of professional announcers. We looked into the spectral tilt and spectral plateau in the frequency domain, as well as the CPP in the quefrency domain. The results confirm for the second point of discussion that when the second PCA component is shifted from a non-expert speaker through checkpoints C1, C2, C3, and Center, all the acoustical properties related to intelligibility appear to be enhanced proportionally.

***Abstract*—This paper addresses the problem of localization, which is inherently non-convex and non-smooth in a federated setting where the data is distributed across a multitude of devices. Due to the decentralized nature of federated environments, distributed learning becomes essential for scalability and adaptability. Moreover, these environments are often plagued by outlier data, which presents substantial challenges to conventional methods, particularly in maintaining estimation accuracy and ensuring algorithm convergence. To mitigate these challenges, we propose a method that adopts an L_1-norm robust formulation within a distributed sub-gradient framework, explicitly designed to handle these obstacles. Our approach addresses the problem in its original form, without resorting to iterative simplifications or approximations, resulting in enhanced computational efficiency and improved estimation accuracy. We demonstrate that our method converges to a stationary point, highlighting its effectiveness and reliability. Through numerical simulations, we confirm the superior performance of our approach, notably in outlier-rich environments, which surpasses existing state-of-the-art localization methods.**

***Index Terms*—Federated learning, Robust learning, distributed learning, localization, non-convex and non-smooth optimization**

I. Introduction

The increasing prevalence of edge devices in the era of the internet-of-things (IoT) and cyber-physical systems has resulted in a significant upsurge in available data. These devices, functioning within a federated network, present unique challenges. In particular, traditional machine learning methodologies often require a central server for data processing, raising privacy concerns [1]. In response to these concerns, federated learning (FL) has emerged as an innovative solution [2]–[4] for edge devices to collectively train a global model using their locally stored data, eliminating the need for direct data sharing [2], [4]. However, federated settings are frequently besieged by outlier data, often exhibiting heavy-tailed distributions [3], [5]. These outliers can considerably distort the accuracy of learning outcomes. Nevertheless, developing robust and computationally efficient solutions for managing outlier data in FL remains a critical research question, which this paper aims to address in the context of localization.

Localization is the process of estimating the location of an object or an event within a given environment. This problem has given rise to a broad range of applications in vehicle localization [6], aviation [7], healthcare [8], environmental [9], and industrial fields [10]. Based on the type of measurements used to estimate position, the localization problem has different formulations which include time-of-arrival (ToA) [11], received-signal-strength (RSS) [12], time-difference-of-arrival (TDoA) [13], angle-of-arrival (AoA) [14], and frequency-difference-of-arrival (FDoA) [15]. In IoT applications, ToA and RSS are particularly effective as they provide relatively simple and cost-effective ways to estimate distances using the existing communication infrastructure. Therefore, in this paper, we focus on distance-based localization that inherently encompasses ToA and RSS techniques, as they can be interpreted as distance measurements [16]. This approach finds relevance across a spectrum of practical scenarios and continues to be an area of research interest.

Conventionally, various methods have been proposed for localization problems, including the parallel projection method [17], projection-onto-convex-sets method [18], nearest local minimum [19], boundary-of-convex-sets [20], recursive weighted least-squares algorithms [21], augmented Lagrangian-based method for localization [16], and iterative re-weighted least-squares [22]. However, these methods have limitations, such as being centralized or sequentially updating estimates, which hinders parallelization and flexibility. More recently, a parallel distributed alternating projection algorithm (DAPA) has been proposed for the distributed case, formulating the localization problem as a ring intersection problem [23]. Despite the advancements of DAPA, challenges remain, particularly in handling three-dimensional localization problems and targets lying outside the sensor's convex hull [24]. To address these limitations, an alternative approach called EL-ADMM has emerged. EL-ADMM directly solves the non-convex and non-smooth event localization problem using the Alternating Direction Method of Multipliers [24]. By bypassing the need for high-computation convex relaxation techniques, EL-ADMM shows promise in handling three-dimensional environments [24]. However, EL-ADMM still faces challenges in outlier handling and lacks comprehensive convergence proof. Given these constraints, there is a compelling research imperative to develop a robust, distributed algorithm capable of efficiently handling three-dimensional localization problems with outliers.

In this paper, we address a challenging class of robust localization problems that require tackling non-convex and non-smooth optimization within a federated setting. The decentralization, energy constraints, and the presence of outliers further

exacerbate the difficulty of accurately estimating locations in such settings. To overcome these challenges, we propose a novel distributed sub-gradient-based algorithm specifically designed to address this problem. Our contributions can be summarized as follows:

- **Efficient Optimization Algorithm**: We introduce a novel optimization algorithm that operates within a single loop framework. This algorithm directly solves the localization problem in its original form, utilizing simple updating steps. The use of this approach leads to increased accuracy and eliminates the need for iterative approximation processes.
- **Theoretical Analysis**: We provide comprehensive theoretical insights into the convergence behavior of our algorithm. Through rigorous mathematical analysis, we elucidate the conditions under which our method is guaranteed to converge, thereby offering deeper insights into its reliability and robustness.
- **Empirical Validation**: We substantiate our theoretical results through extensive numerical simulations. Notably, our algorithm exhibits exceptional resilience in the presence of heavy-tailed noise and outliers. Furthermore, a comparative study with the state-of-the-art EL-ADMM algorithm highlights the superior accuracy and comparable fast convergence rate of our approach.

Mathematical Notations: Scalars are denoted by lowercase letters, column vectors by bold lowercase letters, and matrices by bold uppercase letters. The transpose of a matrix is signified by $(\cdot)^{\mathrm{T}}$. The jth column of a matrix $\mathbf{A}$ is represented as $\mathbf{a}j$. The element in the ith row and jth column of $\mathbf{A}$ is represented as a_{ij}. The sub-gradient of a function $f(\cdot)$ at a given point u is signified by $\partial f(u)$.

II. Preliminaries

We consider the problem of localization with L sensors, where the location of the i-th sensor is denoted by $\mathbf{a}_i$, for $i = 1, 2, \ldots, L$, and $A = \{\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_L\}$ represents the complete set of sensors' locations. The unknown source is located at $\mathbf{x} \in \mathbb{R}^n$, which must be estimated using the range information between the sensors and the source. Let $d_i > 0$, $i = 1, 2, \ldots, L$, represents a noisy observation representing the range between source location $\mathbf{x}$ and i-th sensor location $\mathbf{a}_i$. The range d_i can be expressed as

$$d_i = \|\mathbf{x} - \mathbf{a}_i\| + \epsilon_i, \quad i = 1, 2, \ldots, L, \tag{1}$$

where ϵ_i denotes the noise associated with each range observation.

Additionally, the network of L sensors is modeled as an unweighted undirected graph $\mathcal{G}$ consisting of vertices $\mathcal{V} = 1, \cdots, L$ and bidirectional communication links represented by the edge set $\mathcal{E}$. Each sensor $i \in \mathcal{V}$ can communicate with those in its neighborhood $\mathcal{N}_i$ of cardinality $|\mathcal{N}_i|$. We assume that graph $\mathcal{G}$ is strongly connected.

The maximum-likelihood estimate for the source location $\mathbf{x}$ with additive independent and identically distributed Gaussian noise affecting range measurements can be determined as the solution of the optimization problem [16]:

$$\hat{\mathbf{x}} = \arg\min_{\mathbf{x}} \frac{1}{L} \sum_{i=1}^{L} \left(\|\mathbf{x} - \mathbf{a}_i\| - d_i\right)^2. \tag{2}$$

However, this approach encounters challenges when faced with outlier measurements that do not conform to a Gaussian distribution. These outliers can drastically bias location estimate due to the magnified impact of their squares in each term. One could use conventional filtering techniques to reduce this effect. However, such filtering methods often presuppose knowledge about the noise characteristics, which is not always available or accurate. Additionally, filtering can induce a 'masking effect', in which crucial signal components, particularly those smaller ones sharing frequency characteristics with the noise, are suppressed or obscured [22]. Such an outcome is undesirable in our context as it may lead to the loss of vital information [22]. To counteract this, robust estimation theory offers a way of softly rejecting outliers by using the L_1 loss [25] as given by

$$\hat{\mathbf{x}} = \arg\min_{\mathbf{x}} \frac{1}{L} \sum_{i=1}^{L} \left|\|\mathbf{x} - \mathbf{a}_i\| - d_i\right| = \arg\min_{\mathbf{x}} \sum_{i=1}^{L} f_i(\mathbf{x}), \tag{3}$$

where the local objective function $f_i(\mathbf{x})$ at sensor i is defined as $f_i(\mathbf{x}) = \frac{1}{L}\left|\|\mathbf{x} - \mathbf{a}_i\| - d_i\right|$. The L_1 objective function diminishes the impact of outliers by minimizing the average absolute discrepancy between the Euclidean distance from $\mathbf{x}$ to each sensor $\mathbf{a}_i$ and the corresponding observed range d_i. This approach is particularly beneficial as it ensures that smaller yet crucial variations in the data are preserved, and not overshadowed by outliers.

Even though the L_1 robust formulation can enhance accuracy and handle outliers more efficiently, it is inherently non-smooth and non-convex and not even a difference of convex functions, which makes (3) difficult to solve. Traditionally, convex relaxation approaches have been considered to tackle this problem [22], [25]. These methods, however, can compromise accuracy and are often time-consuming and computation-intensive iterative processes. In the distributed case, the problem exacerbates as one must ensure consensus among the nodes as well as convergence to a solution. To that end, this paper proposes a method for addressing the problem directly with the L_1 loss in a distributed manner.

III. Distributed Robust Localization

The proposed algorithm for localization in a distributed setting called distributed sub-gradient method for robust localization (DSRL), updates each node's estimate of the actual parameter $\mathbf{x}^*$ through a diffusion step and a sub-gradient update step. In the diffusion step, each node uses a diffusion variable, $\mathbf{v}_i$, to incorporate information from its neighboring nodes. At each time instant k, the diffusion step takes place as follows:

$$\mathbf{v}_i^{(k)} = \mathbf{x}_i^{(k)} + \alpha^{(k)} \sum_{j \in \mathcal{N}_i} \left(\mathbf{x}_j^{(k)} - \mathbf{x}_i^{(k)}\right). \tag{4}$$

Algorithm 1: Distributed Sub-gradient Method for Robust Localization (DSRL)

Initialize $\mathbf{x}_i^{(1)}$ for each node i, the weight parameter $\{\alpha_k\}_{k=1}^K$, the step-size $\{\beta_k\}_{k=1}^K$ and the number of iterations K;
for $k = 1, \cdots, K$ **do**
  for $i = 1, \cdots, L$ **do**
    Receive $\mathbf{x}_j$ from neighbors in $\mathcal{N}_i$;
    Update $\mathbf{v}_i^{(k)}$ by (4);
    Update $\mathbf{g}_i^{(k)}$ by (6);
    Update $\mathbf{x}_i^{(k+1)}$ by (5);
  end
end

In this formula, $\mathbf{x}_i^{(k)}$ is the current estimate at node i, while $\mathbf{x}_j^{(k)}$ are the estimates at each neighboring node j. The term $\alpha^{(k)}$ is a scalar weight parameter that adjusts how strongly the estimates of the neighbors influence the node's update. The diffusion step seeks to decrease the discrepancy between each node's estimate and the average estimate of its neighbors, working as a type of approximation to the average consensus algorithm. Instead of a simple average, we apply a weighted adjustment based on the difference between a node's estimate and its neighbors' estimates, thereby aiding the nodes to reach a consensus on the parameter estimate.

In the subsequent step, termed the sub-gradient step, each node updates its estimate of the true parameter $\mathbf{x}^*$ in the manner depicted below:

$$\mathbf{x}_i^{(k+1)} = \mathbf{v}_i^{(k)} - \beta^{(k)} \mathbf{g}_i^{(k)}, \tag{5}$$

where $\beta^{(k)}$ is the step-size at iteration k and $\mathbf{g}_i^{(k)} \in \partial f_i(\mathbf{x}_i^{(k)})$ is any element of the sub-differential set of $f_i(\cdot)$. Each function $f_i(\cdot)$ is neither convex nor smooth, so the distributed sub-gradient method proposed in [26] is adopted for iterative computation of the estimate of $\mathbf{x}$ at each node. The sub-gradient of the local robust localization function $f_i(\cdot)$ with respect to the coefficient $\mathbf{x}_i^{(k)}$ is computed as follows:

$$\partial f_i(\mathbf{x}) = \begin{cases} \frac{\mathbf{x}-\mathbf{a}_i}{L\|\mathbf{x}-\mathbf{a}_i\|} \text{sign}(\|\mathbf{x}-\mathbf{a}_i\| - d_i), & \|\mathbf{x}-\mathbf{a}_i\| > 0 \\ \mathbf{0}. & \|\mathbf{x}-\mathbf{a}_i\| = 0 \end{cases} \tag{6}$$

Algorithm 1 summarizes the proposed method for solving distributed robust localization.

IV. Convergence Proof

In this section, a convergence analysis of the Algorithm 1 is presented. We construct our convergence proof based on the following assumptions.

Assumption 1. *Consider the function $f(\cdot) = \sum_{i=1}^{L} f_i(\cdot)$ and let $CP_f \subset \mathbb{R}^n$ represent the set of its critical points. Then, the complement of CP_f in $\mathbb{R}^n$, expressed as $\mathbb{R}^n \setminus CP_f$, is a dense set in $\mathbb{R}^n$.*

Assumption 2. *The weight parameter $\alpha^{(k)}$ and the step-size $\beta^{(k)}$ are derived from $\alpha^{(k)} = \frac{a}{k^{\tau_\alpha}}$ and $\beta^{(k)} = \frac{b}{k^{\tau_\beta}}$ respectively. Here, $0 < \tau_\alpha < \tau_\beta$, $\frac{1}{2} < \tau_\beta \leq 1$, and both a and b are positive constants.*

While Assumption 1 might appear to be technical, it is in fact a relatively mild condition that guides the positioning and quantity of sensors to ensure convergence to the critical points in our algorithm. As an illustration, this assumption is invariably satisfied when employing an odd number of sensors. Having a non-critical dense set ensures that, through communication and updates, the sensors have enough room to maneuver and collaborate towards converging to a consensus that aligns with the global objective. On the other hand, Assumption 2 guarantees that information can be effectively disseminated across the network.

In order to show the regularity of the objective function we provide the following Lemmas.

Lemma 1. *each $f_i(\cdot)$ is locally Lipschitz continuous.*

Proof. Given that the sub-gradient of each $f_i(\cdot)$ is bounded, it follows that these functions are locally Lipschitz continuous. □

Lemma 2. *There exists a radius $R > 0$ and constants $C_1, C_2 > 0$ such that:*

$$\left\langle \frac{\mathbf{g}}{\|\mathbf{g}\|}, \frac{\mathbf{x}}{\|\mathbf{x}\|} \right\rangle \geq C_1 \quad \textit{and} \quad \|\mathbf{g}\| \leq C_2 \|\mathbf{x}\|,$$

for all $\mathbf{g} \in \partial f_n(\mathbf{x})$ and $\|\mathbf{x}\| \geq R$.

Proof. We select a radius $R = (3 \max_i \max_j |a_{ij}| + \max_i d_i) + 1$. Consequently, $\text{sign}(\|\mathbf{x} - \mathbf{a}_i\| - d_i) = 1$. We proceed to examine the first condition of the lemma. It is evident that

$$\begin{aligned} \left\langle \frac{\mathbf{g}}{\|\mathbf{g}\|}, \frac{\mathbf{x}}{\|\mathbf{x}\|} \right\rangle &= \left\langle \frac{\mathbf{x}-\mathbf{a}_i}{\|\mathbf{x}-\mathbf{a}_i\|}, \frac{\mathbf{x}}{\|\mathbf{x}\|} \right\rangle \\ &\geq \frac{\|\mathbf{x}\|}{\|\mathbf{x}-\mathbf{a}_i\|} - \frac{\mathbf{x}^T \mathbf{a}_i}{\|\mathbf{x}-\mathbf{a}_i\|\|\mathbf{x}\|} \\ &\geq 1 - \frac{\|\mathbf{a}_i\|}{\|\mathbf{x}-\mathbf{a}_i\|} \geq 1 - \frac{\|\mathbf{a}_i\|}{2\|\mathbf{a}_i\|} = \frac{1}{2}. \end{aligned}$$

These inequalities are derived from the conditions that $\|\mathbf{x}\|$ always surpasses $\|\mathbf{x}-\mathbf{a}_i\|$, and that $\|\mathbf{x}\|$ always exceeds $3\|\mathbf{a}_i\|$. These conditions are a direct result of our choice of R. This effectively verifies that $\left\langle \frac{\mathbf{g}}{\|\mathbf{g}\|}, \frac{\mathbf{x}}{\|\mathbf{x}\|} \right\rangle \geq C_1$ for $C_1 = \frac{1}{2}$. For the second condition of the lemma, we are aware that $\|\mathbf{g}\| = 1$ when $\|\mathbf{x} - \mathbf{a}_i\| > d_i$. This is always true given our selection of R. Also, taking into account that $1 \leq \|\mathbf{x}\|$, the inequality $\|\mathbf{g}\| \leq C_2 \|\mathbf{x}\|$ holds for $C_2 = 1$. □

Theorem 1. *Given that the static graph $\mathcal{G}$ is strongly connected, the objective function fulfills Assumption 1, and both the step-size and weight parameter adhere to Assumption 2, the DSRL algorithm is ensured to converge to a critical point.*

Proof. The convergence of our proposed DSRL algorithm is substantiated by verifying that all the prerequisites set forth in

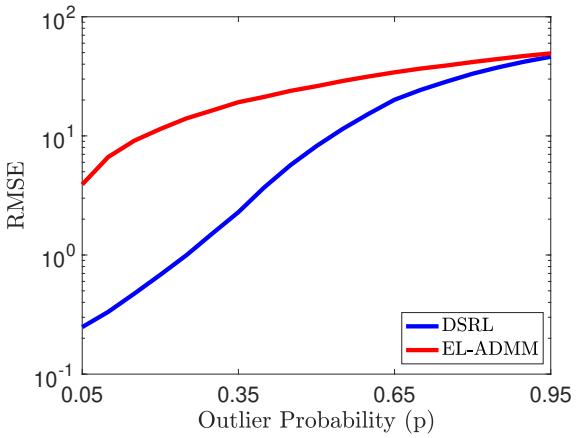

Fig. 1: Steady-state RMSE versus the outlier probability.

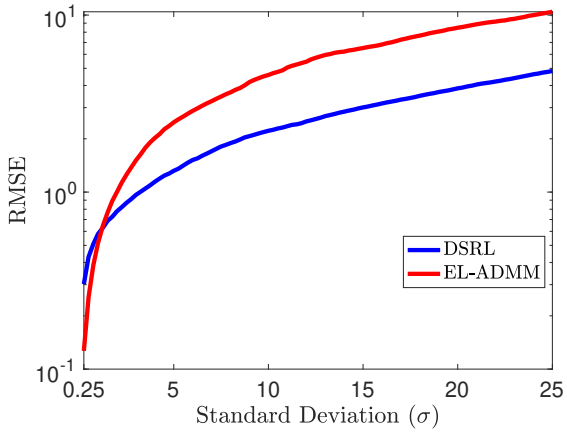

Fig. 2: Steady-state RMSE versus the standard deviation of mixture of Laplacian noise.

[26, Theorem 7], inclusive of the regularity conditions of our robust localization function, are met. The fulfillment of these conditions is demonstrated in Lemma 1 and Lemma 2. □

V. Simulation Results

In this section, we assess the performance of the proposed DSRL algorithm via simulations and draw comparisons with the distributed event localization via the Alternating Direction Method of Multipliers (EL-ADMM) algorithm, as outlined in [24]. The sensor network $\mathcal{G}$ under consideration comprises $L = 31$ nodes, which are uniformly and randomly distributed within a $[-30, 30]^3$ cubic region, and is fully connected. Connections are established between nodes if their distance is less than 25, ensuring a minimum of 2 and a maximum of 10 neighbors per node. In addition, the target is assumed to be uniformly and randomly distributed within the same cubic region. For each iteration, the weight parameter $\alpha^{(k)}$ and the step-size $\beta^{(k)}$ are set to $\frac{0.3}{k^{0.55}}$ and $\frac{3.5}{k^{0.5}}$, respectively. We employ the root-mean-square error (RMSE), denoted by $\sqrt{\frac{\sum_{i=1}^{L} ||\hat{\mathbf{w}}_i - \mathbf{x}||_2^2}{L}}$, as the performance metric. The results are obtained by averaging the outcomes of 1000 independent trials.

In the first scenario, we focus on comparing the accuracy of the algorithms when handling outliers in the measurements. We introduce outliers at varying probability, denoted as p, ranging from 0.05 to 0.95 with increments of 0.05. The outliers, represented as ϵ_i, are drawn from a uniform distribution over the interval $[0, 60\sqrt{3}]$. This is formalized as:

$$y_i = \begin{cases} \epsilon_i, & \text{if } u_i < p, \\ \|\mathbf{x} - \mathbf{a}_i\|, & \text{otherwise}, \end{cases} \tag{7}$$

where u_i is a realization of the uniform distribution on the interval [0,1]. As illustrated in Figure 1, the DSRL algorithm outperforms EL-ADMM consistently across the various frequency of outliers.

In the second scenario, we evaluate the performance of the algorithms under noisy conditions, where the noise follows

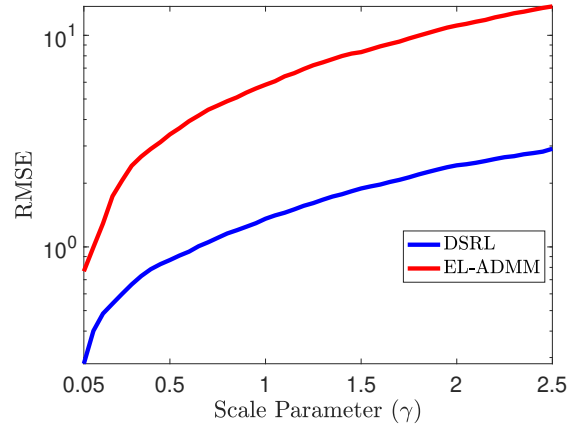

Fig. 3: Steady-state RMSE versus scale parameter of Cauchy noise.

a mixture of Laplacian distributions. The measurements are generated as follows:

$$y_i = \|\mathbf{x} - \mathbf{a}_i\| + \epsilon_i, \quad \forall i \in 1, \cdots, N, \tag{8}$$

where $\{\epsilon_i\}_{i=1}^{N}$ denotes the components of the noise, which are independently and identically sampled from a mixture of Laplacian distributions given by $\sum_{i=1}^{2} c_i \frac{\lambda_i}{2} e^{-\lambda_i |v|}$ Here, $c_1 = 0.9$, $c_2 = 0.1$, and $\lambda_2 = \frac{\lambda_1}{10}$. The parameter λ_1 is related to the standard deviation (σ) and can be calculated as $\lambda_1 = \sqrt{\frac{\sigma^2}{10.9}}$. The value of 10.9 in the denominator arises from the specific weights c_1 and c_2, and it represents the effective contribution of the two components of the Laplacian mixture in relation to the variance. In this setup, 10% of the measurements can be considered outliers. We obtain simulation results for varying standard deviation values, ranging from 0.25 to 25, with increments of 0.25. As illustrated in Figure 2, the DSRL algorithm exhibits superior performance in terms of RMSE, particularly for standard deviation values greater than 1.

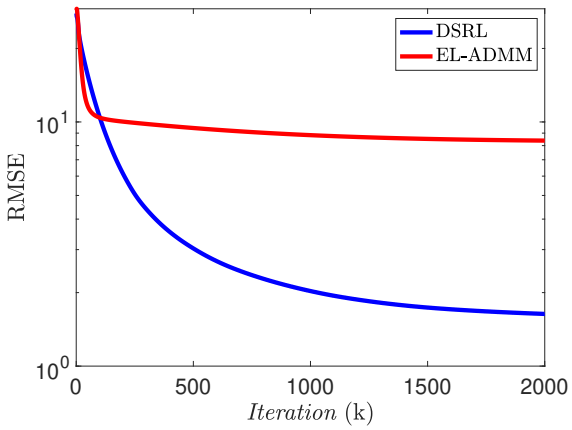

Fig. 4: RMSE versus iterations.

In the third scenario, we assess the accuracy of the algorithms in the presence of Cauchy noise. The measurements are formulated as in (8), where each component ϵ_i is independently and identically distributed according to the Cauchy distribution with the scale parameter γ, i.e., $\epsilon_i \sim \text{Cauchy}(0, \gamma)$. We conduct simulations for varying scale parameters, ranging from 0.05 to 2.5, in increments of 0.05. Figure 3 illustrates that the DSRL algorithm outperforms EL-ADMM in terms of RMSE across different scale parameters. Additionally, for the scale parameter set at 1, Figure 4 demonstrates that DSRL maintains a competitive convergence speed compared to EL-ADMM.

VI. Conclusion

This paper presents a sub-gradient algorithm devised for the distributed robust localization problem that directly tackles non-convex and non-smooth objective functions. This proposed algorithm has been rigorously proven to be convergent. Our simulation results highlight the superiority of our algorithm in terms of root-mean-squared error, compared to the existing state-of-the-art EL-ADMM algorithm. Particularly in outlier settings, the algorithm's effectiveness was consistently apparent.

***Abstract*—Communication errors caused by noisy links can negatively impact the accuracy of federated learning (FL) algorithms. To address this issue, we introduce an FL algorithm that is robust to communication errors while concurrently reducing the communication load on clients. To formulate the proposed algorithm, we consider a weighted least-squares regression problem as a motivating example. We recast this problem as a distributed optimization problem over a federated network, which employs random scheduling to enhance communication efficiency, and solve the reformulated problem via the alternating direction method of multipliers. Unlike conventional FL approaches employing random scheduling, the proposed algorithm grants the clients the ability to continually update their local model estimates even when they are not selected by the server to participate in FL. This allows for more frequent and ongoing client involvement, resulting in performance improvement and enhanced robustness to communication errors compared to when the local updates are only performed when the respective clients are selected by the server. We demonstrate the effectiveness and performance gains of the proposed algorithm through simulations.**

I. Introduction

Federated learning (FL) [1]–[6] is a distributed machine-learning approach that enables the training of models across multiple decentralized devices without transferring the data to any global server. FL allows devices to share their knowledge in terms of model estimates or gradients without revealing their raw data, thereby improving data privacy and security [7]. FL holds significant potential in a range of critical applications, including healthcare [8], finance [9], and industrial IoT [10], [11]. These data-sensitive domains demand utmost priority on data privacy, making FL an ideal approach to safeguard sensitive information while enabling effective machine learning.

The literature on FL encompasses a diverse array of methods that have been extensively investigated to address a multitude of aspects and challenges such as preserving privacy [9], [12]–[14], handling Byzantine attacks [15], [16], and improving communication efficiency [7], [17]. However, a significant number of these works operate under the assumption of ideal communication links, neglecting the presence of communication errors or noise [18]–[22]. In practical real-world applications, however, the communication links connecting clients and the server are susceptible to noise corruption, posing a potential threat to the performance of the model [23]. To tackle this challenge, several studies have introduced different techniques aimed at enhancing the accuracy of FL models when confronted with communication noise. Some works focus on the uplink noise and neglect the downlink noise [24], [25] while some other also consider the effects of the downlink noise [26].

Distributed algorithms that are based on the alternating direction method of multipliers (ADMM) can exhibit a certain degree of robustness to additive communication noise [27]. This is due to the inherent characteristics of ADMM that allow it to alleviate the impact of noise present in the communication channel. However, it requires complete collaboration among all clients, which stands in contrast to the objectives of FL, particularly those associated with system heterogeneity, such as varying computation and storage capacities across different clients. Hence, there exists a need for noise-robust ADMM-based algorithms that achieve convergence even when only a subset of clients participate in each iteration.

In this paper, we introduce a new FL algorithm that exhibits both communication efficiency and robustness to communication noise/errors. Additionally, our algorithm facilitates continual local updates at the clients, even when they are not selected by the server. This results in improved accuracy with no extra communication. We derive the proposed algorithm by using ADMM to solve a weighted least-squares (WLS) regression problem. We consider the communication links in both uplink and downlink to be noisy. To achieve noise robustness, we eliminate the dual variable update step at each client and transmit a linear combination of the last two global model updates. Our extensive simulation results corroborate the effectiveness of the proposed algorithm.

II. Background

Let us consider a federated network with K clients and a server. Each client k has an exclusive dataset denoted by $\mathcal{D}_k = \{\mathbf{H}_k, \mathbf{y}_k\}$ where $\mathbf{y}_k \in d_k$ is a column vector and $\mathbf{H}_k$ is a matrix of size $d_k \times L$. Each client independently trains a local model on its respective dataset using an FL algorithm. The process entails exchanging model updates with the global server, allowing for collaborative model training while preserving data privacy. For client k, a linear regression model relating $\mathbf{H}_k$ to $\mathbf{y}_k$ can be described as

$$\mathbf{y}_k = \mathbf{H}_k \mathbf{x}^* + \boldsymbol{\nu}_k, \tag{1}$$

where $\mathbf{x}^* \in \mathbb{R}^L$ is the global regression parameter vector and $\boldsymbol{\nu}_k$ represents noise or perturbation.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

The goal of FL is to find an estimate of $\mathbf{x}^*$ that is the optimal solution to

$$\min_{\{\mathbf{x}_k\}} \sum_{k=1}^{K} \mathcal{J}_k(\mathbf{x}_k) \ \text{ s.t. } \mathbf{x}_k = \mathbf{x}, \ k = 1, 2, \cdots, K, \tag{2}$$

where $\mathcal{J}_k(\mathbf{x}) = \|\mathbf{y}_k - \mathbf{H}_k\mathbf{x}\|^2_{\mathbf{W}_k}$ is the local objective function at client k and $\mathbf{W}_k$ is the appropriate weight matrix of client k. In addition, $\mathbf{x}_k$ represents the local model estimate at client k, and $\mathbf{x}$ denotes the global model estimate.

We use an ADMM-based approach to solve (2). In this approach, primal and dual updates are computed by each client and transmitted to the global server via a noisy communication channel. Each client implements local iterations to update its local model and shares its updated local model estimate with the global server. The global server aggregates the received model estimates from the clients and updates the global model estimate. The server then sends the updated global model estimate to the clients over a noisy channel. The clients utilize the received global model estimate in updating their local estimates and the process continues until a convergence criterion is met.

To solve (2) using ADMM, we express the related augmented Lagrangian function as

$$\sum_{k=1}^{K} \mathcal{L}_k(\mathbf{x}, \mathbf{x}_k, \boldsymbol{\pi}_k) = \sum_{k=1}^{K} \mathcal{J}_k(\mathbf{x_k}) + \langle \mathbf{x}_k - \mathbf{x}, \boldsymbol{\pi}_k \rangle + \frac{\rho_k}{2} \|\mathbf{x}_k - \mathbf{x}\|_2^2, \tag{3}$$

where $\boldsymbol{\pi}_k \in \mathbb{R}^L$ and $\rho_k > 0$ are, respectively, the Lagrange multiplier vector and the penalty parameter associated with client k. Hence, the corresponding ADMM iterations at each client k are given as

$$\boldsymbol{\pi}_{k,n} = \boldsymbol{\pi}_{k,n-1} + \rho_k(\mathbf{x}_{k,n} - \mathbf{x}_n) \tag{4a}$$

$$\mathbf{x}_{k,n+1} = \hat{\mathbf{x}}_k - \mathbf{N}_k^{-1}(\boldsymbol{\pi}_{k,n} - \rho_k \mathbf{x}_n) \tag{4b}$$

and at the global server as

$$\mathbf{x}_{n+1} = \frac{1}{\sum_{k=1}^{K} \rho_k} \sum_{k=1}^{K} (\rho_k \mathbf{x}_{k,n+1} + \boldsymbol{\pi}_{k,n}) \tag{5}$$

where we define $\mathbf{N}_k = 2\mathbf{H}_k^\intercal \mathbf{W}_k \mathbf{H}_k + \rho_k \mathbf{I}$ and $\hat{\mathbf{x}}_k = 2\mathbf{N}_k^{-1}\mathbf{H}_k^\intercal \mathbf{W}_k \mathbf{y}_k$, and the index n denotes the iteration number.

In the above iterations, each client shares the local estimate $\rho_k \mathbf{x}_{k,n+1} + \boldsymbol{\pi}_{k,n}$ with the global server after computing (4a) and (4b). The global server then aggregates the received estimates to obtain the global estimate as in (5).

As it is evident from the recursions (4) and (5), both primal and dual model updates are sent to the server for it to estimate the global model update. However, by making a careful selection of the initial values, the information of the dual update can be incorporated into the primal update. Therefore, using the initial values $\mathbf{x}_{-1} = \mathbf{0}$, $\boldsymbol{\pi}_{k,-1} = \mathbf{0}$, and $\mathbf{x}_{k,0} = \hat{\mathbf{x}}_k$, we can eliminate the Lagrange multiplier vectors $\boldsymbol{\pi}_{k,n}$ and restate the recursions (4)-(5) as

$$\mathbf{x}_{k,n+1} = (\mathbf{I} - \rho_k \mathbf{N}_k^{-1})\mathbf{x}_{k,n} + \rho_k \mathbf{N}_k^{-1}(2\mathbf{x}_n - \mathbf{x}_{n-1}) \tag{6a}$$

$$\mathbf{x}_{n+1} = \frac{1}{\sum_{k=1}^{K} \rho_k} \sum_{k=1}^{K} \rho_k \mathbf{x}_{k,n+1}. \tag{6b}$$

By defining $\mathbf{s}_{k,n} = 2\mathbf{x}_{k,n} - \mathbf{x}_{k,n-1}$ and $\mathbf{s}_n = 2\mathbf{x}_n - \mathbf{x}_{n-1}$, we can further rewrite (6) as

$$\mathbf{x}_{k,n+1} = (\mathbf{I} - \rho_k \mathbf{N}_k^{-1})\mathbf{x}_{k,n} + \rho_k \mathbf{N}_k^{-1}\mathbf{s}_n \tag{7a}$$

$$\mathbf{s}_{k,n+1} = 2\mathbf{x}_{k,n+1} - \mathbf{x}_{k,n} \tag{7b}$$

$$\mathbf{s}_{n+1} = \frac{1}{\sum_{k=1}^{K} \rho_k} \sum_{k=1}^{K} \rho_k \mathbf{s}_{k,n+1}. \tag{7c}$$

In this algorithm, the clients share $\mathbf{s}_{k,n+1}$ with the server, and the server broadcasts $\mathbf{s}_{n+1}$ to the clients. When the exchange of model parameters occurs over noisy communication channels, the iterations (7) are more robust to communication noise compared to (6) as they utilize a single noisy global estimate received from the server to update the local estimate, i.e., $\mathbf{s}_n$, rather than two in (6), i.e., $\mathbf{x}_n$ and $\mathbf{x}_{n-1}$.

In the downlink, noisy versions of the aggregated global model updates are received by the clients as $\tilde{\mathbf{s}}_n^k = \mathbf{s}_n + \boldsymbol{\zeta}_n^k$ where $\boldsymbol{\zeta}_n^k$ denotes the downlink noise of client k at iteration n. In the uplink, a noisy version of the local model update of each client is received by the server as $\tilde{\mathbf{s}}_{k,n} = \mathbf{s}_{k,n} + \boldsymbol{\eta}_{k,n}$ where $\boldsymbol{\eta}_{k,n}$ denotes the uplink noise of client k at iteration n.

In recursions (7), all clients are required to take part in each global model update. However, FL clients often have limited and diverse communication capabilities. Hence, participation of all clients in each global update round can be costly. Therefore, FL servers usually employ random scheduling of their clients by selecting only a subset of the clients, denoted by $\mathcal{S}_n$, to participate in model aggregation during each iteration n. The scheduling reduces the communications required at each iteration, leading to improved efficiency and better resource management. Utilizing random scheduling and considering noisy communications, we can rewrite the recursions (7) as mentioned in [28] as

$$\mathbf{x}_{k,n+1} = \begin{cases} \left(\mathbf{I} - \rho_k \mathbf{N}_k^{-1}\right) \mathbf{x}_{k,n} + \rho_k \mathbf{N}_k^{-1} \tilde{\mathbf{s}}_n^k, & k \in \mathcal{S}_n \\ \mathbf{x}_{k,n}, & \text{otherwise} \end{cases} \tag{8a}$$

$$\mathbf{s}_{k,n+1} = 2\mathbf{x}_{k,n+1} - \mathbf{x}_{k,n}, \quad k \in \mathcal{S}_n \tag{8b}$$

$$\mathbf{s}_{n+1} = \frac{1}{\sum_{k \in \mathcal{S}_n} \rho_k} \sum_{k \in \mathcal{S}_n} \rho_k \tilde{\mathbf{s}}_{k,n+1}. \tag{8c}$$

III. Proposed Algorithm

It is important to enhance the energy efficiency of FL by reducing its communication load, particularly considering that clients often have constraints on their energy resources in real-world scenarios. Lowering the communication burden on the clients can also improve the scalability and cost-effectiveness of

FL algorithms. The efficiency of communication during model training is related to the amount of data exchanged between the clients and the server. Thus, minimizing the exchanges of models, parameters, gradients, or other relevant information while upholding high accuracy levels presents a significant challenge in FL.

Random scheduling of clients is a practical method to enhance communication efficiency within FL, using which the overall communication load can be effectively reduced and resource utilization can be optimized more efficiently. It helps alleviate the potential bottlenecks that can arise from simultaneous communication by all clients. As a result, it improves the efficiency of data transmissions and plays a role in enhancing the overall performance of FL. However, in the conventional random scheduling approach as in (8), the clients that are not selected during each iteration do not carry out any local update and their most recent local model estimates are not incorporated into the global model aggregation process.

Here, we propose to allow all clients, including those not selected through random scheduling, to update their local model estimates during every iteration. As we will show later, this can improve the performance without introducing any additional communication overhead or imposing any significant increase in computations on the clients or the server. To realize the proposed algorithm, we let the clients store the most recent global model estimate received from the server and the server store the latest local model estimates received from the clients. Hence, the clients continually update their local models using their most recent global model estimate and the server updates the global model using the latest local updates from all clients. When a client is selected at iteration n, its latest local model estimate is made up-to-date at the server and the global model estimate received from the server replaces its older version at the client.

Therefore, the recursions of the proposed resource-efficient and noise-robust FL algorithm featuring continual local updates are given by

$$\mathbf{x}_{k,n+1} = (\mathbf{I} - \rho_k \mathbf{N}_k^{-1})\mathbf{x}_{k,n} + \rho_k \mathbf{N}_k^{-1}\left[a_{k,n}\tilde{\mathbf{s}}_n^k + (1-a_{k,n})\tilde{\mathbf{s}}_m^k\right] \tag{9a}$$

$$\mathbf{s}_{k,n+1} = 2\mathbf{x}_{k,n+1} - \mathbf{x}_{k,n}, \quad k \in \mathcal{S}_n \tag{9b}$$

$$\mathbf{s}_{n+1} = \frac{1}{\sum_{k=1}^{K} \rho_k} \sum_{k=1}^{K} \rho_k \left[a_{k,n}\tilde{\mathbf{s}}_{k,n+1} + (1-a_{k,n})\tilde{\mathbf{s}}_{k,m}\right], \tag{9c}$$

where $a_{k,n}$ represents random scheduling, i.e., $a_{k,n} = 1$ when $k \in \mathcal{S}_n$ and $a_{k,n} = 0$ otherwise. In addition, $\tilde{\mathbf{s}}_m^k$ represents the most recent global model estimate received from the server and stored in client k, which is utilized when the client is not chosen by the server. Moreover, $\tilde{\mathbf{s}}_{k,m}$ denotes the most recent local model estimate associated with client k, which is stored at the server and utilized during iterations when the client is not selected through random scheduling. We summarize the proposed algorithm in Algorithm 1.

Algorithm 1 The proposed communication-efficient and noise-robust FL algorithm with continual local updates.

Parameters: penalty parameters ρ_k, number of clients K, set of clients $\mathcal{S}$

Initialization: global model $\mathbf{x}_0 = \mathbf{x}_{-1} = \mathbf{0}$, local models $\mathbf{x}_{k,0} = \hat{\mathbf{x}}_k$

For $n = 1, \cdots, N$

The server randomly selects a subset $\mathcal{S}_n$ of its clients and sends the aggregated global model $\mathbf{s}_n$ to them.

Client Local Update:

If $k \in \mathcal{S}_n$

Receive $\tilde{\mathbf{s}}_n^k$, a noisy version of $\mathbf{s}_n$, from the server.
Store the latest global model $\tilde{\mathbf{s}}_m^k = \tilde{\mathbf{s}}_n^k$.
Update the local model as
$\mathbf{x}_{k,n+1} = (\mathbf{I} - \rho_k \mathbf{N}_k^{-1})\mathbf{x}_{k,n} + \rho_k \mathbf{N}_k^{-1}\tilde{\mathbf{s}}_n^k$.
Send $\mathbf{s}_{k,n+1} = 2\mathbf{x}_{k,n+1} - \mathbf{x}_{k,n}$ to the server.

Else

Update the local model as
$\mathbf{x}_{k,n+1} = (\mathbf{I} - \rho_k \mathbf{N}_k^{-1})\mathbf{x}_{k,n} + \rho_k \mathbf{N}_k^{-1}\tilde{\mathbf{s}}_m^k$.

EndIf

Aggregation at the Server:

The server receives $\tilde{\mathbf{s}}_{k,n+1}$, noisy versions of the locally updated models from the selected clients $k \in \mathcal{S}_n$ and aggregates them with $\tilde{\mathbf{s}}_{k,m}$, the stored local model estimates of the non-selected clients via

$$\mathbf{s}_{n+1} = \frac{1}{\sum_{k=1}^{K} \rho_k} \sum_{k=1}^{K} \rho_k \left[a_{k,n}\tilde{\mathbf{s}}_{k,n+1} + (1-a_{k,n})\tilde{\mathbf{s}}_{k,m}\right].$$

EndFor

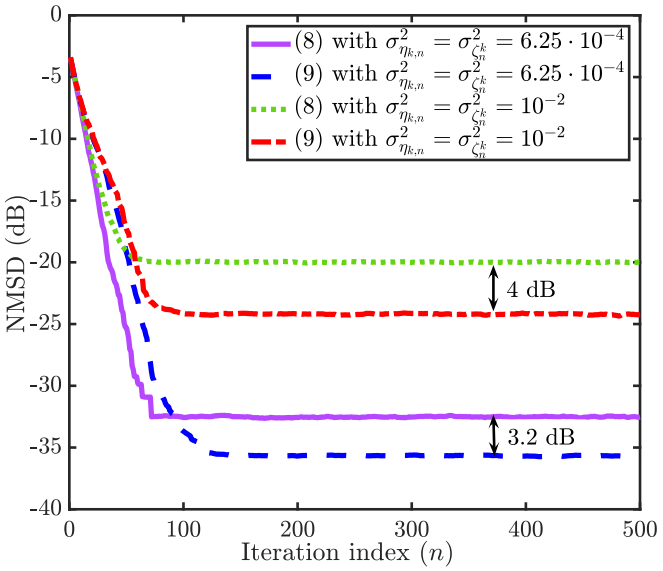

Fig. 2. NMSD of (8) and (9) versus iteration number for $|\mathcal{S}_n| = 10$ and different link noise variances.

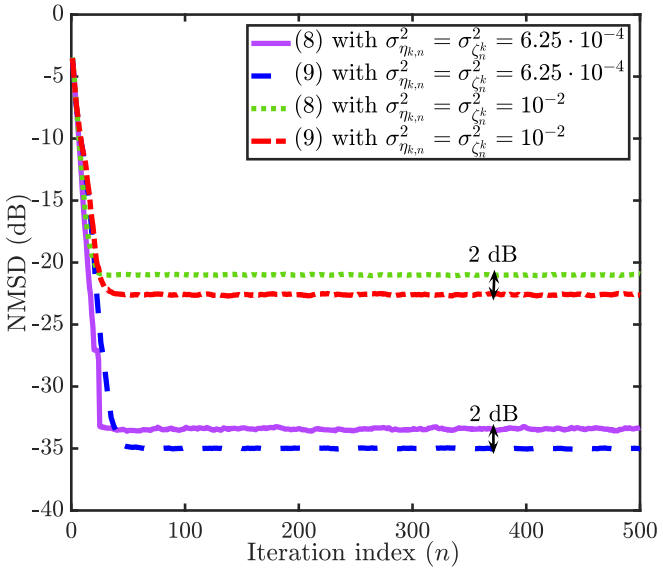

Fig. 3. NMSD of (8) and (9) versus iteration number for $|\mathcal{S}_n| = 25$ and different link noise variances.

IV. Simulation Results

In this section, we conduct a series of numerical experiments to examine the performance of the proposed algorithm. We consider a scenario with $K = 100$ clients directly connected to a global server. The goal of the federated network is to estimate a global model $\mathbf{x}^*$ of dimension $L = 128$. To induce data imbalance among the clients, we draw the size of each client's local dataset, d_k, from a uniform distribution, i.e., $d_k \in \mathcal{U}(50, 90)$. Each client k has synthetic and imbalanced non-IID data $\{\mathbf{H}_k, \mathbf{y}_k\}$ with the matrices $\mathbf{H}_k$ drawn from a multivariate normal distribution $\mathcal{N}(\mu_{\mathbf{H}_k}, \sigma^2_{\mathbf{H}_k})$ where $\mu_{\mathbf{H}_k} \in \mathcal{U}(-0.5, 0.5)$ and $\sigma^2_{\mathbf{H}_k} \in \mathcal{U}(0.5, 1.5)$. The weight matrices are set to the inverse covariance matrix of $\mathbf{y}_k$ at each client k, i.e., $\mathbf{W}_k = \Sigma^{-1}_{\mathbf{y}_k} = \mathbb{E}[(\mathbf{y}_k - \mathbb{E}[\mathbf{y}_k])(\mathbf{y}_k - \mathbb{E}[\mathbf{y}_k])^\intercal]^{-1}$. We set the global parameter vector $\mathbf{x}^*$ arbitrarily by drawing each entry from a standard normal distribution $\mathcal{N}(0, 1)$. The observation noise $\boldsymbol{\nu}_k$ at each client k is zero-mean IID Gaussian with variance 10^{-4}. The additive noise in both uplink and downlink are zero-mean IID white Gaussian. In all experiments, we set the penalty parameter to $\rho_k = 1$ for all clients. At each iteration n, the server selects a subset of the clients with equal probability of selection assigned to each client. We evaluate the performance using the network-wide average normalized mean-square deviation (NMSD) defined at each iteration n as

$$\text{NMSD}(n) = \frac{1}{K} \sum_{k=1}^{K} \frac{\|\mathbf{x}_{k,n} - \mathbf{x}^\star\|_2^2}{\|\mathbf{x}^\star\|_2^2}. \tag{10}$$

We obtain the learning curves (i.e., NMSD in dB vs. iteration number n) by averaging over 100 independent trials.

In Figs. 1-3, we present a performance comparison between the proposed algorithm, i.e., (9), and its closest contender, i.e. (8), which does not feature continual local updates. We obtain the results by including noise in the communication links and utilizing random scheduling for communication efficiency. We set the number of clients selected at each iteration to $|\mathcal{S}_n| \in \{4, 10, 25\}$ and use different link noise variances of $\sigma^2_{\boldsymbol{\eta}_{k,n}} = \sigma^2_{\boldsymbol{\zeta}_n^k} \in \{6.25 \cdot 10^{-4}, 10^{-2}\}$. We plot the corresponding learning curves in the figures. We observe that the proposed algorithm exhibits robustness against communication noise/error even when a small portion of the clients participate in every FL round. It also outperforms (8) significantly in terms of the steady-state NMSD in all considered cases. In summary, the results demonstrate that permitting the clients, which are not selected by random scheduling, to continually update their local models leads to a notable reduction in the steady-state NMSD without compromising the convergence rate. Moreover, as expected, when the variance of the noise in the communication links increases, the learning accuracy decreases.

V. Conclusions

We proposed a new FL algorithm that leverages random scheduling to enhance communication efficiency while being robust to additive noise in the communication links, in part, due to eliminating the dual parameters and minimizing the use of noisy estimates in update equations. The key novel feature of the proposed algorithm is that it allows the clients to update their model estimates locally even when they are not selected by the global server for participation in FL as per random scheduling. Our simulation results showed that the continual local updates lead to performance improvements in terms of both learning accuracy and robustness to link noise.

***Abstract*—We develop a Gaussian process regression model to fill gaps in LBS (Location-Based-Service) data. We demonstrate our model's performance in two experiments with real app-based data, in which it outperforms alternative imputation methods.**

I. Introduction

The proliferation of Location-Based Services (LBS) in the past two decades have generated massive amount of time- and location-stamped data. Human mobility patterns can be inferred from such data and those patterns, in terms of individual users' visit patterns in time and space have found a wide variety of applications including, for example, quantifying urban vitality [1], understanding commuting patterns [2], and predicting pandemic spreading [3].

While LBS data offers sample sizes orders of magnitudes greater than traditional travel surveys, it is also sparse—for a substantial portion of users, there is a significant number of gaps in the data (extended periods where there is no data). When the LBS dataset has gaps, derived mobility patterns are vulnerable to bias, meaning that they may misrepresent individuals' actual movements [4]–[6]. Filling in gaps in LBS data is thus important to researchers and practitioners alike.

In this study, we develop a GP framework to fill in gaps in LBS data at the individual level. Our framework imputes a user's latitudes and longitudes simultaneously based on a set of predictor variables (primarily time). We train the framework's parameters on longitudinal trajectory data.

Our contributions include: 1) We introduce the use of smooth kernels (i.e., the rational quadratic kernel) and kernels with periodicities (i.e., the periodic kernel) in modeling human mobility data; and 2) We benchmark our model against other gap-filling imputation methods, demonstrating its effectiveness under a range of scenarios.

The rest of the paper is organized as follows. Section II briefly summarizes related work on gap-filling in LBS data. Section III outlines our methodology. Section IV describes the dataset we used in our experiments. Sections V and VI illustrate our results and provide a brief discussion.

II. Related Work

In general, missing data imputation methods for LBS data fall in one of three categories: (1) leverage time-series smoothing and interpolation methods, (2) integrate external data sources to facilitate learning or (3) employ machine learning-based methods. The first approach uses existing methods for smoothing and time-series interpolation to impute missing data points. These range from simpler methods like linear interpolation to more complex ones like seasonal auto-regressive integrated moving average (SARIMAX) [5], [7]–[9]. The drawback of these models is they are often not flexible enough to handle the non-linear nature of individual-level trajectory data.

The second approach leverages external data sources to make inferences about the original dataset. Common external datasets include real-time video feeds, transit agency-issued smart cards, and even aggregated credit card purchase histories [10], [11]. The drawback of such approaches is the difficulty of obtaining additional datasets—for many applications, external sources may not be readily available. Data acquisition and pre-processing for multiple data sources can also be time-consuming.

The third approach define kernels or activation functions to try predicting the similarity of two trajectories, then using the more complete trajectory to impute missing values in the more sparse trajectory [12]–[14]. The drawback of these approaches is that even if two trips have the exact same ground-truth trajectory, varying data sampling rates may distort the shape of the trajectory observed in the data.

III. METHODOLOGY

Human mobility exhibits some distinct features. The first one is their spatio-temporal autocorrelations—observations at nearby time inputs tend to be spatially close to one another. This is termed as history dependency, meaning that where one is at time t depends upon their location at $t-1$. To model this phenomenon, we use the rational quadratic kernel

$$\boldsymbol{K}_{RQ}(x,x') = \Omega^2(1+\frac{(x-x')^2}{2\alpha l^2})^{-\alpha} \quad (1)$$

where x and x' are two scalar inputs (representing time), Ω is the output variance, determining the average distance of the function away from its mean, $\alpha > 0$ is the scale mixture parameter, determining the relative weighting of large-scale and small-scale variations in the data, and $\ell > 0$ is the lengthscale, specifying the smoothness of the function (i.e., the frequency of the gradient of the function to change sign). Note that as x and x' approach each other, the term with the exponent $-\alpha$ goes to 1, signifying the increasing likelihood of nearby points to covary.

The second feature of human mobility is that there exist anchor points such as home and work and visits to other activity locations such as stores and recreation sites often center around anchor points *[16]–[18]*. Additionally, those visits often exhibit return patterns of different lengths. In other words, there are rhythms of activity and travel patterns—people usually go to their workplaces and return home every day, inducing correlations between the days of the week. Other behavior like grocery shopping, going out with friends, or attending family gatherings happens less frequently, and hence has longer intervals between consecutive instances. These activities tend to be correlated between the weeks of the month and sometimes even the months of the year (i.e., Christmas, Thanksgiving, etc.). To reflect these patterns, we incorporate categorical variables like days and weeks by representing them as sets of binary variables, using a one-of-k encoding. For example, as the days of the week x_d can take one of seven values, $x_d \in \{M, Tu, W, Th, F, Sa, Su\}$, then a one-of-k encoding of x_d will correspond to seven binary inputs, and one-of-k $(Tu) = [0,1,0,0,0,0,0]$. One approach to embed multiple inputs in a GP framework is to multiply kernels defined on each individual input. This family of kernels is called Automatic Relevance Determination (or ARD), so named due to the existence of a different lengthscale parameter for each input dimension d [19]. In this case, the kernel function $\boldsymbol{K}_{RQ}$ in Equation 1 becomes:

$$\boldsymbol{K}_{RQ-ARD}(x,x') = \prod_{d=1}^{D} \Omega_d^2 \left(1+\frac{(x-x')^2}{2\alpha\ell_d^2}\right)^{-\alpha} \quad (2)$$

where ℓ_d is the lengthscale parameter for input dimension d. Thus, if the optimal lengthscale for a given categorical variable (i.e., day of the week) is small, the model has determined relatively low correlation between data in that category. On the other hand, categorical input dimensions with large lengthscales imply relatively little variation (in other words, high correlation) along those dimensions in the output variable (i.e., locations).

In addition to a one-of-k encoding strategy, we also use periodic kernels, which allow GPs to model functions that repeat themselves

$$\boldsymbol{K}_{PER}(x,x') = \Omega^2 \, exp\left(-\frac{2\sin^2(\pi|x-x'|/p)}{\ell^2}\right) \quad (3)$$

where the period length p determines the distance between repetitions of the function and the lengthscale ℓ works in the same way as in the RQ kernel.

IV. DATASET

We employ privacy-protected, passively-generated LBS data from Spectus, a U.S.-based data solution provider specializing in geospatial analytics. The dataset contains time-stamped location traces of 50 anonymous, opted-in individuals in the Greater Seattle Area between December 2019 and July 2020. More specifically, the data includes timestamps, unique device identifiers, latitude and longitude coordinates, and a measure of data precision (i.e., a location radius for which we have 95% confidence). The dataset does not include any demographic or socioeconomic information. Locational data is sent to Spectus servers in encrypted form, via an HTTPS protocol through three options: an Application Protocol Interface (API), through a publisher that has licensed Spectus' software development kit, or via direct server-to-server integration [20].

V. EXPERIMENTS AND RESULTS

We benchmark our model against alternative missing data imputation methods, including simple exponential smoothing, exponential smoothing [8], Holt-Winters [7], ARIMA and SARIMAX [9]. Simple exponential smoothing (SES), exponential smoothing (ES), and the Holt-Winters (Holt) method all work similarly—they weigh the average of past observations in producing forecasts, giving exponentially lower weights as the time gap increases. SES is most suitable for forecasting data with no clear trend or seasonal pattern. ES allows for forecasting with a trend and the Holt-Winters method uses three types of exponential smoothing to model the level (the typical value), the trend (the slope), and the

seasonality (repeating patterns) of data. ARIMA and SARIMAX are both linear regression models fit for forecasting univariate time series data. Each of these methods are regarded as reliable, well-studied alternatives commonly used to impute missing values in time-series, and therefore make a useful comparison. We "simulate" gaps in the selected 50 users by reserving a subset of their data for testing, and we choose this subset such that the temporal occupancy of their training data meets a lower target temporal occupancy (i.e., between 0 and the user's value) according to the temporal resolution being tested. We tested six different temporal resolutions (τ) from one week to fifteen minutes. Due to space limits, we show three intervals here: one week, one day and one hour.

For the benchmark algorithms, we used only the monotonically-increasing $\boldsymbol{t}_u$ as an input since they do not have a straightforward way to deal with categorical or binary variables. For each benchmark algorithm, we selected the best-fit parameters after cross-validating with multiple attempts.

Figure 1 shows the mean absolute error, the root mean square error, and the median absolute deviation of the six models we compared across for 1 week and 1 day. In all of the tests, our model outperformed the other models: The average error was always the lowest, and the 5th and 95th percentile bounds tended to be closer.

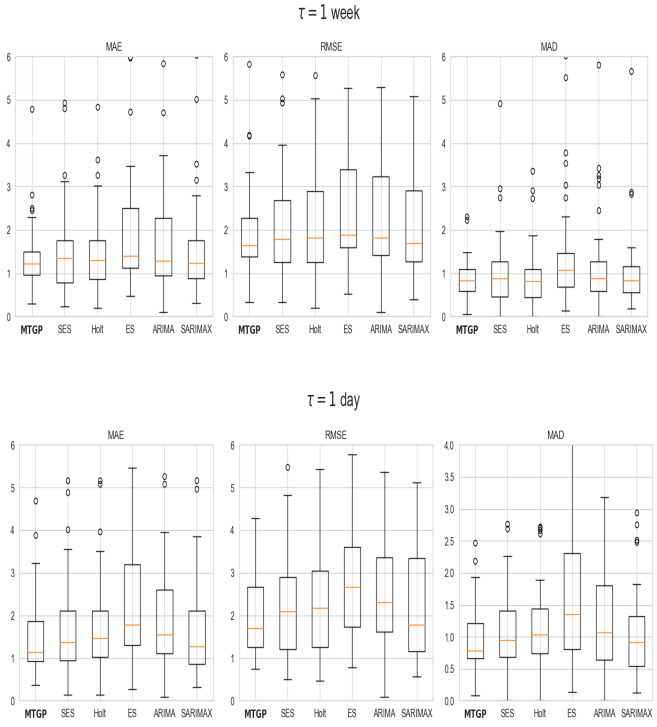

Figure 1. Median absolute error, root mean square error and median absolute deviation of predicted coordinates across different methods (MTGP is our method)

VI. Conclusions

To fill in gaps in the LBS data, we have developed a novel framework using Gaussian processes. We introduced and demonstrated the effectiveness of RQ and PER kernels in the context of LBS data for human mobility modeling, and highlighted the ARD extension of these kernels for fitting high-dimensional data (whether continuous or binary). In results, we show that our model outperformed five existing methods for filling gaps of different lengths in LBS data.

While the current study is motivated from the need to directly address the significant gap issue exhibited in passively-generated LBS data [5], the implications of this work can be significant in a number of aspects. The study opens us the opportunity of creating city-wide simulations of human mobility patterns using those passively-generated LBS data directly. This is in contrast with the current process where parametric models are first estimated using the household travel survey data (which often represents about or less than 0.1% of the population in an urban area) and then those models are extrapolated to a synthetic population.

***Abstract*—In this paper we develop an online distributed learning algorithm for unlabeled data. Here a goal is to detect anomalies from streaming data. The assumption is that data is drawn from a probability distribution, but that at some unknown time data could be drawn from a different distribution. We assume the data comes from distributed sources and develop an online Federated Learning (FL) algorithm based on online kernel methods using Random Fourier Features (RFF). This work combines previous work on online unsupervised kernel algorithms with online supervised kernel algorithms using FL and RFF. There are many applications of this work including detecting bad power grid data.**

I. Introduction

In this day and age we are seeing an explosion of data coming from a variety of sources and locations at different rates. Much of this data come from distributed sources such as sensors, IoT devices, mobile devices, cameras, individuals, groups, or organizations. There is a need to process, learn, and make inferences from the data. Here we consider data gathered by edge devices or clients with information passed to a central server or the cloud. In the past, data was sent from the clients to the cloud where processing, learning and making decisions would occur as shown in Fig. 1a) and labeled as the centralized learning model. However, edge devices now have much more computational power with faster processors (GPUs) allowing more computations and learning to occur at the edge. In addition there are many other concerns with sending data from edge devices to the cloud. There are security and privacy concerns of sending data and information to the cloud. There is also concerns about an excess amount of communications between the edge devices and the cloud. Federated Learning (FL) was developed by [1] to address these issues where processing and learning takes place at the edge device and not passed to the cloud. This is shown in Fig. 1b) where information, but not data is passed to the cloud. The cloud assists in the learning process by sending collective information back to each edge device so that collaborative learning can occur. The FL model is also able to handle heterogeneous data and heterogenous systems.

There are many applications for FL where there are concerns about data privacy, communication costs, and handling heterogeneous data and systems. These include mobile communications, autonomous systems with communications between autonomous cars for real-time information and decision making,

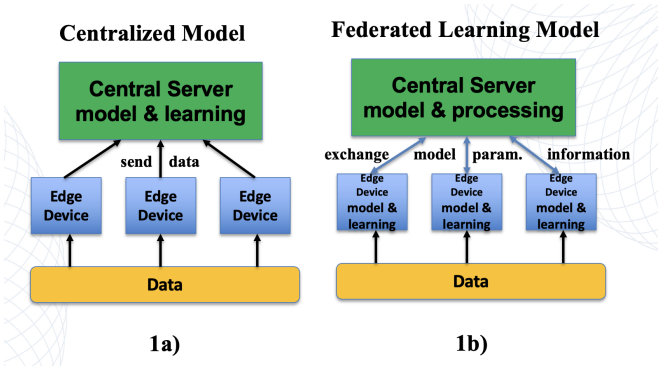

Fig. 1. Collaborative learning models

healthcare applications include sharing information between different hospitals, manufacturing for predictive maintenance, and smart grid applications for demand-side management, [2]. For demand-side management consider a group of homes in a community. Each home may be identical or similar in terms of the architecture, but energy usage in each home may be very different depending on the occupants, their energy preferences, and energy consuming devices in the home. This includes heating, air conditioning, hot water heaters, and appliances. Homes may also have rooftop solar panels, battery storage, and charging stations for Electric Vehicles (EV)s. This is a good application for FL as at each home gets data from many heterogeneous sources and there are privacy issues. This include environmental sensors monitoring local climate including solar irradiance, electrical grid data, data from sensors monitoring energy usage, and possibly data from sensors monitoring EV charging. From this data we can learn about household energy usage while preserving comfort, conserving energy and reducing costs.

There has been considerable research and interest in FL algorithms with the following papers giving a good discussion of FL research [3], [4]. Most of the learning algorithm for FL are supervised learning algorithms. In previous work we developed online kernel regression algorithms that used principles of FL, [5], [6]. The algorithms developed in [6] are based on edge devices (clients) learning data received using online kernel methods implemented using Random Fourier Features (RFF),

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

[7]. The clients send weight information to a server where the server coordinates learning by aggregating information from the clients and then sending this information back to the clients. Communication savings are achieved as we only sample a small number of clients at each update and the client only sends a small fraction of RFF coefficients when sampled. This is called Partial Sharing-Based Online Federated Learning (PSO-FED). PSO-FED is shown to converge and through simulations have good learning performance (even when a small fraction of RFF are transmitted). The algorithm is also shown to have some robustness against data poisoning (Byzantine attacks).

In this paper we extend our learning algorithms to unsupervised learning. Although the vast majority of machine learning deals with supervised learning algorithms where a target output is associated with each input data a considerable amount of data is unlabeled. Many learning algorithms have been developed for unsupervised learning ranging from clustering algorithms where similar input data is grouped together to Principal Component Analysis (PCA) which is a statistical method for reducing the dimensionality of a dataset by linear transforming the dataset to find the coordinates with the largest variance. Here we will focus on anomaly detection with a survey of machine learning methods presented in [8]. Here we will examine where data is drawn from a probability distribution in an online manner. At some point data is drawn from an anomalous distribution and the goal is to detect this change. We first formulate an online kernel algorithm following [9] and then use RFF to approximate the kernels to detect the change. We then adapt this algorithm based on distributed learning using principles of FL.

Let us briefly discuss two applications for anomaly detection. Consider a network of environmental sensors monitoring water quality. The sensors could be placed under water in a lake. Each sensor would periodically sample environmental conditions such as temperature, pH, turbidity, and perhaps other chemicals. PAD-OFL could learn the support of the distribution under normal conditions. Anomalies could occur due to natural conditions such as unusual algae growth or due to human factors such as the release of pathogens and/or pollutants into the lake. In a second application consider monitoring a power grid for bad data. Sensor could be distributed on the grid to monitor voltage, current, and other electrical measurements. Bad data could be the result of natural circumstances such as a downed power line due to fallen trees or a malicious man-made attack where bad data is injected. A more detailed discussion presenting simulation results is presented for detecting bad power grid data in the applications section.

The paper is organized as follows. In Section 2 we first discuss using a one class least squares kernel algorithm for modeling a probability distribution. We then approximate the kernels using RFF, and develop an online learning algorithm for anomaly detection. In Section 3 we assume the data comes from distributed sources (clients) and information is processed by a central server. We then develop a FL model for anomaly detection. Section 4 presents a simple example and an application detecting bad data for the electric power grid where algorithms of Section 3 are used. Section 5 summarizes the paper and discusses further directions.

II. Modeling Distributions and Anomaly Detection

A. Using Kernel Methods

In a key paper by Schölkopf, [10] a one-class support vector is used to model the support of a probability distribution. Here we will assume inputs $x(i), 1 \leq i \leq m$ are drawn from a sample of a random vector $X \in \mathcal{R}^n$. This can be represented by

$$\min \frac{1}{2}||w||^2 - \rho + \gamma \sum_i \xi_i \tag{1}$$

$$\text{subject to } w^T\phi(x(i)) \geq \rho - \xi_i. \text{ and } \xi_i \geq 0,$$

where $\phi(\cdot) : \mathcal{R}^n \rightarrow \mathcal{Z}$ is the mapping to a high dimensional feature space such that the dot product of ϕ is usually computed by evaluating a kernel $k(x, y) = \phi(x)^T\phi(y)$. The parameter $\gamma > 0$ is a regularization parameter and controls the fraction of possible outliers [10] and ξ_i are non-zero slack variables. The goal here in feature space is to have as many data points (in feature space) $\phi(x(i))$ as possible to lie on one side of a hyperplane (described by $f(x) = w^T\phi(x) - \rho = 0$) away from the origin such that the distance to the origin, ρ/w is as large as possible. This is know as the One-Class Support Vector Machine (SVM). The hyperplane solution can be found by solving the dual optimization problem [10]

$$\min \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j k(x(i), x(j)) \tag{2}$$

$$\text{subject to } 0 \leq \alpha_i \leq \gamma \text{ and } \sum_i \alpha_i = 1,$$

where α_i are the Lagrange multipliers. The solution for the weight vector w is given by

$$w = \sum_i \alpha_i \phi(x(i)).$$

We would like to consider online learning algorithms for this problem and can use a different squared error cost function which leads to a simpler online learning algorithms based on linear adaptive filters. This was implemented by Choi in [11] using a squared error loss function and is referred to as the Least Squares OC-SVM (LS-OC-SVM). For this optimization problem the goal is to perform linear regression in feature space with the hyperplane again as far away from the origin as possible. In the input space the manifold formed by the equation $f(x) = w^T\phi(x) - \rho = 0$ describes a surface where most of the support of the probability distribution lie near to f(x). The LS-OC-SVM optimization problem can be formulated as

$$\min J(w, \rho) = \min \frac{1}{2}||w||^2 - \rho + \frac{\gamma}{2}||\xi||^2 \tag{3}$$

$$\text{subject to } w = \mathbf{\Phi}\alpha \text{ and } \xi_i = \mathbf{1}\rho - \mathbf{\Phi}^T w.$$

where the feature input matrix $\mathbf{\Phi} = [\phi(x_1), \ldots, \phi(x_m)]$, $\alpha = [\alpha_1, \ldots, \alpha_m]^T$, and $\mathbf{1}$ represents a column vector of 1s. Note hear that for the LS-OC-SVM we have constraints that are equality constraints as opposed to the OC-SVM where we have constraints that are inequality constraints. Defining the kernel matrix $\mathbf{K} = \mathbf{\Phi}^T\mathbf{\Phi}$ we can then make substitutions in equation (3) to get the following

$$J(\alpha, \rho) = \frac{1}{2}\alpha^T\mathbf{K}\alpha + \frac{\gamma}{2}||\mathbf{1}\rho - \mathbf{K}\alpha||^2 \tag{4}$$

This is a quadratic function of the variables α and ρ with the solution found by solving a system of linear equations given by

$$\begin{bmatrix} \mathbf{1}^T\mathbf{1} & -\mathbf{1}^T\mathbf{K} \\ -\mathbf{1} & \mathbf{K} + \mathbf{I}/\gamma \end{bmatrix} \begin{bmatrix} \rho \\ \alpha \end{bmatrix} = \begin{bmatrix} 1/\gamma \\ \mathbf{0} \end{bmatrix} \tag{5}$$

where $\mathbf{0}$ is a column vector of zeros and $\mathbf{I}$ is an identity matrix.

Here all the input data are support vectors and the hyperplane in the dual space is given by $f(x) = \alpha^T\mathbf{k}(x) - \rho = 0$ where $\mathbf{k}(x) = \mathbf{\Phi}^T\phi(x)$. A problem with solving the set of linear equations, from equation (5) is that the matrix $\mathbf{K}$ grows as the number of input data grow, m as all input data are support vectors for the LS-OC-SVM. For m data the computational complexity for the solution grows as m^3 and alternative subspace methods are needed when m grows large. Subspace methods require that a dictionary of support vectors are chosen. For online learning the dictionary is grown online as data is processed. In [9] an online dictionary is grown using an approximate linear dependence (ALD) criterion, [12]. Alternatively, in [13] a dictionary is grown using a simpler coherence criterion. A problem with these methods is that they add complexity to the learning problem and we propose an alternate solution in the next subsection.

B. Approximating Kernels with Random Fourier Features

In a landmark paper by Rahimi and Recht, [7] they showed that if the kernel function can be expressed in terms of one variable, that is $k(u, v) = k(u - v)$, then we can have an alternative approach to construct a set of basis functions. Here assume that $k(u, u) = 1$. From Bochner's theorem we can then represent the kernel function in terms of its inverse n-dimentsional Fourier transform by

$$\begin{aligned} k(u-v) &= \left(\frac{1}{2\pi}\right)^n \int_{-\infty}^{\infty} \ldots \int_{-\infty}^{\infty} p_W(\omega) \exp(j\omega^T(u-v)) d\omega_1 \ldots d\omega_n \\ &= \mathbf{E}_W[\psi_\omega(u)\psi_\omega(v)^*] \end{aligned} \tag{6}$$

where $\psi_\omega(u) = \exp(j\omega^T u)$ and $*$ represents complex conjugate. From the righthand side of the equation we have $\psi_\omega(u)\psi_\omega(v)^*$ is an unbiased estimate of $k(u-v)$ as $p_W(\omega)$ is an n-dimensional probability density function. Note that

$$k(u - v) = \mathbf{E}_W \cos(\omega^T(u - v))$$

since $p_W(\omega)$ is real and even function of its n components (as $k(u, v)$ is real, even, and positive semi-definite). Let $c_\omega(u) = \sqrt{2}\cos(\omega^T u + \theta)$ where ω is drawn from $p_W(\omega)$ and θ is drawn from a uniform $[0, 2\pi]$ random variable. We then have

$$\begin{aligned} \mathbf{E}_{W,\theta}[c_\omega(u)c_\omega(v)] &= \mathbf{E}_{W,\theta}[\cos(\omega^T(u-v)) + \cos(\omega^T(u+v) + 2\theta)] \\ &= k(u - v) \end{aligned}$$

where the last equality holds as the expectation of the second term is 0.

Let $(\omega_j, \theta_j), 1 \leq j \leq D$ be D samples drawn from W and θ. We then have

$$k(u, v) = \langle \phi(u), \phi(v) \rangle \approx \frac{1}{D} \sum_{j=1}^{D} c_{\omega_j}(u) c_{\omega_j}(v) = c^T(u)c(v) \tag{7}$$

where $c(u) = \frac{1}{\sqrt{D}}[c_{\omega_1}(u), \ldots, c_{\omega_D}(u)]^T$. Here we approximate the kernel by drawing D samples and averaging. As an example of W let the kernel function be

$$k(u, v) = \exp(\sigma^2||u - v||^2/2)$$

then the kernel function is a Gaussian kernel and the inverse Fourier transform gives a Gaussian random vector with each component being iid with zero mean and variance σ^2. From the kernel representation result we then have the estimate of $f(\cdot)$ given by

$$\begin{aligned} f(x) &= \alpha^T k(x) - \rho = \sum_{i=1}^{m} \alpha_i k(x(i), x) - \rho \\ &\approx \sum_{i=1}^{m} \alpha_i c(x(i))^T c(x) - \rho. \end{aligned} \tag{8}$$

If we let $\beta = \sum_{i=1}^{m} \alpha_i c(x(i))$, then we have that

$$f(x) \approx \beta^T c(x) - \rho. \tag{9}$$

This reduces the problem to a linear regression problem in D-dimensional space generated by the RFF with the goal of finding the parameters β and b. Let $\mathbf{C} = [c(x(1)), \ldots, c(x(m))]$. Then with regularization we are trying to find β and ρ to minimize

$$J(\beta, \rho) = \frac{1}{2}||\beta||^2 + \frac{\gamma}{2}||e||^2 - \rho$$

where $e = \mathbf{C}^T\beta - \rho\mathbf{1}$. Solving this optimization problem is found by taking gradients and partial derivatives and setting to 0 resulting in

$$\nabla_\beta J(\beta, \rho) = (\mathbf{I} + \gamma\mathbf{C}\mathbf{C}^T)\beta - \gamma\mathbf{C}\mathbf{1}\rho = 0 \tag{10}$$

and

$$\frac{\partial J(\beta, \rho)}{\partial \rho} = \gamma m\rho - \gamma\mathbf{C}^T\beta - 1 = 0 \tag{11}$$

resulting in the following set of linear equations,

$$\begin{bmatrix} 1 & -{m_c}^T \\ -m_c & \mathbf{R}_c + \mathbf{I}/(m\gamma) \end{bmatrix} \begin{bmatrix} \rho \\ \beta \end{bmatrix} = \begin{bmatrix} 1/(m\gamma) \\ 0 \end{bmatrix} \tag{12}$$

where $m_c = \frac{1}{m}\mathbf{C}\mathbf{1}$ and $\mathbf{R}_c = \frac{1}{m}\mathbf{C}\mathbf{C}^T$. The solution is found by solving a system of $D + 1$ linear equations.

C. Anomaly Detection and Online Learning

Solving for β and ρ gives us a manifold described by $g(x) = \beta^T c(x) - \rho = 0$. Given we use enough training data m and enough RFF, D the support of the random variable X lies close to this manifold with the distance of a point x from the manifold given by

$$d(x) = \frac{|g(x)|}{\sqrt{\beta^T c(x)^T c(x)\beta}} \tag{13}$$

Following [9], if the distance of a data point is far from the manifold we classify this as an anomalous data point. Here we define a threshold value $\delta > 0$ such that if $d(x) > \delta$ then the data point is an anomaly. The setting of δ determines the fraction of points that are classified as anomaly data.

Here we assume that the first m data points are drawn from the random variable X. This can be considered the baseline data. The LS-OC-SVM can be trained to find the manifold using batch methods solving equation (12) or by online methods. Online methods include using the Recursive Least Square (RLS) algorithm or the Least Mean Square (LMS) algorithm described in [14]. The nice thing is that instead of working with kernel online learning algorithms we work with simpler linear adaptive filter algorithms.

After seeing the m data points we are presented with more data and need to determine if the data is anomalous data. Here we set the parameter δ, initialize $\beta(m)$ and $\rho(m)$, and let $z(k) = c(x(k))$ by solving equation (12), and then use the LMS learning algorithm to update the parameters. The learning algorithm is given below.

==========

Centralized Anomaly Detection with Online Learning using Kernels and RFF (CAD-OL)

1) **Initialization: Learn** $\beta(m)$ **and** $\rho(m)$**, set** $\delta > 0$**, set step sizes** μ_1, μ_2**, and** $k = m$**.**
2) **Get data point,** $x(k+1)$
3) **If** $x(k+1)$ **is anomaly data that is (**$d(x(k+1)) > \delta$**), label point** $A(k+1) = 1$ **and**

$$\beta(k+1) = \beta(k), \;\; \rho(k+1) = \rho(k)$$

4) **otherwise update parameters using LMS algorithm estimating gradients and derivatives from equations (10) and (11)**

$$e(k+1) = z(k+1)^T \beta(k) - \rho(k),$$

$$\beta(k+1) = (1 - \frac{\mu_1}{\gamma m})\beta(k) - \mu_1 e(k+1) z(k+1),$$

$$\rho(k+1) = \rho(k) + \mu_2(\frac{1}{\gamma m} + e(k+1)),$$

and $A(k+1) = 0$

5) $k \leftarrow k+1$**, go to 2)**

==========

Note that CAD-OL can detect anomalies if δ is set correctly with the vector of anomalies recorded in A. It also tracks slowly varying changes in the distribution as the manifold parameters slowly change as new data is presented.

III. Online Unsupervised Federated Learning using PSO-FED

As mentioned in the introduction many sources of data come from distributed sources and this Section develops the models and Federated Learning (FL) algorithms for this scenario. Here we assume we have L clients and also assume that clients receive data synchronously at each update, but this can be easily modified to asynchronous updates [5], [15]. At time k client l receives input data $x(k,l)$ with $z(k,l) = c(x(k,l))$. There is also a server that communicates with all the clients and helps to coordinate learning. One approach as mentioned earlier is a centralized learning approach where the clients send all data to the server. Then the server can just use CAD-OL discussed in the previous section. As mentioned earlier this results in high communication costs and loss of data privacy. This motivates the need to use FL algorithms.

Here we combine the unsupervised anomaly detection learning algorithm discussed in the previous section, CAD-OL with PAO-FED discussed in [6]. At each update the server chooses some random set of $P << L$ clients who each communicate with the server about their parameter information. When a server chooses a client, that client gets the server model of the parameters and adaptively updates their parameter based on its current input, $x(k,l)$ (CAD-OL step 4) unless that data point is an anomaly. The server then takes the sum of all the P clients updates as its new parameter estimate. The process then repeats as the server chooses a new set of P clients at the next update. In [6] this is referred to as Online-Fed learning.

To implement PAO-FED, [6] we start at each update by choosing $R << D$ parameters of the vector β for each client. Each client can have the same components chosen (coorinated) or choose different components (uncoordinated). Initially, these can be chosen randomly or sequentially. To denote which components of β are chosen we will define a selection matrix $S(k,l)$ at time k for client l which is a diagonal matrix of dimension D with 1s on the diagonal element where there will be an update on that component of β and 0s otherwise. We also let $\mathcal{P}(k)$ denote the set of clients chosen at time k. The algorithm for each client is similar to CAD-OL for edge devices with a server aggregating the selected clients and sending this information to each of the chosen clients. At each update the clients must also rotate which components of β are updated to iterate for the next update. We initially assume that we learn the support of the distribution.

==========

Partial Sharing Anomaly Detection with Online FED Learning using Kernels and RFF (PAD-OFL)
(learning support of distribution)

1) **Initialization: Set** $\beta(0)$**,** $\rho(0)$ **,** $\beta(0,l), \rho(0,l), 1 \leq l \leq L$**, set step sizes** μ_1, μ_2**, determine initial chosen components,** $S(0,l),\ 1 \leq l \leq L$**, and** $k = 0$**.**
2) **Get data points,** $x(k,l)$**, choose** P **clients,** $\mathcal{P}(k)$**, and communicate** $S(k,l)\beta(k)$ **to selected clients.**

3) **Client Update: If** $j \in \mathcal{P}(k)$

$$\beta'(k,j) = S(k,j)\beta(k) + (\mathbf{I}_D - S(k,j))\beta(k,j)$$

$$e(k+1,j) = z(k+1,j)^T\beta'(k.j) - \rho(k,j),$$

$$\beta(k+1,j) = (1-\frac{\mu_1}{\gamma m})\beta'(k,j) - \mu_1 e(k+1,j)z(k+1,j),$$

Else

$$e(k+1,j) = z(k+1,j)^T\beta(k.j) - \rho(k,j),$$

$$\beta(k+1,j) = (1-\frac{\mu_1}{\gamma m})\beta(k,j) - \mu_1 e(k+1,j)z(k+1,j),$$

Endif

$$\rho(k+1,j) = \rho(k,j) + \mu_2(\frac{1}{\gamma m} + e(k+1,j),$$

4) **Selection matrix update:** $S(k,j+1) = \mathbf{circshift}(\mathbf{diag}(S(k,j)),r)$**. Shift of** r**.**
5) **Server update: average client update parameters to get global update**

$$\beta(k+1) = \frac{1}{P}\sum_{j\in\mathcal{P}(k)} \beta(k+1,j)$$

$$= \frac{1}{P}\sum_{j\in S_k} S(k+1,j)\beta(k+1,j) + (\mathbf{I}_D - S(k+1,j))\beta(k)$$

$$\rho(k+1) = \frac{1}{P}\sum_{j\in\mathcal{P}(k)} \rho(k+1,j)$$

6) $k \leftarrow k+1$**, go to 2)**

==========

The second part of PAD-OFL is to detect anomalies. Here the algorithm is the same as for learning support of distribution except that we have a check if data point $x(k,l)$ is an anomaly by checking if $d(x(k,l)) >$ after step 2). The procedure is the same as CAD-OL. For PAD-OFL note that at each update the client l only communicates R components of $\beta(k,l)$ to the server and the server only communicates R components of $\beta(k)$ to each client.

IV. Application of Algorithm

Let us first examine a simple example that was presented in [9]. This is the synthetic square-noise dataset with normal points labeled in blue and noisy points labeled as red. This is shown in Fig. 2. If we assume the normal points are drawn from a probability distribution we can get the distribution support lies within two square boxes that contain the blue points. It is not difficult to simulate the LS-OC-SVM to construct the square boundary boxes approximately and then being able to detect the red point anomalies. The online CAD-OL has also been implemented and can get a good approximation of the two square boundary boxes and detect anomalies using Gaussian kernels and RFF. Similarly, PAD-OFL can be implemented with a number of clients to get the two square boundaries and detect the red point anomalies.

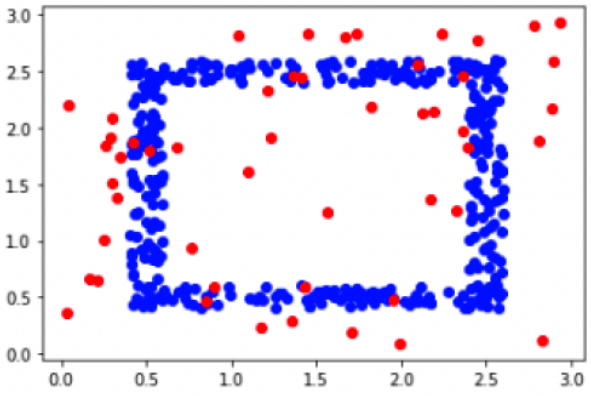

Fig. 2. Synthetic square-noise data set

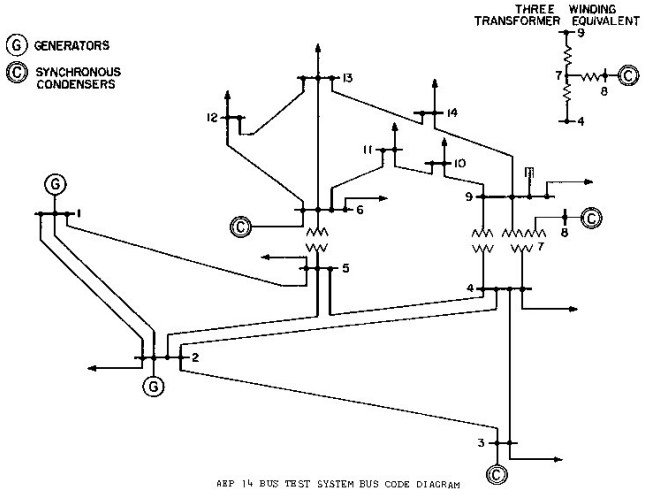

Fig. 3. IEEE 14-bus test system

For real applications, the probability distributions could be in high dimensions with complicated support. A goal is to implement the algorithms developed here on some of these applications. Here we briefly discuss one example of detecting bad electric power grid data.

Power injection	At buses 1, 2, 3, 8
Power flow	At branches 1-2, 1-5, 2-4, 2-5, 4-5, 4-7, 4-9, 5-6, 6-11, 6-14, 9-10, 9-14, 12-13
Voltage magnitude	At buses 3, 6, 8, 10, 14

Table 1. Measurement configuration for IEEE 14-bus system

In [9], detection of bad power grid data was considered. The IEEE 14-bus system [16] shown in Fig. 3 was used to test for bad grid data. A standard residual test for non-critical branch measurements was able to detect bad grid data, however branch P4-7 is a critical branch that is not observable and the standard residual test does not work. If we use an online LS-OC-SVM

using a kernel RLS algorithm we can detect bad grid data for branch P4-7. The experiment was done by considering a vector $x = [P_{4-7}, P_{4-2}, P_{4_5}, P_{4-9}]^T$ which contains the critical measurement along with measurements from neighboring buses. The true value for this flow is $P_{4-7} = 0.2285 p.u.$ We created a stream of 1000 samples by adding zero mean Gaussian noise with variance .0004 to the true value. The data was trained on a LS-OC-SVM to produce a manifold where the support of the distribution lies close to the manifold. Gaussian kernels were used and first trained on 700 training data. Then 300 test data were used with 5 of the data points injected with bad data. The LS0-OC-SVM was able to detect all five bad data points.

We then used CAD-OL using RFF using the LMS learning algorithm with suitably adjusted hyperparameters and small learning step sizes. This algorithm like the LSO-OC-SVM was also able to detect all five bad data points. Note that much power grid data is measured from distributed sources and we then applied the PAD-OFL to attempt to detect the bad grid data. We used 10 clients where data was equally and randomly distributed among these clients and then used the LMS algorithm where at each update we chose 3 of the clients to update. A total of 30 RFF were used and at each update we chose 5 of these RFF to update. The savings in communication cost over using all RFF is a factor of six. PAD-OFL using these parameters was also able to detect all five bad data points. PAD-OFL achieved communication savings and also reduced computations compared with centralized approaches and using LSO-OC-SVM.

We have discussed a power grid application where we could implement online FL algorithms such as PAD-OFL. There are many other applications where online anomaly detection for distributed sources using PAD-OFL could be used. These include personalized healthcare, networked autonomous vehicles, and precision agriculture with some of these applications are discussed in [2].

V. Summary and Further Direction

This paper discussed implementing online unsupervised learning algorithms for anomaly detection. We consider situations where data is coming from distributed sources and use principles of Federated Learning. We also use kernel methods and represent kernels using random Fourier Features (RFF). The paper combines implementation of LS-OC-SVM [9], with RFF [7], and using the PAO-FED algorithm [6]. The algorithm developed is called Partial Sharing Anomaly Detection with Online FED Learning using Kernels and RFF (PAD-OFL). We simulated results detecting bad power grid data showing the efficacy of both CAD-OL and PAD-OFL.

There is much further work to be considered including using PAD-OFL on numerous other applications and understanding the analytical behavior of PAD-OFL using tools from signal processing and information theory.

***Abstract*—Machine learning (ML) applications to time series energy utilization forecasting problems are a challenging assignment due to a variety of factors. Chief among these is the non-homogeneity of the energy utilization datasets and the geographical dispersion of energy consumers. Furthermore, these ML models require vast amounts of training data and communications overhead in order to develop an effective model. In this paper, we propose a communication-efficient time series forecasting model combining the most recent advancements in transformer architectures implemented across a geographically dispersed series of EV charging stations and an efficient variant of federated learning (FL) to enable distributed training. The time series prediction performance and communication overhead cost of our FL are compared against their counterpart models and shown to have parity in performance while consuming significantly lower data rates during training. Additionally, the comparison is made across EV charging as well as other time series datasets to demonstrate the flexibility of our proposed model in generalized time series prediction beyond energy demand. The source code for this work is available at https://github.com/XuJiacong/LoGTST_PSGF.**

I. Introduction

The Alternative Fuels Data Centre lists more than 54,000 EV charging stations (CSs) currently in operation in the United States. It is projected that the number of EVs on the road will rise by more than 4000% by 2030 [1]. As a result, there is a strong need to effectively and intelligently predict energy demands for EV CSs so as to mitigate their impact on the power grids without upgrading/expansion capability. Generally, the power grid supplies the energy for CSs once requests from EVs are received. Predicting the amount of energy needed at each CS across different periods of time will allow the power suppliers of CSs to purchase the desired amount of electricity at lower rates in order to save money and make charging at public stations more efficient – a key step towards smart charging [2]. In addition, the power grid can coordinate energy consumption via schedule management to reduce energy costs and waste of resources.

Energy utilization is a form of time series prediction algorithm that has been thoroughly studied in the past. Majidpour et al. [3] compared fast machine learning-based time-series prediction algorithms and found that the nearest neighbor algorithm showed improved accuracy. Ryu et al. [4] proposed deep learning (DL) load forecasting models and showed that DL methods exhibited better performance compared to other forecasting models. Paterakis et al. [5] compared a DL method with the eight most commonly used machine learning methods such as nearest neighbors, support vector machines, Gaussian processes, and regression trees, in time series energy prediction and showed that the DL method outperformed all eight other methods. However, conventional DL algorithms trained on individual CS nodes may not achieve high prediction accuracy due to insufficient data and failure to consider the influence of other CSs, particularly the ones in the neighborhood [6].

We introduce machine learning-based approaches that can not only improve the accuracy of time series prediction but also significantly reduce the communication overhead involved in training a machine learning algorithm involving a dispersed series of nodes. In particular, we first introduce a communication model using the power provider as a centralized node to gather all information from the individual CS nodes in a considered metropolitan area (e.g., Houston, or London, or Amsterdam, etc.). We then develop an ML algorithm to help the power provider more accurately predict energy demands for the CSs while simultaneously utilizing less data than previous algorithms. Our focus thus is two-fold. First to more accurately predict energy usage at CSs and second to lower the data utilization required to implement the prediction algorithm across a broad collection of CSs spread out geographically.

Specifically, we adopt a federated learning (FL) approach [7], [8] to energy demand prediction. As seen in Fig. 1, FL is a form of distributed learning wherein updates to model parameters are calculated locally on individual devices rather than transmitting massive volumes of data to centralized servers for global model development. These local model updates are then transmitted to a centralized server for aggregation into a global model. Once the global model has been updated according to various algorithms, the updated global model is transmitted out to the CSs for the next round of training. In this fashion the individual data never leaves the local CSs, some of the computation is offloaded to local CSs, and a globally

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

useful DL model is created. This reduces the increasing strain placed on communication networks while accomplishing the goal of training a useful global model. Thus, the advantage with FL is that the CSs only need to share their trained model parameters obtained from their individual local datasets instead of sharing their entire datasets, which generally are of large volume and often are protected by data privacy laws and security regulations.

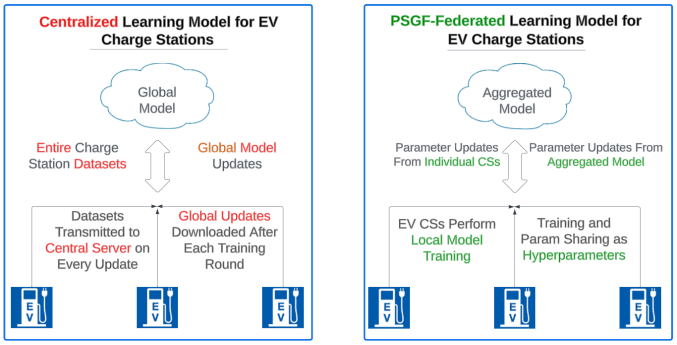

Fig. 1. FL architectures vs Centralized: In centralized learning (left), data is sent to the cloud, where the ML model is built. The model is accessed by a user through an API sending a request to access one of the available services. In FL [7,8] (right), each CS trains a model and sends only its updated parameters to a server for aggregation. Data is kept locally on devices and knowledge is shared selectively with peers through an aggregated model.

The EV charging prediction task for an individual client is a uni-variate time-series forecasting problem, which has been previously investigated. For example, using the UK EV dataset [9], Saputra et al. [10] showed that simple location-based node clustering improves the accuracy of energy demand prediction up to 24.63% and decreases communication overhead by 83.4% compared with other baseline machine learning algorithms. Different from previous works [6], [10] that treat the hourly energy consumption as the prediction output, we aggregate 24 hours of energy consumption as one data point upon which to perform daily prediction. This time aggregation is done to assist in dealing with inconsistencies present in various portions of the UK EV dataset [9] wherein certain chargers were offline for maintenance etc. at random times and therefore present discontinuities on an hourly level, whereas the daily data exhibits more clear trends of energy consumption variation and less meaningless randomness.

Inspired by the great success of transformer architectures for language and vision tasks, many advanced transformer architectures have been proposed for time series forecasting in the last two years. These transformer-based models have demonstrated better prediction performance compared with traditional RNNs and recent work PatchTST [11] outperforms its multi-layer perceptron (MLP) counterpart and shows state-of-the-art performance when tested on standard time-series forecasting benchmark datasets. In this paper, we incorporate the ideas from recent advances in efficient 2-D vision transformers and propose an improved lighter model called Local and then Global Time Series Transformer (LoGTST).

For generic FL, sharing model parameters among all clients and the server will involve heavy communications overhead costs which has the unwanted byproduct of slower convergence in real-time. To reduce the communication cost and convergence time, Online-Fed randomly down-selects a specific set of CS clients for model updating. Partial Sharing-based Online FL (PSO-Fed) [12] further alleviates this problem by only randomly sharing a partial subset of model parameters to those selected clients. However, in each global iteration, the clients in both of these two models can only access their own information to train on or stay idled not training during this particular iteration, which will hinder the convergence speed and limit that specific CS's generalization ability. Thus, we propose Partial Sharing Global Forwarding FL (PSGF-Fed) that is built upon PSO-Fed but enables the server to randomly share a small number of partial parameters to all the clients thus enabling all CSs to train during each iteration. In this way, PSGF-Fed is able to reduce the total communication overhead by accelerating the convergence speed of each local model so that fewer total iterations of training are required.

Through the generated results, we demonstrate that our proposed novel LoGTST architecture can achieve similar prediction performance with current baseline model: PatchTST [11] but involves around half of its number of trainable parameters, and our PSGF-Fed updating strategy offers better trade-off between prediction accuracy and communication cost compared with PSO-Fed [12] and Online-Fed. Also, we present additionally the flexibility via hyper-parameters between model performance and data overhead. This serves to demonstrate that our combination of LoGTST prediction model and PSGF-Fed distributed training strategy constitutes an efficient ML pipeline for energy demand forecasting of electrical vehicles.

II. Method

The learning system in this application consists of two major parts: the DL model and the FL strategy. For better prediction accuracy, the DL model should be able to capture the local and global trends of the input time series, and the FL policy should aggregate the information from all the clients and lead the model to a quick convergence with minimal bandwidth consumption. With the constraints of communication overhead driving larger parameter sets, the space complexity of the learning model should be as small as possible and the time and the amount of information sharing between server and clients should be minimized.

A. MetaFormer

Current research on the model architecture design for time series forecasting can be divided into two camps: Transformer and MLP. Different from previous transformer architectures, PatchTST [11] splits a time-series into patches and tokenizes these patches into vectors by patch embedding following Vision Transformer (ViT) [13]. This new transformer outperforms MLPs and other transformers such as DLinear [14] and FEDFormer [15] on many popular benchmarks.

The self-attention operation [16] in traditional transformers possesses the advantages of global dependency parsing and dynamic weight generation. However, self-attention brings a

large amount of space and time complexity to the overall model. The authors of MetaFormer [17] summarize recent advances on vision transformer and argue that it is the transformer architecture itself that contributes to the performance of ViT on vision tasks. They also replace the self-attention operation with a simple pooling operation and demonstrate that PoolFormer shows better efficiency than most recent variants of ViT considering the complexity and the accuracy.

Similar to PatchTST, we introduce the MetaFormer architecture into the task of 1-D time series forecast. As shown in Figure 2, we replace self-attention with Time-MLP and Identity operations as the token-mixer and propose two variants of MetaFormer: MLPFormer and IDFormer. In our experiments, we observed the surprising finding that the simplest identity operation performs as well as PatchTST. Since our goal is to reduce the model complexity while minimizing loss of accuracy, we favor most of the transformer blocks to be the simplest IDFormer in our final model.

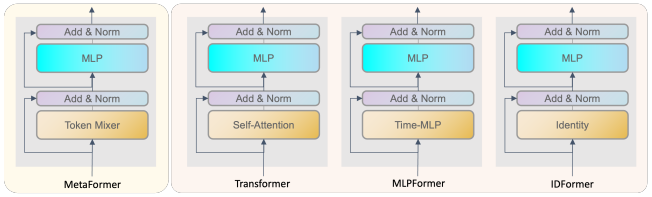

Fig. 2. Architectures of MetaFormer and its variants. Time-MLP refers to the MLP operation along the series of tokens; Identity means there is no operation.

B. LoGTST

Figure 3 depicts the basic architecture of our proposed LoGTST model.

RevIN. The Reversible Instance Normalization (RevIN) [18] module normalizes the input signal for each sample, which consists of one look-back window and one prediction horizon, and records the normalization factors for future denormalization of the output signal. In this way, RevIN is able to symmetrically remove and restore the statistical information of a time-series instance and improve the model's stability.

Tokenization and DeTokenization. The tokenization process is the same as Patch Embedding in PatchTST [11]. Here we call it Tokenization to follow the convention in computer vision and natural language processing. Given the input uni-variate time series as $\mathbf{x}$ and its length as L, the tokenization process can be simply accomplished by applying 1-D convolution on $\mathbf{x}$ with a predefined kernel of size P and stride S. The kernel size can also be seen as the patch length and the number of tokens is $N = [L/S]$. The DeTokenization process directly flattens feature vectors $\mathbf{x}_{hidden}^{(i)}$, where $i = 1, 2, ..., N$, concatenates the flattened vectors, and applies MLP for prediction, which can be represented as

$$\text{Pred} = \text{MLP}\{\text{Concat}[\text{Flat}(\mathbf{V}_0), \text{Flat}(\mathbf{V}_1), ...]\} \quad (1)$$

IDFormer and Transformer: In the transformer branch, we replace the early two transformer blocks by IDFormer blocks to reduce total model complexity and prevent early attention on naive features and keep the last transformer block to parse dependencies between hidden vectors. The patch embeddings $\mathbf{x}_p \in \mathbb{R}^{D\times N}$ should be merged with additive learnable positional encoding $\mathbf{W}_{pos}$ by $\mathbf{x}_d = \mathbf{x}_p + \mathbf{W}_{pos}$ in case of the attention mechanism treating all the feature vectors equally. For each head $h = 1, 2, ..., H$, we define three learnable matrices: $W_h^Q, W_h^K \in \mathbb{R}^{D\times d_k}$ and $W_h^V \in \mathbb{R}^{D\times D}$. Then, the calculation of multi-head self-attention can be written as:

$$O_h^T = \text{Attention}(Q_h, K_h, V_h) = \text{softmax}\{\frac{Q_h K_h^T}{\sqrt{d_k}}\}V_h \quad (2)$$

Loss: Following previous work for time series forecasting [11], [15], we also use MSE to measure the discrepancy between the prediction and the reality. Defining the number of input variables as M and the prediction horizon as T, then the total loss can be calculated by $\mathcal{L} = 1/M \sum_{i=1}^{M} \|\hat{\mathbf{x}}_{L+1:L+T}^{(i)} - \mathbf{x}_{L+1:L+T}^{(i)}\|^2$. Note that there is only one channel ($M = 1$) for the task EV charging forecasting.

C. PSGF-Fed

The difference between our proposed PSGF-Fed and previous works is illustrated in Figure 4.

Online-Fed. Instead of exchanging the model parameters with all the clients, the server of Online FL (Online-Fed) will randomly select a subset of clients in every iteration for communication efficiency. Denote the selected subset of client indices as S_n, where $C = |S_n|$ refers to the number of selected clients and n represents the current iteration. There is no need to perform local updates for unselected clients because the local model will be directly replaced by the server model when these clients are selected in future iterations. Define the local model parameters for client i in iteration n after local update as $\mathbf{w}_{n+1}^i$, then the global model can be updated by:

$$\mathbf{w}_{n+1} = \frac{1}{C}\sum_{i\in S_n} \mathbf{w}_{n+1}^i \quad (3)$$

PSO-Fed [12]. It reduces the granularity of communication to the parameter level for better efficiency and randomness. PSO-Fed randomly selects a subset of clients S_n and also randomly selects a subset of parameters $\mathbf{S}_n^i$ for client i for parameter exchange between server and clients. Different from Online-Fed, the unselected clients can still update their local models because when they are selected, not all of the local parameters will be replaced. The $\mathbf{S}_n^i$ can be a $D \times D$ diagonal matrix with M ones for selected diagonal elements and $D-M$ zeros. Then the selected local model can be updated by:

$$\mathbf{w}_{n+1}^i = \text{LocalUpdate}(\mathbf{S}_n^i \mathbf{w}_n + (\mathbf{I}_D - \mathbf{S}_n^i)\mathbf{w}_n^i) \quad (4)$$

The server generates the global model by aggregating the local parameters and this can be accomplished by:

$$\mathbf{w}_{n+1} = \frac{1}{C}\sum_{i\in S_n} \mathbf{S}_{n+1}^i \mathbf{w}_{n+1}^i + (\mathbf{I}_D - \mathbf{S}_{n+1}^i)\mathbf{w}_n \quad (5)$$

The communication overhead is then significantly reduced compared with Online-Fed while maintaining comparative convergence speed.

Fig. 3. Overview of the architecture of our proposed **LoGTST**. The input and output signals are processed by Reversible Instance Normalization (RevIN) module before and after the learning model, respectively. For fair comparison with PatchTST, we only change the first and second transformer blocks to IDFormer blocks so that the model can fully process the local features and keep the final transformer blocks for parsing of global dependency.

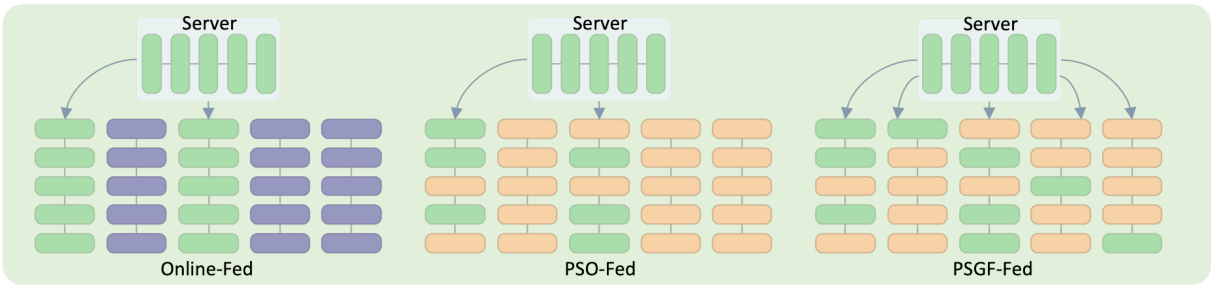

Fig. 4. Illustration of the model parameters' sharing from server to clients for Online-Fed, PSO-Fed [12], PSGF-Fed (ours). The green rectangles refer to shared parameters. The purple rectangles will remain idle during the following local update while the orange and green rectangles will be updated.

PSGF-Fed. PSO-Fed enables self-learning for each unselected client, which guarantees its fast convergence speed even though only partial parameters are shared. However, training a local model only on limited local data for many local iterations (or even several global iterations) without any global information has the risk of overfitting or weakening the generalization ability. To alleviate this issue, we propose a new online FL policy, namely PSGF-Fed, where the server will randomly select a small subset of model parameters and share them with each client. In this way, all the clients will receive some global information from the server, which will regularize the local training process. Define $\mathbf{F}_n^i$ as the parameter forwarding diagonal matrix of unselected client i with N ones for diagonal elements (selected forwarding parameters) and $D-N$ zeros, then the local training for this client can be represented by

$$\mathbf{w}_{n+1}^i = \text{LocalUpdate}(\mathbf{F}_n^i \mathbf{w}_n + (\mathbf{I}_D - \mathbf{F}_n^i)\mathbf{w}_n^i) \qquad (6)$$

The number of selected forwarding parameters (N) for each client can be adjusted to reach the best trade-off between convergence speed and communication overhead. All the selected local models will still be updated by (4) following PSO-Fed.

III. Experiments

A. Centralized Time Series Forecasting

1) Datasets: Following previous works, we evaluate our model performance on five public-domain datasets: Weather and four electricity transformer temperature (ETT) datasets (ETTh1, ETTh2, ETTm1, ETTm2) [19], which contain multivariate time series with more than 10k timesteps. These five datasets have been extensively utilized for benchmarking time series forecasting models and are introduced in detail by [20]. Since our ultimate goal is to deal with the prediction of univariate EV charging task, the forward process for each channel uni-variate series is independent of LoGTST and the model weights are shared between different channels.

2) Setting: For fair comparison, we build our model based on the codebase of PatchTST [11], FEDformer [15], and Autoformer [20] to guarantee the same experimental setup. Specifically, we train the model by stochastic gradient descent using Adam optimizer [21] and adjust the learning rate according to the cycle learning rate policy [22]. The total number of epochs is 100, but the training process will be early stopped with patience of 20 epochs to prevent overfitting. We also include previous representative models Informer [19] and Pyraformer [23] in our result comparison.

3) Results: Results in Table I show the accuracy of our LoGTST design when compared against other industry-leading architectures while functioning with less than half of the parameters available to most other models. Comparison is made across five different datasets using both the mean square error and mean absolute error. In both error measurements, across varying lengths of time prediction and across multiple time series datasets the LoGTST consistently improves upon or nearly matches the PatchTST/64 design which proved the closest competition. LoGTST does so while having only 45% the available parameters of PatchTST/64 and 58% of the parameters of PatchTST/42. When examined more closely, the toughest competition is in the area of shorter-term look-ahead where the metric is held to only 96. In this case, our LoGTST was marginally outperformed by the PatchTST networks but only by MSE of less than 0.01 and only in 3/5 cases. When the time length metric was increased to a longer look-ahead of 192, 336, or 720, the LoGTST is superior in 10/15 cases and is within 0.004 or less MSE across all other five.

B. Distributed Time Series Forecasting

1) Datasets: The EV dataset [9] was obtained from charging stations in Dundee city, the UK during 2017-2018, which has 65,601 transactions that include IDs from 58 CSs, transaction ID for each CS, EV charging date, EV charging time, and consumed energy (in kWh) for each transaction. There are

EXPERIMENTAL RESULTS OF LOGTST (OURS) AND OTHER RECENTLY PROPOSED MODELS FOR CENTRALIZED TIME SERIES FORECASTING TASK. WE CALCULATE MEAN SQUARE ERROR (MSE) AND MEAN ABSOLUTE ERROR (MAE) OF THE PREDICTED SERIES AND GROUND TRUTH FOR ALL THE MODELS TO QUANTIFY THEIR PERFORMANCE. FOLLOWING PREVIOUS WORKS, WE ALSO CHANGE THE PREDICTION LENGTH TO BE 96, 192, 336, 720 TO FULLY EXAMINE THE LONG-TIME SERIES FORECASTING PERFORMANCE. NOTE THAT PATCHTST/64 HAS A LONGER LOOK-BACK WINDOW THAN PATCHTST/42.

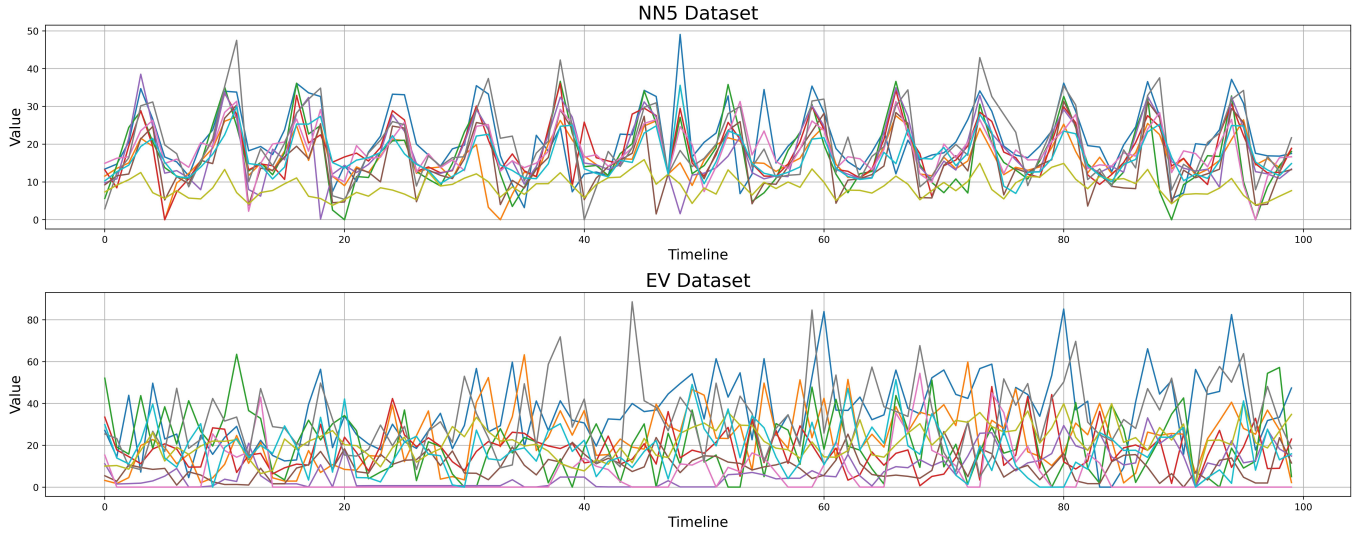

Fig. 5. Overview of the data for NN5 and EV charging datasets. We randomly select 10 clients from day 0 to day 99 of each dataset for data visualization. We can notice that the pattern of NN5 is much more obvious than EV charging dataset, where some of the data points are missing for some clients.

a large amount of missing data in the dataset, so we clean the entire dataset by removing the charging stations that stopped providing data during the period. Different from previous works [6], [10], we merge the 24-hour energy consumption into one day and focus on daily prediction since most of the hourly data is zero and involves much more randomness compared with daily data. As shown in Figure 5, even after the data cleaning, the data quality for EV dataset [9] is still quite low, which may not be able to fully benchmark the performance of current models. Thus, we also conduct experiments on NN5 dataset [24], which as shown in Figure 5 is of high quality and has a clear seasonal pattern to demonstrate the generalization ability of our method. The NN5 data consists of two years of daily cash money demand at various automatic teller machines (ATMs or cash machines) at different locations in England.

2) Setting: Following previous work [6], [10], all the clients are clustered using K-means clustering algorithm based on the distances measured by dynamic time warping (DTW) [25]. Then, the FL process are conducted independently between different clusters. The look-back window is set to be 128 steps and the prediction horizons are scheduled to be 4 and 2 for NN5 and EV datasets considering their dataset sizes. We still

use Adam optimizer with the initial learning rate to be 10^{-3}. The ratio of selected clients is set to be 50% for all three methods: Online-Fed, PSO-Fed, and PSGF-Fed. Both of the ratio of forward parameters of PSGF-Fed and the ratio of sharing parameters of PSO-Fed and PSGF-Fed are adjusted accordingly to find t heir o ptimal p erformance. T he training process will be stopped when the model reaches convergence (the training loss stops decreasing for 10 rounds). RMSE is used to quantify the prediction performance.

3) Results (NN5): As seen in Table II, when trained and tested against the NN5 time series dataset, the initial online FL, data-intensive training performs well with an MSE of 6.02 but at the cost of transferring approximately 1.5 billion parameters during training. The previous generation PSO FL architecture achieves slightly worse performance of 6.10 while only transferring 0.75 billion parameters. Our PSGF FL model achieves 6.08 MSE while only transferring 0.38 billion parameters under the 30/30 hyper-parameter implementation. This is a significant i mprovement i n c ommunication c ost overhead with a marginal performance improvement in addition when compared to the PSO FL model.

Figure 6 depicts the trade-off between communication cost and prediction loss. It is seen that With similar prediction accuracy, PSGF-Fed reduces the communication cost by at least 25% of PSO-Fed for the NN5 dataset.

TABLE II

	40%	5.25E+08	6.10
	30%	3.77E+08	6.08
	20%	3.18E+08	6.11

4) Results (EV): Similar to the NN5 results, the PSO federate learning is able to reduce the number of parameters passed during training by approximately 50 percent while maintaining performance within 2 percent of the original online federate learning model. As shown in Table III, our PSGF architecture is demonstrated to reduce passed parameter numbers by 77 percent while maintaining performance similar to that of the PSO model. Additionally, when given a matched communication budget as the PSO model, our PSGF architecture is able to outperform the PSO by 0.25 MSE. This shows the flexibility and robustness of our improved PSGF model in data overhead as well as performance.

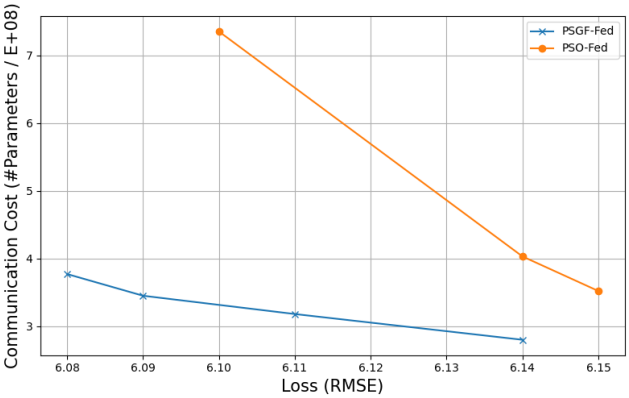

Fig. 6. The trade-off between communication cost and prediction loss (bottom left is better). With similar prediction accuracy, PSGF-Fed reduces the communication cost by at least 25% of PSO-Fed.

IV. CONCLUSIONS

In this paper, we have proposed a communication-efficient time series forecasting model by combining LoGTST in transformer design and a PSGF-Fed strategy in FL. Simulations have demonstrated that our LoGTST trained with PSGF-Fed offers the best trade-off between communication overhead and performance for energy demand forecasting of a geographically dispersed series of EV charging stations. Tests of our proposed forecasting model on other time series datasets also showed superior performance over existing approaches, making it applicable to generalized time series prediction beyond energy demand for EV charging.

***Abstract*—This paper proposes a radiated sound field reproduction method for a surrounding loudspeaker array. The conventional method controls the direction of the virtual sound image by a vector base amplitude panning (VBAP). The real sound source like human speech and musical instruments has a directivity pattern and should be considered to reproduce the sound field. However, the VBAP-based method cannot represent the directivity pattern because VBAP only controls the amplitude of an audio signal. In this paper, we propose the radiated sound field reproduction method for a surrounding loudspeaker array based on higher-order ambisonics (HOA). Based on HOA, the proposed method calculates the driving function of the virtual sound source by using the directivity pattern of the virtual sound source. Simulation results show that the proposed method achieves to represent the radiation sound with a normalized reproduction error of -20 dB in the target region.**

I. Introduction

Recently, the demand for highly realistic sound field reproduction systems has been increasing with the development of imaging technologies. 22.2 multichannel audio [2] is one of the sound field reproduction systems and consists of a surrounding loudspeaker array. In 22.2 multichannel audio, vector base amplitude panning (VBAP) [3] is used to control the direction of a three-dimensional (3-D) sound image. VBAP controls the direction of the sound image by selecting three loudspeakers from a surrounding loudspeaker array and weighing each speaker. However, VBAP controls only amplitude, and is difficult to reproduce a radiated sound image. To solve this problem, Iwai et al., proposed the 3-D sound image reproduction method based on spherical harmonic expansion [1]

The directivity pattern of a real sound source changes depending on the frequency and is important to percept the direction of sound [4]. Therefore, it is required to consider the frequency-dependent directivity of the virtual sound image for the reproduction of the radiation sound.

Radiating speaker arrays consisting of multiple loudspeaker elements mounted on a polyhedron or sphere enclosure are conventionally used to control the radiation directivity characteristics [5]. However, it is difficult to reproduce a radiated sound image using a surrounding loudspeaker array.

In this paper, we propose a system to construct a virtual sound source that has desired radiation characteristics in the 22.2 multichannel sound system. The proposed method calculates the driving function of the virtual sound source by using the directivity pattern of the virtual sound source based on higher-order ambisonics (HOA) [6]. We evaluate reproducibility by computer simulation.

II. Proposed method for radiated sound field reproduction for surrounding loudspeaker array based on higher-order ambisonics

A. Outline

In this paper, we propose radiated sound field reproduction for the surrounding loudspeaker array. A 3-D sound field can be represented by spherical harmonic expansion [7]. First, the proposed system calculates the coefficients of the spherical harmonic expansion which represent desired radiation characteristics. Then, the proposed system calculates sound pressure on each microphone when we locate a spherical microphone in the radiation sound in a computer simulation. Then, the proposed system calculates the driving signals of each loudspeaker which reproduces radiation sound based on HOA from sound pressures on each microphone. In this section, we state in detail.

B. Spherical harmonic expansion

The spherical harmonic function $Y_{nm}(\theta, \phi)$ is shown as the general solution of the 3-D wave equation and expressed by the following equation [7]:

$$Y_{nm}(\theta,\phi) = \sqrt{\frac{(2n+1)}{4\pi}\frac{(n-m)!}{(n+m)!}} P_{nm}(\cos\theta) e^{jm\phi}, \quad (1)$$

here, $\theta(0 \leq \theta \leq \pi)$ is polar angle, $\phi(0 \leq \phi \leq 2\pi)$ is azimuth, $n(0 \leq n \leq \infty)$ is degree of spherical harmonic function, $P_{nm}(\cdot)$ is Lejandre's function, j is imaginary unit. Figure 1 shows the real part of the spherical harmonic function. The spherical harmonic function is an orthogonal function. Therefore, it is possible to express a sound field as expansion coefficients using the spherical harmonic function. In the case

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

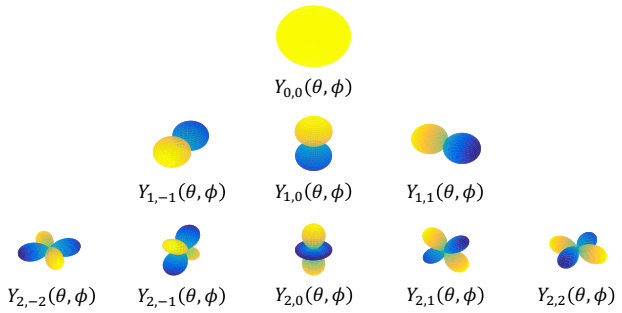

Fig. 1: Real part of spherical harmonics

where the sound source is outside the radius r, one of the solutions for the wave equation is represented with polar coordinates expressed by the following equation:

$$p(\boldsymbol{r},k)=\sum_{n=0}^{\infty}\sum_{m=-n}^{n}A_{nm}^{\text{int}}(k)y_n(kr)Y_{nm}(\theta,\phi), \tag{2}$$

here, $\boldsymbol{r}=(r,\theta,\phi)$, k is the wavenumber, $A_{nm}^{\text{int}}(k)$ is the expansion coefficient of the internal acoustic field, $y_n(kr)$ is the spherical Bessel function. When the sound pressure $p(r,k)$ is known at $r=a$, $A_{nm}{}^{\text{int}}(k)$ is expressed by the following equation:

$$A_{nm}^{\text{int}}(k)=\int_0^{\pi}\int_0^{2\pi}\frac{p(a,\theta,\phi,k)}{y_n(ka)}Y_{nm}(\theta,\phi)^*\sin\theta d\theta d\phi, \tag{3}$$

here, $(\cdot)^*$ is the complex conjugate. Then, the radiated sound field where the sound source is inside of the radius r is expressed by the following equation:

$$p(\boldsymbol{r},k)=\sum_{n=0}^{\infty}\sum_{m=-n}^{n}A_{nm}^{\text{ext}}(k)h_n(kr)Y_{nm}(\theta,\phi), \tag{4}$$

here, $A_{nm}^{\text{ext}}(k)$ is the expansion coefficient of radiated sound field. Assuming that sound pressure $p(\boldsymbol{r},k)$ is known at $r=b$, A_{nm}^{ext} is expressed by following equation:

$$A_{nm}^{\text{ext}}(k)=\int_0^{\pi}\int_0^{2\pi}\frac{p(b,\theta,\phi,k)}{h_n(kb)}Y_{nm}(\theta,\phi)^*\sin\theta d\theta d\phi. \tag{5}$$

C. Higher-order ambisonics (HOA)

In HOA, the desired sound field is reproduced in the reproduction field by HOA encoding and decoding based on spherical harmonic expansion.

The procedure of HOA encoding is as follows. First, we estimate $A_{nm}^{\text{int}}(k)$ by recording a sound field using a small spherical microphone array located in the desired sound field. As (2) calculates the infinite sum, it is required to the finite number of expansion order N_{int}. $(N_{\text{int}}+1)^2$ microphones are required to reproduce the desired sound field at least when limiting the order by N_{int}. When microphone array which radius r_q used, the signal $s(\boldsymbol{r}_q,k)$ recorded by a microphone located on (θ_q,ϕ_q) expressed by the following equation:

$$s(\boldsymbol{r}_q,k)=\sum_{n=0}^{N_{\text{int}}}\sum_{m=-n}^{n}A_{nm}^{\text{int}}(k)b_n(kr_q)Y_{nm}(\theta_q,\phi_q), \tag{6}$$

here, $b_n(kr_q)$ is the radial function decided by the shape of the microphone array. Table I shows $b_n(kr)$ for the shape of the microphone array and Fig. 2 shows the amplitude of $b_n(kr)$. The signal $s(r_q,k)$ expressed by (6) can be rewritten as the following equation:

$$\boldsymbol{s}(k)=\boldsymbol{Y}\cdot\text{diag}\left[b_n(kr_q)\right]\boldsymbol{A}(k), \tag{7}$$

here, diag$[\cdot]$ is diagonal matrix.

$$\boldsymbol{s}=\left[s(\boldsymbol{r}_1,k),\ldots,s(\boldsymbol{r}_q,k),\ldots,s(\boldsymbol{r}_Q,k)\right], \tag{8}$$

$$\boldsymbol{Y}=\begin{bmatrix}Y_{0,0}(\theta_1,\phi_1) & \cdots & Y_{N_{\text{int}},N_{\text{int}}}(\theta_1,\phi_1)\\ \vdots & \ddots & \vdots\\ Y_{0,0}(\theta_Q,\phi_Q) & \cdots & Y_{N_{\text{int}},N_{\text{int}}}(\theta_Q,\phi_Q)\end{bmatrix}, \tag{9}$$

$$\boldsymbol{A}=\left[A_{0,0}^{\text{int}}(k),\ldots,A_{N_{\text{int}},N_{\text{int}}}^{\text{int}}(k)\right]. \tag{10}$$

Then, $s(k)$ is the recording signal vector in the wave domain, Y is the matrix of the spherical harmonic function, and $A(k)$ is the expansion coefficient vector. From (7), $\boldsymbol{A}$ is expressed by the following equation:

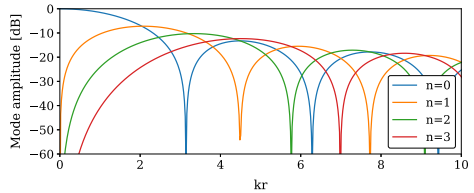
$$\boldsymbol{A}(k)=\boldsymbol{Y}^{+}\cdot\text{diag}\left[\frac{1}{b_n(kr_q)}\right]\boldsymbol{s}(k), \tag{11}$$

here, $(\cdot)^{+}$is the Moore-Penrose inverse matrix. An expansion coefficient becomes unstable in HOA encoding when we use a hollow omnidirectional array in prohibited frequency at which $y_n(kr)=0$ [8]. Then, radial functions of a ridged microphone array or a hollow cardioid microphone array are proposed to avoid prohibited frequency [8].

Then, we calculate the driving signals of each loudspeaker based on the expansion coefficient by HOA decoding. The spherical harmonic expansion on location $\boldsymbol{r}_s$ expressed by the following equation [6]:

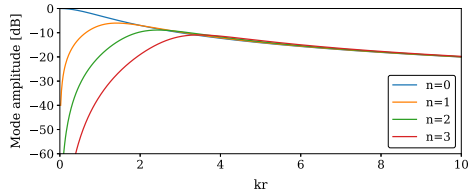
$$\frac{e^{jk|\boldsymbol{r}-\boldsymbol{r}_s|}}{4\pi|\boldsymbol{r}-\boldsymbol{r}_s|}=\sum_{n=0}^{\infty}\sum_{m=-n}^{n}jkh_n(kr_s)y_n(kr)Y_{nm}(\theta,\phi)Y_{nm}(\theta_s,\phi_s)^*. \tag{12}$$

From (2) and (12), the expansion coefficients of a point source are expressed by the following equation:



$$A_{nm}^{\text{int}}(k)=jkh_n(kr_s)Y_{nm}(\theta_s,\phi_s)^*. \tag{13}$$

In this paper, we decode HOA coefficients assuming a point source. Thus, the driving signal $d(\boldsymbol{r}_l,k)$ of loudspeaker $l(1\leq l\leq L)$ which located $\boldsymbol{r}_l=(r_l,\theta_l,\phi_l)$ and decoding matrix $\boldsymbol{C}$ are expressed by the following equations:



$$\boldsymbol{d}(k)=\boldsymbol{C}^{+}\cdot\text{diag}\left[\frac{j^n}{jkh_n(kr_l)}\right]\boldsymbol{A}(k), \tag{14}$$

TABLE I: $b_n(kr)$ for the various array configurations.

D. Radiation sound reproduction

In this paper, we aim to construct a virtual sound source that has desired radiation characteristics by reproducing a radiated sound field based on HOA. The procedures of the proposed method are shown below.

[Step 1]Calculating radiation characteristics

The expansion coefficients of the radiated sound field with directivity patterns are calculated by the signals recorded by microphones located around the actual sound source. The discrete formula of (5) which sampled by microphones $q'(1 \leq q' \leq Q')$ located $\boldsymbol{r}_{q'} = (r_{q'}, \theta_{q'}, \phi_{q'})$ is expressed by the following equation:

$$A_{nm}^{\mathrm{ext}}(k) = \sum_{q'=1}^{Q'} \frac{p(\boldsymbol{r}_{q'}, k)}{h_n(kr_{q'})} Y_{nm}(\theta_{q'}, \phi_{q'})^*, \tag{17}$$

[Step 2]Calculating sound pressure on a microphone in a radiation sound

We assume a spherical microphone array with multiple microphones arranged on a sphere centered at position r_c in the radiated sound field. Sound pressure at the position of the q-th microphone $\boldsymbol{r}_q$ is calculated by (4). In this paper, we consider the directivity of microphones. Thus, recorded signals by each microphone are expressed by the following equation:

$$s(\boldsymbol{r}_q, k) = w_q p(\boldsymbol{r}_q, k), \tag{18}$$

$$w_q = \alpha + (1-\alpha) \frac{(\boldsymbol{r}_s - \boldsymbol{r}_c) \cdot (\boldsymbol{r}_s - \boldsymbol{r}_q)}{|\boldsymbol{r}_s - \boldsymbol{r}_c||\boldsymbol{r}_q - \boldsymbol{r}_q|}, \tag{19}$$

here, $\boldsymbol{r}_s$ is the position of the sound source. The directivity coefficient w_q corresponds to the recording of the open sphere when $\alpha = 1$ and cardioid when $\alpha = 0.5$, respectively.

[Step 3]Calculating loudspeaker driving signal based on HOA

The driving signals for each loudspeaker are obtained by encoding into expansion coefficients using (11) and decoding the expansion coefficients into driving signals using (14).

III. Objective Evaluation

We perform the computer simulation to evaluate the effectiveness of the proposed method.

A. Simulation conditions

We evaluate the reproducibility of the radiated sound field by comparing the desired sound field and the sound field reproduced by the proposed method in the computer simulation. Here, the desired sound field is generated by the radiation that has desired radiation characteristic and calculated by (4). We use radiation characteristics of the human voice shown in [4]. Figure 3 shows the polar pattern of the used radiation characteristic. We calculate the reproduced sound field assuming 22.2 multichannel audio as a surrounding loudspeaker array. In this simulation, a reproduced sound field is calculated by the open sphere ($\alpha = 1$) and the cardioid ($\alpha = 0.5$) in (11) and (19). The reproduced radiated sound field is represented by the following equations:

$$p(\boldsymbol{r}, k) = \sum_{l=1}^{L} d(\boldsymbol{r}_l, k) G(\boldsymbol{r}|\boldsymbol{r}_l), \tag{20}$$

$$G(\boldsymbol{r}|\boldsymbol{r}_l) = \frac{e^{jk|\boldsymbol{r}-\boldsymbol{r}_l|}}{4\pi|\boldsymbol{r}-\boldsymbol{r}_l|} \left(\beta - (1-\beta)\left(1 + \frac{j}{k|\boldsymbol{r}-\boldsymbol{r}_l|}\right)\cos\gamma_l\right), \tag{21}$$

here, $G(\cdot)$ is the transfer function of a directional sound source [9]. In this simulation, we assume that each loudspeaker is unidirectional ($\beta = 0.5$) and set γ_l to maximize the outputs of each loudspeaker on the center of the 22.2 multichannel audio. Table II shows simulationg conditions. Microphones are arranged as a Fibonacci spiral.

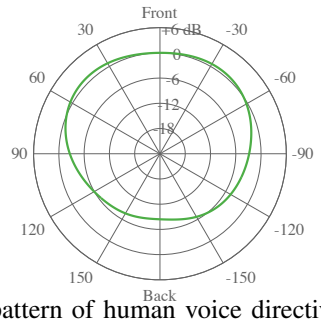

Fig. 3: Polar pattern of human voice directivity (500 Hz)

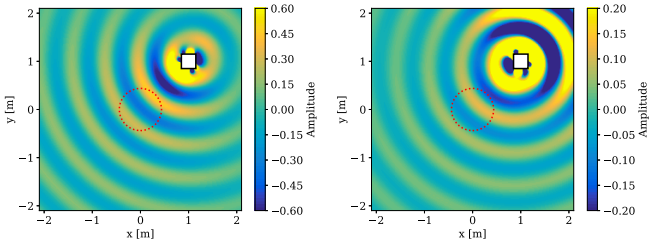
TABLE II: Experimental conditions

Frequency	500 Hz
Expansion order	$N_{\text{ext}} = 6, N_{\text{int}} = 4$
Number of microphones	$Q = 49$
Radius of microphones	$r_q = 0.05$ m
Number of loudspeakers	$L = 22$
Radius of loudspeakers	$r_l = 1.9$ m

B. Evaluation metric

In this simulation, a squared error between the desired sound field $p_{des}(r, k)$ and the reproduced sound field $p_{rep}(r, k)$ calculated by (20) is evaluated by normalized reproduction error (NRE). NRE is expressed by the following equation.



$$\text{NRE}(\boldsymbol{r}, k) = 10 \log_{10} \frac{|p_{\text{des}}(\boldsymbol{r}, k) - p_{\text{rep}}(\boldsymbol{r}, k)|^2}{|p_{\text{des}}(\boldsymbol{r}, k)|^2}, \qquad (22)$$

here, the lower the NRE value is, the better the reproduction ability is.

C. Simulation results

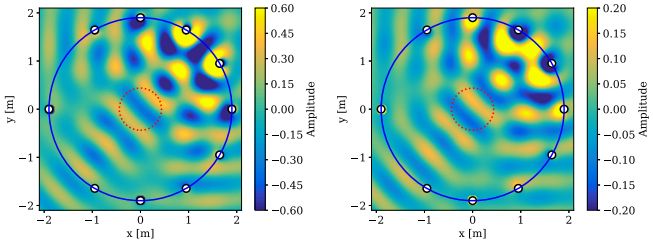


Figure 4 and 9 show the desired sound field. In Figs. 4 and 9, the white square on $(x, y) = (1, 1)$ shows the location of a sound source. Figures 5 and 10 show the reproduced sound field using the open sphere, Figs. 6 and 11 show NRE (open sphere), Figs. 7 and 12 show the reproduced sound field using a Cardioid, Fig. 8 shows NRE (cardioid). In Fig. 4-13, "Front" shows that the sound source radiates to the audience and "Back" shows that the sound source radiates to the opposite side of the audience. A red circle displayed by a dashed line shows the reproduction area r_0, a blue circle displayed by a solid line shows the radius of the loudspeaker array, white squares on the loudspeaker array show loudspeaker positions on the middle layer of the 22.2 multichannel audio. r_0 shows area that the reproduction error is about 4%, and $r_0 \approx N_{\text{int}}/2\pi f$ [10]. Here, f shows the frequency of the sound.

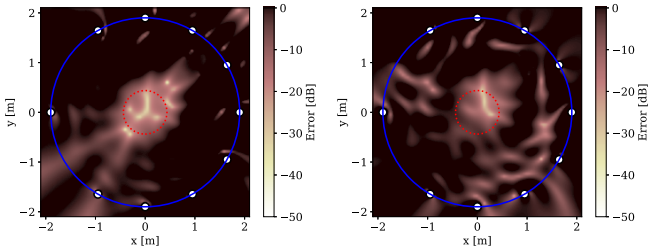
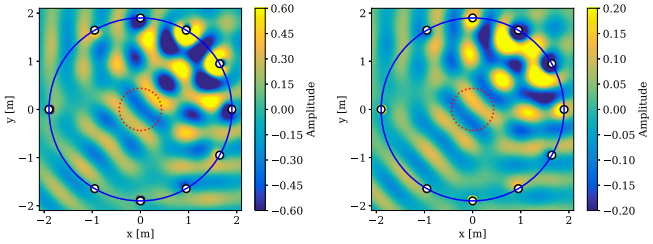
From Figs. 4, 5, 7, 9, 10 and 12 it can be seen that the amplitude of the reproduced area is almost similar to that in the desired sound field. Here, the frequency response of the sound source in each direction is reproduced with NRE = -20 dB. However, the reproduction accuracy of "Back" is less than "Front" according to Figs. 6, 8, 11 and 13. This is because "Back" includes many higher-order components of spherical harmonic function and has complex radiation characteristics. Thus, "Back" should be expanded with a higher expansion order than "Front".



(a) Front (b) Back

Fig. 4: Desired sound field (500 Hz)

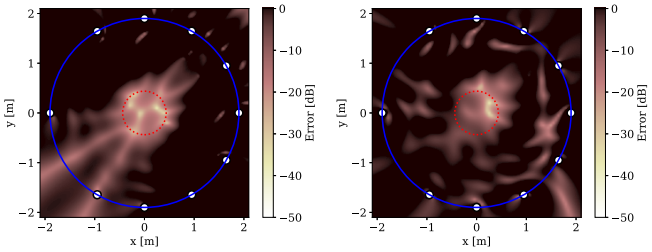


(a) Front (b) Back

Fig. 5: Reproduced sound field (open sphere) (500 Hz)

(a) Front (b) Back

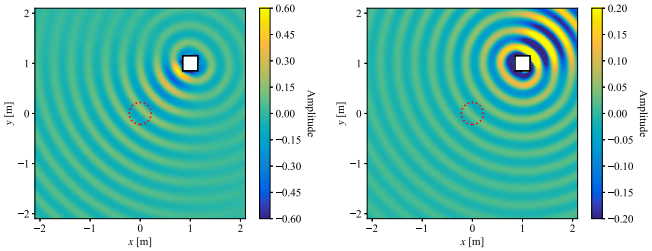
Fig. 6: NRE (open sphere) (500 Hz)



(a) Front (b) Back

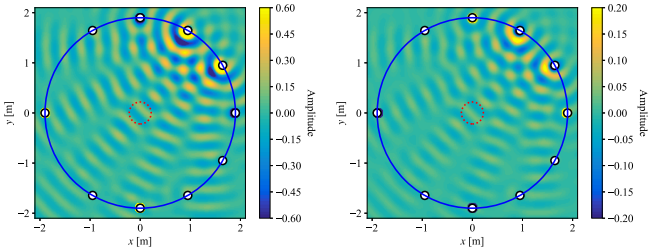
Fig. 7: Reproduced sound field (cardioid) (500 Hz)

In Figs. 6, 8, 11 and 13, NRE for "Front" and "Back" are similar regardless of the directivity of microphones. Therefore, it is possible to avoid an inhibited frequency by using cardioid microphones when reproducing the radiation sound from the radiated directivity data by the proposed method. The reproduced area r_0 depends on reproduction frequency although NRE is the same regardless of reproduction frequency. From the above, the effectiveness of the proposed method is shown.



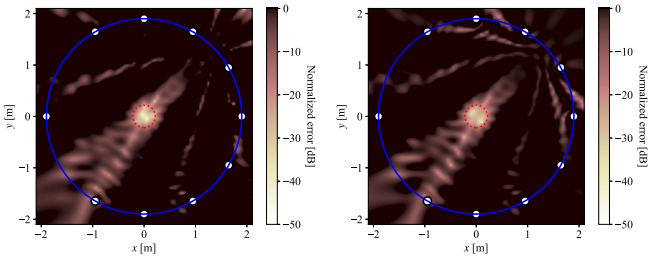
IV. Conclusions

In this paper, we propose a radiated sound field reproduction method for a surrounding loudspeaker array. Simulation results



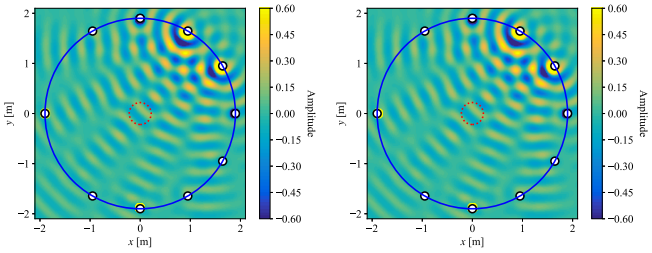
(a) Front (b) Back

Fig. 8: NRE (cardioid) (500 Hz)



(a) Front (b) Back

Fig. 9: Desired sound field (1000 Hz)



(a) Front (b) Back

(a) Front (b) Back

Fig. 11: NRE (open sphere) (1000 Hz)

(a) Front (b) Back

Fig. 12: Reproduced sound field (cardioid) (1000 Hz)

(a) Front (b) Back

Fig. 13: NRE (cardioid) (1000 Hz)

showed that the proposed method reproduced desired sound field with NRE = −20 dB in cases of "Front" and "Back". Simulation results also showed that the proposed method can avoid prohibiting frequency by using cardioid microphones when reproducing a radiated sound field. In the future, we aim to reproduce the radiation sound with high accuracy regardless of the direction of radiation.

Abstract—**This paper presents a learning-based multichannel active noise control (L-MANC) method that utilizes a model-matching framework along with a sensor interpolation approach. In a feedforward ANC scenario, L-MANC aims to cancel the primary noise field for an extended control region with a limited number of measurements. To achieve global control, the training data is generated by interpolating the acoustic transfer functions (ATFs) based on a small number of measurements via kernel ridge regression. Noise control filters for the secondary loudspeakers are learned using a convolutional recurrent neural network (CRNN) in an encoder-decoder architecture. In the training phase, the network parameters are obtained using the mean square error criterion in a model-matching paradigm. Simulations are performed for an ANC system consisting of a nine-loudspeaker linear array and eight measured control points. The proposed L-MANC approach is tested for various unseen scenarios with variations in reverberation time and location of the primary noise source. The proposed system has demonstrated superior ANC performance in terms of mean square noise reduction (MSNR) over several baselines.**

I. INTRODUCTION

Active Noise Control (ANC) is a noise control technique that aims to suppress unwanted noise by using an anti-noise signal generated by secondary loudspeakers [1] . In recent years, spatial ANC has received considerable attention [2] . ANC systems using multiple secondary loudspeakers have been suggested to achieve a broadened control region [3] . ANC systems have typically been implemented using adaptive filters such as the Filtered-x Least Mean Square (Fx-LMS) and Filtered-x Recursive Least Square (Fx-RLS) algorithms [4] [5] . These algorithms attempt to minimize the power of the residual noise at the error microphone locations [6] . The single-channel adaptive ANC was extended to adaptive MANC [7] for global ANC. However, the computational complexity of adaptive filters increases considerably with the number of loudspeakers and microphones [8] Moreover, the learning nature that involves convergence of error hampers the performance of noise reduction, especially for the transient primary noise. Adaptive algorithms could have convergence problems in the face of perturbation of environment or transient signals, resulting in poor noise reduction performance [9] .

Recently, the advent of deep neural networks (DNNs) has shed some light on ANC research [10] In this paper, a learning-based feedforward multichannel ANC approach is proposed to achieve the ANC performance within an extended region. In addition, a special technique is developed to interpolate the acoustic transfer functions (ATFs) based on a limited number of measurements. In light of the model matching principle [11] we design a DNN-based controller for multichannel ANC. Our approach adopts a CRNN implemented in an encoder-decoder structure to generate the loudspeaker signals for noise suppression. Furthermore, to achieve spatially extended control based only on a limited number of ATF measurements, we employ the kernel ridge regression method [12] to interpolate the ATFs for training data generation. This approach reduces the need for tedious room impulse response (RIR) measurements. By using a large number of interpolated ATFs, the residual noise signal can be minimized over an extended region.

The paper is organized as follows. Sec. II provides an overview of related work, with a particular focus on model-matching ANC approaches. Sec. III introduces the proposed L-MANC method and outlines the construction of a CRNN. Detailed information on the experimental setup, dataset

selection, and CRNN parameters are presented in Sec. IV. The results and discussions are presented in Sec. V, while the conclusion is given in Sec. VI.

II. RELATED WORK

In this section, the ANC problem via a model-matching principle is introduced. Multichannel ANC based on Tikhonov regularization (TIKR), linearly constrained minimum variance (LCMV), and the Fx-LMS methods are used as the baselines.

A. ANC as a Model Matching Problem

The architecture of a model-matching ANC is illustrated in Fig. 1. The single-channel input signal $x(f)$ at the frequency f is multiplied by the noise control filter vector $\mathbf{h}(f) \in \mathbb{C}^{J\times 1}$ to obtain the outputs. Each output is multiplied elementwise by the secondary-path ATF matrix $\mathbf{G}^s(f) \in \mathbb{C}^{K\times J}$ measured between the secondary loudspeaker inputs and the pressure responses $\mathbf{y}(f)$ at the control points. The objective of this architecture is to minimize the matching error between the predicted signal $\mathbf{y}(f)$ and the desired signal $\mathbf{d}(f)$. The vector $\mathbf{g}^p(f) \in \mathbb{C}^{K\times 1}$ represents the primary path ATFs from the primary noise source to all control points. The frequency index is omitted hereafter for brevity. Therefore, the goal of the model-matching principle is to generate the opposite phase of $\mathbf{g}^p$, as given by:

$$\underbrace{\begin{bmatrix} g_1^p \\ \vdots \\ g_K^p \end{bmatrix}}_{\mathbf{g}^p} = \underbrace{\begin{bmatrix} G_{11}^s & \cdots & G_{1K}^s \\ \vdots & \ddots & \vdots \\ G_{J1}^s & \cdots & G_{JK}^s \end{bmatrix}}_{\mathbf{G}^s} \underbrace{\begin{bmatrix} h_1 \\ \vdots \\ h_J \end{bmatrix}}_{\mathbf{h}}, \tag{1}$$

where G^s_{jk}, j = 1, …, J, and k = 1, …, K denotes the ATF between the jth loudspeaker and the kth measured point, h_j represents the noise control filter for the jth loudspeaker, and g^p_k is the ATF between the primary noise and the kth measured control point. In this model-matching ANC system, the learnable CRNN is employed to obtain the ANC controllers.

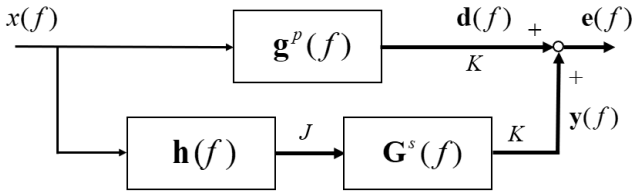

Fig. 1: The framework of the model-matching ANC.

For underdetermined systems ($J > K$), the solution of a regularized least squares approach, TIKR [13] can be acquired through employing the cost function as follows:

$$\min_{\mathbf{h}_{TIKR}} \|\mathbf{G}^s\mathbf{h}_{TIKR} + \mathbf{g}^p\|_2^2 + \beta^2 \|\mathbf{h}_{TIKR}\|_2^2, \tag{2}$$

where $\mathbf{h}_{TIKR}$ is the noise control filter, β is the regularization parameter tuned via the L-curve method [14] and $\|\cdot\|_2$ denotes the $l2$-norm. Thus, the solution of (2) can be obtained [15]

$$\mathbf{h}_{TIKR} = -(\mathbf{G}^{sH}\mathbf{G}^s + \beta^2\mathbf{I})^{-1}\mathbf{G}^{sH}\mathbf{g}^p. \tag{3}$$

Although TIKR has good ANC performance at the control points, the noise reduction performance degrades significantly at the adjacent region of the control points. To overcome this limitation, the LCMV [11] method can be adopted to globally enhance the ANC performance. The constrained optimization problem can be defined as:

$$\min_{\mathbf{h}_{LCMV}} (\mathbf{e}_i^H\mathbf{e}_i), \text{ s.t. } \mathbf{G}_m^s\mathbf{h}_{LCMV} = -\mathbf{g}_m^p \tag{4}$$

where $\mathbf{e}_i = \mathbf{g}_i^p + \mathbf{G}_i^s\mathbf{h}_{LCMV}$ represents the error vector at the interpolated points, $\mathbf{g}_i^p$ and $\mathbf{g}_m^p$ are the ATF vectors from the noise to the interpolated and measured points, respectively, $\mathbf{G}_i^s$ and $\mathbf{G}_m^s$ denote the ATF matrices from the secondary loudspeakers to the interpolated and measured points, respectively, and $\mathbf{h}_{LCMV}$ is the optimal noise control filter of the LCMV approach. By the method of Lagrange multipliers, the optimal filter can be solved as:

$$\begin{aligned}\mathbf{h}_{LCMV} = {} & (\mathbf{G}_i^{sH}\mathbf{G}_i^s + \varsigma\mathbf{I}_J)^{-1}\mathbf{G}^{sH}[\mathbf{G}^s(\mathbf{G}_i^{sH}\mathbf{G}_i^s + \varsigma\mathbf{I}_J)^{-1}\mathbf{G}^{sH} + \mu\mathbf{I}_K]^{-1}\cdot \\ & [\mathbf{G}^s(\mathbf{G}_i^{sH}\mathbf{G}_i^s + \varsigma\mathbf{I}_J)^{-1}\mathbf{G}_i^{sH}\mathbf{g}_i^p - \mathbf{g}^p] - (\mathbf{G}_i^{sH}\mathbf{G}_i^s + \varsigma\mathbf{I}_J)^{-1}\mathbf{G}_i^{sH}\mathbf{g}_i^p,\end{aligned} \tag{5}$$

where μ and ζ are the regularization parameters selected using particle swarm optimization (PSO) [16]

B. Filtered-x multichannel least mean square algorithm

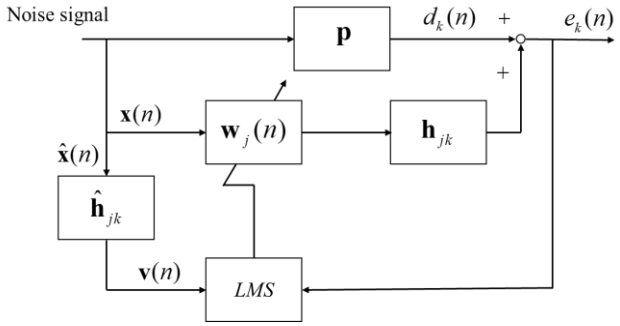

Fig.2: Block diagram of the ANC system using the Fx- LMS algorithm

The block diagram of the Fx- LMS algorithm is shown in Fig. 5. Consider the noise source input vector as follows:

$$\mathbf{x}(n) = [x(n)\ \cdots x(n-L+1)]^T \tag{6}$$

where L represents the filter length and n is the sample index. In the primary path, the desired signal $d_k(n)$ can be obtained by convolving the noise signal with the primary path $\mathbf{p} \in \mathbb{R}^K$. In

the intermediate path, the kth error signal $e_k(n)$ can be derived as follows:

$$e_k(n) = d_k(n) + \sum_{j=1}^{J} \mathbf{h}_{j,k}^T [\mathbf{w}_j^T(n)\mathbf{x}(n)] \quad (7)$$

where the adaptive filter coefficient is denoted as $\mathbf{w}_j(n) = [w_{j,0}(n) \ \dots \ w_{j,L-1}(n)]^T$, and the secondary path RIR $\mathbf{h}_{j,k}$ can be written as follows:

$$\mathbf{h}_{j,k} = [h_{j,k,1} \quad \cdots \quad h_{j,k,N}] \quad (8)$$

where N represents the FIR filter length. In the lower path, without loss of generality, we simply treat $\hat{\mathbf{h}}_{j,k} = \mathbf{h}_{j,k}$, then the filtered input $\mathbf{v}_{jk}(n) = \hat{\mathbf{x}}(n) * \hat{h}_{jk}(n)$, where $\hat{\mathbf{x}}(n) = [x(n) \ \dots \ x(n-N+1)]^T$. Lastly, the filter coefficient can be updated by

$$\mathbf{w}_j(n+1) = \mathbf{w}_j(n) - \mu \sum_{k=0}^{K} \mathbf{v}_{jk}(n)^T e_k(n). \quad (9)$$

III. PROPOSED METHOD

This section describes the proposed L-MANC system within a model-matching framework. L-MANC adopts CRNN as a learnable function $CRNN(\cdot)$ for the ANC controllers. The kernel ridge regression method is employed for interpolated ATFs between measured points. In particular, this approach allows for more efficient training by using fewer measured points, resulting in improved control performance. During the training stage, the pre-generated RIRs at measured and interpolated points are utilized for the target signals captured by the error microphones. L-MANC aims to cancel the primary noise at an extended area.

A. Learning-based Model-Matching Approach

The L-MANC system is formulated in the time-frequency domain, as shown in Fig. 3. The ATF between the primary noise and the kth microphone is denoted as $g_k^p(t,f)$. $G_{jk}^s(t,f)$ represents the secondary path, where the ATF between the jth secondary loudspeaker and the kth error microphone is pre-measured or pre-interpolated. The indices t and f represent the time frame and the frequency bin, respectively. Therefore, the kth desired signal $d_k(t,f)$ can be obtained from the noise source $X(t,f)$ as

$$d_k(t,f) = X(t,f) g_k^p(t,f). \quad (10)$$

Next, the input signal $X(t,f)$ is decomposed into its real and imaginary parts, $X_r(t,f)$ and $X_i(t,f)$. These two parts are concatenated to construct the input matrix $\mathbf{X}(t,f) = [X^r(t,f) \ X^i(t,f)]^T \in \mathbb{R}^2$. Then, $\mathbf{X}(t,f)$ is fed into the neural network, $CRNN(\cdot)$ to obtain filtered signals, $\mathbf{Y}(t,f) \in \mathbb{R}^{2J}$:

$$\mathbf{Y}(t,f) = CRNN(\mathbf{X}(t,f)), \quad (11)$$

where $\mathbf{Y}(t,f)$ is formed by the real and imaginary parts of the J signals for the loudspeaker, $Y_j^r(t,f)$ and $Y_j^i(t,f)$, $j = 1, \dots, J$, as given by $\mathbf{Y}(t,f) = [Y_1^r(t,f) \ Y_1^i(t,f) \ \dots \ Y_J^r(t,f) \ Y_J^i(t,f)]^T$.

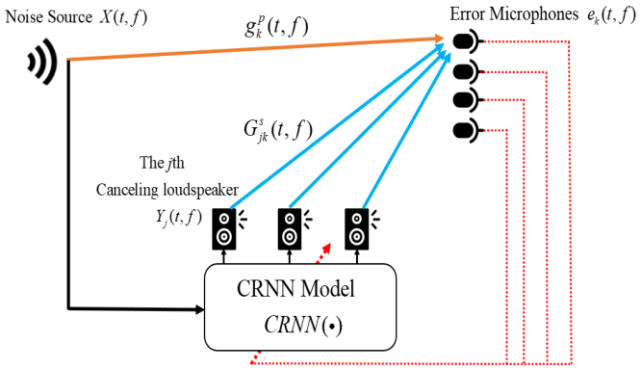

Fig. 3: The proposed L-MANC based on the model matching principle.

Then, the network output for each jth secondary loudspeaker is reformulated into the complex form of $Y_j(t,f)$ and multiplied by the ATF $G_{jk}^s(t,f)$ from the jth secondary loudspeakers to the kth error microphones. The error signal $e_k(t,f)$ between the desired and estimated signals can be expressed as

$$e_k(t,f) = d_k(t,f) + \sum_{j=1}^{J} G_{jk}^s(t,f) Y_j(t,f). \quad (12)$$

For global ANC, the kernel ridge regression method [12] is used to interpolate the ATFs between the measured points, which allows for accurate control for both measured and interpolated points.

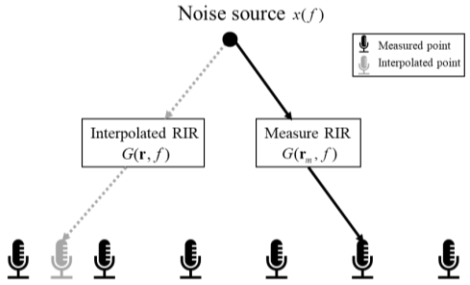

Fig. 4: Schematic diagram for defining the sensor interpolation problem.

B. ATF interpolation using kernel method

The schematic diagram of the sensor interpolation problem is shown in Fig. 4. In practical implementation, the training performance can be affected by the limited usage of the microphones. Hence, the goal of sensor interpolation is to increase the ATFs in between the control region and improve the performance in the CRNN training process. The objective

function of the ATF interpolation using kernel method is formulated as

$$\min_{\hat{G}} \mathcal{J} = \sum_{m=1}^{M} \left| \hat{G}(\mathbf{r}_m) - G(\mathbf{r}_m) \right|^2 + \beta \left\| \hat{G} \right\|_{\mathcal{H}}^2, \tag{13}$$

where $\hat{G}(\mathbf{r}_m)$ and $G(\mathbf{r}_m)$ denote the interpolated and measured ATFs at the position vector $\mathbf{r}_m$ of the mth microphone, respectively, M represents total number of measure points, β is the regularization parameter, and $\|\cdot\|_{\mathcal{H}}^2$ is the inner product within the Hilbert space $\mathcal{H}$. A closed-form solution of the interpolated $\hat{G}(r)$ can be obtained as [12]

$$\hat{G}(\mathbf{r}) = \boldsymbol{\kappa}^T(\mathbf{r}) \left(\mathbf{K} + \beta \mathbf{I}_M \right)^{-1} \mathbf{G}, \tag{14}$$

where $\mathbf{I}_M$ denotes the $M \times M$ identity matrix, and $\mathbf{r}$ is position vector within the control region,

$$\mathbf{K} = \begin{bmatrix} j_0(k\|\mathbf{r}_1 - \mathbf{r}_1\|_2) & \cdots & j_0(k\|\mathbf{r}_1 - \mathbf{r}_M\|_2) \\ \vdots & \ddots & \vdots \\ j_0(k\|\mathbf{r}_M - \mathbf{r}_1\|_2) & \cdots & j_0(k\|\mathbf{r}_M - \mathbf{r}_M\|_2) \end{bmatrix}, \tag{15}$$

$$\boldsymbol{\kappa}^T(\mathbf{r}) = \begin{bmatrix} j_0(k\|\mathbf{r} - \mathbf{r}_1\|_2) & \cdots & j_0(k\|\mathbf{r} - \mathbf{r}_M\|_2) \end{bmatrix}, \tag{16}$$

is the Gram matrix and kernel function in which k is the wave number, and $j_0(\cdot) = \sin(\cdot)/(\cdot)$ denotes the zeroth-order spherical Bessel function, also known as the sinc function.

C. Network Architecture

The CRNN [17] in encoder-decoder architecture is employed in the proposed L-MANC, as illustrated in Fig. 5. The encoder consists of five convolutional layers to extract acoustic features from the input signal $\mathbf{X}(t, f)$. Batch normalization (BN) along with the exponential linear unit (ELU) activation function is applied after each convolutional layer, hyperbolic tangent (Tanh) activation function for last convolutional layer. The decoder part comprises five deconvolutional layers that reconstruct the signal. The skip

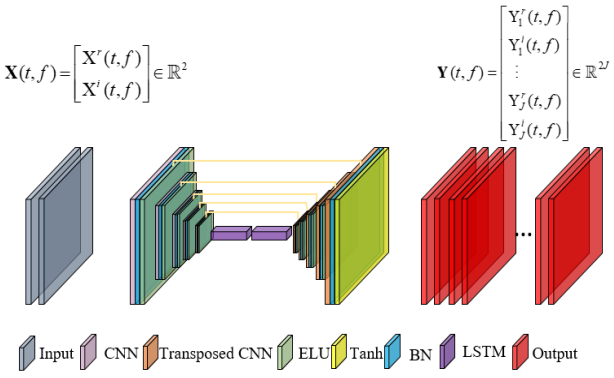

Fig. 5: The network architecture of CRNN.

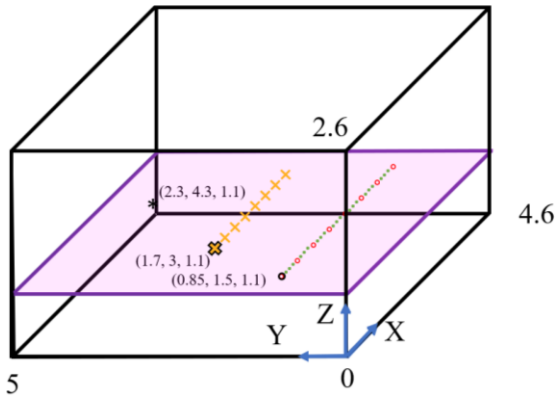

Fig .6: Environmental setups for the data generation. "*" represents the noise source, and "×" represents the secondary loudspeakers. "◦" represents the measured point, while "•" denotes the interpolated points.

connections concatenate each output layer in the encoder and the previous layer in the decoder. These skip connections allow the network to preserve salient features for the decoder. To effectively capture a broader context in the frequency domain, a stride of 2 is applied to all convolutional and deconvolutional layers along the frequency dimension. Zero padding is applied in each encoder-decoder layer to maintain the size consistency. Two long short-term memory (LSTM) units [18] between the encoder and decoder are included in the proposed architecture. The loss function of L-MANC is defined as the averaged error signal power

$$\mathcal{L} = \frac{1}{KFT} \sum_{k=1}^{K} \sum_{f=0}^{F} \sum_{t=0}^{T} \left| e_k(t,f) \right|^2 \tag{17}$$

where $|\cdot|$ denotes the absolute operation.

IV. SIMULATION SETTINGS

A. Dataset Generation and Parameter Settings

The simulation environment is illustrated in Fig. 6. A rectangular room with dimensions of 4.6 × 5 × 2.6 m was considered in the simulation. The ATFs at the control points were generated by the image source method (ISM) [19] In the L-MANC system, one noise source, nine secondary loudspeakers, and eight error microphones were used. The noise source was placed at (2.3, 4.3, 1.1) m. The nine secondary loudspeakers were placed from (1.7, 3, 1.1) m to (2.9, 3, 1.1) m with an equal spacing of 0.15 m between the loudspeakers. The eight error microphones were placed from (0.85, 1.5, 1.1) m to (3.65, 1.5, 1.1) m with an equal spacing of 0.4 m between the microphones. To extend the control region within the limited

control points, the kernel ridge regression method was used to interpolate the ATFs at the intervals between each pair of error microphones, with equal spacing of 0.1 m. A total of 21 additional interpolated points of ATFs were generated. The control frequency range is within the aliasing frequency of the deployment of the loudspeaker array for the control region, which is 1143 Hz to be specific. Within the control frequency range, the interpolated ATFs show good agreement with the ground-truth ATFs generated by ISM. In this room, the reverberation time (T60s) of 0.2 seconds was used for the training and testing stage. To improve the performance of the CRNN in the proposed L-MANC, a large variety of noise data were adopted in the training stage. For the generation of the training set, several 2-second audio clips were randomly selected from the NOISEX-92 database [20] to create 10000 training data. For the testing dataset, we used five types of unseen input noise, including four types of industrial machine sounds (fan, pump, valve, slider) [21] and speech data [22] 1200 non-speech and 300 speech unseen clips were generated for the validation of L-MANC. Each noise signal from the training and testing dataset was sampled at a rate of 16 kHz. The short-time Fourier transform (STFT) with a 20 ms Hann window and a 10 ms frame shift was applied to obtain the network input, $X(t, f)$. The optimizer used in the training process was AMSGrad [23] with a learning rate of 0.001. The batch size was set to be 15. The training process was stopped when the training loss was not decreased after 10 consecutive epochs. The network architecture and the hyperparameters are summarized in Table. 1. Hyperparameters are specified in the format of (kernel size, strides, output channel number), and T denotes the number of the time frames in an STFT spectrogram.

B. Evaluation Metrics

The validation of the proposed method and the baselines is performed on the time domain processed signals. Therefore, the evaluation metric, MSNR [24] is defined as follows:

$$\mathrm{MSNR} = 10\log_{10}\frac{\sum_{k=1}^{K}\sum_{n=0}^{T_s}\left|d_k(n)\right|^2}{\sum_{k=1}^{K}\sum_{n=0}^{T_s}\left|e_k(n)\right|^2}, \tag{18}$$

where $d_k(n)$ represents the nth sample point of the primary noise signal that needs to be canceled at the kth error microphone, $e_k(n)$ represents the nth sample point of the error signal at the kth error microphone, and T_s is the total number of samples. The larger MSNR value indicates better ANC performance.

Table. 1: Detail of the hyperparameters of the CRNN architecture

Layer name	Input size	hyperparameters	Output size
Conv2d_1	2×513×T	(3, 2), (2, 1), 20	20×256×T
Conv2d_2	20×256×T	(3, 2), (2, 1), 40	40×127×T
Conv2d_3	40×127×T	(3, 2), (2, 1), 80	80×63×T
Conv2d_4	80×63×T	(3, 2), (2, 1), 128	128×31×T
Conv2d_5	128×31×T	(3, 2), (2, 1), 256	256×15×T
Reshape_1	256×15×T	-	T×3840
LSTM_1	T×3840	3840	T×3840
LSTM_2	T×3840	3840	T×3840

V. SIMULATION RESULTS

A. Comparison of L-MANC and the baselines

Table. 2 summarizes the MSNR values by using the proposed method and the baselines. The value of the measured point is determined as the average of the MSNR values of all the measurement points, and the same principle applies to the interpolated point. It can be seen that L-MANC demonstrates superior MSNR performance compared to other baseline approaches. Since TIKR attempts to minimize the error at the measured control points, the MSNR performance obtained at the measured points can be compared to that of L-MANC.

Table. 2: MSNR obtained by (a) L-MANC, (b) Fx-MCLMS, (c) TIKR, (d) LCMV

	Measured	Interpolated
L-MANC	21.04	19.38
Fx-MCLMS	6.62	2.77
TIKR	20.65	1.09
LCMV	13.48	7.93

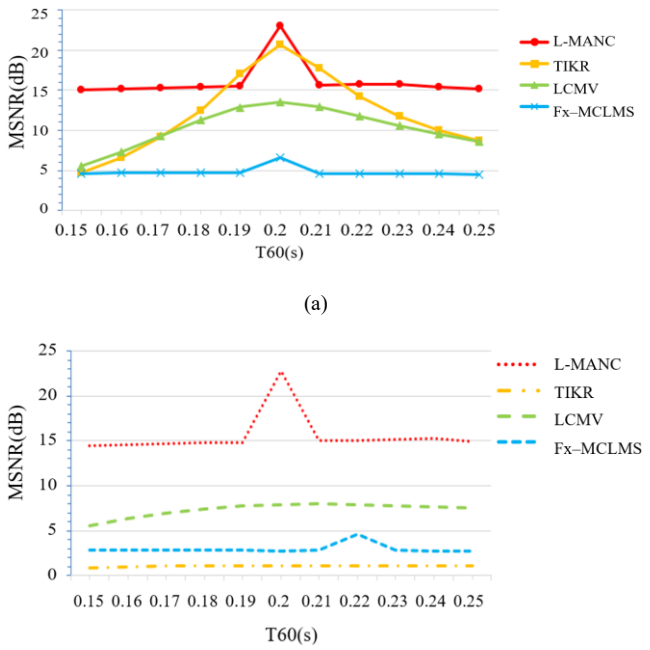

Fig. 7: MSNR values for four different ANC methods under different reverberation time (T60) from 0.15 s to 0.25 s. (a) MSNR value at the measured points, and (b) MSNR value at the interpolated points

However, its performance degrades significantly at the adjacent region of control points. In contrast, because LCMV addresses the error at the interpolated points while maintaining the performance at the control points, the MSNR obtained within the extended control points is not considerably degraded. However, L-MANC still shows superior performance at both measured and interpolated points.

Table. 3: MSNR obtained by L-MANC under different T60 environments

T60(s)	Measured	Interpolated
0.8	22.74	20.75
1.0	21.67	19.71
1.3	21.89	19.93

To ensure the versatility and generalizability of the proposed methodology, variations were introduced in the T60 values. As described in the section of data generation, the measured RIRs were generated with T60 = 0.8, 1.0, and 1.2s to simulate more realistic environment. Multiple networks were trained according to a specific T60 value based on the procedure of our L-MANC approach. The results in Table 3 present the summary of the ANC performance in terms of MSNR values across different T60 environments. The proposed method demonstrates consistent ANC performance across different environment and delivers outstanding results no matter in the measured or interpolated points.

B. Robustness of L-MANC

In this section, we investigate the robustness of the ANC methods in the face of variations on reverberation time and the primary noise positions.

1. Variations in reverberation time

The effectiveness of the ANC algorithms is evaluated by considering various reverberation times, covering a range of T60 from 0.15 s to 0.25 s. The results of the MSNR are shown in Fig. 7. In the study, the ATFs for the L-MANC and other algorithms were generated using T60 values of 0.2 s. All the approaches showed their highest performance at T60 = 0.2s at the measured points. Furthermore, our proposed approach consistently demonstrated the effectiveness across all T60 scenarios compared to the baselines. At the interpolated points, only the L-MANC method demonstrated performance comparable to that of the measured points. The other algorithms exhibited variation more than 5dB from the performance at the measured points, providing further confirmation of the superior results across different T60 values.

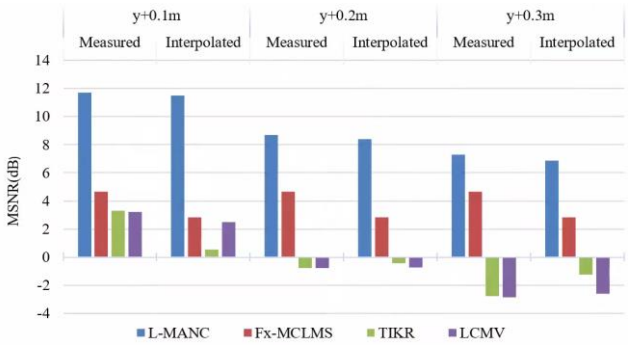

Fig. 8: MSNR performance for perturbed primary noise positions.

2. Variations in the primary noise positions

The proposed ANC is evaluated for perturbed noise source positions. The noise source that is initially located at (2.3, 4.3, 1.1) m is moved along the y-axes from 0.1 to 0.3 m with the increments of 0.1 m. The results are summarized in Fig. 8. It is clear that a slight movement of the noise source causes the MSNR to decrease for these ANC approaches. However, L-MANC shows superior performance compared to the baselines at all measured points and interpolated points. Furthermore, because the interpolated points were considered

during the training phase, the spatial variance in terms of MSNR in L-MANC between the measurement and interpolation points is small. These results indicate that the ANC performance of L-MANC can be achieved in a broadened region in the face of the primary noise position variations.

VI. CONCLUSIONS

In this paper, a learning-based feedforward ANC technique, L-MANC, has been formulated in the light of the model-matching principle. The CRNN network with an encoder-decoder structure is used to generate the loudspeaker signals and to reduce the error signal captured by the microphones. To ensure practicality in real-world scenarios, the unmeasured ATFs within a given region can be interpolated by the kernel ridge regression method. This allows the DNN to be trained with very limited measurements. The experimental results have demonstrated the superior ANC performance achieved by the proposed L-MANC compared to several baseline methods by using the objective metric, MSNR. The proposed method outperforms other baseline approaches in both the measured and interpolated points, indicating that comprehensive ANC control within a defined region can be achieved. The robustness of L-MANC is also validated for the variations in the reverberation time and noise positions compared to the baselines.

***Abstract* — In this paper, we propose an active noise control (ANC) system for axial fan and conduct a real time experiment. The experimental results compare three different experimental setups to verify the impact of microphone protection on system performance. The experimental results show that the final experimental setup can achieve satisfactory performance.**

I. INTRODUCTION

In the operation of electrical and electronic products, heat dissipation occurs between power consumption and energy conversion. In order to prevent high temperature from causing system malfunction, shutdown or even loss, we must rely on cooling devices to reduce the ambient temperature to stabilize the system, and fans play an important role here. Usually, traditional passive noise control is used to prevent fan noise, such as using sound-absorbing materials to isolate noise, or changing the material, number, and angle of fan blades, and using institutional design to make the noise generated by the fan less harsh.

Since the main function of the fan is to generate air pressure and air flow, at least the air flow out of the entrance must be retained, the passive noise elimination material to isolate the noise has its imperfections. The ANC system uses the principle of superposition [1] to offset the noise energy by using the anti-noise generated by the speakers. Compare to the passive noise control method, it can handle the noise better without affecting the function of the fan itself.

This paper introduces an axial fan system using ANC, which aims to reduce fan noise and avoid affecting the airflow in and out of the fan, and finds that wind interference directly affect the system performance by comparing the performance of three different settings and two different algorithms.

II. PROPOSE SYSTEM

In this section, we introduce the fan fundamental frequency equation and analyze the noise spectrum of the axial fan, and then propose the fan ANC algorithms. We set up the experiment on a steel frame mold to perform noise reduction for the location of the axial fan outlet, and compare the performance difference between them in three different settings.

A. Noise analysis of axial fan

Fan noise consists of two components, narrowband noise and broadband noise. Broadband noise is generated by the turbulent structure of the fan and the collision of airflow. The narrowband noise of a fan is generated when the fan blade rotates and radiates outward from the gap between the end of the fan blade and the fan casing. The Blade Pass Frequency (BPF) of this noise is proportional to the fan speed s (rpm) and the number of fan blades n [2], The BPF is generated as:

$$BPF = n * s / 60 \tag{1}$$

The fan noise is composed of this frequency and its multiplier frequency.

The fan used in this experiment is an axial fan with 7 blades, an operating voltage of 12 volts, and a rotational speed of 7000 rpm. According to the fundamental frequency calculation formula (1), the noise fundamental frequency can be obtained to be about 817Hz. We use a microphone to measure the noise spectrum of the fan at 30 cm in front of the air outlet, as shown in Fig. 1. Since this experiment focuses on eliminating noise within 3000Hz, the fundamental frequency of 817Hz, its double frequency of 1634Hz and its triple frequency of 2451Hz are the most important narrowband noises. From the spectrum, it could be seen that there is a high-energy noise in the 0~500Hz part. Since we are recording from the air outlet of the fan, it is the sound caused by the wind hitting the microphone. In this experiment, the 1x1 feedback FXLMS [3] algorithm and the 1x1 parallel form narrowband FXLMS

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

algorithm would be used to suppress the noise at the air outlet of the fan for narrowband noise.

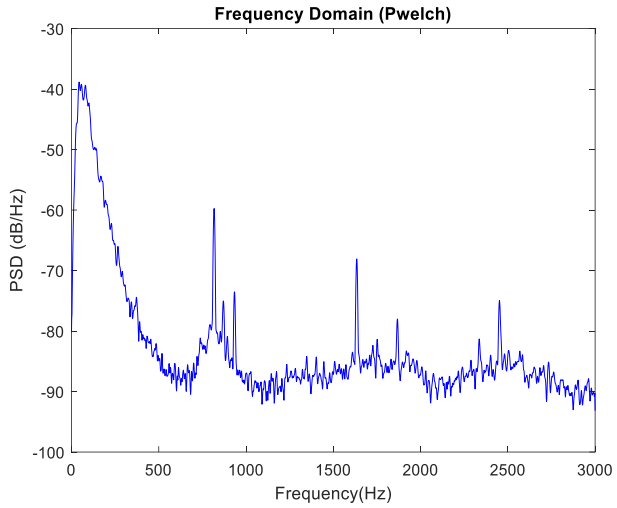

Fig. 1 The noise spectrum of the fan at 30 cm in front of the air outlet.

B. *Feedback FXLMS algorithm*

The architecture of the single channel feedback ANC system is shown in Fig. 2. In the feedback FXLMS algorithm [4], the reference signal $x(n)$ is obtained by combining the error signal $e(n)$ and the output signal $y(n)$, and the calculation formula is as follows:

$$x(n) \equiv d'(n) = e(n) + \sum_{m=0}^{M-1} \hat{s}_m y(n-m) \qquad (2)$$

where $\hat{s}_m$ is the coefficient of the M-order estimated secondary path filter $\hat{S}(z)$. The system obtains the output signal $y(n)$ from the reference signal $x(n)$ through the filter $W(z)$:

$$y(n) = \sum_{l=0}^{L-1} w_l(n) x(n-l) \qquad (3)$$

The signal $x(n)$ becomes $x'(n)$ after passing through the estimated secondary path:

$$x'(n) = \sum_{m=0}^{M-1} \hat{s}_m x(n-m) \qquad (4)$$

And update the filter coefficients with $x'(n)$, μ and $e(n)$. Where μ is the step size:

$$w_l(n+1) = w_l(n) + \mu x'(n-l) e(n), l = 0,1,\dots,L-1 \qquad (5)$$

Update the coefficient $w_l(n)$ obtained by the finite impulse response (FIR) of the adaptive filter until the system converges to achieve the effect of denoising.

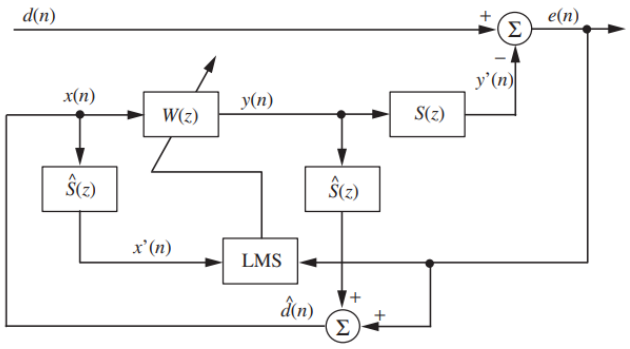

Fig. 2 The block diagram of adaptive feedback ANC system.

C. *Parallel form narrowband FXLMS algorithm*

Parallel form narrowband ANC [5] is based on the FXLMS algorithm, which splits the signal obtained by the non-acoustic sensor into multiple reference signals at a single frequency. Its block diagram is shown in Fig. 3.

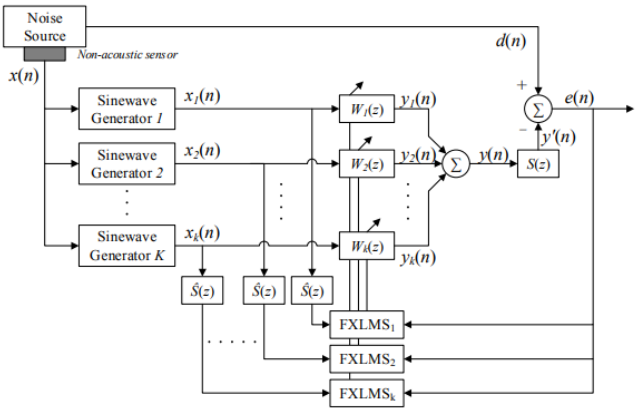

Fig. 3 The block diagram of parallel form narrowband ANC system.

The reference signal $x(n)$ can be split into multiple sine wave signals $x_1(n)$, $x_2(n)$ to $x_K(n)$:

$$x_k(n) = A_k \cos(\omega_k n), k = 1,2,\dots,K \qquad (6)$$

where K is the total number of sine wave signals. And the output signal $y(n)$ is accumulated after the filter of the adaptive filter $W_k(z)$:

$$y(n) = \sum_{k=l}^{K} \sum_{l=0}^{L-1} w_{kl}(n) x_k(n-l) \qquad (7)$$

The reference signal $x_k(n)$ becomes $x'_k(n)$ after passing through the estimated secondary path:

$$x'_k(n) = \sum_{m=0}^{M-l} \hat{s}_m x_k(n-m), k = 1, \dots, K \quad (8)$$

where $\hat{s}_m$ is the coefficient of the M-order estimated secondary path filter $\hat{S}(z)$.

$$w_{kl}(n+1) = w_{kl}(n) + \mu_k x'_k(n-l)e(n) \quad (9)$$

where $l = 0,1, \dots, L; k = 1,2, \dots, K$ and μ_k is the step size. Constantly update and adjust the filter coefficients in (9) until the system converges.

D. Experimental Setup

We would use a 10cm acrylic duct to stick to the air outlet of the fan and seal it. The purpose is to make the noise easy to control, and use the acrylic duct to limit the direction of sound travel. The installation configuration is shown in Fig. 4. The speaker was installed in the center of the fan outlet where there

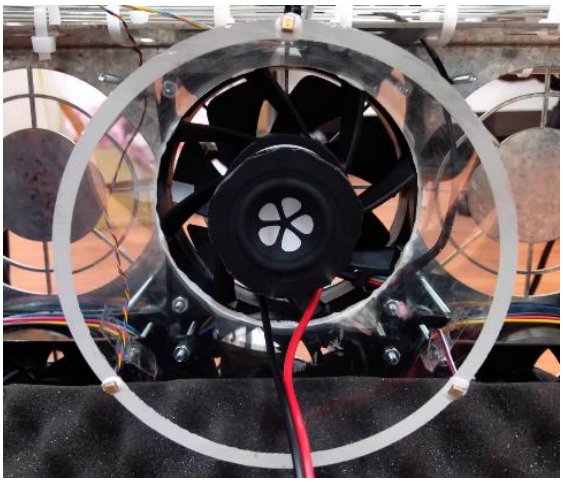

Fig. 4 Experimental setup of ANC fan system.

was no wind. Three error microphones were arranged on the nozzle. The angle between the microphones was 120°, and the received signals were added and averaged.

In order to measure the global noise cancellation effect, 25 microphone measurement points were placed 20 cm in front of the fan outlet, as shown in Fig. 5. And according to equation (10), the noise energy distribution is calculated. P is the energy, N is the sampling number, $y(n)$ is the amplitude of the sampling point.

$$P = 10 * log_{10}[\ 1/N * \sum_{n=1}^{N-1} y(n)^2\ ] \quad (10)$$

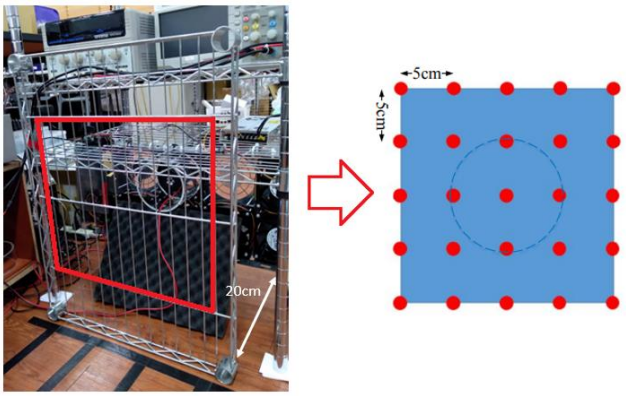

Fig. 5 Axial fan noise distribution measurement points.

III. Real-Time Experiments Results And Analysis

This section introduces the developed axial fan ANC real-time experiments. We improved the initial settings to verify the impact of microphone protection on system performance. After analyzing and comparing, we got the best setting results and showed the noise reduction results of the experiment.

A. Microphones without any protection

Since the microphones were not protected in the settings of the Fig. 4, its frequency spectrum was largely masked by broadband, resulting in only the fundamental frequency and its triple frequency being exposed. We used the feedback algorithm for noise reduction, as shown in Fig. 6. Since the feedback algorithm replaces the reference microphone by

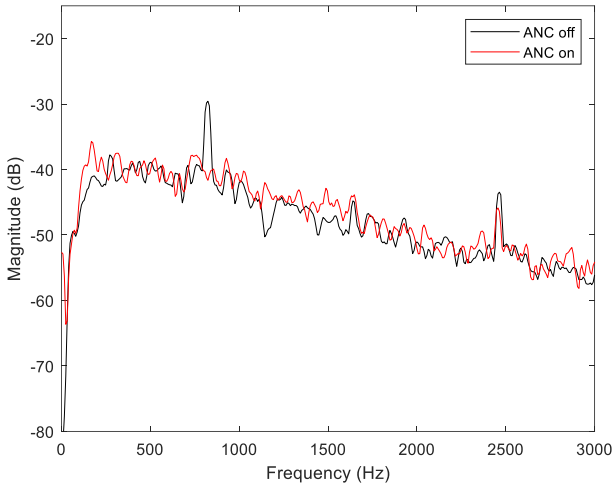

Fig. 6 The spectrum measured at the error microphone in the feedback system.

combining the past error signal with the output signal, the noise must be predictable [6]. However, because the microphones were not protected, the error microphones would feedback a broadband noise generated by the wind, that is, unpredictable noise, to the system for update, which would affect the system performance.

Next, we used the parallel form narrowband algorithm to perform ANC, and set 817Hz and 2451Hz as reference signals. The frequency spectrum is shown in the Fig. 7. It could be found that when ANC was on, although the fundamental frequency dropped, a broadband noise was generated, which exceeded the energy of ANC off. We speculate that this is also the result of the microphone not being protected.

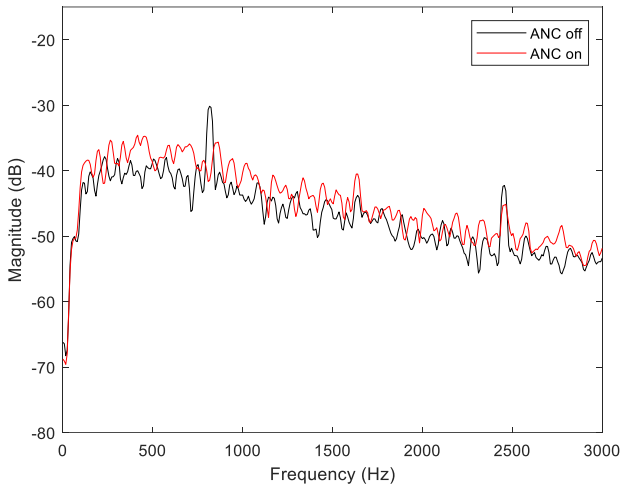

Fig. 7 The spectrum measured at the error microphone in the narrowband system.

B. Microphones with tape protection

In order to solve the above problem, we would use the settings in Fig. 8 and use the tape to protect the microphones. First, we performed the feedback algorithm, as shown in Fig. 9, it could be seen that when the ANC was on, there was no additional broadband noise. The effect of ANC was much better than the settings of unprotected microphones and the fundamental frequency could be reduced by 15dB. In addition, we used parallel form narrowband to perform ANC, as shown in Fig. 10, which was also better than the previous settings, the double frequency of 1634Hz could also be reduced by 2 or 3dB.

C. Microphones with acoustic sponge protection

We would use the settings in Fig. 11 and use the sound-absorbing sponges to protect the microphones. First, we

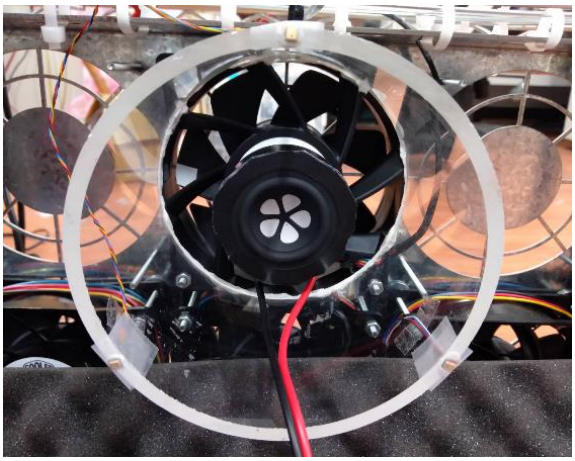

Fig. 8 We used the tape to protect the microphones.

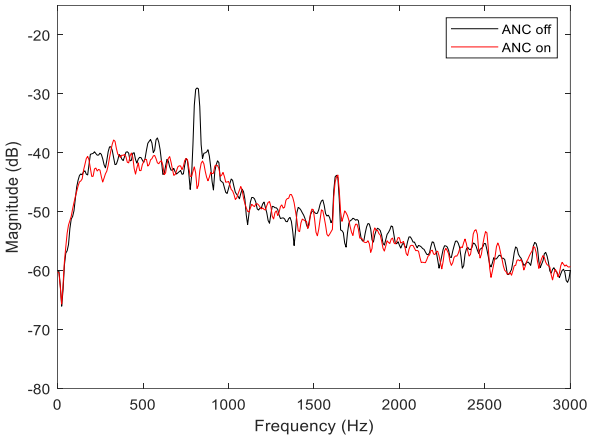

Fig. 9 The spectrum measured at the error microphone in the feedback system.

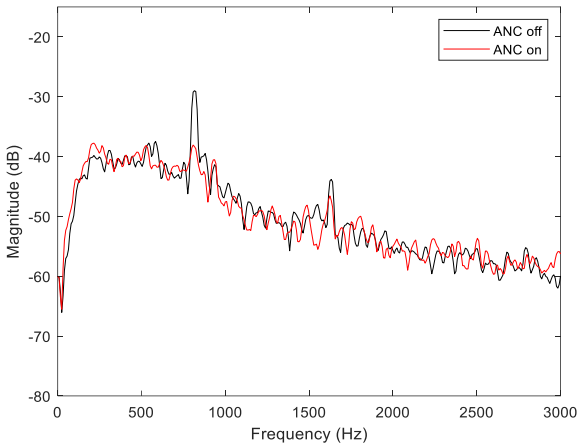

Fig. 10 The spectrum measured at the error microphone in the narrowband system.

performed the feedback algorithm, as shown in Fig. 12, it could be seen that when the ANC was on, there was no additional broadband noise. Applying the feedback algorithm to this setting could reduce the fundamental frequency by about 18dB.

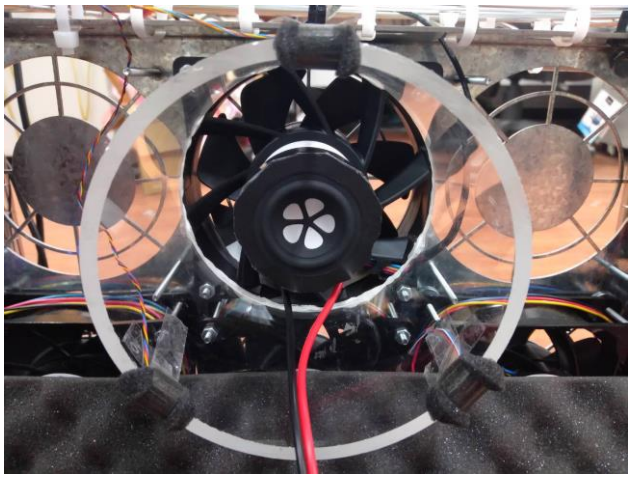

Fig. 11 We used the sound-absorbing sponge to protect the microphone.

From this spectrum, it could be seen that the energy after the reduction of the fundamental frequency was still higher than the energy of the double and triple frequencies, meaning that the noise energy of 1634Hz and 2451Hz was too low, so that the system only processed the noise with stronger energy. That's why we can see that only the fundamental frequency has effect.

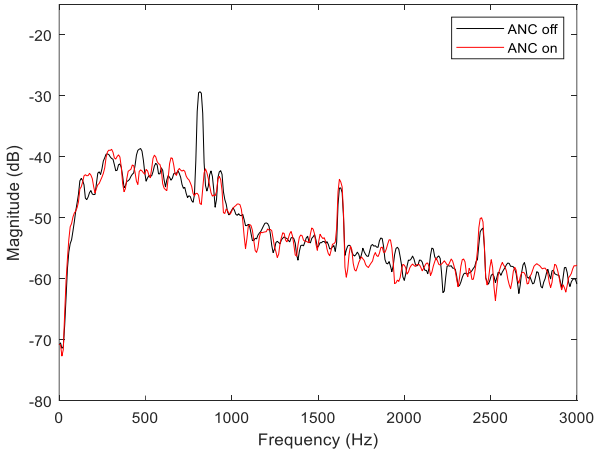

Fig. 12 The spectrum measured at the error microphone in the feedback system.

We used parallel form narrowband to perform ANC, and set 817Hz, 1634Hz, and 2451Hz as reference signals. The frequency spectrum is shown in the Fig. 13. We can see from

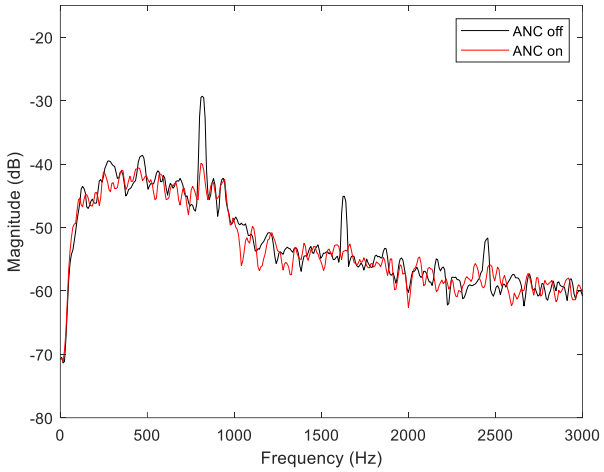

Fig. 13 The spectrum measured at the error microphone in the narrowband system.

the spectrum that there was no broadband noise, and the single frequencies were eliminated at the frequencies of the reference signals we set. This proves that the poor performance of the previous setup was due to the influence of the wind, and that if we protected the microphones well, we could make the system perform better.

We also used the method in Fig. 5 to measure the noise energy distribution diagram of the parallel form narrowband system with acoustic sponge protection. We subtracted the energy of ANC off from the energy of ANC on, and plotted the distribution diagram of the noise reduction energy, as shown in Fig. 14. It could be seen that the main noise reduction was distributed at the overlap of the microphones and the upper right corner, which showed that this system was effective and could achieve global noise reduction.

IV. CONCLUSIONS

We optimized the ANC performance of the axial fan system by changing the setting. From the experiment, we can know that the important factor will affect the system performance, it is the wind. And the microphones need to be protected to avoid the noise caused by the wind. It has been proved by experiments that if the microphone is well protected, the performance of ANC system can be improved.

***Abstract*—This paper proposes a hybrid system of the selective fixed-filters active noise control (SFANC) and the modified error filtered-x DCT-LMS (MEFxDCTLMS) algorithm. Conventional SFANC systems have a problem that the noise reduction performance deteriorates due to the incorrect selection of fixed filters. In addition, the conventional SFANC system uses the spectrogram by short-time Fourier transform (STFT) of the reference signal detected by the reference microphone as an input in a two-dimensional convolutional neural network (2D-CNN). However, the processing delay for calculating the spectrogram delays the fixed filter selection in SFANC, resulting in degraded noise reduction performance. To compensate for the fixed filter, we propose a system in which an adaptive filter based on MEFxDCTLMS is vertically connected to SFANC. This improves the degradation of the noise reduction performance due to the mis-selection of the fixed filter and improves the robustness against changes in the target noise. Furthermore, by using Sliding DCT instead of STFT, the fixed filter selection can be performed at the appropriate timing while maintaining the selection accuracy of 2D-CNN, thereby improving the noise reduction performance.**

I. Introduction

In recent years, the development of transportation and industrial equipments has caused the noise in a variety of situations. Active noise control (ANC) systems [1]-[3] are used to reduce such noise. It is an effective method to reduce the noise level at the noise control point using anti-noise. Anti-noise with the same amplitude and opposite phase for the unwanted noise is generated and emitted to reduce the noise at the noise control point based on the principle of superposition. Conventional ANC systems typically use noise control filters designed by adaptive algorithms [4] such as filtered-x normalized least mean square (FxNLMS) algorithm to generate anti-noise.

Among the ANC methods that have been proposed, the selective fixed-filters ANC (SFANC) [5]-[9] is expected to be a computationally efficient noise reduction method because it is based on pre-designed fixed filters. However, there are some problems in SFANC. The SFANC system uses the convolutional neural network (CNN) [10]-[13] as the noise classifier and switches multiple pre-designed noise control filters according to the noise. This allows the system to respond quickly to changes in the noise. In conventional 2D-CNN based SFANC, acoustic signals are transformed to a frequency-domain representation using the short-time Fourier transform (STFT) [14]. The STFT calculation is performed by applying a window function to the signal and summing the extracted samples. Therefore, to increase the frequency resolution, it is necessary to use a window function with a long window length. However, a longer window length increases the computational complexity and decreases the response speed to noise changes, making it unsuitable for implementation in ANC systems. In addition to the STFT, the sliding discrete cosine transform (SDCT) is another method of transforming a signal into the frequency domain [15]. SDCT can instantly convert a signal from the time domain to the frequency domain using a recursive formula and requires far fewer operations than STFT. Sliding Discrete Fourier Transform (STFT), a method similar to SDCT, requires an additional operation to calculate absolute values to convert from the real time domain to the complex frequency domain. In this paper, SDCT is used as input for 2D-CNN in SFANC.

Another problem in SFANC is that immediately after noise variation, the filter selected by the classifier may not match the correct filter suitable for the noise. To solve this problem, a hybrid algorithm of SFANC and FxNLMS has been proposed in applied research of SFANC [8]. The hybrid system achieved high tracking performance for noise fluctuations. Moreover, it is stated that future developments in this research are expected to combine SFANC with other adaptive algorithms. Therefore, we propose to combine SFANC with modified error FxDCT-LMS (MEFxDCTLMS) algorithm. In this paper, we show the effectiveness of the hybrid SFANC-MEFxDCTLMS system.

II. Hybrid SFANC-MEFxDCTLMS

In the Hybrid SFANC-MEFxDCTLMS, 2D-CNN using SDCT is used as the classifier and the MEFxDCTLMS based adaptive filter fine-tunes the secondary noise.

A. Sliding Discrete Cosine Transform

DCT is a method of converting a time domain signal into the frequency domain. This method is more efficient than DFT because it uses a cosine function and outputs only the real part. The DCT coefficients of the signal sequence $u(n)$ at time n are defined as

$$C_m(n) = \frac{1}{2} k_m (-1)^m W_{2M}^{m/2} A_m(n), \quad (m = 0, 1, \cdots, M-1), \quad (1)$$

where

$$k_m = \begin{cases} \sqrt{2} & (m = 0) \\ 1 & (\text{otherwise}) \end{cases}, \quad (2)$$

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

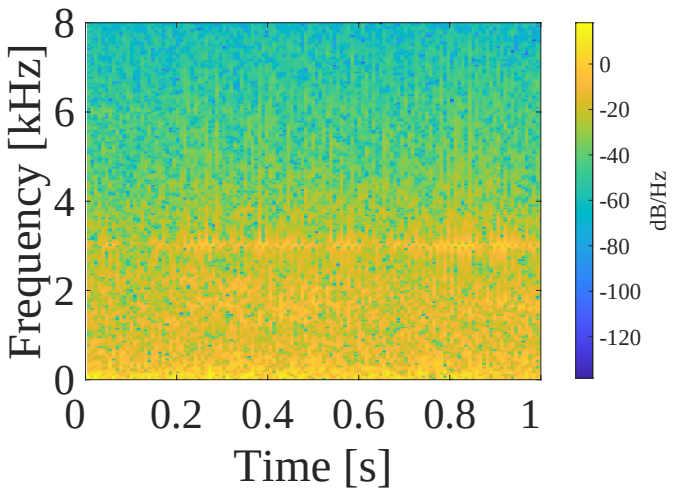

Fig. 1. DCT coefficient color map of airplane noise.

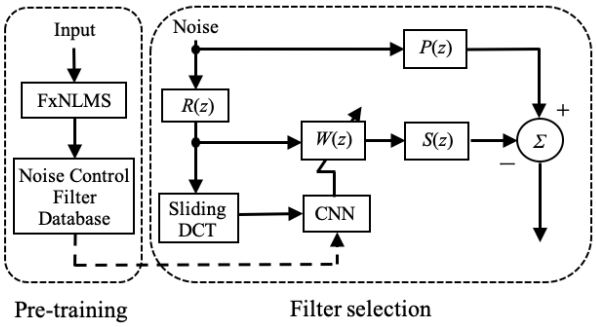

Fig. 2. Block diagram of SFANC.

$$W_{2M} = \exp\left(-\frac{j2\pi}{2M}\right). \tag{3}$$

M is the number of taps, $A_m(n)$ is the sum of two complementary DFT presented by

$$A_m(n) = A_m^{(1)} + A_m^{(2)}. \tag{4}$$

where

$$A_m^{(1)}(n) = W_{2M}^{m} A_m^{(1)}(n) + u(n) - (-1)^m u(n-M), \tag{5}$$

$$A_m^{(2)}(n) = W_{2M}^{-m} A_m^{(2)}(n) + W_{2M}^{-m}\left(u(n) - (-1)^m u(n-M)\right). \tag{6}$$

The SDCT is obtained from the first-order difference equation, so the computational complexity is negligible. Fig. 1 shows an example of the SDCT coefficients obtained from equation (1) arranged in a time series. Fig. 1 plots the SDCT coefficients for 1 second of aircraft noise on a color map.

B. Selective Fixed-filter ANC with SDCT input CNN

Fig. 2 shows a block diagram of the SFANC system, where $P(z)$ is the primary path, $S(z)$ is the secondary path, and $W(z)$ is the noise control filter selected from the filter database by CNN. The SFANC system is divided into two main stages. The first is the fixed filter pre-design stage. Fixed filters are pre-designed and stored in a database using adaptive algorithms for noise with different frequency spectra. The second is the noise control stage. The noise control filter that provides the best reduction for the noise acquired with the reference microphone is selected from the database and applied to the ANC system. In SFANC systems, CNNs are commonly used as noise classifiers because they are well suited to handle the frequency representation of noise signals.

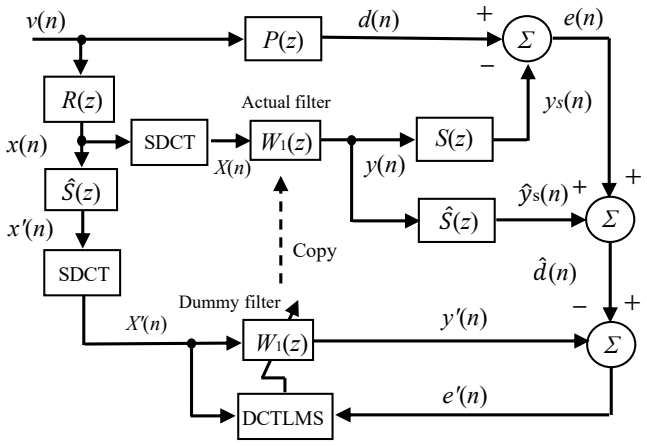

Fig. 3. Block diagram of MEFxDCTLMS based ANC system.

C. MEFxDCTLMS Algorithm

MEFxDCTLMS is an application of MEFxNLMS with a different adaptive algorithm. Fig. 3 shows a block diagram of the MEFxDCTLMS based ANC system, where $P(z)$ is the primary path, $S(z)$ is the secondary path, $\hat{S}(z)$ is the model of the $S(z)$, and $W_1(z)$ is the noise control filter based on MEFxDCTLMS.

In Fig. 3, the noise control filter $W_1(z)$ is updated by

$$w_m(n+1) = w_m(n) + \frac{\mu}{\hat{\lambda_m}(n)} X'_m(n) e'(n). \tag{7}$$

where μ is the step size parameter for the noise control filter, $X'_m(n)$ is the filtered SDCT coefficients, $e'(n)$ is the error signal given as $e'(n) = \hat{d}(n) - y'(n)$, and $\hat{\lambda}$ is the eigenvalue expressed by the recursive equation

$$\hat{\lambda_m}(n) = \gamma \hat{\lambda_m}(n-1) + \frac{1}{n}(X'^2_m(n) - \gamma \hat{\lambda_m}(n-1)). \tag{8}$$

The forgetting factor γ is used in the range of 0 to1. After updating, the filter weight coefficients are copied to noise control filter $W_1(z)$. This system uses a secondary path model to generate the corrected error signal, so the delay caused by the secondary path can be disregarded. Therefore, the step size parameter can be larger than when using the error signal, which speeds up the convergence of the algorithm.

D. Implementation of MEFxDCTLMS in SFANC

Fig. 4 shows a block diagram of the hybrid MEFxDCTLMS-SFANC system. In the proposed method, an adaptive filter

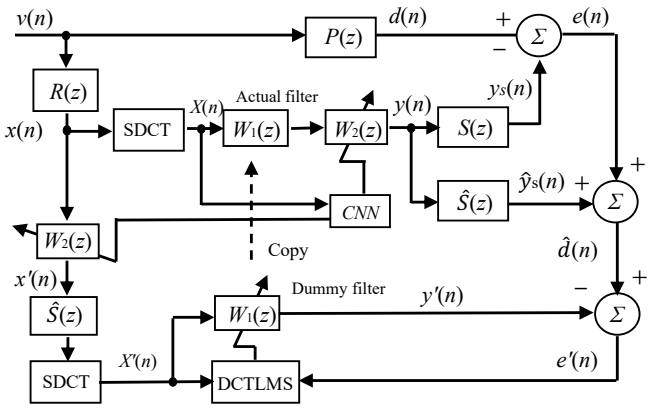

Fig. 4. Block diagram of the hybrid MEFxDCTLMS and SFANC system.

for fine tuning is connected in series with a fixed filter. This allows the adaptive filter to play a supplementary role to the fixed filter, and it is thought that it can achieve higher noise reduction than only the fixed-filter ANC. MEFxDCTLMS performs background optimization with dummy filters. Therefore, if adaptive algorithms are not needed, computational efficiency can be improved by running only the SFANC system. The system determines that the type of noise has changed by comparing the filter selection results with those of the past. Only fixed filters can be introduced at the moment the noise changes to allow time for the adaptive filter to converge.

III. Simulation Results

In this section, a 2D-CNN to be used as a noise classifier is trained by using audio datasets and implemented in SFANC. Further, this section verifies effectiveness of the proposed method for non-stationary noise through noise reduction simulations.

A. 2D-CNN Learning

Fig. 5 shows the CNN model architecture used for SFANC system. The middle layer of the CNN uses two convolution layers, batch normalization, ReLU activation function, and a Maxpooling layer. Of the 96,000 acoustic datasets, including synthetic and environmental sounds, e.g. household appliances and factory noise, car and airplane engine noise, 10,000 each are used for testing and validation, with the remainder used for training.The acoustic datasets are converted to the frequency domain by SDCT and the training labels are given in 15 classes based on the frequency characteristics of the acoustic signal. The number of training epochs is 50 and the Adam algorithm is used for optimization. The classification accuracy of the 2D-CNN on the test data was 97.06%.

B. Pre-designed Noise Control Filters

The pre-design of noise control filters by optimization using the broadband noise is shown in Table I. Design conditions for noise control filters are shown in Table II. Noise control

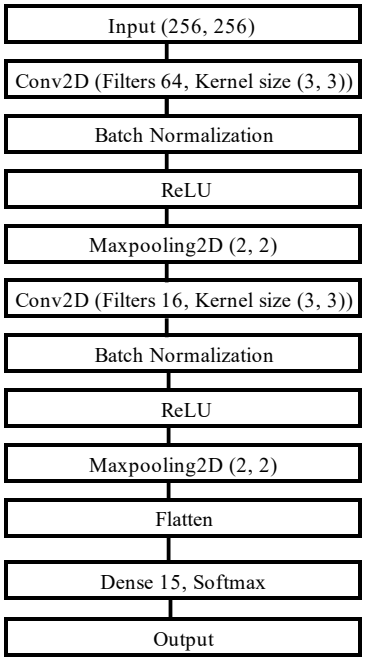

Fig. 5. The 2D-CNN architecture in SFANC system.

TABLE I

Label 1-8	20-1000 Hz, 1000-2000 Hz, ⋯, 7000-8000 Hz
Label 9-12	20-2000Hz, 2000-4000 Hz, ⋯, 6000-8000 Hz
Label 13,14	20-4000 Hz, 4000-8000 Hz
Label 15	20-8000 Hz

filters for SFANC are pre-designed using the MEFxDCTLMS algorithm. Each filters are effective for signals with a frequency response similar to that of the signal used in the pre-design. These filters are stored in a database and the appropriate filters are selected from the CNN classification results and used in the SFANC system. Each of the filters created in this study can reduce the target noise by 15 to 20 dB. In this study, the labeling of datasets is done using these 15 filters. Each noise control filter is applied to the signal data and a label is given corresponding to the filter with the highest reduction.

C. Comparison of Noise Reduction Performances

The noise reduction performance of the proposed and conventional methods is compared by computer simulations. In the proposed method, the compensation filter $W_1(z)$ based on MEFxDCTLMS is initialized at system startup, constantly updated in the background, and copied to the system. Fig. 6 shows spectrogram of input noise. The input signal for verification is switched every 0.5 seconds between six different types of noise with different frequency characteristics, such

as train, washing machine, and factory noise. Figs. 7-9 show noise reduction performance of conventional and proposed ANC systems, and Fig. 10 compares them. Fig. 11 shows the transition for the selection of noise control filter. From Fig. 10, the conventional SFANC method degrades the reduction performance due to the incorrect filters, whereas the proposed method improves it. This is because the MEFxDCTLMS-based filter works to compensate for the fixed filter output. In another aspect, ANC based on MEFxDCTLMS has degradation in reduction performance from the time of system startup until the adaptive filter converges. On the other hand, the proposed method immediately selects a fixed filter when the noise changes, and thus has better tracking performance than ANC based on MEFxDCTLMS. However, the noise reduction effect after adaptive algorithm convergence is the same, the proposed method has instantaneous performance degradation immediately after noise change. This is caused by a delay between the occurrence of a noise change and its detection. To avoid this problem, delay compensation could be added when switching filters.

IV. Conclusions

In this paper, we proposed the hybrid MEFxDCTLMS-SFANC system with SDCT input 2D-CNN. In this system, an adaptive compensation filter is added to SFANC to improve robustness. Computer simulation results show that the proposed method is robust against noise variations and filter misselection. However, it was also found that the reduction performance drops momentarily immediately after the noise changes. To solve this problem, we plan to add delay compensation for filter selection. We will also study systems that are robust to transmission path variations in noise.

***Abstract*—This paper presents some recent algorithms developed by the authors for real-time adaptive active noise (AANC) control systems. These algorithms address some of the common challenges faced by AANC systems, such as speaker saturation, system divergence, and disturbance rejection. Speaker saturation can introduce nonlinearity into the adaptive system and degrade the noise reduction performance. System divergence can occur when the secondary speaker units are over-amplified or when there is a disturbance other than the noise to be controlled. Disturbance rejection is important to prevent the adaptive system from adapting to unwanted signals. The paper provides guidelines for implementing and operating real-time AANC systems based on these algorithms.**

Keywords: adaptive active noise control algorithm, output saturation, 2GD-FxLMS, leaky FxLMS

I. Introduction

Active noise control (ANC) system produces anti-noise to cancel out unwanted noise [1], [2], [3], [4], [5], [6], [7], [8], [9], [10]. However, adaptive ANC (AANC) in real-time [9], [11], [12], [13], [14] may fail if the audio amplifier is overdriven to saturation, causing the adaptive algorithm to diverge. Saturation distortion affects both the amplitude and phase of the secondary path in ANC [15], [16]. Some nonlinear algorithms based on neural networks or Volterra filters [17] can handle saturation distortion, but they are costly and complex to implement, and the vanishing gradient issue is a problem for real-world scenarios. Moreover, they do not solve the problem of insufficient power when the control signal exceeds the amplifier threshold. Thus, these nonlinear solutions are not practical for real applications and may only be used for partially overdriven actuators. Furthermore, the nonlinear adaptive algorithm without constraints is not a desired solution. A better approach is to limit the amplifier's output power and keep it within a certain power budget. Some of the common algorithms for this approach are (i) clipping or rescaling algorithms [18], which either truncate the output signal above the threshold or adjust the weight of the control filter; (ii) leaky-type filtered-reference Least Mean Square (FxLMS) algorithm [19], which adds a leak term or penalty factor to stabilize the algorithm, but requires trial and error to choose the optimal factor; (iii) A two-gradient FxLMS (2GD-FxLMS) [20] algorithm, which imposes a specific output constraint with no extra computation compared to the conventional FxLMS algorithm. Recent research has revealed new insights into constraint-FxLMS algorithms. This paper highlights the key differences and evaluates their merits and drawbacks. A typical block diagram of the ANC with saturation effect can be viewed in Fig. 1 and will be used throughout the discussion of different constraint FxLMS.

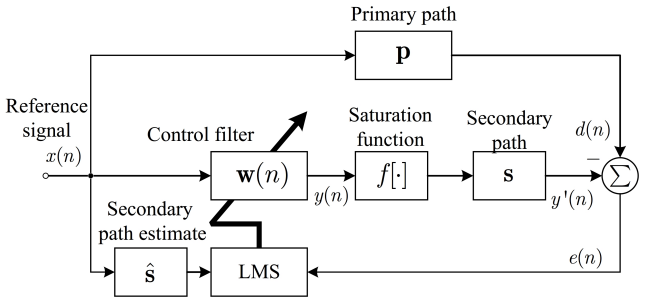

Fig. 1. Block diagram of the ANC with the saturation effect.

Before we move into the definition, explanation, and implementation of the various types of constraint FxLMS algorithms, we have defined a table of variables and their descriptions for ease of reading.

$\mathbf{w}(n)$: weight vector of the control filter	$e(n)$: error signal
$\mathbf{x}(n)$: reference signal vector	$\mathbf{x}'(n)$: filtered reference signal vector
μ: step size of the adaptive algorithm	γ: leaky factor
ρ^2: output power constraints	$\mathbf{s}$: impulse response of secondary path
L: length of the control filter	$d(n)$: disturbance
λ: Lagrangian factor	σ^2:variance of disturbance
y_{o}: optimal output	σ_{x}: variance of reference
$\mathbf{w}_{\mathrm{o}}$: optimal weight vector	η: degree of nonlinearity
$\mathbf{R}_{\mathrm{x}'}$: autocorrelation matrix of $\mathrm{x}'(n)$	$\mathbf{R}_{\mathrm{y}}$: autocorrelation matrix of $y(n)$
I: identity matrix	$\mathbf{P}_{\mathrm{dx}'}$: cross-correlation vector of $d(n)$ and $x'(n)$
λ_{o}: optimal Lagrangian factor	γ_{o}: optimal leaky factor
G_{s}: power gain of the secondary path	$S(e^{j\omega})$: transfer function of the secondary path

II. Clipping FxLMS

The clipping algorithm mainly truncates the parts of the output signal that exceeds a certain voltage level. However,

This research is supported by the Ministry of Education, Singapore, under its Academic Research Fund Tier 2 (Award No. MOE-T2EP50122-0018).

this output amplitude constraint approach has a drawback of stability, distorts the attenuated noise, and may converge slowly. Therefore, in this paper, we will not consider this approach. A similar type of clipping algorithm is the nonlinear FxLMS algorithm [21], which consists of an exponential term that clips off the output signal when the control signal exceeds the output constraints.

Even though the clipping FxLMS algorithms can deal with an amplitude that exceeds the constraint, these simple approaches may not be ideal as these algorithms distort the attenuated noise, require an accurate model of the output-saturation model, and have significant residual distortion.

III. Output Constraint: Leaky-type FxLMS Algorithms

The leaky FxLMS (LFxLMS) algorithm [22], [23] introduces a leak term (or penalty coefficient) that constrains the control effort and stabilizes the algorithm. The general LFxLMS algorithm is given as

$$\mathbf{w}(n+1) = (1-\mu\gamma)\mathbf{w}(n) + \mu e(n)\mathbf{x}'(n), \tag{1}$$

$$e(n) = d(n) - f\left[\sum_{l=0}^{L-1} s_l \mathbf{w}^{\mathrm{T}}(n-l)\mathbf{x}(n-l)\right]. \tag{2}$$

In the LFxLMS algorithm, the selection of the leak factor plays a crucial role in balancing noise control and constraint satisfaction. However, due to the ad-hoc selection of the leak factor, the output signal may not always adhere to the imposed constraint. The time-domain version of the LFxLMS algorithm results in noise reduction errors and slower convergence. To address this issue, recent versions of the algorithm use frequency-domain constraints that only penalize frequency bins exceeding the constraint. Despite these improvements, the performance of the algorithm is still greatly influenced by the empirical choice of the leak factor.

Recently, an optimal leak factor selection method for output-constrained LFxLMS algorithm [23], [24] has been proposed. This latter technique ensures that the LFxLMS reaches optimal control within its specific output power constraint. A leak factor can be derived on-the-fly based on the application's measured primary and secondary acoustic paths. The cost function with a specific output constraint [25]

$$\begin{aligned} &\min_{\mathbf{w}} \mathrm{J}(\mathbf{w}) = \mathbb{E}\left[\left|d(n) - \sum_{l=0}^{L-1} s_l \mathbf{w}^{\mathrm{T}}(n-l)\mathbf{x}(n-l)\right|^2\right] \\ &\text{s.t. } g(\mathbf{w}) = \mathbb{E}\left[\left|\mathbf{w}^{\mathrm{T}}(n)\mathbf{x}(n)\right|^2\right] \le \rho^2, \end{aligned} \tag{3}$$

where $\mathbb{E}(\cdot)$ denotes the expectation of the argument. The Lagrangian function [26] based on (3) is defined as

$$\mathbb{L}(w,\lambda,\theta) = J(w) + \lambda\left[g(w) + \theta^2 - \rho^2\right]. \tag{4}$$

The Lagrangian factor λ is used in the above cost function to introduce constraints into the optimization problem, and the optimal Lagrangian factor, λ_{o} is derived as:

$$\lambda_{\mathrm{o}} = \frac{\mathbb{E}\left\{y'_{\mathrm{o}}(n)d(n)\right\} - \mathbb{E}\left\{y'_{\mathrm{o}}(n)^2\right\}}{\rho^2}. \tag{5}$$

The optimal Lagrangian factor, which includes the variance of the output signal from the control filter and the output filtered that passes through the secondary path (includes DAC, amplifier, secondary speaker, and the acoustic transfer path from speaker to error microphone), is shown below:

$$\lambda_{\mathrm{o}} = \frac{\sigma^2_{y_o}\sum_{l=0}^{L-1} s_l^2}{\rho^2}\left(\sqrt{\frac{\sigma_d^2}{\sum_{l=0}^{L-1} s_l^2\sigma^2_{y_o}}} - 1\right). \tag{6}$$

To further simplify the above expression, we can introduce a new term, known as the degree of nonlinearity of the system, η^2:

$$\eta^2 = \max\left(\frac{\sigma_d^2}{\sum_{l=0}^{L-1} s_l^2\rho^2}, 1\right), \tag{7}$$

which leads to

$$\lambda_{\mathrm{o}} = \sum_{l=0}^{L-1} s_l^2(\eta - 1). \tag{8}$$

The optimal control filter with output constraint is given as:

$$\mathbf{w}_{\mathrm{o}} = \left(\lambda_{\mathrm{o}}\sigma_{\mathrm{x}}^2\mathbf{I} + \mathbf{R}_{\mathrm{x}'}\right)^{-1}\mathbf{P}_{\mathrm{dx}'}. \tag{9}$$

The optimal control filter using LFxLMS is given as:

$$\mathbf{w}_{\mathrm{o}} = \left(\gamma\mathbf{I} + \mathbf{R}_{\mathrm{x}'}\right)^{-1}\mathbf{P}_{\mathrm{dx}'}. \tag{10}$$

Therefore, comparing these two optimal control filters, we have a sufficient condition (under white noise):

$$\gamma = \lambda_{\mathrm{o}}\sigma_{\mathrm{x}}^2. \tag{11}$$

In practical cases, we have to replace the sufficient condition as:

$$\gamma = \lambda_{\mathrm{o}}\mathbf{R}_{\mathrm{x}}. \tag{12}$$

Substituting the optimal Lagrangian factor into the above yields the optimal leak factor as shown:

$$\gamma_{\mathrm{o}} = G_{\mathrm{s}}(\eta - 1)\mathbf{R}_{\mathrm{x}}, \tag{13}$$

where $G_s = \sigma^2_{y'_{\mathrm{o}}}/\rho^2$ is the power gain of the secondary path and can be written as the energy of the secondary path if the control signal is narrowband over $[\omega_1, \omega_2]$ and the degree of nonlinearity of the system are:

$$G_{\mathrm{s}} = \frac{1}{2\pi}\int_{\omega_1}^{\omega_2}\left|S\left(e^{j\omega}\right)\right|^2 d\omega, \tag{14}$$

$$\eta^2 = \max\left(\frac{\sigma_{\mathrm{d}}^2}{G_{\mathrm{s}}\rho^2}, 1\right). \tag{15}$$

All the above statistic terms can be measured from the ANC system before its normal control operation. It is important to note that the LFxLMS algorithm with optimal leak factor is useful in ensuring that the solution does not violate the constraint, and at the same time, obtains a satisfying noise reduction performance. Since the optimal LFxLMS does not

allow the control filter to operate beyond the constraint, there is no need to include any system saturation model in the derivation. Furthermore, unlike other algorithms, no primary path is required in the implementation of the optimal LFxLMS algorithm.

As mentioned, there is still a drawback of the above optimal LFxLMS algorithm as several parameters can only be obtained from the control signal's statistical observation before its normal control operation. As the autocorrelation matrix of reference input, secondary path, disturbance power, and the secondary path may change during real-time control, the pre-derived leaky term may not be suitable during its real-time control process.

A more practical solution, which is based on inverse adaptive modeling [27], [28], can estimate the optimal LFxLMS for different types of noise distribution in practice. This latter method also does not require the assumption of the type of noise signal. The power gain of the secondary path, G_s can be approximated as the ratio of the variance of disturbance and its corresponding control signal.

$$G_s = \frac{\sigma_{\mathrm{d}}^2}{\sigma_{\hat{\mathrm{y}}_{\mathrm{d}}}^2}. \tag{16}$$

But to predict the control signal from the disturbance, we need to estimate the inverse model $c(n)$ of the secondary path, as shown in Fig. 2, and the predicted control signal (or anti-noise) is $\hat{y}_d = \mathbf{c}_{\mathrm{o}}^{\mathrm{T}}\mathbf{d}(n)$. From these equations, we can estimate the power gain across a frame of K samples

$$G_{\mathrm{s}} = \frac{\sum_{k=0}^{K} d^2(n-k)}{\sum_{k=0}^{K} \hat{y}_{\mathrm{d}}^2(n-k)}, \tag{17}$$

and the optimal leak term is given as

$$\gamma_{\mathrm{o}} = \frac{\sum_{k=0}^{K} d^2(n-k)}{\sum_{k=0}^{K} \hat{y}_{\mathrm{d}}^2(n-k)}(\eta - 1)\mathbf{R}_{\mathrm{x}}. \tag{18}$$

Our proposed algorithm OLFxLMS [27] can be applied to different ANC applications and handling different types of noise, with only a slight increase in computational complexity compared to other algorithms.

A recent paper [29] introduces the modified FxLMS algorithm to continuously estimate the disturbance power and the power of the secondary path, and thus, a time variable penalty factor can be derived iteratively. This latter approach expands the ability of the constraint-based leaky FxLMS algorithm to handle dynamic noise sources in real-time, and still be able to constraint within its maximum power output.

IV. Output Constraint: gradient project based FxLMS Algorithms

In this class of output constraint FxLMS algorithm, modifying the direction of the error gradient, or gradient projection, does not alter the cost function. The search is usually taken along or below the constraint contour. For example, the rescaling FxLMS algorithm [30], which rescales the weight and output signal of the control filter, is a form of gradient

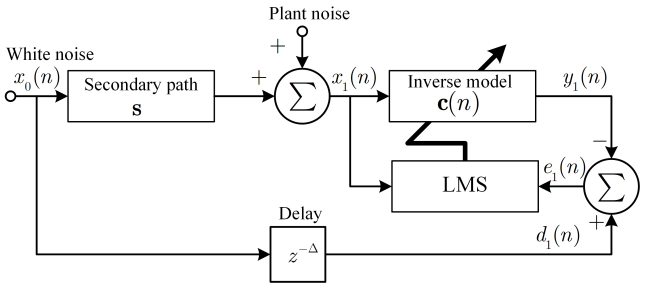

Fig. 2. Block diagram of adaptive inverse modeling for the secondary path.

TABLE I
Pseudocode of 2GD-FxLMS Algorithm

Two gradient FxLMS algorithm(2GD-FxLMS)
Input: Reference signal $x(n)$ and error signal $e(n)$ **Output**: Clipped output signal $y_{\text{out}}(n)$
Step 1: $y(n) = \mathbf{w}^{\mathrm{T}}(n)\mathbf{x}(n)$; $\mathbf{x}'(n) = \hat{s}^{\mathrm{T}}(n)\mathbf{x}(n)$. **Step 2**: If $\lvert y(n)\rvert \le \rho$ $\mathbf{w}(n+1) = \mathbf{w}(n) + \mu_1 e(n)\mathbf{x}'(n)$; else $\mathbf{w}(n+1) = \mathbf{w}(n) - \mu_2 y(n)\mathbf{x}(n)$. **Step 3**: If $y(n) > \rho$, $y_{\text{out}} = \rho$; else if $y(n) < -\rho$, $y_{\text{out}} = -\rho$; else $y_{\text{out}} = y(n)$.

projection algorithm. However, this algorithm increases computational load and can lead to a reduction in sampling frequency for practical implementation. To combine the modification of search direction and imposing a constraint, we can derive an optimal solution, which is referred to as the output constraint two-gradient descent (2GD) FxLMS algorithm [20], [31]. Several variants of the 2GD FxLMS take into account faster convergence, minimum mean square error, and extension to multiple channels. A pseudocode of the baseline 2GD-FxLMS algorithm is listed in Table I.

When the average output power of the control filter is within the constraint ($\mathbb{E}\left[y^2(n)\right] \le \rho^2$), the weight update is given by

$$\mathbf{w}(n+1) = \mathbf{w}(n) - \frac{1}{2}\mu\frac{\nabla J(\mathbf{w})}{\|\nabla J(\mathbf{w})\|}. \tag{19}$$

In contrast, when the average output power exceeds the constraint ($g(\mathbf{w}) > \rho^2$), the weight update changes to

$$\mathbf{w}(n+1) = \mathbf{w}(n) - \frac{1}{2}\mu\frac{\nabla g(\mathbf{w})}{\|\nabla g(\mathbf{w})\|}. \tag{20}$$

By replacing the normalized gradient and average power constraint with the instantaneous gradient and amplitude constraint, the update equation can now be expressed as

$$\begin{cases} \mathbf{w}(n+1) = \mathbf{w}(n) + \mu_1 e(n)\mathbf{x}'(n), & \mathbb{E}\left\{y(n)^2\right\} \le \rho^2 \\ \mathbf{w}(n+1) = \mathbf{w}(n) - \mu_2 y(n)\mathbf{x}(n), & \mathbb{E}\left\{y(n)^2\right\} > \rho^2 \end{cases} \tag{21}$$

The main advantage of the 2GD-FxLMS algorithm is its ability to continuously update even when the output of the control filter exceeds the amplifier threshold; therefore, it possesses

TABLE II
COMPARATIVE EVALUATION OF THE DIFFERENT TYPES OF CONSTRAINT-BASED FXLMS ALGORITHMS

Algorithms:	**2GD-FxLMS**	**Optimal Leaky FxLMS**
Advantages	· Light computational load · A simple operator to switch between modes · Smaller residual error · Perform better in broadband noise · Enhance system stability and quality of anti-noise. · Able to implement a light-weight multi-channel 2GD-FxLMS.	· An optimal leaky FxLMS can avoid output saturation distortion and provides good noise reduction. · Online estimation of optimal leak factor that can handle different types of noise.
Disadvantages	· Noise reduction performance is usually inferior to other constraint-based algorithms. · May result in slower convergence, but can be solved using momentum and variable step size.	· Higher computational cost may not be desired for MCANC. Can use MOV-FxLMS [29] to reduce complexity. · More steps in determining the optimal leak term, but can be done online.
Usages	In practical real-time implementation of MCANC for open aperture and spatial ANC for controlling high-amplitude acoustic noise sources.	

the switching mechanism, and its computational complexity is the same as the iterative FxLMS algorithm. To put it simply, the 2GD-FxLMS forces the amplifier and speaker to operate in their linear region. Several real-time implementations of the 2GD FxLMS algorithms have been tested in air ducts.

There are several recent improvements in the 2GD FxLMS algorithm, namely:

(i) **Momentum 2GD-FxLMS** algorithm [32] with variable step size. We introduce a momentum factor to improve the convergence speed of the baseline 2GD-FxLMS algorithm and added a computation-effective variable step size approach to further reduce the steady-state error due to the switching nature of the 2GD-FxLMS.

(ii) **Multi-channel 2GD-FxLMS (or 2GD-MCFxLMS)** [33] is an extension of the single-channel 2GD-FxLMS algorithm. However, with the increase in the number of multiple output amplifiers, the output saturation nonlinearity also increases in the multiple-channel compared to the single-channel 2GD-FxLMS algorithm. Additionally, having multiple channel ANC (MCANC) applications means more effort is required to maintain the system components. Constantly subjecting the system to high-amplitude anti-noise reproduction can shorten the lifespan of the amplifiers/speakers and increase maintenance costs.

V. CONCLUSIONS

Table II provides a comprehensive comparison of various constraint-based FxLMS algorithms. These algorithms effectively address the issues of actuator overdriving and nonlinearity caused by saturation. Both the 2GD-FxLMS and optimal Leaky FxLMS algorithms employ a similar constraint-based approach to derive the adaptive FxLMS algorithm.

Typically, imposing a strong constraint on the FxLMS algorithm directs more effort towards achieving the desired output power. However, this approach compromises the level of noise reduction. In other words, constraint-based FxLMS algorithms are tailored to specific requirements and struggle to perform optimally in meeting both objectives simultaneously. Therefore, this paper proposes deriving an optimal leak factor that strikes a balance between noise reduction and satisfying power constraints. We provide a summary of two existing approaches, namely the 2GD-FxLMS and optimal leaky FxLMS algorithms, highlighting their unique properties, advantages, disadvantages, and practical applications.

The focus on real-time implementation in this study is of great value to practitioners, as it enables them to incorporate the optimal leak factor and 2GD into their adaptive ANC (FxLMS) systems. This applied research approach effectively bridges the gap between academic studies and practical implementations, facilitating more efficient noise control in real-world applications.

***Abstract*— It is defined in IEEE 802.16e that there are five different Quality of Service (QoS) classes, which include: UGS, rtPS, nrtPS, ertPS, and BE. This paper compares the throughput performance measurement results between the UGS and BE scheduling services for every modulation and coding scheme (MCS), which have been implemented in our FPGA-based real-time OFDM multi-user system. There are two FPGA-based RF transceiver boards involved in the one-slot experiment and three FPGA-based RF transceiver boards involved in the two-slot experiment. The downlink transmission is done in FDD, using 241 MHz as the center frequency, and the uplink transmission is done in TDD, using 261 MHz as the center frequency. The transmission scenario used in this experiment is point-to-multipoint (P2MP). The throughput measurement is taken under LOS conditions using cables and quarter-wave antenna connections. We observed that the BE service has higher downlink and uplink throughput compared to the UGS service by utilizing one uplink slot. However, there are almost 50% drops in the throughput results for every MCS in the BE implementation when two uplink slots are utilized. There are some limitations to this experiment, involving the number of subscriber stations, a connection timeout issue, and the experimental condition. Therefore, it is advised to increase the number of subscriber stations and test the system under several wireless conditions for future development.**

Keywords*— *QoS, UGS, BE, OFDM, Multi-user, P2MP, Throughput

I. Introduction

The IEEE 802.16 standard, commonly known as Worldwide Interoperability for Microwave Access (WiMAX), is a recent wireless broadband standard that has promised high bandwidth over long-range transmission [1]. It is defined in IEEE 802.16e that in order to meet different Quality of Service (QoS) requirements, such as throughput, packet error rate, jitter, system availability, and delay, there are five different scheduling mechanism categories to allocate the downlink and uplink transmission opportunities for different PDUs [2]. Those categories are: unsolicited grant service (UGS), real-time polling service (rtPS), non-real-time polling service (nrtPS), extended real-time polling service (ErtPS), and best effort service (BE).

The summary of the applications for each category can be observed in Table I.

TABLE I
THE SUMMARY OF QOS CATEGORIES APPLICATIONS [1]

QoS Category	Applications	QoS Specifications
UGS Unsolicited grant service	VoIP	Maximum sustained rate, maximum latency tolerance, and jitter tolerance.
rtPS Real-time polling service	Streaming audio or video	Maximum reserved rate, maximum sustained rate, maximum latency tolerance, and traffic priority.
ErtPS Extended real-time polling service	Voice with activity detection (VoIP)	Minimum reserved rate, maximum sustained rate, maximum latency tolerance, jitter tolerance, and traffic priority.
nrtPS Non-real-time polling service	File Transfer Protocol (FTP)	Minimum reserved rate, maximum sustained rate, and traffic priority.
BE Best Effort service	Data transfer, Web browsing, etc.	Maximum sustained rate and traffic priority.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

These five service classes can be divided into two main categories: non-real-time and real-time. UGS, rtPS, and ErtPS are categorized in the real-time category. The nrtPS and BE are categorized in the non-real-time category. The real-time services have strict constraints on delay and delay jitter. This makes scheduling more difficult to meet the delay constraint and tolerate the delay jitter with optimal throughput [3]. On the other hand, the non-real-time category has no strict constraints on these parameters. Therefore, common scheduling schemes can be applied, such as weighted fair queue (WFQ) and a variation of the round-robin (RR) algorithm [3].

In this paper, we present throughput measurement results of the UGS and BE scheduling services of a real-time orthogonal frequency division multiplexing (OFDM) system that is developed from our previous work [4] and implemented in the AD9361 SDR-FPGA platform [5]. The throughput results are used to obtain a performance measurement comparison between the implementations of each scheduler for every MCS in our system.

This paper is organized as follows. Section II presents an overview of the designed OFDM system. Section III describes the experimental setup, including hardware configuration and specifications. Section IV discusses measurement results and the achieved performance of each implemented service. The conclusions of this work are summarized in Section V.

II. System Design

A. The Design of The OFDM Multi-user System

The OFDM multi-user system is composed of the hardware, kernel space, and user space layers. The hardware layer consists of the Ethernet (PS) and the PHY transceiver (FPGA). The kernel space layer includes drivers (the Ethernet driver and the OFDM driver), the MAC layer (the OFDM MAC), and the net device. TCP/IP, and system calls. The user space is responsible for IP table forwarding. The overall system design is depicted in Fig. 1.

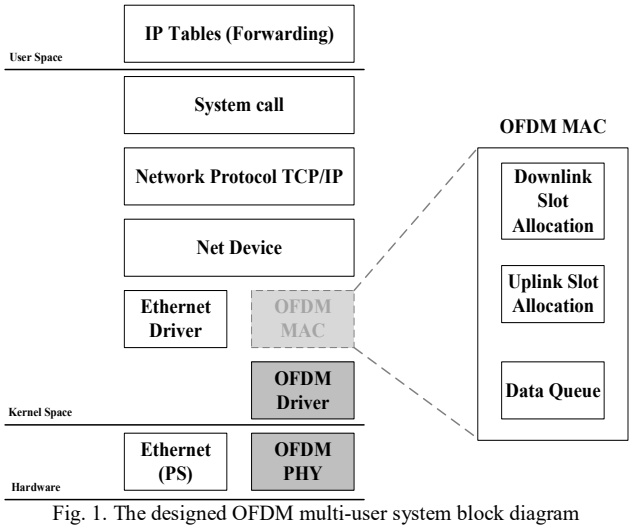

Fig. 1. The designed OFDM multi-user system block diagram

B. MAC Header Frame Structure

The QoS scheduler is implemented in the OFDM MAC, which is located in the kernel space layer. The OFDM MAC is also responsible for slot allocation, TDMA synchronization, and the data queue. Fig. 2 describes the frame structure of the MAC header. The MAC header is arranged by the frame control, the source address, and the destination address. The total length of the MAC header is 13 bytes.

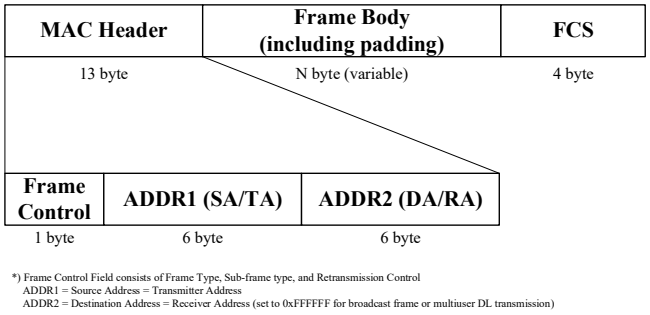

Fig. 2. MAC header frame structure

Furthermore, Table II presents the detailed specification of the frame control of the MAC header. The total size of the frame control is 1 byte and consists of the frame type (from bit-0 up to bit-1), the sub-frame type (from bit-2 up to bit-5), and the retransmission control (bit-6).

TABLE II
THE MAC HEADER FRAME CONTROL

Frame Type		Sub Type		Retry	
Bit-1 … Bit-0		Bit-5 … Bit-2		Bit-6	
00	Management	0001	Beacon	0	Normal
		0010	Association request	1	Retry
		0011	Association response		
		0100	Authentication request		
		0101	Authentication response		
		0110	RTS (Request-to-Send)		
		0111	CTS (Clear-to-Send)		
		1000	Slot reservation		
		1001	Slot confirmation		
		1010	Slot ranging		
01	Control Frame	0001	ACK (Acknowledge)		
10	Data Frame	0001	Multi-user Data Frame		
		0010	Broadcast Data Frame		

C. TDMA of The UGS Scheduler

The TDMA of the UGS scheduler is shown in Fig. 3. Each uplink slot has a fixed delay value in order to transmit the uplink frames.

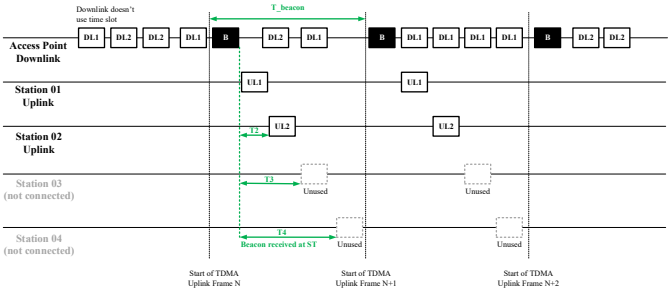

Fig. 3. The TDMA of the UGS scheduler

The delay value for each uplink timeslot is determined by the uplink slot number and the frame duration of each MCS. The delay value for each slot is calculated by (1), where T(n) is the

delay of the uplink slot, n is the uplink slot number (starts from zero), and T_{frame} is the frame duration for each MCS.

$$T(n) = n * T_{frame} \quad (1)$$

The frame duration of each MCS is obtained from the total of the number of symbols, the signal, the preamble, and the guard band, which can be calculated using (2), times the sum of symbol and cyclic prefix duration, which is calculated by (3).

$$N_{frame} = N_{sym} + N_{signal} + N_{preamble} + N_{guard} \quad (2)$$

$$T_{frame} = N_{frame} * (T_{symbol} + T_{CP}) \quad (3)$$

It is known that for 3.5 MHz bandwidth, the sum of the symbol and cyclic prefix durations is equal to 80 µs. A 0.5 ms guard duration is added to the final calculation of the frame duration to ensure every frame is fully transmitted. Therefore, the frame duration for each MCS in the 3.5 MHz bandwidth can be observed in Table III.

TABLE III
THE FRAME DURATION FOR EVERY MCS IN 3.5MHZ BANDWIDTH

BW [MHz]	MCS	N_frame	T_symbol + T_CP [µs]	Frame Duration [ms]
3.5	0	151	80	12.58
	1	75	80	6.50
	2	40	80	3.70
	3	51	80	4.58
	4	28	80	2.74

The uplink timeslot delay value for every MCS using the 3.5 MHz bandwidth is presented in Table IV.

TABLE IV
THE UPLINK TIMESLOT DELAY VALUE FOR EVERY MCS IN 3.5MHZ BANDWIDTH

BW [MHz]	MCS	Frame Duration [ms]	Delay T0 [ms]	Delay T1 [ms]	Delay T2 [ms]	Delay T3 [ms]
3.5	0	12.58	0	12.58	25.16	37.74
	1	6.50	0	6.50	13.00	19.50
	2	3.70	0	3.70	7.40	11.10
	3	4.58	0	4.58	9.16	13.74
	4	2.74	0	2.74	5.48	8.22

D. TDMA of The BE Scheduler

The TDMA of the BE scheduler is shown in Fig. 4. It can be observed that, if there is no other station connected, the only station connected is able to utilize more uplink slots for the uplink frame transmission.

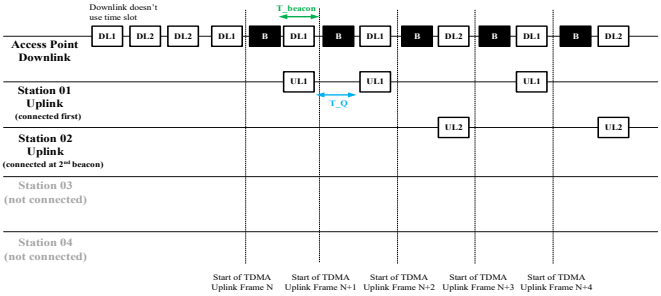

Fig. 4. The TDMA of the BE scheduler

However, if there is a new station connected, the transmission of the uplink frame of each connected station will be scheduled by the round-robin algorithm. The round-robin algorithm scheme can be observed in Fig. 5.

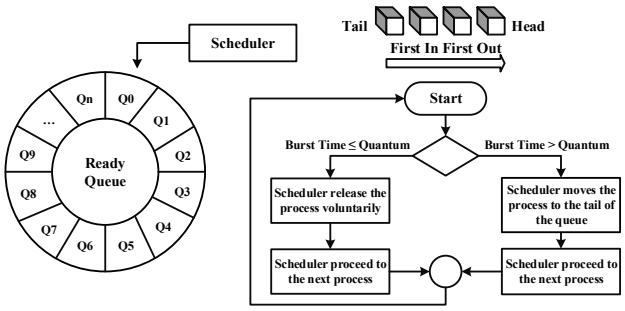

Fig. 5. The round-robin algorithm scheme

It is known that the round-robin algorithm is generally used for a timesharing system. This algorithm is similar to the first come, first served (FCFS) algorithm; however, there is a preemption in order to do the switching of the processes. A time unit, called a time quantum or time slice, is defined to determine the interval between processes. Every process will be inserted into a ready queue, which can be visualized as a circular queue.

Let S_0, S_1 … S_n be n-stations having A_i, B_i, and r_i where i=0,1,2 … n, as their arrival time, burst time, and number of rounds required for completion, respectively. Let Q_0, Q_1 … Q_n be n-station slots in the ready queue. Therefore, we use (4) to arrange every station into the station slots in an FCFS manner.

$$Q_{A_n} = S_n \quad (4)$$

Furthermore, let q denote a fixed-time-quantum in time units. The number of rounds required for completion, r_i, can be calculated using (5) [6].

$$r_i = \begin{cases} B_i \text{ div } q, if\ B_i \bmod q = 0 \\ (B_i \text{ div } q) + 1, otherwise. \end{cases} \quad (5)$$

The symbols 'div' and 'mod' denote modulus and division operators, respectively. Both B and q are assumed to be integers. Every process will be executed for one complete time quantum in each round except for the last round, where it may be less than or equal to one time quantum. The time requirement for a station slot Q_i in its last round, denoted by q_i, is the remainder of B_i /q.

The remaining burst time is updated after every round. The remaining burst time and the executed portion are denoted respectively by $B_{i,j}$ and $q_{i,j}$ for the i^{th} slot in j^{th} round. Therefore, the remaining time requirement of a station slot Q_i in r^{th} round can be given by (6) and the q_{r-1} can be calculated by (7) [6].

$$B_{i,r} = B_{i,r-1} - q_{i,r-1} \quad (6)$$

$$q_{r-1} = \begin{cases} q_i, if\ B_{i,r-1} < q \\ q, if\ B_{i,r-1} \geq q \end{cases} \quad (7)$$

The output of the round-robin algorithm is a Gantt chart consisting of the scheduled station slots. The quantum time, which is used in the scheduler implementation, is 1 time unit.

III. Performance Measurement Setup

In order to measure the throughput performance of the implemented schedulers in our real-time OFDM multi-user system, several variables, such as the AD9361 parameter configuration and the experiment setup, need to be configured and defined.

A. AD9361 Configuration

The AD9361 configuration includes the bandwidth, sampling frequency, downlink center frequency, uplink center frequency, and gain control configuration. We employ *iperf* software [7] in the AD9361 software driver to calculate the throughput. The AD9361 configuration is provided in Table V.

TABLE V
THE AD9361 PARAMETERS CONFIGURATION

Parameter	Value
Bandwidth [MHz]	3.5
Sampling Frequency [Msps]	20
Downlink Center Frequency [MHz]	241
Uplink Center Frequency [MHz]	261
TX Gain [dB]	-10
RX Gain Control	Fast Attack

B. Experiment Setup for One-slot Performance Measurement

The one-slot performance measurement is taken in ideal conditions using two U.FL-to-U.FL cables. It involves two transceiver boards: one behaves as an access point (AP), and the other behaves as a subscriber station (ST-01). The maximum number of slots connected is set to 4, interconnected with a point-to-multipoint (P2MP) topology. The one-slot performance measurement diagram and experiment setup can be observed in Figs. 6 and 7, respectively.

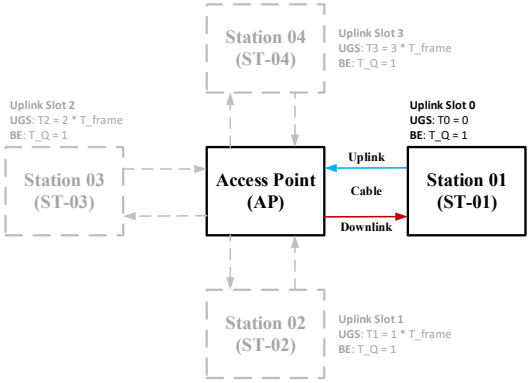

Fig. 6. The one-slot performance measurement setup diagram

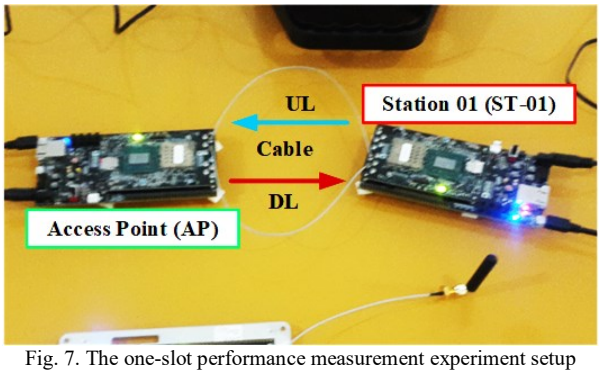

Fig. 7. The one-slot performance measurement experiment setup

C. Experiment Setup for Two-slot Performance Measurement

The two-slot performance measurement is taken in an indoor line-of-sight (LOS) condition using six quarter-wave antennas. It involves three transceiver boards: one behaves as an access point (AP), and the others behave as subscriber stations (ST-01 and ST-02). The maximum number of slots connected is also set to 4, interconnected with point-to-multipoint (P2MP) topology. The two-slot performance measurement diagram and experiment setup can be observed in Figs. 8 and 9, respectively.

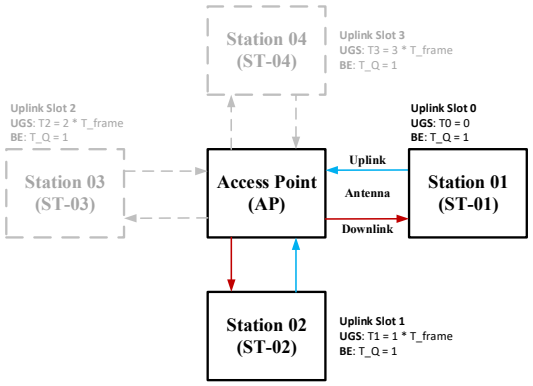

Fig. 8. The two-slot performance measurement setup diagram

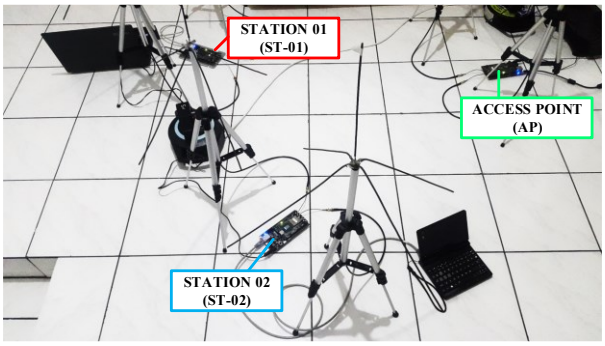

Fig. 9. The two-slot performance measurement experiment setup

IV. Performance Measurement Result

A. One-slot UGS Throughput Measurement Result

The throughput measurement results for the UGS implementation involving only one subscriber station connected to the access point and utilizing only one uplink slot are presented in Table VI.

TABLE VI
ONE-SLOT UGS THROUGHPUT MEASUREMENT RESULT

MCS		Throughput [Mbps]	
		Downlink	Uplink
0	BPSK FEC 1/2	Timeout	Timeout
1	QPSK FEC 1/2	0.83	0.48
2	16-QAM FEC 1/2	1.52	0.86
3	QPSK FEC 3/4	1.27	0.67
4	16-QAM FEC 3/4	2.22	1.17

There is a connection timeout issue for the MCS 0 (BPSK FEC ½) which causes failure in the throughput measurement process. It can be observed that the highest achievable downlink and uplink throughput by implementing the UGS in the one-slot experiment, respectively, is 2.22 Mbps and 1.17 Mbps by employing MCS 4: 16-QAM FEC ¾.

B. *One-slot BE Throughput Measurement Result*

The throughput measurement result for the BE implementation by involving only one subscriber station connected to the access point and utilizing only one uplink slot is presented in Table VII.

TABLE VII
ONE-SLOT BE THROUGHPUT MEASUREMENT RESULT

MCS		Throughput [Mbps]	
		Downlink	Uplink
0	BPSK FEC 1/2	0.64	0.53
1	QPSK FEC 1/2	1.48	1.16
2	16-QAM FEC 1/2	2.01	1.45
3	QPSK FEC 3/4	1.87	1.32
4	16-QAM FEC 3/4	3.04	1.87

Unlike the UGS service, there is no connection timeout issue in any MCS in the BE service implementation. It can be observed that the highest throughput achieved by the implementation of the BE service in the one-slot experiment is respectively 3.04 Mbps and 1.87 Mbps by employing MCS 4: 16-QAM FEC ¾.

C. *One-slot Throughput Comparison between UGS and BE*

The throughput comparison between the UGS and the BE for the one-slot experiment for every MCS can be visualized in Fig. 10.

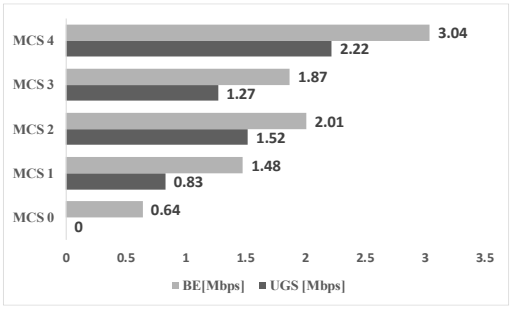

Fig. 10. The downlink throughput results comparison between the UGS and BE for every MCS from the one-slot experiment

As shown in Fig. 10, for every MCS, the throughput result of the BE implementation surpasses the throughput result of the UGS implementation. The range of differences in the throughput results between the UGS and the BE service for each MCS varies from 0.48 Mbps up to 0.82 Mbps.

The uplink throughput comparison between the UGS and the BE for the one-slot experiment for every MCS can be visualized in Fig. 11.

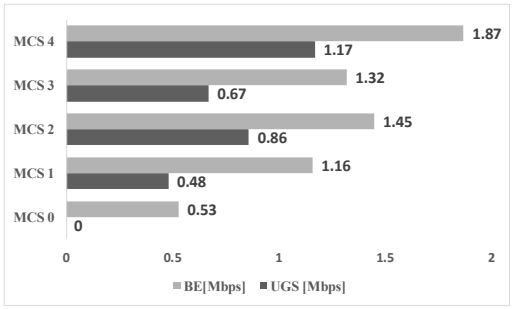

Fig. 11. The uplink throughput results comparison between the UGS and BE for every MCS from the one-slot experiment

As shown in Fig. 11, for every MCS, the throughput result of the BE implementation surpasses the throughput result of the UGS implementation. The range of differences in the uplink throughput results between the UGS and the BE service for each MCS varies from 0.53 Mbps up to 0.70 Mbps.

D. *Two-slot UGS Throughput Measurement Result*

The throughput measurement results for the UGS service implementation by involving two subscriber stations connected to the access point, utilizing two uplink slots, is presented in Table VIII.

TABLE VIII
TWO-SLOT UGS THROUGHPUT MEASUREMENT RESULT

MCS		Throughput [Mbps]					
		ST-01		ST-02		Average	
		DL	UL	DL	UL	DL	UL
0	BPSK FEC 1/2	Timeout					
1	QPSK FEC 1/2	0.81	0.51	0.69	0.48	0.75	0.50
2	16-QAM FEC 1/2	1.52	0.86	1.29	0.85	1.41	0.86
3	QPSK FEC 3/4	1.15	0.67	1.11	0.56	1.13	0.62
4	16-QAM FEC 3/4	1.83	1.17	1.75	1.18	1.79	1.18

Based on Table VIII, the highest average downlink and uplink throughput achieved by each station by employing the UGS service is 1.79 Mbps and 1.18 Mbps, respectively, using MCS 4: 16-QAM FEC ¾. The timeout issue still persists and causes failure to the throughput performance measurement of the MCS 0: BPSK FEC ½.

E. *Two-slot BE Throughput Measurement Result*

Table IX presents the throughput measurement results for the BE service implementation by involving two subscriber stations connected to the access point, utilizing two uplink slots.

TABLE IX
TWO-SLOT BE THROUGHPUT MEASUREMENT RESULT

MCS		Throughput [Mbps]					
		ST-01		ST-02		Average	
		DL	UL	DL	UL	DL	UL
0	BPSK FEC 1/2	0.27	0.27	0.27	0.27	0.27	0.27
1	QPSK FEC 1/2	0.88	0.39	0.74	0.51	0.81	0.45
2	16-QAM FEC 1/2	1.58	0.97	1.39	0.97	1.49	0.97
3	QPSK FEC 3/4	1.08	0.79	1.07	0.79	1.08	0.79
4	16-QAM FEC 3/4	1.89	1.02	1.48	1.25	1.69	1.14

By observing Table IX, the highest average downlink and uplink throughput achieved by each station by employing the BE service is 1.69 Mbps and 1.14 Mbps, respectively, using MCS 4: 16-QAM FEC ¾.

F. *Two-slot Throuhgput Comparison between UGS and BE*

For every MCS in the two-slot experiment, the average throughput result achieved by each subscriber station by implementing the UGS service is almost the same as the average throughput result achieved by each subscriber station by implementing the BE service. There are slight differences in the average throughput results between the UGS and the BE service for each MCS, which ranged from 0.05 Mbps up to 0.27 Mbps for the downlink and from 0.04 Mbps up to 0.27 Mbps for the uplink. Fig. 12 shows the average downlink throughput comparison between the UGS and the BE implementation for every MCS in the two-slot experiment.

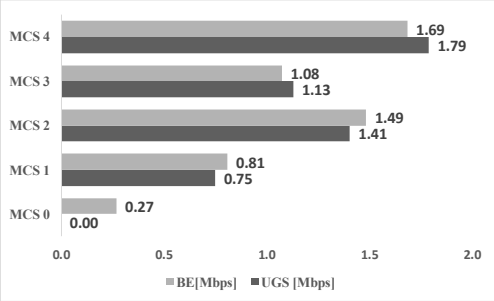

Fig. 12. The average downlink throughput results comparison from each station between the UGS and BE for every MCS from the two-slot experiment

Fig. 13 shows the average uplink throughput comparison between the UGS and the BE implementation for every MCS in the two-slot experiment.

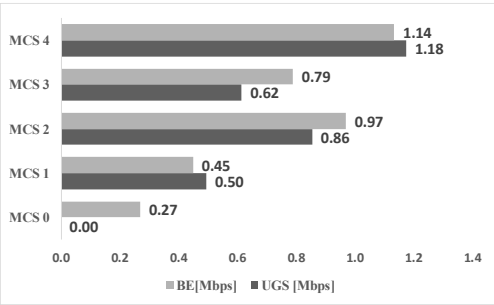

Fig. 13. The average uplink throughput results comparison from each station between the UGS and BE for every MCS from the two-slot experiment

G. *One-slot and Two-slot Throughput Comparison*

Fig. 14 visualizes the comparison of the downlink throughput results achieved by each station from both one-slot and two-slot experiments for every MCS by implementing UGS and BE services.

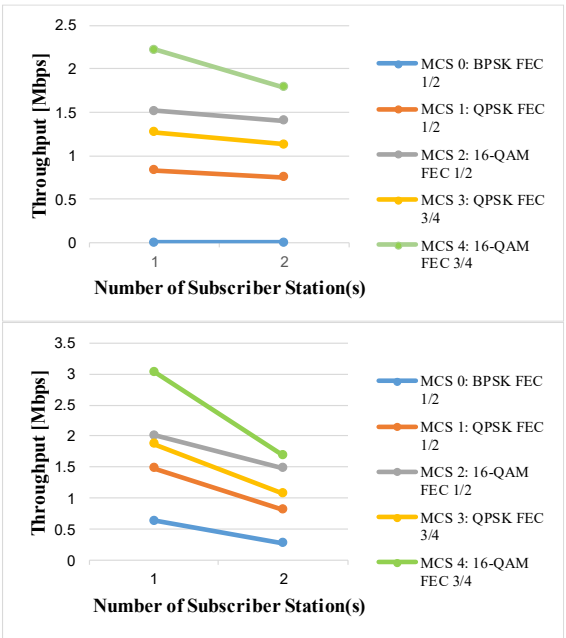

Fig. 14. The downlink throughput results achieved by each station from both one-slot and two-slot experiments for every MCS by implementing UGS (above) and BE (below) services

Fig. 15 visualizes the comparison of the uplink throughput results achieved by each station from both one-slot and two-slot experiments for every MCS by implementing UGS and BE services.

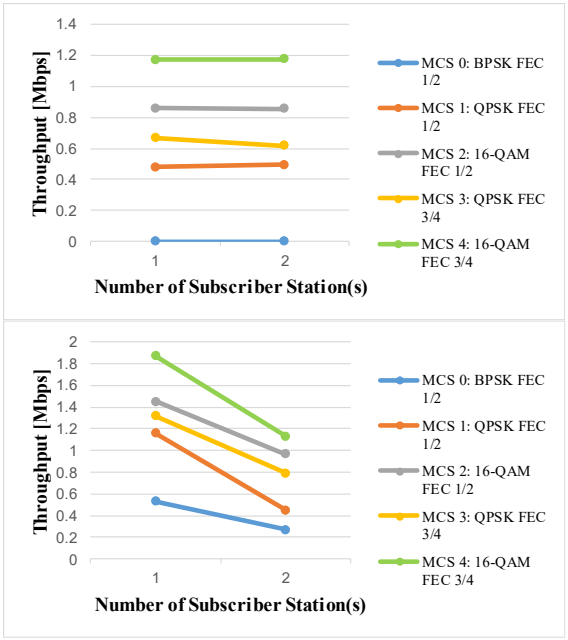

Fig. 15. The uplink throughput results achieved by each station from both one-slot and two-slot experiments for every MCS by implementing UGS (above) and BE (below) services

V. Conclusion

In this paper, we have presented a throughput performance measurement between two QoS implementations (UGS and BE) of a real-time OFDM multi-user system. The performance measurement is aimed at comparing the throughput result for every MCS with the implementation of the UGS and BE schedulers, utilizing one uplink slot and two uplink slots. Based on the real-time throughput evaluation, the throughput of the BE implementation is higher than the throughput of the UGS implementation for every MCS when only one uplink slot is utilized. However, when two uplink slots are utilized, there are almost 50% drops in both downlink and uplink throughput of the BE implementation. On the other hand, the throughput of the UGS remains relatively stable when two uplink slots are utilized.

There are some limitations to this experiment. One of them is the number of subscriber stations involved in this experiment, which is less than enough to show the reliability of each scheduler. We also found that in the UGS implementation, there is a connection timeout issue for the MCS 0: BPSK FEC ½. This issue is not found in the BE implementation. Therefore, it is advised to do further investigation in order to solve the timeout issue of MCS 0 in the UGS implementation. The other limitation is that the condition of the experiment is still under ideal conditions. Therefore, for future development, it is advised to increase the number of subscriber stations in order to gain insight into the schedulers' reliability and to test the system under several wireless conditions in order to show how environmental non-idealities can affect the transmission.

Algorithm Development for Stepwise Valve Deflation Method in Blood Pressure Measurement

Trio Adiono*, Reina Puteri Ramadhani*, Clarance Amadeus*, Sindy Novaria Cicilya Sinaga◦
*School of Electrical Engineering and Informatics, Bandung Institute of Technology
◦PT. Xirka Dama Persada, Indonesia.

***Abstract*— This paper aims the development a Pump-based Leakless NIBP (Non-Invasive Blood Pressure) system using the oscillometric principle and a stepwise valve deflation method. The stepwise deflation method involves a controlled and gradual reduction of pressure inside the arm cuff, which enables the utilization of a single controlled valve. Evaluation results show error rates between 2.05 and 5.6, accuracy ranging from 86.0% to 99.1%, and low standard deviations (1.57 to 3.91) for error, and (0.84% to 9.78%) for accuracy. Most presets meet the ±5 error threshold, but further optimization is needed for preset 5 to align with Ministry of Health regulations, eliminating the need for multiple valves and air leakage.**

Keywords*—NIBP, Blood pressure measurement, Stepwise deflation, oscillometric algorithm, valve controlled.*

1. Introduction

Creating a portable, accurate, and practical blood pressure monitor is very important because blood pressure is one of the most vital metrics of healthiness [1]. An accurate and practical blood pressure monitor empowers individuals to measure their blood pressure independently, without relying on the medical staff, facilitating easier and faster monitoring.

Currently, numerous portable blood pressure monitors are available in medical stores, known for their affordability, user-friendliness, and compliance with medical standards [1][12]. Although, the key to their effective performance of the right algorithm. This algorithm includes how the device reads the raw pressure data and processes it into systolic and diastolic blood pressure values. Despite their significance, many of these algorithms are not publicly disclosed and remain an open research problem.

In this paper, we aim to introduce an algorithm for blood pressure measurement, utilizing the stepwise deflation method in conjunction with an oscillometric-based approach. Stepwise deflation is a method of acquiring raw pressure data [3]. Oscillometric based algorithm is a well-known algorithm to process raw pressure data. Nevertheless, there is no universally optimal set of parameters for this algorithm, as its performance can vary across different conditions. Therefore, the objective of this paper is to provide a comprehensive explanation of all the algorithm's parameters employed for blood pressure measurement.

2. Previous Work

In this section, some of the previous works will be explained. This section will be divided into 2 parts, each to address the previous works in the cuff deflation algorithm and the previous works in the oscillometric algorithm.

2.1. Cuff Deflation Algorithm

Basically, there are 2 different algorithms for cuff deflation, which are linear deflation and stepwise deflation. In the linear deflation algorithm, the cuff is pumped to a pressure higher than the systolic pressure of the patient and deflated at a constant rate. The pressure of the cuff is monitored until the pressure in the cuff is fully deflated. The resulting raw data is a linear declining cuff pressure waveform with an oscillometric waveform superimposed in it. In the stepwise deflation algorithm, the cuff is pumped in the same way as the linear deflation algorithm but is held and deflated for a certain period. The pressure of the cuff is monitored every time the cuff pressure is held. The resulting raw data is a stepwise declining cuff pressure waveform with an oscillometric waveform superimposed on each level. Stepwise deflation method needs an electronically controlled valve to control the deflation of the cuff. The deflation process usually takes 10-12 steps [1]. The pressure drop in each step can differ, but often is about 4-6 mmHg [2]. In each step, one or more pulses are detected before the cuff is deflated into the next step.

Typically, the commercially available blood pressure monitor device uses stepwise deflation [3]. The stepwise deflation is preferred because it is less susceptible to noise. However, this method increases the measurement time, and this method requires strict timing control to control the deflation time. To reduce the measurement time, an adaptive timing control algorithm has been proposed. In [4], the pressure difference in each deflation step is changed corresponding to the amplitude of the pulse found in each pressure level. In [5], the valve open time is altered in each deflation step corresponding to the amplitude of the pulse found in each pressure level.

2.2. Signal Processing Algorithm

The oscillometric algorithm is a widely used algorithm in blood measurement devices. It is done by separating the Oscillometric Waveform (OMW) from the cuff pressure waveform, then processing it to obtain Mean Arterial Pressure (MAP), Systolic Blood Pressure (SBP), and Diastolic Blood

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Pressure (DBP). To process the raw data and calculate blood pressure, many methods have been proposed. These methods can be statistical-based, DSP-based, Neural Network Based, or empirical.

MAP, SBP, and DBP can be calculated directly from the oscillometric pulse shape [6]. This method can be an excellent one to study the oscillometric pulse, but it needs a good understanding of Digital Signal Processing (DSP) and is noise prone. The more common way to extract MAP, SBP, and DBP is by using a ratio. SBP and DBP can be found as fixed ratios from the MAP. To find these ratios, statistical methods such as Bayes [7] [8], AI methods such as Neural Networks [9] and Fuzzy [10], and empirical methods [11] [12] [13] have been proposed. These methods usually have trade-offs between accuracy, robustness, and complexity.

3. Method

3.1. Pump-based Leakless NIBP Measurement Hardware

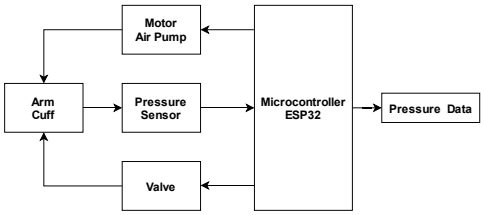

Fig. 1. Block Diagram of Hardware System

Figure 1 depicts the block diagram of the pump-based leakless NIBP system that we have implemented. In this method, we utilized an internal cuff in NIBP Simulator for the arm cuff. The Microcontroller ESP32 controls the motor air valve for cuff inflation and the valve for deflation at the desired time intervals. The cuff pressure is measured by the air pressure sensor. The pump-based leakless NIBP measurement eliminates the need for a precision dump valve for controlling the deflated airflow. Instead, this system employs a single controlled valve to manage the deflation of the airflow. Fig.2 illustrates the direction of airflow during inflation (indicated by the blue arrow) and deflation (indicated by the red arrow).

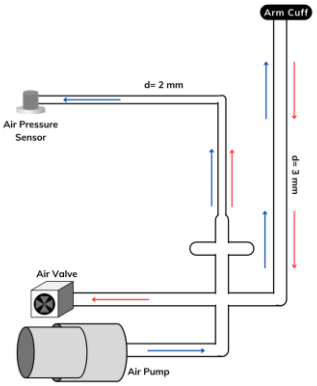

Fig. 2. Illustration of Airflow when inflated (blue) and deflated (red)

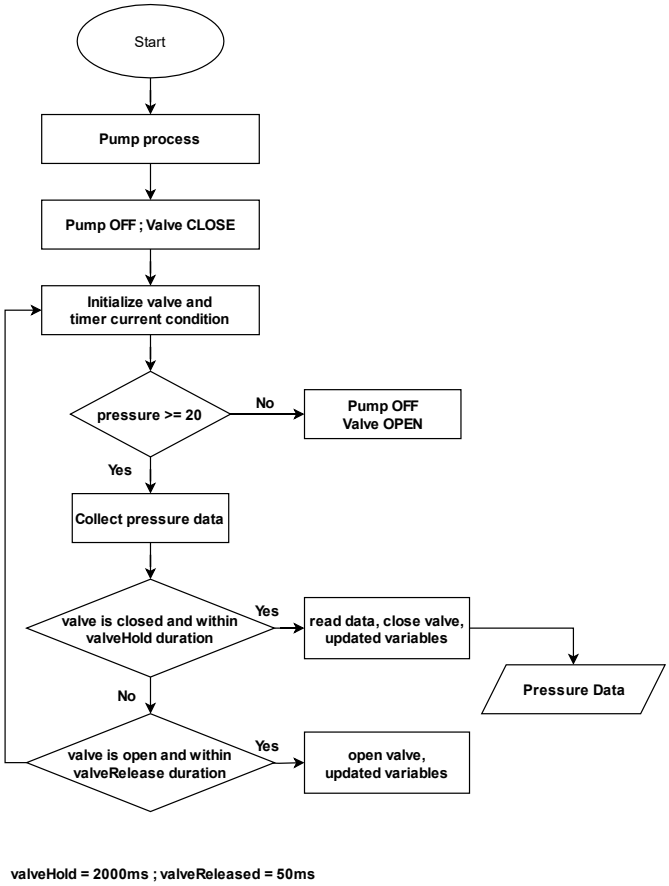

Fig. 3. Flowchart for stepwise deflation (*valve controlled*)

The pressure data acquisition process is performed in the digital domain within the microcontroller, where data is collected with valve control. After the pumping process is completed, the valve is controlled at pressures above 20 mmHg. During deflation, the valve remains closed for the valveHold duration and then opens for the valveRelease duration. Throughout the open-close cycle, pressure data will be captured only when the close cycle.

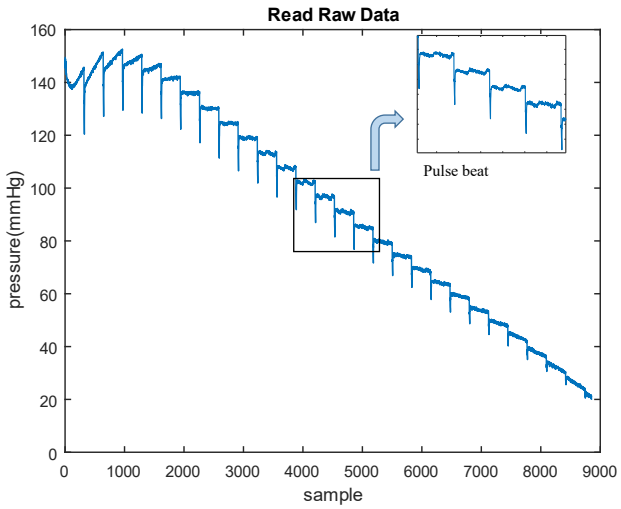

Fig. 4. Raw Pressure Data of step-wise deflation

In this step-wise deflation method, the control of the valve is very important. To ensure seamless recording of the pulse signal without interruptions, we have set the valve hold duration to 2000ms. Furthermore, we're considering establishing the lowest measurable heart rate at 30 bpm (0.5Hz or 2 seconds). The overarching goal is to detect one pulse beat for each step when the lowest bpm value is attained. For the valve release duration, we have chosen 50 ms, resulting in pressure exiting within the range of 4-6 mmHg. After the pressure falls below 20 mmHg, indicating the absence of a pulse beat, the valve will fully open until reaching 0 mmHg. The pressure data values will then be forwarded to the signal processing stage to estimate the values of MAP, SBP, and DBP.

3.2. Dataset Creation

We created and evaluated a dataset to test the accuracy of our algorithm. The dataset is distributed in accordance with the NIBP testing standards for bedside monitor evaluation, as specified by the Ministry of Health of the Republic of Indonesia in 2018, as outlined in Table 1. Data acquisition was conducted using the CONTEC MS200 NIBP Simulator to generate cuff pressure waveforms for specific BPM, SBP, and DBP values. We introduced variations by using all standard presets, each with BPM variations of 30, 60, 120, and 180, and this process was repeated 5 times for each setting, resulting in a total dataset of 140 data points.

The pressure threshold for data acquisition in presets 1, 5, 6, and 7 was established at 150 mmHg. As for presets 2, 3, and 4, the pressure threshold is determined by adding 30 to the systole score for each respective preset. The data acquisition results were stored in .txt format.

TABLE I. DATASET DISTRIBUTION

Setting Standard Variation	Blood Pressure (mmHg)		
	Systole	*Mean*	*Diastole*
Preset 1	120	93	80
Preset 2	150	116	100
Preset 3	200	166	150
Preset 4	255	215	195
Preset 5	60	40	30
Preset 6	80	60	50
Preset 7	100	76	65

3.3. Algorithm and Parameter Selection

The signal processing algorithm is implemented using MATLAB R2023a, benefiting from its versatile functions for signal graph plotting, facilitating signal analysis, and designing filters. The utilization of MATLAB's visualization and signal processing capabilities offers a robust foundation for the effective exploration and interpretation of NIBP data. With its powerful capabilities and various built-in tools for signal processing, MATLAB allows for efficient development and analysis of NIBP data. Fig. 5 illustrates the block diagram of the implemented algorithm.

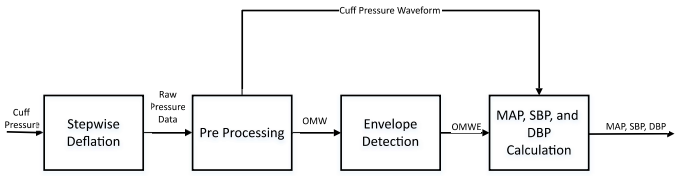

Fig. 5. Block Diagram of the Algorithm

- ***Pre-processing***

The primary goal of the algorithm is to detect the oscillometric signal to identify the values of MAP, SBP, and DBP. To achieve this, we utilize Low Pass Filter, High Pass Filter, and Moving Average filter. The LPF filter allows low-frequency components below its cut-off frequency to pass through, as shown in Fig. 6 (top), effectively eliminating environmental noise and producing a smoother cuff pressure signal. On the other hand, the HPF filter passes signals with frequencies higher than its cut-off frequency, as depicted in Fig. 6 (middle), facilitating the extraction of the oscillometric waveform. To further improve the signal quality, we apply a moving average filter, resulting in the smoothed signal displayed in Fig. 6 (bottom). For precise control over the filtering process, detailed parameters are utilized and listed in Table II.

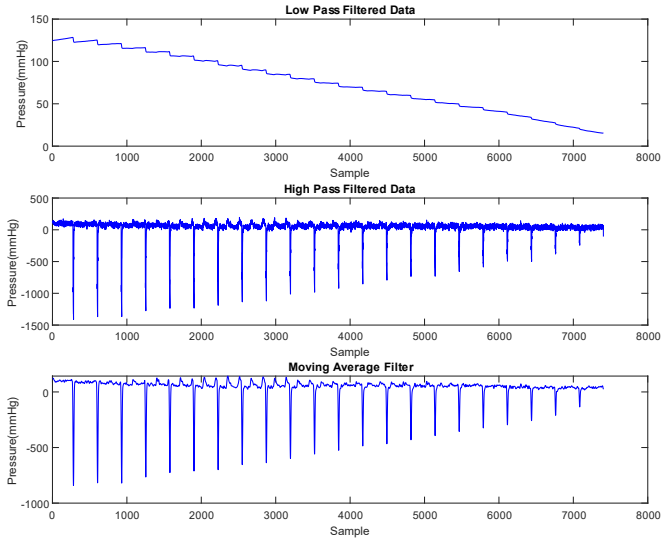

Fig. 6. Low Pass Filtered (top) , High Pass Filtered (middle), Moving Average Filter (bottom)

In the preprocessing stage, alongside filtering, we implement the process of signal amplification and offsetting data is utilized to increase the magnitude of the oscillometric waveform. Oscillometric waveforms may occasionally display small fluctuations or low amplitudes, especially in clinical scenarios involving weaker pulses. Moreover, this process enables the distinction between peak signals and noise,

contributing to consistent data processing and facilitating waveform comparisons across different signals. The application of signal amplification and offsetting assists in detecting and analyzing oscillometric waveforms, thereby simplifying the examination process.

- ***Envelope Detection***

After obtaining the oscillometric waveform, an upper envelope of the signal will be generated. This envelope is commonly referred to as the Oscillometric Waveform Envelope (OMWE). To obtain OMWE, an envelope detector algorithm is used. The algorithm takes the maximum amplitude of the oscillometric waveform in a certain frame length and adjusts the signal envelope to reach that maximum value. If the current envelope amplitude is lower than the maximum value, the envelope amplitude is incremented proportional to the error between the current envelope amplitude and maximum amplitude, and if the current envelope amplitude is higher than the maximum value, the envelope amplitude is decremented proportional to the error between current envelope amplitude and maximum amplitude. The presence of lower spikes in the HPF result is inconsequential as we focus on the upper envelope.

- ***MAP, SBP, and DBP Calculation***

The MAP, SBP, and DBP values are calculated based on the envelope values. The first step is to determine the MAP value from the maximum envelope value. In searching for the maximum MAP value, we limit it to ensure that the value does not reside at the beginning or at the end of the signal. Once the MAP value is obtained, the SBP and DBP values are determined by considering the ratios and control points in relation to data segments on both sides of the MAP value. Fig. 7 demonstrates the synchronization of the resulting indices on the envelope signal with the cuff pressure signal data obtained from the LPF.

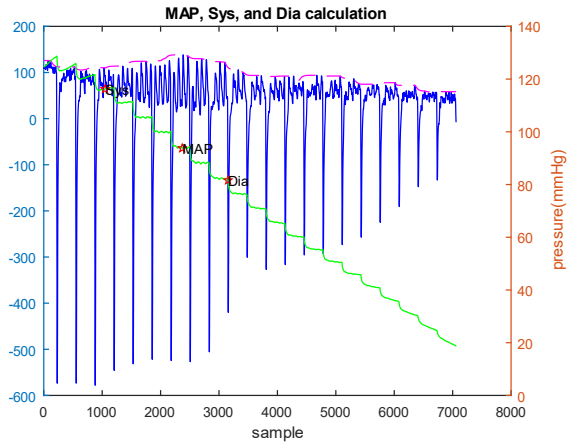

Fig. 7. MAP, Sys, and Dia Estimation

Several parameters have been selected for implementation in the algorithm. Detailed information regarding the values of each parameter used can be found in Table II.

TABLE II. ALGORITHM PARAMETER

Parameters	Value
Cut-off LPF	15 Hz
Cut-off HPF	0.3 Hz
Frame Moving Average	15 ; 10
Frame Length of Envelope	300
Ratio Sys	0.7
Ratio Dia	0.8

4. Result and Discussion

In the cuff pressure data acquisition process using the stepwise deflation method, we control the valve according to the flowchart shown in Fig.3, where the valve is closed during the valve hold period (2000ms) and opened during the valve release period (50ms). Performance graphs for each hold and release step are presented in Fig.10 and Fig.11, illustrating the time (milliseconds) taken for each operation. Table III provides valuable insights into the valve-controlled performance, showcasing the mean and standard deviation of errors and accuracy for each valve condition.

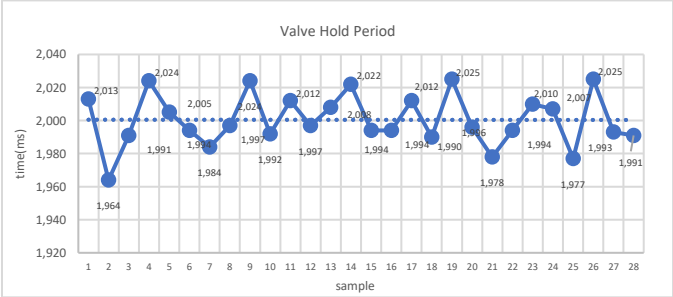

Fig. 8. Graph of Valve Hold Period in Measurement

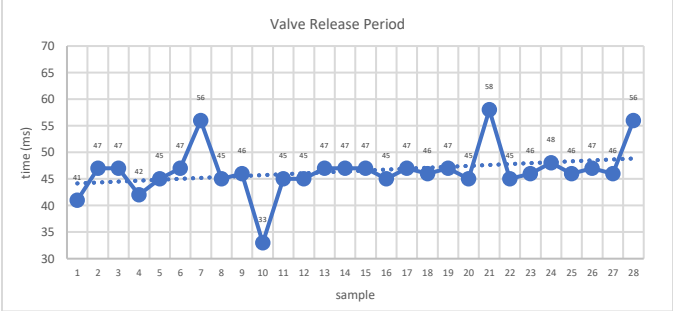

Fig. 9. Graph of Valve Release Period in Measurement

TABLE III. VALVE CONTROLLED PERFORMANCE

Valve Condition	Error (s)		Accuracy	
	Average	*St.Deviation*	*Average*	*St.Deviation*
Hold (Closed)	0.012893	0.008702	99.36%	0.44%
Release (Opened)	0.00493	0.002918	90.14%	5.84%

Notably, there is a significant difference in standard deviation values between the valve hold and valve release periods. The larger standard deviation during the valve release period suggests increased data variability, likely influenced by the instrument's ability to synchronize timing in very short intervals during the 50ms valve release.

The algorithm's performance in measuring MAP, SBP, and DBP values through cuff pressure data acquisition using the stepwise deflation method was assessed. We examined the results from the bpm-based approach (Table IV and Table V) and the preset-based approach (Table VI and Table VII) as listed in Table I. We observed the mean and standard deviation of errors and accuracy for each MAP, SBP, and DBP value.

TABLE IV. AVERAGE OF BPM-BASED PERFORMANCE

BPM	Error (mmHg)			Accuracy		
	Sys	Dia	MAP	Sys	Dia	MAP
30	3.91	3.20	3.11	96.83%	95.65%	96.03%
60	3.176	3.353	4.176	97.07%	95.06%	95.03%
120	3.94	4.29	4.83	95.75%	93.56%	94.10%
180	3.74	4.51	4.89	96.26%	92.97%	93.80%

TABLE V. STANDARD DEVIATION OF BPM-BASED PERFORMANCE

BPM	Error (mmHg)			Accuracy		
	Sys	Dia	MAP	Sys	Dia	MAP
30	3.27	2.31	2.22	2.31%	4.12%	4.02%
60	2.61	2.22	3.41	3.48%	4.69%	6.36%
120	2.97	2.52	2.99	4.63%	5.53%	5.32%
180	2.92	2.72	3.01	4.01%	7.57%	5.35%

TABLE VI. AVERAGE OF PRESETSS-BASED PERFORMANCE

Standard Setting Variation	Error (mmHg)			Accuracy		
	Sys	Dia	MAP	Sys	Dia	MAP
1	3.55	4.40	4.10	97.04%	94.50%	95.59%
2	4.80	3.70	4.25	96.80%	96.30%	96.34%
3	2.80	4.05	3.55	98.60%	97.30%	97.86%
4	2.30	3.95	4.85	99.10%	97.97%	97.74%
5	5.10	4.10	5.60	91.50%	86.33%	86.00%
6	4.25	4.50	4.40	94.69%	91.00%	92.67%
7	3.90	2.05	5.10	96.10%	96.85%	93.29%

TABLE VII. STANDARD DEVIATION OF PRESET-BASED PERFORMANCE

Standard Setting Variation	Error (mmHg)			Accuracy		
	Sys	Dia	MAP	Sys	Dia	MAP
1	2.98	2.95	3.74	2.48%	3.68%	4.02%
2	3.05	2.00	2.81	2.04%	2.00%	2.42%
3	2.67	2.61	3.50	1.33%	1.74%	2.11%
4	2.15	2.70	3.07	0.84%	1.39%	1.43%
5	3.65	2.57	3.91	6.09%	8.58%	9.78%
6	3.19	2.28	3.27	3.99%	4.57%	5.45%
7	2.47	1.57	2.77	2.47%	2.42%	3.64%

From the obtained measurements, we calculated the average values of errors and accuracy for both the bpm-based and preset-based approaches. The maximum error value was found to be 5.6, while the minimum was 2.05. As for accuracy, the maximum value reached 99.1%, and the minimum value was 86.0%. Additionally, we computed the standard deviation values for both error and accuracy in both approaches. The maximum standard deviation for error was 3.91, and the minimum was 1.57. For accuracy, the maximum standard deviation was 9.78%, and the minimum was 0.84%.

According to the NIBP testing standards for bedside monitor evaluation, as defined by the Ministry of Health of the Republic of Indonesia in 2018, a desirable error value is ±5 to avoid false diagnoses for individuals. Referring to Table VI, presets 1, 2, 3, 4, 6, and 7 exhibit an average error <5 for SBP, DBP, and MAP. Although, for preset 5, the SBP and MAP values have an error >5. As indicated in Table I, which presents the dataset distribution, preset 5 possesses the lowest values. This algorithm has not yet yielded optimal outcomes for presets with lower values.

The standard deviation values provide insights into the consistency of the algorithm's performance. The relatively low values of standard deviation for error (ranging from 1.57 to 3.91) and accuracy (ranging from 0.84% to 9.78%) indicate that the algorithm's estimations are relatively stable across multiple runs and scenarios. The lower the standard deviation, the more consistent the algorithm's performance.

5. Conclusion and Recommendations

This paper focuses on the cuff pressure data acquisition process using the stepwise deflation method. The selection of a 2000ms duration for the valve to remain closed is appropriate as it allows for accurate recording of pulse beats. Similarly, the 50ms duration for the valve to open is also suitable as it effectively reduces the pressure by 4-6 mmHg, enabling the recording of data without prolonging the process.

The signal processing algorithm has provided optimal results (±5 mmHg error) for presets 1, 2, 3, 4, 6, and 7 at each BPM. The relatively low values of standard deviation for error and accuracy indicated a consistent performance of the algorithm across multiple runs and scenarios. These findings emphasize the stability and reliability of the algorithm's estimations.

In the future, it is expected that there will be further development and optimization of the algorithm to yield favorable outcomes within a wider range of measurement values, particularly for low blood pressure data.

***Abstract*—Due to safety reasons, the development of Reinforcement Learning (RL) based Traffic Signal Controller (TSC) can not be perform in real-world environment. A training and hardware/software co-simulation platform is needed to verify that the RL-based TSC works well before being deployed in real-world environment. In this paper we discuss the design and development of such platform using SUMO and python for 2-agent Q-Learning Algorithm. The platform receives Q-Matrix from an external device and then process the Q-Matrix to control the environment. Overall, the design works well. The platform could train the RL Agent and could affect the environment. Improvement could be made in minimizing the execution time of the simulation.**

I. Introduction

Traffic signals are designed to regulate traffic at an intersection. In Indonesia, many of the traffic signals are pre-timed [1]. The Department of Transportation first do a survey of traffic condition on a certain area and then create traffic signal plans based on the traffic. The plans are designed to be dynamically switched based on the time of the day. Some of the traffic signals are also designed to be coordinated with its adjacent intersections. The commonly used way to perform coordination is by setting green time offset between adjacent intersections which is called as "green wave" [2]. However, this method is not optimised for a highly fluctuating traffic and prolonged congested intersections [1], [3].

A more advanced way in traffic signal control that is deployed in big cities are Adaptive Traffic Control System (ATCS) which is a self-optimising control based on real-time vehicle data [1]. However, the ATCS are unable to handle oversaturated traffic well [3]. In addition, the abundance of traffic data and the very complex nature of traffic results in the need of a model-free traffic signal controller (TSC) [4], [5].

Reinforcement Learning (RL) is one of the methods that is being developed to solve the problems. RL does not require a model for complex traffic behavior, thus has a good outlook for future TSC [4]–[6]. RL-based TSC is, however, infeasible to be directly deployed in real-world due to safety reasons. Therefore, a platform to train RL-based TSC is needed. The platform must perform hardware/software cosimulation, that is verifying that hardware and software function correctly together [7].

In this paper, we discussed the development of a training platform for a Q-learning TSC. The platform provides Q-learning training environment that represents real-world condition of Dago-Cikapayang and Dago-Sulanjana intersections in Bandung. The traffic volume data is based on traffic counting at those intersection during peak hour. The TSC is also designed to comply with regulations of minimum duration of a traffic signal phase. Several simplification is, however, made, that is, the geometric of the intersection to become two adjacent 4-way intersection and the vehicle that is simulated is only car.

II. Related Works

A. Q-Learning

Reinforcement Learning is a branch of machine learning where the learning *agent* picks an action given a state with a goal to maximize its long-term reward. The agent at time t observes the current state of the environment, s_t, and takes an action, a_t. This in turn changes the environment to its next state, s_{t+1}, and gives the agent a reward, r_t. One of the learning and exploring methods for RL agent is Q-Learning Algorithm. The Bellman Equation, used for calculating the maximum future reward, is given in the equation below.

$$Q_{t+1}(s_t, a_t) \leftarrow Q_t(a_t, s_t) + \alpha\delta_t(s_t, a_t) \tag{1}$$

B. Simulator of Urban MObility (SUMO)

Environement simulation is needed for the training of RL agents. There are three modelling levels in traffic simulator: macroscopic, mesoscopic, and microscopic. Macroscopic traffic simulator simulates the aggregate behaviour of the traffic flow, while microscopic traffic simulator simulates the individual behaviour of the vehicle. On the other hand, mesoscopic

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

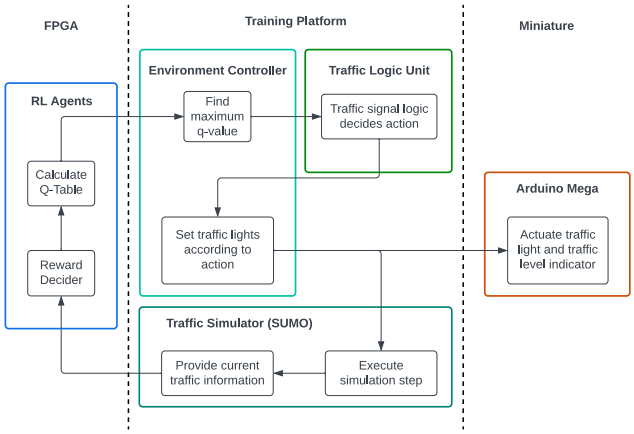

Fig. 1. Process Diagram for the RL Training Platform

model of traffic simulation is in the middle between microscopic and macroscopic [8]. The complexity of the simulation increased as the detail of the simulation increased.

In this paper, we use a microscopic traffic simulator to simulate the environment due to the required level of details. Some examples of microscopic traffic simulator are Vissim and SUMO. SUMO is chosen due to the open-source nature of the program, which requires no license, and due to the availability of its interface to Python called TraCI (Traffic Control Interface). TraCI provides us convenience in getting and providing data from and to the simulation.

C. Serial Communication

The training platform is designed to send the decided action to a two adjacent 4-way intersection miniature. The decided action is taken shown by the traffic light LEDs and the queue length is shown by LED strips on each approach of the intersection. The miniature is run by Arduino Mega. Communication between the training platform and Arduino Mega is required. Communication is established by serial communication due to its practicality both on Arduino and on a PC.

III. Design

The training platform consists of four main parts: Simulator, Environment Controller, Traffic Logic Controller, and Communication Module. The interaction between those parts is shown in the figure 1. RL agents, which are planted on an FPGA, produce q-tables. The q-tables are in the form of 3D array. Environment controller find the maximum q-value from the q-tables. The j and k index of the maximum q-values corresponds to the wished action and target level. However, this action and target level do not directly be actuated in SUMO or miniature, since the traffic signals needs to comply to other rules. The wished action and target level is then processed in a Traffic Logic Controller.

Traffic Logic Controller decides which action to take based on several conditions. The conditions are made such that the resulting action complies with regulations of traffic signals. The decided action, then, is sent back to Environment controller to set the traffic signals. The traffic signal states is then transferred both to Arduino Mega and SUMO Traffic Simulator. After displaying the current traffic signal state, SUMO will take the next step in the simulation and updates the current traffic conditions. The information then transmitted to FPGA to be considered for the reward of the action.

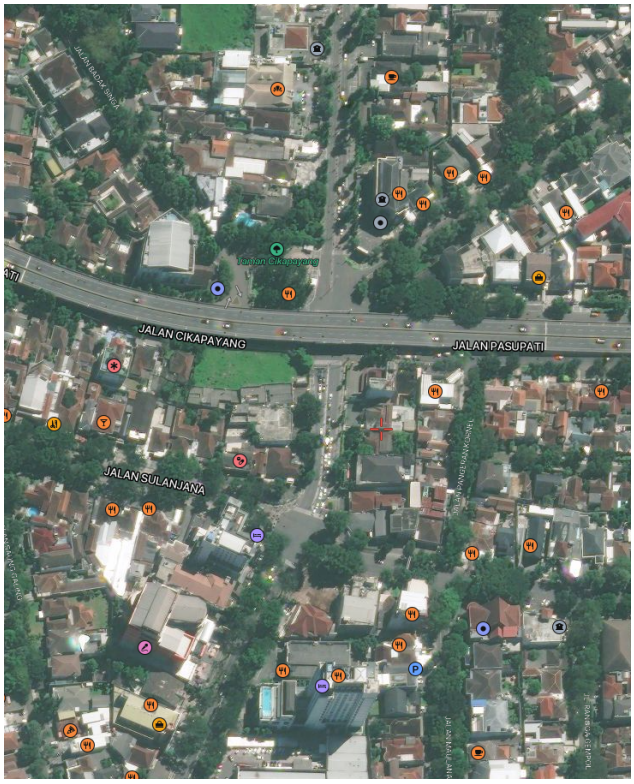

Fig. 2. Satellite imagery of Dago-Cikapayang and Dago-Sulanjana intersections.

A. Simulator Design

The simulator design involves intersection geometric design and traffic condition reproduction. Our aim is to design a simulation that reproduce peak hour traffic condition at Dago-Sulanjana and Dago-Cikapayang intersection.

1) Intersections Geometric Design: Figure 2 shows the satellite imagery of Dago-Cikapayang and Dago-Sulanjana Intersections which is the focus of this paper. The simplified version of the Intersections needs to be produced. Dago-Sulanjana intersection is kept as it is. It has 4 approaches. The western and eastern approaches of Dago-Sulanjana is a two-lane two-way undivided roads (2/2 UD). The northern and southern approach of the intersection is a four-lane two-way divided roads (4/2 D).

At the Dago-Cikapayang intersection, originally there are five approaches. The eastern, northern, western, and the southern approaches of Dago-Cikapayang intersection are available for both entering and exiting the intersection. The north-eastern approach is an exit-only approach to Jalan Dipatiukur. The

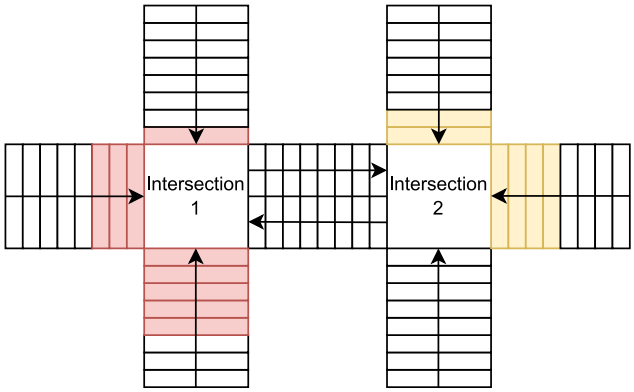

Fig. 3. Dago-Cikapayang and Dago-Sulanjana Intersection Model

TABLE I
NUMBER OF VEHICLES CROSSING DAGO-SULANJANA AND DAGO-CIKAPAYANG INTERSECTIONS (PASSENGER CAR EQUIVALENT)

Direction of Origin	Dago-Cikapayang	Dago-Sulanjana
Eastern Approach	784	648
Northern Approach	1548	1204
Western Approach	1116	420
Southern Approach	1780	1264

simulation will focus on the intersection and the link between Dago-Cikapayang and Dago-Sulanjana. Thus, vehicles exiting the approaches — except for the link — is not relevant for the simulation. On the other hand, running Multi-agent Q-Learning algorithm for two 4-way intersections is more feasible memory wise. Therefore, the Dago-Cikapayang intersection is simplified to a 4-way intersection. Each approaches of the intersection is a 4/2 D roads.

As Q-Learning algorithm requires discrete states, the queue length of each approach at both intersection must be divided into discrete levels. Considering the memory limitation of the Xilinx PYNQ FPGA that is used for RL Algorithm computation, the queue length on each approach is divided into 4 levels. The design of the intersection geometric is shown by figure 3.

2) Traffic Flow Design: To produce a more realistic traffic data we did a traffic counting on Dago-Cikapayang and Dago-Sulanjana intersection at peak hour. During the peak hour, bottleneck that causes queue in the middle of the intersection often happens. The simulation should be able to reproduce this event. The obtained data is shown in table I, table II, and table III. Table I shows the traffic counting result. The number of vehicles in the table is a result of Passenger Car Equivalent (PCE) conversion. The numbers of motorcycle, light vehicles, and heavy vehicles are all converted to PCE. The turning ratio in Dago-Cikapayang intersection and Dago-Sulanjana intersection are shown in table II and table III correspondingly. The data in the tables is recorded in an hour, thus in the simulation the data should be spread in an hour too.

TABLE II
TURNING RATIO OF DAGO-CIKAPAYANG INTERSECTION

Direction of Origin	Left-turn ratio	Right-turn ratio
Eastern Approach	0.133	0.623
Northern Approach	0.067	0.299
Western Approach	0.073	0.656
Southern Approach	0.162	0.309

TABLE III
TURNING RATION OF DAGO-SULANJANA INTERSECTION

Direction of Origin	Left-turn ratio	Right-turn ratio
Eastern Approach	0.32	0.336
Northern Approach	0.149	0.066
Western Approach	0.202	0.202
Southern Approach	0.123	0.164

B. Traffic Logic Unit Design

Traffic Logic Unit receives maximum q-value of the current state with its j and k index from the q-matrix 3D array. The j index corresponds to which action to take, while the k index corresponds to the target level of the lane to which an action is given. Traffic Logic Unit decides which action to take by considering the current state, thus q-value, and other considerations.

One of the considerations that should be taken into account by Traffic Logic Unit is regulations of the local government. In Indonesia, the government regulates the minimum duration of yellow signal of 3 seconds [9]. In addition to that, other knowledge or wisdoms could be added too. During our observation, we noticed that the shortest duration of green signal in Dago-Cikapayang and Dago-Sulanjana intersection is 20 seconds. We decided to retain the minimum green time of 20 seconds to prevent quick change of only several seconds of green. A quick change of traffic signal could poses danger to crossing pedestrians due to the size of the intersection. The Traffic Logic Unit's workflow is illustrated by the Finite State Machine (FSM) on the Figure 4 below.

C. Environment Controller Design

Environment controller has the job to influence the environment simulated by the training platform. Control of the environment is done by giving action based on the Q-Learning Algorithm. The action is giving green signal to a certain lane based on q-value and other rules. As figure 1 describes, Q-table is received by Environment Controller from FPGA. The first task that the environment controller must do is to find the maximum q-value at current traffic condition. After the maximum q-value is obtained, Environment Controller send the data to Traffic Logic Unit to be processed further.

The Environment Controller then received the final action that should be applied to the environment from the Traffic Logic Unit. The second task of the Environment Controller is to codify the actions to be applied to the environment in accordance to the agreed communication mechanism.

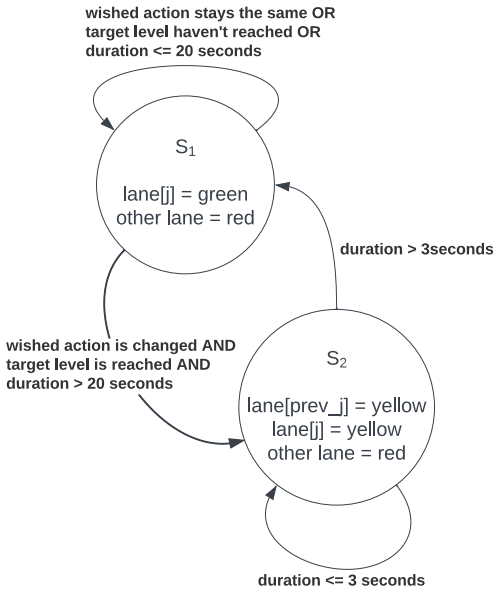

Fig. 4. Finite State Machine of RL-mode Traffic Logic Unit

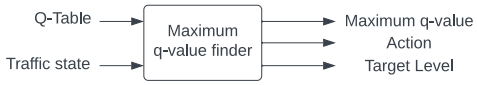

Fig. 5. Diagram of Maximum Q-Value Finder

1) Maximum Q-Value Finder: The Maximum Q-Value Finder should accomplishes the first task of the Environment Controller. It receives Q-Table from FPGA and current traffic state of the intersection as an input and produce maximum Q-value, action, and target level of the current state. It works by converting received Q-Table into 3D array. The function then find the row of the current state and find the maximum q-value on that row. It returns the maximum q-value itself, the index j of the q-value which corresponds to the action that should be done, and the index k of the q-value which corresponds to the target level that should be achieved by lane-j. The maximum Q-Value Finder function is illustrated in Figure 5.

2) Communication Module: A communication module is required for communication between FPGA, the training platform, and the miniature as illustrated in figure 1. In addition, a communication between Python and SUMO is also needed to be established. Miniature, which is run by Arduino Mega, and Training Platform, which is based on Python, communicates through serial connection. The library *pyserial* is used in Python. As mentioned in section II-B, the communication with SUMO is done through TraCI.

As the communication is established, the form of communicated message is needed to be agreed. TraCI has its own message format for traffic signals phase actuation. The Environment Controller needs to produce a message that comply to this format. For the serial communication with Arduino, a message format is also needed.

a) SUMO Phase State Encoder: SUMO's TraCI receives traffic light phase state in a string as a tuple of light definitions from rugGyYuoO, for red, red-yellow, green, yellow, off. In our Dago-Cikapayang and Dago-Sulanjana network, the phase state definition consists of 16 characters. The first four characters is controls the traffic signals of the eastern approach, the second four characters for the northern approach, the second last four characters for the western approach, and the last four character for the southern approach.

SUMO Phase State Encoder encode the actions that needs to be actuated to the TraCI string format. Based on the FSM of the Traffic Logic Unit in Figure 4, the state of the FSM, the action — index j of maximum q-value, which corresponds to the lane number that should be given green — and the previous action should be codified into TraCI string format. The state of the FSM is relevant to decide which action should be taken: giving green light to lane-j or giving yellow light to lane-j and lane-$previous_j$. The final string is later sent to SUMO through TraCI.

b) Arduino Phase State Encoder: Since a traffic intersection miniature is connected to the training platform, a communication mechanism between the training platform to Arduino Mega is needed. Serial communication is chosen because of its availability in Arduino Mega and its practicality. A message format is also needed in order to communicate well between devices.

One of the design consideration of the message format is the length of message. Serial communications send data bytes-by-bytes. Therefore, a message that is too long is undesirable since it could have a big delay. It also consumes more memory and costs more processing power. The size of a char that is transmitted with serial communication is 1 byte. The number of bytes will later affect the chosen baud rate of the serial communication. Due to the fact that a simulation of 1 step in SUMO corresponds to 1 second in the real-world, length of the transmitted message do not matter much. However, to make it more time efficient in testing, we would like to run the simulation with delay of each step of 0.1 second. With a typical baud rate of $9,600$ bits per second, the size of transmitted data needs to be at most 12 bytes, thus 12 characters.

According the FSM in Figure 4, there are 3 data that are needed to be transferred for a Traffic Light in an intersection: state of the FSM, current action, and the previous action. There are 2 states of the FSM, 4 possibilities of current action, and 3 possibilities of previous action. In summary, there are 24 states for a Traffic Light in an intersection. Since we have 2 intersection, we have 576 combined states.

We decided to convert the FSM's state, current action, and previous action of both intersection into integer. We then represent the integer in 3-digit hexadecimal and send the hexadecimal to Arduino Mega using serial communication. To convert those 6 elements to integer, the formula (2) is used. DC corresponds to Dago-Cikapayang and DS corresponds to Dago-Sulanjana.

$$msg_{int} = DC_{state} + 2 \cdot DS_{state} + 4 \cdot DC_{action} + 16 \cdot DS_{action} + 64 \cdot DC_{prev_action} + 256 \cdot DS_{prev_action} \quad (2)$$

Other than traffic light information, the transfer of current traffic level information of both Dago-Cikapayang and Dago-Sulanjana intersection is needed. Each approach of the intersection has 4 levels. This results in 256 states per intersection. We converted each intersections state into 2-digit hex and then append them to the 3-digit hex of traffic light states. In the end, we will have a 7-digit hex with the first three digit represent the traffic light states, the fourth and fifth digit represent Dago-Cikapayang traffic levels, and the last two digits represent Dago-Sulanjana traffic levels.

D. GUI Design

The training platform needs a GUI to show the simulation data in a more precise manner. The GUI will show the number of vehicles on each lanes and its level. Other than that, the GUI will also have the button to start the simulation.

IV. Design Implementation

In this part, the design stated in the previous chapter is implemented. The results are also shown to proof that the design is implemented correctly.

A. SUMO Implementation & Results

The microscopic traffic is simulated with SUMO. The design is being implemented by importing Dago-Cikapayang and Dago-Sulanjana intersections from OpenStreetMaps. The road network is then edited to conform to the design. Discrete levels on each of the approaches is implemented by placing a detector with the length of 100 meters. Each levels then equivalent of 25 meters queue. The traffic flow is implemented by creating random trips of vehicles and then sample the random trips based with turn counts data. The sampling results in $6,974$ trip routes with total counting of $8,760$. The number is very close to the sum of traffic counting data in Table I which is $8,764$. Figure 6 shows the final intersection geometric implemented in SUMO. When the simulator is run, the traffic congestion and bottleneck occurs. It shows that the simulation has been correctly implemented.

B. Traffic Logic Unit Implementation

Traffic Logic Unit is implemented with Python as smaller functions that is illustrated in Figure 7. Each of the functions is tested individually. The individual testing runs well. The testing of Traffic Logic Unit will be combined with the Environment Controller in the next section since the two is closely related.

C. Environment Controller Implementation & Results

The Environment Controller is implemented with Python too. The first function that is implemented is the maximum q-value finder. The maximum q-value finder is implemented as *q_matrix_2d_to_matrix* function. The testing is done by loading a CSV with 256 rows 16 columns. The columns represents 4 elements of array of 4. The Q-Table from the CSV is successfully loaded to 3D matrix. The result that is printed in the console is in accordance to the source CSV file.

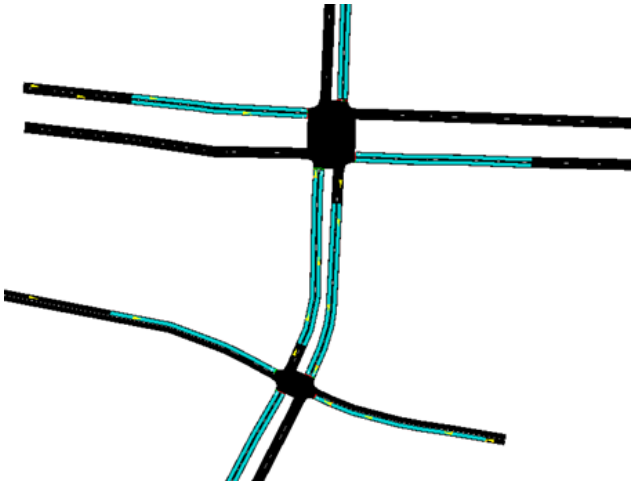

Fig. 6. Intersection geometry in SUMO

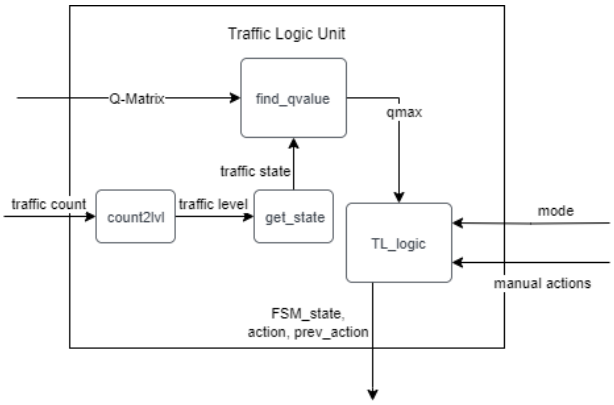

Fig. 7. Smaller function in Traffic Logic Unit Implementation

The second part of the Environment Controller that is implemented is the communication module. In accordance to the design, we implemented the SUMO Phase State Encoder and Arduino Phase State Encoder. The testing of Arduino Phase State Encoder is done by giving entering input of FSM state of Dago-Cikapayang (in the Table IV indicated by number 1), FSM state of Dago-Sulanjana (2), action of Dago-Cikapayang (3), action of Dago-Sulanjana (4), previous action of Dago-Cikapayang (5), previous action of Dago Sulanjana (6), traffic state of Dago-Cikapayang (7), and traffic state of Dago-Sulanjana (8). We send the message to Arduino and programmed the Arduino to resend the received message. The correct response would be, our console receives the message back. The result of this testing is shown in Table IV. The results in the table shows that the module has been implemented correctly since our console receive the exact message that we sent.

D. GUI Implementation & Results

The GUI is implemented using tkinter library on Python. The GUI shows global variables of vehicle counts and queue length in the form of discrete levels. Besides, there is also

TABLE IV
TESTING OF ARDUINO COMMUNICATION MODULE

Input								Output	
1	2	3	4	5	6	7	8	From Arduino	Ref
1	1	0	2	3	1	228	27	b'1e0e41b\r \n'	1e0e41b
2	2	3	0	1	1	217	82	b'14fd952\r \n'	14fd952
1	1	3	0	1	1	10	111	b'14c0a6f\r \n'	14c0a6f
2	2	1	2	3	0	106	84	b'0e76a54\r \n'	0e76a54
1	1	1	1	0	0	0	0	b'0140000\r \n'	0140000
2	2	3	3	2	2	255	255	b'2bffffff\r \n'	2bffffff

a button to start the simulation. As the simulation run, the Python script calls TraCI to updates the number of vehicles in each step. The number of vehicles then processed that results in levels. At the same time, GUI needs to show the data. Therefore, threading is used to allows part of programs to run concurrently.

The GUI is shown by Figure 9. The number of vehicles that is shown in the GUI is consistent with the number of vehicle that is in the simulation. The simulation is shown in Figure 10. From Figure 10, we could manually count that on the eastern approach of Dago-Cikapayang (the northern junction), there are 0 cars, 13 cars on the southern approach, and 28 cars in the detector area on the western approach. We can conclude that the GUI shows the data appropriately and has been implemented correctly.

V. ANALYSIS & DISCUSSION

In this paper, the execution time of the simulation is analysed and the match between SUMO and miniature traffic light phase and traffic state is verified.

A. Execution Time

Execution time of SUMO is measured between simulation without miniature and simulation with miniature. When the PC that runs simulation is connected to the miniature, communication between PC and miniature (Arduino Mega) is done. Table V shows the result of execution time in 10 different measurements with miniature. On the other hand, Table VI shows the result of execution time in 10 measurements without miniature In each measurement the simulation is set to have 3601 steps.

Based on the measurement, the average execution time is 574.987 seconds for total simulation which means an average duration of 159.674 milliseconds per step. Without miniature, the average execution time for 3601 steps is 460.323 seconds and 127.82 milliseconds per step. It is shown that there is a speedup of 0.8 when miniature is connected to the PC. With 95% confidence interval, the difference between simulation with- and without miniature is in the range of 58.663 seconds and 170.663 for 3601 simulations or between 25.84 milliseconds and 37.84 milliseconds for each step.

One of the predicted causes of this delay is the communication delay between PC and Arduino. Theoretically, for the transmission of 7 characters using serial, 7 bytes is needed.

TABLE V
MEASUREMENT OF EXECUTION TIME WITHOUT MINIATURE

Measurement Number	Duration (s)	Duration per step (s)	Step per second
1	552.436	153.412	6.518
2	575.949	159.941	6.252
3	577.042	160.244	6.240
4	578.972	160.781	6.219
5	576.653	160.137	6.244
6	575.841	159.911	6.253
7	579.044	160.801	6.219
8	577.409	160.347	6.236
9	578.351	160.609	6.226
10	578.172	160.559	6.228

TABLE VI
MEASUREMENT OF EXECUTION TIME WITH MINIATURE

Measurement Number	Duration (s)	Duration per step (s)	Step per second
1	480.863	133.536	7.489
2	458.438	127.309	7.855
3	456.613	126.802	7.886
4	457.938	127.170	7.863
5	455.050	126.367	7.913
6	460.809	127.967	7.815
7	457.657	127.092	7.868
8	460.323	127.832	7.822
9	463.118	128.608	7.776
10	452.417	125.636	7.959

With baud rate of 9600 bits per second, 5.6 milliseconds is needed. However, as the simulation is done in discrete steps, the duration of the simulation also play an important role in determining the communication duration.

Figure 8 shows the execution time for each step in simulation. It is shown that the execution time increases as the step increases and forms a logarithmic curve. This causes by the increase of simulation complexity as the simulation goes on. In the early stage of the simulation, the number of cars simulated is low, therefore the computational power needed to process the simulation is low. This results in faster execution time. As the step increases, more cars spawn in the simulation. Thus, more computation is needed. The simulation is a microscopic simulation, where each car is simulated uniquely in detail. Therefore the need of computational power is high.

B. SUMO and Miniature Traffic Light Phase and Traffic State Verification

As the miniature and the simulator GUI together display traffic light conditions, a verification should be done. Verification is done by comparing the traffic light phase in simulator and in Arduino. The simulation is set to have 3601 steps and is controlled by RL TSC. The verification results in 97.501% match between the traffic light phase and traffic state that is shown in the miniature and in SUMO.

The error is caused by delay between subsystems. Every change in traffic light phase or traffic state has a delay of 2 steps, e.g., if a change occurs at step 38 in SUMO, the change will be presented in miniature in step 40. However,

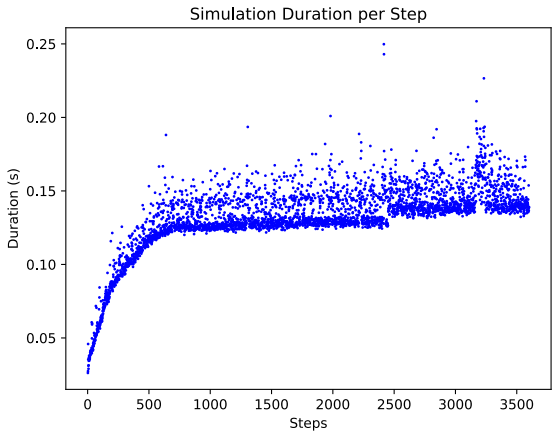

Fig. 8. Execution time per step

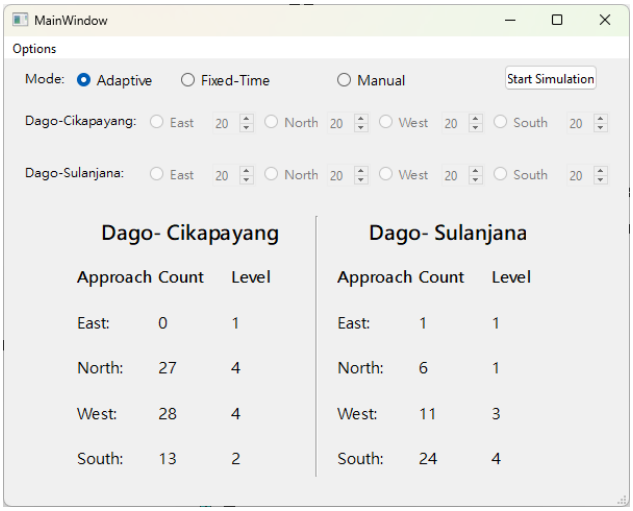

Fig. 9. GUI of the training platform

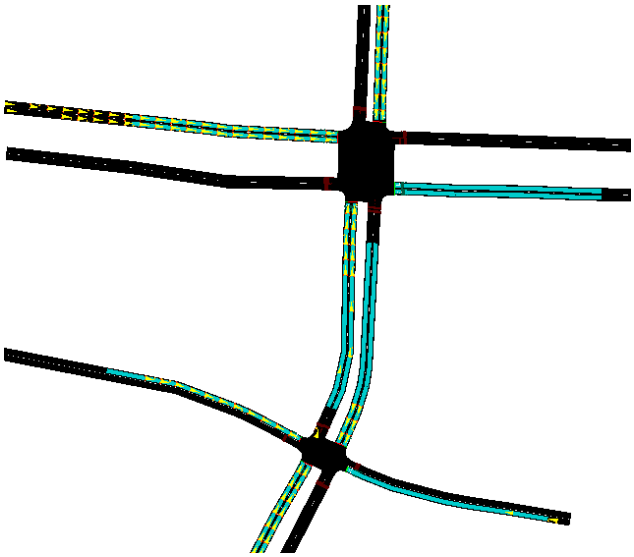

Fig. 10. SUMO simulation for GUI testing

this is recorded when the duration of each simulation step is set to 10 milliseconds. Referring to Figure 8, the duration of delay is varied according to the step of the simulation. An adjustment to the simulation step duration is needed so that the unsynchronization is reduced.

VI. Conclusion

Overall, the system has been implemented correctly and works appropriately. This is shown during the testing of the GUI in Figure 9 and Figure 10. The simulation is running well. It means that the underlying functions is implemented correctly. The behavior of the traffic light comply with regulations and the intended design. However, the system currently take Q-Matrix from CSV. The intended design was, the system is connected to FPGA and communicates directly with the FPGA. Further development in the communications with FPGA is needed. The mechanism of the communications should be designed.

Improvement could also be made as an effort in making the simulation faster. A device dedicated to simulate the environment could provide a good computational power for simulation, especially when the complexity of the simulation is high. In addition, an adjustment to the simulation step time is needed in order to reduce the unsynchronization between simulator and miniature.

***Abstract*—The Convolutional Neural Network (CNN) is a frequently used algorithm used technique for processing pixel data and visual images. Nevertheless, the utilization of extensive network sizes poses significant obstacles to the underlying technology's throughput and energy efficiency. Various methods have been devised to enhance the efficiency and computing speed of Convolutional Neural Network (CNN) acceleration, improving the accuracy of the CNN process. Compression techniques have been employed in the algorithmic aspect to minimize the number of parameters in each layer, enhancing the detection process's efficiency. Pruning is a compression technique that involves the removal of neurons and synapses that do not play a substantial role in the detection process, hence minimizing their impact on the Neural Network layer. The compression method generates sparse data, wherein a significant amount of data has a value of zero. Various pruning techniques provide distinct types of sparse data, encompassing organized structured sparse and unstructured sparse data.**

The consequent form of sparse data structure has many advantages and downsides. Based on an analysis of various extant sparse data structures, an innovative accelerator has been developed to perform convolution operations using various types of sparse data obtained via distinct pruning procedures. The design architecture outlined in this study involves the removal of all zero-valued data weights through a pruning technique following the training process. The accelerator will process all non-zero weights by performing the convolution process promptly, utilizing the "weight stream" data. The findings from the conducted design testing indicate that the utilization of trimmed sparse data leads to improved performance in terms of faster output during the convolution process. The researchers conducted experiments utilizing diverse types of sparse weighted data, encompassing both structured and unstructured forms. These experiments provided evidence that the hardware accelerator is capable of performing convolutional computing operations with different variations of sparse data. The convolution procedure utilizing the developed accelerator is projected to yield a reduction of 56% in the computation results of all layers in YoloV3-Tiny. In the context of data calculations, including a sparsity percentage of up to 30%, it can be observed that the convolution process exhibits a reduction of 25% in relation to the overall convolution process.

I. Introduction

CNN is widely recognized as a prominent approach for constructing a robust architecture to facilitate model detection. Several detection model algorithms have been devised in image processing to comprehend images, discern objects, and effectively categorize them. The utilization of Convolutional Neural Networks (CNN) in image processing has been observed in a multitude of applications, including but not limited to autonomous cars, video surveillance, facial recognition, and other activities related to image processing. The structure of CNN exhibits similarities to the cognitive processes involved in visual information processing in the human brain. The layers of the CNN algorithm progressively extract more intricate information as the data traverses the network. This method enables the model to comprehend abstract and detailed elements inside images.

The CNN architecture incorporates a mechanism for parameter sharing. In the convolution layer, every neuron employs uniform weights to identify characteristics throughout the entirety of the image. This approach effectively decreases the number of parameters the model has to learn, enabling CNN to be trained using extensive datasets without requiring excessive computer resources. The utilization of CNN, which has the ability to learn and identify common characteristics seen in extensive image datasets, renders it suitable as an initial framework for transfer learning. This conditions implies that a model trained on a substantial dataset can be applied to several tasks, or a smaller dataset can be utilized with slight modifications. Additionally, this practice aids in conserving time and computational resources while training novel models. The advent of CNN has led to significant progress in image processing and computer comprehension. The model's performance and efficiency in image processing applications have been further improved by the development of more complex CNN architectures like ResNet, VGG, and Yolo.

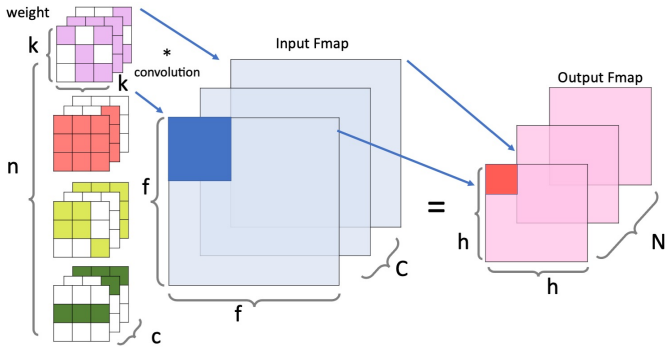

Fig. 1. Convolution Process

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

CNN is a deep learning method specifically developed to analyze and manipulate data presented in a grid-like structure, such as a two-dimensional image. There has been a proliferation of studies involving CNN, leading to widespread implementations of AI in fields as disparate as computer vision, robotics, autonomous vehicles, and medical diagnostics. CNN, short for Convolutional Neural Network, is a computational model that draws inspiration from the mechanisms behind visual perception in mammals. Compression is a viable technique for expediting the acceleration process, achieved by enhancing the speed of the detection process through the utilization of the Convolutional Neural Network (CNN) algorithm. The CNN process acceleration improvement procedure encompasses three main stages: the Algorithm, Structural, and Hardware level [1]. Compression techniques, such as pruning, occupy a position inside the redundancy process at the structural level. At this stage of the structure, various compression techniques are implemented, including pruning and quantization, in order to compress the weights of data or filters used in the detection phase. The acceleration process is implemented at the algorithmic level through the incorporation of additional algorithms into the architecture of the detection model. Similar to the convolution procedure, the efficacy of the convolution process can be enhanced by including convolution algorithms such as Winograd, Fast Fourier Transform (FFT), and General Matrix Multiply (GEMM). At the hardware level, the acceleration of the CNN process is achieved through the development of specialized devices capable of enhancing the speed and efficiency of the fundamental computations involved in the CNN algorithm. Furthermore, a pertinent concern that arises in the realm of hardware pertains to the methods of parallelization and data movement reduction. In the context of detection, particularly real-time detection, a substantial volume of data will be necessary for the detection process.

Commonly operated hardware components for the detecting process encompass Field-Programmable Gate Arrays (FPGAs), Central Processing Units (CPUs), Graphics Processing Units (GPUs), and Application-Specific Integrated Circuits (ASICs). The CPU stands out as a widely utilized and essential component among the array of available hardware components. However, the CPU exhibits limitations in terms of efficiency due to its nature as a hardware component designed for general-purpose computing operations. The utilization of hardware accelerators, such as GPU, FPGA, and ASIC, in conjunction with the CPU, is a common practice in computing. A hardware accelerator is a dedicated device designed to execute specific activities with enhanced efficiency.

Hence, this study aims to develop an innovative design architecture for conducting convolution on the Tiny Yolo V3 image detection or inference object process. The proposed architecture will leverage sparse weight data to effectively decrease the computing burden while maintaining the accuracy of the system's outcomes. The convolution process will be reduced due to convolving just non-zero weight data since it excludes the processing of zero weight values and the subsequent input feature map. However, the architecture being constructed must maintain accuracy. This design architecture is achieved by ensuring that the architectural design does not alter the weight value and accurately maps the output to return the convolution result data to the appropriate output index.

II. Prelinimary

A. Previous Work

Research has been conducted in the field of hardware acceleration for the purpose of manufacturing specialized hardware for sparse data. Notably, there exists hardware that employs the YOLO (You Only Look Once) detection algorithm, which boasts a streamlined architecture and enables real-time detection with enhanced speed. Hardware improvements have been made to the convolution architecture of Yolo by incorporating Winograd into the convolution process [2]. In addition, the hardware described in [3] employs an alternative convolution method that utilizes GEMM to enhance the speed of the convolution process. In the realm of hardware optimization for convolution processes, a notable approach has been the integration of the FFT method with the Winograd algorithm. This combination, as discussed in [4], has enhanced convolution operations efficiency.

The third category of accelerator employs sophisticated convolution algorithms, such as the frequency domain convolution scheme [5], in its hardware design to minimize the computational burden, precisely the number of multiply-accumulate (MAC) operations, in contrast to direct spatial convolution algorithms. Consequently, this approach yields a significant performance improvement for the implemented accelerator. The accelerator architecture described in reference [2] employed the Winograd convolution technique, resulting in a notable 47% reduction in workload for the YOLOv1 algorithm. This improvement was achieved with a little trade-off, as the detection accuracy only experienced a slight 1% loss. The ultimate implementation attains a detection rate of 15.3 frames per second (fps) and utilizes 1024 digital signal processing (DSP) blocks on a Xilinx FPGA. The author of this study implemented the YOLO algorithm by effectively utilizing pipeline architecture, loop unrolling, and data reordering techniques on a PYNQ FPGA platform. The hardware accelerator sequentially processes each of these hidden layers. Additionally, the initial and final layers operate through software implementation, resulting in diminished frame rates. In the study conducted by the authors in [6], they introduced a variant of YOLO-v2 that incorporates binary networks and a regression support vector machine (SVM). The author devised the co-stream binary convolutional circuit, wherein each layer is processed sequentially. While previous iterations of designs achieved improved efficiency by decreasing algorithmic complexity, they failed to consider the corresponding decrease in external memory access.

B. Sparse Structured

The pruning algorithm is employed to selectively remove network connections to preserve the detection results accuracy

concerning the original network configuration. Observing the actuality of the training step for the detection model, a procedure is implemented to eliminate all connections that possess weights below a specified threshold. The pruning process involves converting a densely linked neural network layer into a sparser layer or network. The initial stage of this procedure involves an examination of the network topology, followed by an identification of critical connections and subsequent removal of non-essential connections. Subsequently, the network undergoes retraining to enable the surviving connections to compensate for removing the previously eliminated connections. The process of pruning and retraining can be iteratively employed to decrease the complexity of a network, resulting in the generation of sparse data. [7].

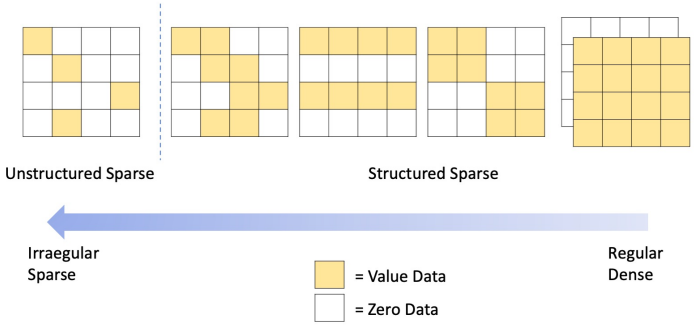

Fig. 2. Structure of data sparse

Sparsity refers to conditions in which a significant portion of a given dataset consists of zero values. Sparsity data can manifest in various forms, such as arrays, vectors, matrices, and tensors. In contrast, dense data refers to data that has a higher proportion of non-zero values. The sparsity value of the data weight is found to be significant during the pruning process. Hence, this study aims to develop a specific architecture that can effectively execute convolution for image detection objects in Tiny Yolo model inference. This architecture will leverage sparse weight data to minimize the computing burden while ensuring that the accuracy of the system's outcomes remains unaffected. The convolution process can be optimized by performing computation only on non-zero data. This optimization reduces the computational load by excluding the processing of weight values that are 0, as well as the input feature map that follows them. Nevertheless, the architectural integrity will be preserved as the design ensures that the weight value remains unchanged and the output is accurately mapped to the appropriate output index.

III. Proposed Method

A. Bitmap Indexing

Indexing or creating an index in the context of sparse data involves identifying and numbering elements inside a data structure. This index serves to provide information about the position of non-zero elements or elements that possess significant values within the sparse data structure. Given that a significant portion of the values inside the sparse data exhibit null characteristics, it becomes necessary to only retain and retrieve the non-zero elements for further computational procedures. Indexes facilitate the association of these items with their respective positions inside a data structure optimized for efficiency. Numerous indexing techniques have been used to leverage sparse data, including CSR (Compressed Sparse Row), CSC (Compressed Sparse Column),COO(Coordinate Format) Bitmap, etc.

Figure 3, part a, depicts the data structure known as CSR, which represents sparse matrices. The matrix rows are organized in an array format in this representation, requiring three distinct data types. Data weight is an Array that consists of non-zero values extracted from the matrix sequentially based on the rows. Furthermore, the Array contains the column index of every non-zero element within the matrix. The third component is called the Indice Pointer, an array that stores the starting index of each row within the data and indices array. CSC format is a sparse matrix representation with the same structure as the CSR format. The matrix is partitioned into vertical columns organized in a two-dimensional array. In the context of Indice Pointer data, the Array comprising the index consists of each column of the matrix, commencing with the data array and corresponding indices.

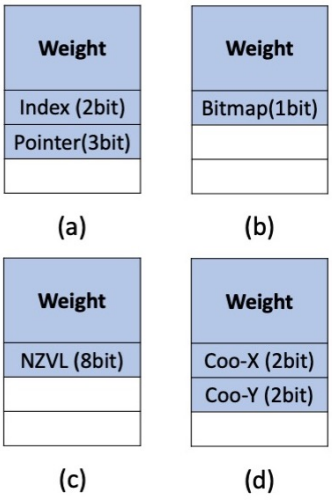

Fig. 3. Indexing method to exploit sparse position, (a)CSC&CSR, (b)Bitmap, (c)NZVL[8], (d)COO

COO refers to the non-zero elements of a matrix, which are identifiable by their corresponding coordinate pairs (row, column). A bitmap is a form of binary representation that represents a collection of elements. In the Bitmap, there exists an entry for every element, with a value of 1 denoting the presence of the element (non-zero) and a value of 0 indicating the absence of the element (zero). Bitmaps are commonly employed in situations where a significant proportion of elements possess a value of zero, whereas only a small subset of elements exhibit non-zero values. Indexing plays a crucial role in all of these representations as it enables the identification of

the precise location of non-zero items. This, in turn, facilitates rapid execution of mathematical operations or other forms of data manipulation. The hardware accelerator effectively utilizes indexing to expedite the retrieval of certain elements, hence avoiding the need to traverse the whole data structure. Additionally, it is advantageous in terms of conserving storage capacity and reducing execution time, which are crucial factors when handling big and intricate datasets, particularly in the context of real-time detection procedures.

The analysis of Figure 3 reveals that the utilization of distinct indexing strategies has a discernible impact on the amount of memory capacity that is needed. The process of indexing utilizing CSR and CSC representations requires the inclusion of two supplementary data elements in order to determine the location of non-zero values. The utilization of 2-bit and 3-bit data widths in this context bears a resemblance to the indexing technique employed in COO, wherein two additional 2-bit data elements are utilized. The study by the authors [8] employs an alternative indexing technique, namely a binary map and NZVL (Not Zero Value List), with the NZVL data width set at 8 bits. Hence, the hardware accelerator architecture in this study incorporates a bitmap indexing technique, which necessitates a data width of only 1 bit. The utilization of bitmap indexing also enables the efficient representation of diverse types of sparse data inside the dataflow process through "weight streams".

B. *Weight Stream*

The convolution procedure involves utilizing the input data, which consists of the pruning weight input and the Fmap input. Fmap, short for Feature Map or Activation Map, refers to the outcome of the convolution process. The proposed accelerator will prioritize the convolution process in the layer with the highest sparsity value, specifically layer 6. This implies that the input picture utilized will be the convolution output from the preceding layer.

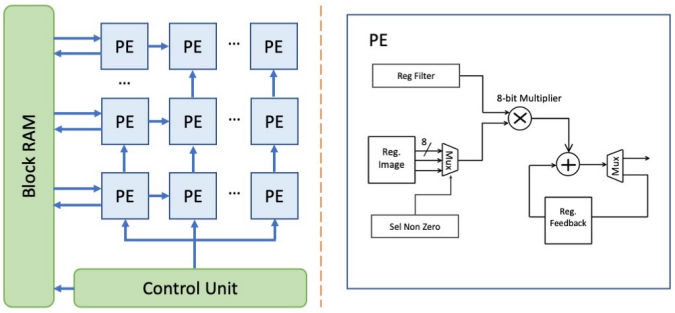

Fig. 4. Architecture Hardware Accelerator

As depicted in Figure 1, the convolution process involves an input weight size and an input feature map (fmap). The variables K, C, and N are utilized to denote the magnitude of the input weights. The kernel, a fundamental component in model detection designs, can be categorized into two sizes: 3×3 and 1×1 in terms of weight. In the process of convolution, the dimensions of the output channels (C) must match the dimensions of both the input weights and the input feature map (fmap). The variable N represents the number of filters present in a single layer. The size of the fmap input, denoted as $F \times F \times C$, refers to the dimensions of the input matrix. Consequently, the implementation of a heavy data flow architecture is deemed necessary for this accelerator. Subsequently, employing a single fmap operation, the input received via channel 0 will undergo convolution with distinct weights from channel 0 for a total of N iterations. The planned accelerator will utilize a Fmap input of dimensions 3×3. The utilization of a structured format, such as the one depicted in Figure 2, offers the benefit of facilitating a systematic approach to reading and selecting non-zero data. Nevertheless, a lower sparsity number has an impact on the computational load required by the hardware during the inference procedure. In the context of data analysis, unstructured data can give rise to sparse data sets characterized by a substantial number of non-zero values. This abundance of non-zero values can have a considerable impact on computational processes, leading to a significant reduction in efficiency. However, the presence of unstructured data poses challenges in terms of data readability once the final mapping procedure is conducted to generate suitable output data that can be further processed in subsequent stages. The present research introduces an architectural framework capable of effectively handling two distinct types of sparse data representations, namely structured and unstructured. This is achieved through the utilization of a data flow architecture that incorporates a weight stream.

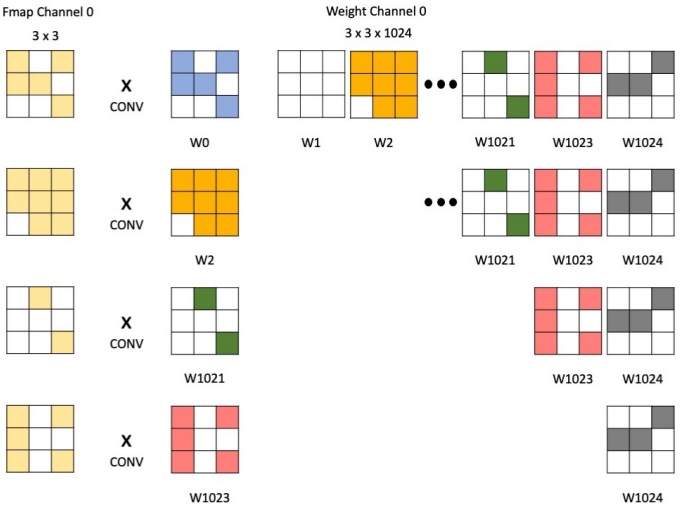

Fig. 5. Weight Stream Data Flow Architecture

The weights that have undergone compression during the software process result in the retention of solely non-zero or value-based data inside the weight data. When all data zeros are present on the same channel, it enables a continuous flow of weight through the accelerator, generating a convolution product that aligns with the input bitmap utilized for selecting the feature map input. Hence, invoking the fmap input several

times is unnecessary to execute the convolution procedure N times. However, invoking the function once for a given channel is sufficient. Utilizing a convolution accelerator with a data flow of this nature facilitates the efficient reuse of data, hence obviating the need for more power during the iterative process of utilizing the same data.

Figure 4 depicts the intended architectural architecture, whereby the data selection process that will be fed into the convolution process is present in each processing node. Additionally, each processing element is interconnected inside a parallel network. Figure 5 depicts the process known as the ”weight stream.” The data from current weights will be sequentially processed without any processing delay for different weights. Simultaneously, the selection of fmap data for the convolution process will also be conducted without any delay in the overall process.

IV. Experimental Results

In the hardware design process or circuit design, it is essential to conduct testing to achieve the required output before its implementation into the Field-Programmable Gate Array (FPGA). During the accelerator design phase for the convolution process, a simulation methodology is employed to verify the alignment of the design outcomes with the system design and the intended objectives. Furthermore, within the context of this simulation process, it will provide an assessment of the performance of the designed system. The simulation method is conducted using various input conditions to evaluate the efficacy of the design.

The decision was made to utilize a timing diagram to modify this accelerator's architecture. A timing diagram is a graphical representation that depicts the temporal relationship between one or more elements by displaying their respective values at specific points in time. Utilizing a timing diagram in the simulation aims to offer valuable insights during the design phase, facilitating the attainment of the intended output. The timing diagram can also depict the outcomes of the convolution accelerator architecture, wherein the input weight is provided to the hardware consecutively. This enables the identification of any potential calculation errors, facilitating accurate convolution results.

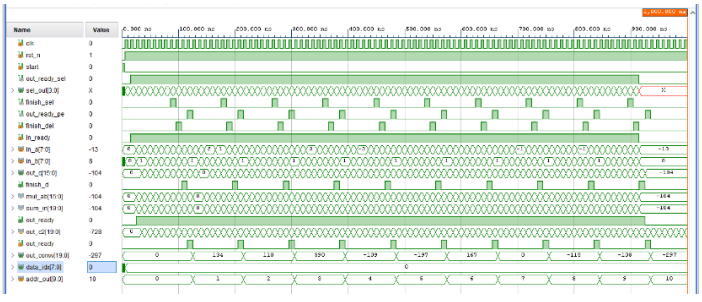

Fig. 6. Output Simulation using dense data

The timing diagram results depicted in Figure 6 demonstrate that each weight necessitates an equivalent amount of time throughout the convolution output acquisition operation, specifically 12 clock cycles for each datum. The time diagram illustrates the convolution process of a processing unit characterized by sequential multiplication and propagation of data flow. Each multiplication between one kernel weight requires a total of nine clock cycles. Performing a 3×3 matrix multiplication with an input feature map of size 3×3.

The output value of the data selected is determined by the non-zero data position of the input data bitmap and is activated when the 'in_ready' signal is active. Additionally, the input weight process is initiated. However, it is essential to note that the input fmap and input weight cannot coexist simultaneously. This is due to the fact that the input fmap experiences a delay of one clock cycle as a result of the initial 'sel_out' selection process. Consequently, the data input weight is also delayed by one clock cycle before continuously flowing into the module processing element. As depicted in Figure 6, the input weight 'in_a' and the input feature map data 'in_b' are concurrently inputted. The requirement of 92 clock cycles is due to the dense nature of the input data, which ensures that no information is omitted from the 10 data weights. In the meanwhile, it is seen that each weight necessitates a total of 11 clock cycles. Given the presence of 9 input weights and the utilization of a sequential PE architecture, the multiplication operation involving 9 data inputs necessitates nine clock cycles. However, an additional two clock cycles are incurred due to the requirement of a preliminary select index process within the architecture for data entry. The initial clock cycle is allocated for the select index operation. In contrast, an additional clock cycle is required for the final data storage step, which corresponds to the number of convolution outputs.

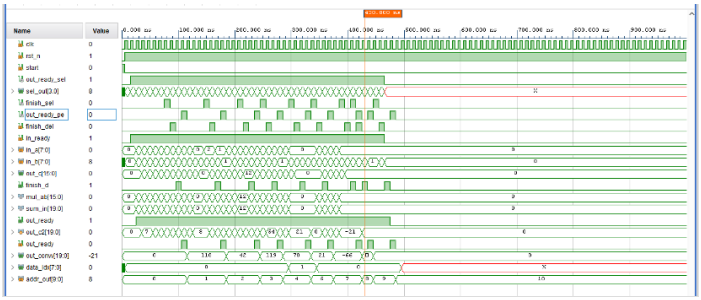

Fig. 7. Output Simulation using sparse data

In this experiment involving sparse data, we will utilize the same dataset as the previous one. However, specific data points will be modified to have a value of 0. The objective is to examine the impact of employing dense data in the results of the timing diagram from the previous simulation. It is important to note that all bitmap index data and relative index have been generated prior to conducting the simulation. Nevertheless, in the context of simulating sparse data, using the same input data weight in conjunction with bitmap data allows for incorporating sparse data and input index bitmap. This facilitates the multiplication process within the convolution, resulting in the propagation of zero data. It is anticipated that

the computational time required to perform the convolution process ten times will be shorter than the dense data procedure.

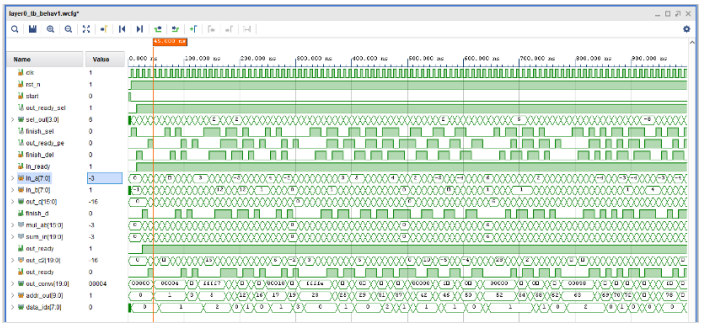

Fig. 8. Output Simulation using all kind of sparse and dense data

The convolution procedure for the inference process at one layer is shown in Figure 8. The results presented in this study demonstrate a range of weight data in different forms and quantities, spanning from sparse to dense distributed weight data. It is seen that both structured and unstructured sparse data can yield satisfactory outputs without inducing processing delays, even in cases where there are variations in the data structure across different weight data sets. Established on the test results, which were conducted in adherence to the prescribed architecture, specifically by employing the techniques of skipping zero data and utilizing compressed bitmap data, it is evident that there exists a disparity in the number of clock cycles required to accomplish the convolution of the data weights. Due to the compression of the bitmap data, the accelerator will exclusively handle nine data weights, while the remaining data will be contained within each weight. According to the data presented in Figure 7, it can be observed that the 5th data weight possesses a cumulative data weight of zero. Additionally, there is an absence of non-zero data inside this weight. Consequently, the bitmap data included within this weight will be eliminated, excluding the 5th weight from the accelerator process.

At the outset, there were nine data weights assigned to each weight. Consequently, for a total of ten data weights, the convolution process will involve a cumulative dataset of 90 data points. The sparse data simulation procedure involves skipping zero data points and not utilising compressed bitmap data. In this particular scenario, only 45 data points are obtained from a set of 10 data weights. The process of convolving the entire data weight, starting from the initial data bitmap entry, requires a total of 47 clock cycles. Compared to the convolution outcomes depicted in Figure 7, the technique as mentioned earlier yields identical results consisting of nine convolutions.

Upon conducting the simulation, it was determined that the number of convolution processes required to handle sparse data can be calculated. The results of this calculation indicate that the convolution process utilizing the designed accelerator is projected to yield a reduction of 56% in the calculation results of all YoloV3-Tiny layers. In the context of data calculations

TABLE I
COMPARISON OF SPARSE HARDWARE DESIGN

No	*Architecture*	*Sparse*	*Indexing*	*Dynamic*	*Pruning Rate*
1	Sparse-Yolo[9]	Unstructured	CSR	Dynamic	89%
2	RDL[8]	Unstructured	NZVL	Dynamic	59.5%
3	This Work	Unstructured Structured	Bitmap	Static	70% 30%

involving sparsity percentages of up to 30%, it can be observed that the convolution process experiences a reduction of 25% concerning the overall convolution process. Determining the number of multiplication operations involved in a convolution operation is contingent upon the resultant dimensions of the convolution output. The utilization of an equation can achieve the determination of the output size of the convolution process:

$$h = \frac{f - k + 2P}{S} + 1, \tag{1}$$

where h represents the output size, which can refer to the length or width dimension depending on the context in which the size is calculated. The variable f represents the input size, which can refer to length or width, depending on the specific dimensions being calculated. The variable k denotes the size of the kernel, which refers to the length or width of the kernel. P represents the quantity of padding applied to the input. Without any additional padding, the value of P equals zero. When padding is employed, the variable P encompasses the total quantity of padding on both sides, which is typically executed symmetrically. And the variable S represents the step or stride length employed during the execution of the convolution operation. Stride refers to the displacement distance by which the kernel is displaced during each iteration of the convolution process. Without a stride, the value of S is equal to 1.

The formula above will quantitatively assess the production within a single dimension. The output data for the convolution process will be specified by the number of input channels included in the weight data. The number of multiplication operations performed in a convolution process can be determined by utilizing the equation subsequent to acquiring the size of the output resulting from the convolution process using the equation :

$$Num_{mult} = h \times h \times k \times k \times c \times N, \tag{2}$$

where Num_{mult} denotes the quantity of multiplications, which is determined by the product of the number of weight data and output data. The reduction in data weight resulting from the pruning procedure and the acquisition of numerous zero data points can effectively decrease the computational burden associated with multiplication operations. Quantifying the multiplications performed in each layer makes it possible to determine the percentage of convolutional operations before and after implementing the architectural design proposed in this research study.

Furthermore, compared to the hardware architectures presented in Table 1, the architectural design proposed in this paper offers the benefit of employing several types of sparse data structures, encompassing organized and unstructured formats. able 1 presents a comparison between the implementation of the YOLO version employed in this study and the YOLO version utilized in the paper referenced as [9]. This study employs an alternative iteration of the convolution-based design while maintaining the fundamental structure. The article titled "Sparse-Yolo" [9] achieved a sparsity value of 89% through the implementation of the pruning process approach. This implies that a mere 11% of the data necessitates processing during the convolution procedure. In addition, the study employs an alternative detection model, specifically the general Convolutional Neural Network (CNN) model, with a structured sparse block form, resulting in a sparsity level of 50% [10]. However, in the case of other works, such as [11], the hardware accelerator is constructed using either random sparse or non-random data. The structure of the data exhibits a sparsity of 62.5%, while the data index width is relatively high, measuring 10 bits. Hence, the architectural design of this paper confers benefits in the processing of many types of sparse data. The present study explores the implementation of the hardware architectural design for conducting computational processes, including both structured and unstructured data. The findings indicate that the accuracy achieved by this approach is comparable to that of alternative hardware-based computing methods.

The determination of the reduction percentage value for the convolution procedure is derived by evaluating the number of convolution computations that need to be performed utilizing the available sparse data. There is a discernible distinction in computational outcomes between utilizing a data sparsity of 30% exclusively with non-zero data and employing the same sparsity value of 30% while still processing all zero values without skipping them. Hence, employing different sparse data structured leads to a higher percentage value of computational speed while effectively handling zero data by skipping it.

V. Conclusions

Once the procedure has determined the output size in each layer, it becomes possible to calculate the total number of clock cycles for each layer. The number of clock cycles required for processing sparse data in a processing element (PE) is equivalent to the number of multiplications executed in the PE. This is due to the sequential nature of the multiplication process in the PE. The subject in question. The accelerator system requires an additional clock cycle at its initiation to process bitmap data specifically for the purpose of picking fmap input data. In addition, it is necessary to allocate an additional clock cycle at the conclusion of the convolution operation in order to save the resultant value. By using this architecture and "weight stream" dataflow, implementing zero data skipping from any structured sparse data (structured / untructured) in the convolution process can potentially enhance hardware's computational efficiency. The accelerator's efficiency is enhanced due to the decreased memory-to-weight ratio after trimming, leading to a reduction in the number of chip design regions. This reduction is attributed to the ability to decrease the required processing parts for computation.

***Abstract*—Convolutional neural networks (CNNs) and Transformer-based models are being widely applied in medical image segmentation thanks to their ability to extract high-level features and capture important aspects of the image. However, there is often a trade-off between the need for high accuracy and the desire for low computational cost. A model with higher parameters can theoretically achieve better performance but also result in more computational complexity and higher memory usage, and thus is not practical to implement. In this paper, we look for a lightweight U-Net-based model which can remain the same or even achieve better performance, namely U-Lite. We designed U-Lite based on the principle of Depthwise Separable Convolution so that the model can both leverage the strength of CNNs and reduce a remarkable number of computing parameters. Specifically, we propose Axial Depthwise Convolutions with kernels 7×7 in both the encoder and decoder to enlarge the model's receptive field. To further improve the performance, we use several Axial Dilated Depthwise Convolutions with filters 3×3 for the bottleneck as one of our branches. Overall, U-Lite contains only 878K parameters, 35 times less than the traditional U-Net, and much more times less than other modern Transformer-based models. The proposed model cuts down a large amount of computational complexity while attaining an impressive performance on medical segmentation tasks compared to other state-of-the-art architectures. The code will be available at: https://github.com/duong-db/U-Lite.**

I. Introduction

Artificial Intelligence (AI) has been recently deployed in many hospitals for practical use in developed countries. According to Health Equity Magazine (2018), AI helps store and access a large amount of information effectively. Currently, the amount of medical information has doubled every three years. It is estimated that if a doctor wants to keep up with all medical news, he must read 29 hours a day, which is impossible. On the other hand, a deep learning model can also assist in diagnosing medical images. The IBM Watson healthcare system (USA) shows that 90% of the recommendations made by their AI system are consistent with the suggestions of medical experts but taking only 40 seconds to complete all processes. Realizing the importance of AI in the medical field, many study efforts have been made to improve the performance of deep learning models.

Computer Vision is one of the most prominent applications of AI in the medical field. Besides diagnosing diseases based on clinical symptoms, modern medicine also diagnoses diseases based on subclinical symptoms from images obtained from medical devices. Therefore, deep learning models are developed for segmenting tumors and cells or abnormal areas, thereby supporting doctors in disease identification and diagnosis and the severity of the disease. In 2015, Ronneberger et al. introduced U-Net [1] as a highly effective model for medical image segmentation. After the success of U-Net, many follow-ups work did different research to optimize U-Net and offered numerous variants with higher performance such as Unet++ [2], ResUnet++ [3], Double Unet [4], Attention Unet [5], to name just a few. They all are deep learning models developed based on CNNs. There is no denying that the appearance of CNNs has created a great revolution in computer vision fields.

Recently, Vision Transformer [6] and MLP-like architectures (MLPs) have been widely used and have become a new de facto standard in Computer Vision. Vision Transformer considers each patch of an image as a token and feeds them through the Multi-head Self-attention mechanism as they successfully did with sentences in Natural Language Processing (NLP). In the medical segmentation task, TransUnet [7] can be considered one of the high-performing models in accuracy and efficiency. Following the success of TransUnet, Transformer-based models continued to be developed. Pyramid Vision Transformer (PVT) [8] is utilized as the backbone of many high-performance models such as MSMA-Net [9], Polyp-PVT [10]. Meanwhile, MLP-like architectures are also very research-focused. MLPs leverage

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

the advantage of conventional MLP to encode the features along each of their dimensions. AxialAtt-MLP-Mixer [11] gives exceptionally reliable performance on many medical image datasets by applying axial attention to replace the token mixing in MLP-Mixer [12]. Different from CNNs, the models based on Transformers or MLPs concentrate on the global receptive field of the image, thus costing much in computational complexity and being overly heavy for the training process.

To successfully implement in practice, a machine learning model first needs to achieve high accuracy and secondly, it should be fast and compact enough to integrate into mobile medical devices. Nevertheless, there is often a trade-off between the need for high accuracy and the desire for low computational cost. These above studies can theoretically achieve impressive performance, but many may give heavy operation and slow calculation speed due to the massive number of parameters. To solve this problem, some attempts for a lightweight architecture can be mentioned as Mobile-Unet [13], DSCA-Net [14], and MedT [15]. In this paper, we rethink an efficient lightweight architecture for the medical segmentation task to further explore a high-performing model which can effectively address this issue. In short, the main contributions of this paper are three-fold:

1) Propose the usage of Axial Depthwise Convolution module based on the concept of Depthwise Separable Convolution. This module helps the model solve every complex architecture problem: enlarging the model's receptive field while reducing the heavy computation burden.
2) Propose U-Lite, a lightweight and simple CNN-based architecture. As far as we know, U-Lite is one of the few models that surpasses a recent highly efficient compact network UNeXt [16] in terms of both accuracy and the number of parameters.
3) We have successfully implemented the model on medical segmentation datasets and achieved considerable results.

II. Related Work

U-Net. Introduced in 2015 [1], U-Net is an effective deep-learning CNNs-based model for biomedical image segmentation. U-Net follows the U-shape architecture with a typical encoder-decoder structure. The encoder uses convolution, activation, and normalization layers to extract high-level features of the input image. Meanwhile, max-pooling layers are applied to capture multi-scale features, allowing the model to handle different shapes and sizes of objects. The decoder utilizes upsampling layers to rescale the size of encoded features back to the original image's size. To preserve spatial information, U-Net adds skip connections between the encoder and decoder, which improves the model's performance and solves the vanishing gradient problem.

Depthwise Separable Convolution. Depthwise Separable Convolution splits the convolution into two steps: depthwise and pointwise. Depthwise convolution encodes the features per channel, while pointwise convolution encodes these features along their depth dimension. Depthwise Separable Convolution delivers almost the same performance as traditional convolution while using fewer parameters, thereby reducing computational complexity, and making the model more compact. Therefore, this technique has been widely used in many modern deep learning models, for example, InceptionNet [17] and MobileNets [18].

III. Proposed Model

An overview of our proposed model U-Lite is illustrated in Fig. 1. We follow the symmetric encoder-decoder architecture of U-Net and design U-Lite in an efficient way so that the model can leverage the strength of CNNs while maintaining the number of computational parameters as small as possible. To this end, an Axial Depthwise Convolution module is thoughtfully proposed, shown in Fig. 2. Describing the operation of U-Lite, an input image at shape $(3,H,W)$ is fed to the network through 3 stages: encoder stage, bottleneck stage, and decoder stage. U-Lite follows the hierarchical architecture, where the encoder extracts six different level features in shape $\left(C_i, \frac{H}{2^i}, \frac{W}{2^i}\right)$, where $i \in \{0,1,2,..,5\}$. The bottleneck and decoder take part in processing these features as well as upscaling them to the original shape to obtain the segmented mask. We also use skip connections between the encoder and decoder. It is worth noting that although the design of U-Lite is simple, the model still performs well on the segmentation task thanks to the contribution of Axial Depthwise Convolution module.

A. Axial Depthwise Convolution module

The success of Vision Transformer [6] promotes various works on researching and improving this special structure. Swin Transformer [19] reduces the computational complexity of Transformer by limiting self-attention computation to non-overlapping local windows of size 7×7. ConvNext [20] realizes this modification and adopts convolutions with kernel size 7×7 to CNN architecture, bringing ResNet up to 86.4% top-1 accuracy on ImageNet. Meanwhile, a recent new paradigm, Vision Permutator [21] makes use of linear projections to separately encode the feature representations along the height and width dimensions. This variant of MLP-like architecture is supposed to readily attain promising results in Computer Vision. Our exploration is motivated by a natural question: *What would happen if we replaced the cruciform receptive field of Vision Permutator with a local receptive field version, in the comparable manner as Swin Transformer did with Vision Transformer?*

To give a simple answer, we proposed Axial Depthwise Convolution module, as a combination of Vision Permutator's and ConvNext's designs (Fig. 2). The mathematical formulation of this operator is expressed as follows:

$$x' = x + \mathrm{DW}_{1\times n}(x) + \mathrm{DW}_{n\times 1}(x) \tag{1}$$

$$y = \mathrm{GELU}\Big(\mathrm{PW}_{C_1\to C_2}\big(\mathrm{BN}\left(x'\right)\big)\Big) \tag{2}$$

where, x is input feature, y is output feature; DW, PW and BN stand for Depthwise Convolution, Pointwise Convolution, and Batch Normalization respectively; $1 \times n$ and $n \times 1$ are the kernel sizes of the convolutions; C_1 and C_2 represent the number of input and output channels of the feature map. In our experiment, $n = 7$. To achieve a minimal and flexible design, we use a unique Pointwise Convolution

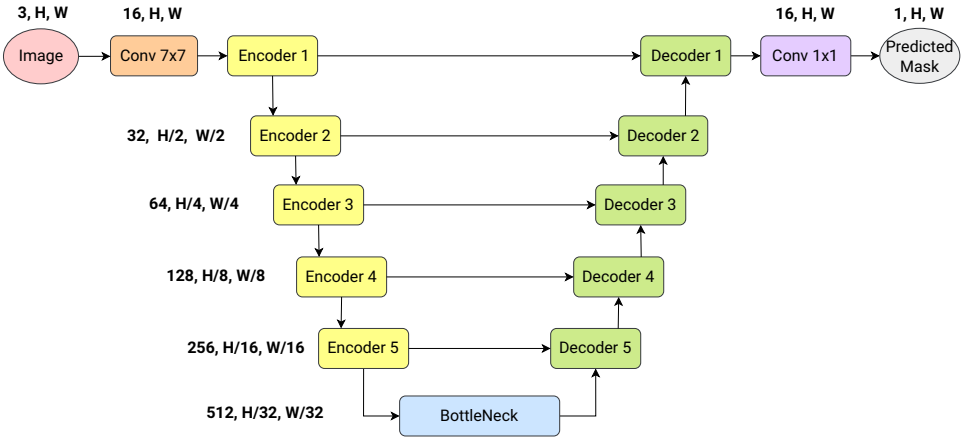

Fig. 1: The proposed U-Lite architecture.

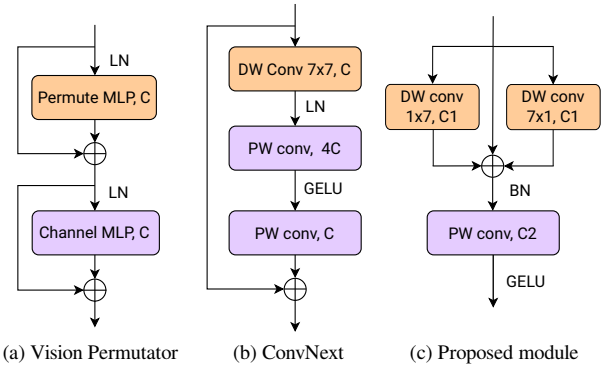

Fig. 2: Architectures of (a) Vision Permutator, (b) ConvNext, and (c) Proposed Axial DW Convolution module. The proposed module is inspired by Vision Permutator's and ConvNext's designs.

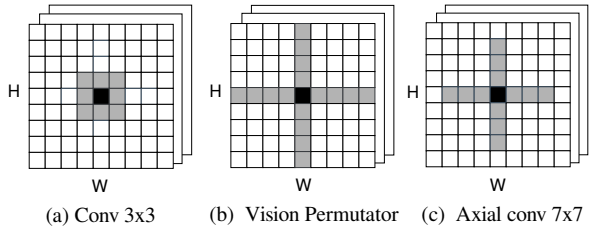

Fig. 3: The receptive field comparison between Convolution 3×3, Vision Permutator, and Axial convolution 7×7. Axial convolution 7×7 offers a large receptive field compared with Convolution 3×3 while using fewer computational parameters than Vision Permutator.

without adding residual connection, allowing us to adjust the number of input channels adaptively.

B. Encoder Block and Decoder Block

The design principles of the encoder and decoder blocks are established as follows:

- Utilize the Depthwise Separable Convolution architecture. This is an important key to successfully building a lightweight model from scratch. Depthwise Separable Convolution delivers almost the same performance as traditional convolution while using fewer parameters, therefore reducing computational complexity, and making the model more compact.

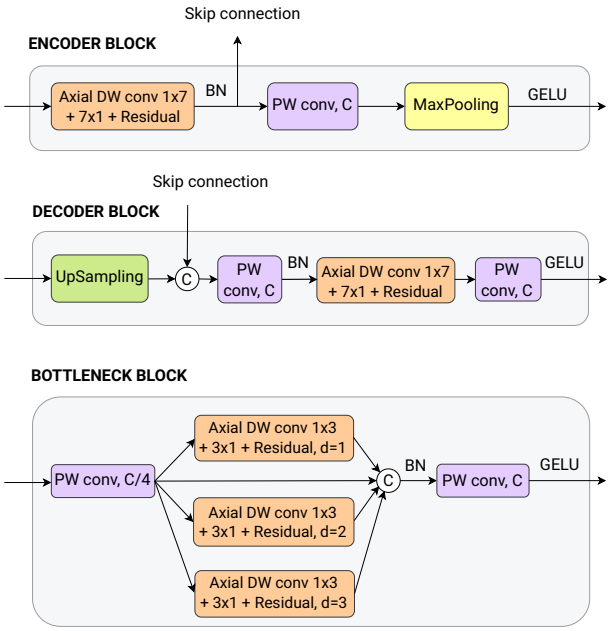

Fig. 4: Encoder, decoder, and bottleneck blocks. Designed based on Depthwise Separable Convolution concept. Each block adopts one Batch Normalization layer and ends with a GELU activation function.

- Limit the use of unnecessary operators. Simply using normal MaxPooling and UpSampling layers. There is no need for a high-parameter-consuming operator such as Transposed Convolution. A Pointwise Convolution operator can play two roles simultaneously: encoding features along the depth of the feature map while flexibly changing the number of input channels.
- Each encoder and decoder block adopts one Batch Normalization layer and ends with a GELU activation function. We have made a performance comparison between Batch Normalization and Layer Normalization but there is not much difference. GELU is applied since it is proven to give an improvement in accuracy when using GELU compared to ReLU, and ELU.

The successful encoder and decoder structures of U-Lite are depicted in Fig. 4.

C. Bottleneck Block

To further boost the performance of U-Lite, we apply Axial Dilated Depthwise Convolutions with kernel size $n = 3$ to the bottleneck block (Fig. 4). The applied dilation rates are $d = 1, 2, 3$. We use axial dilated convolutions with a kernel of size 3 for two reasons: 1) a kernel of size 3 is more suitable with the spatial shape of bottom-layer features, where the height and width of such features are reduced multiple times, and 2) it gives a better performance when using dilated convolutions with different rates to capture multi-spatial representations of high-level features at the bottom stage. To further reduce the number of learnable parameters, a pointwise convolution layer is adopted at the beginning of the bottleneck block. This helps scale down the channel dimension of the last feature layer before feeding them to the Axial Dilated Depthwise Convolution mechanism.

IV. Experiments

A. Implementation Detail

Dataset. To evaluate the performance in the segmentation task, we trained our proposed model on three datasets. The first dataset, ISIC 2018, contained 2594 images of skin lesions. We used 2334 images for training and 260 images for testing. The second dataset, DSB 2018, included 617 images of cell nuclei. We split this dataset into 80% for training and 20% for testing. The third dataset, GlaS, consisted of 165 images of colorectal adenocarcinoma, of which 85 were used for training and 80 for testing. In all the experiments, the images were resized to 256×256.

Training strategy. We conducted U-Lite on the PyTorch framework running on NVIDIA Tesla T4 GPU with 15GB of memory. During the training phase with 200 epochs, training data were augmented by several techniques including random rotation, horizontal flip, and vertical flip. We employed Adam optimization [25] algorithm with the initial learning rate $1e-3$ and used the Dice Loss function, which is defined as:

$$\mathscr{L}_{\text{Dice}}(G,P) = 1 - \frac{2\sum_{i=1}^{N} G_i P_i}{\sum_{i=1}^{N} (G_i + P_i)} \tag{3}$$

where N is the total number of pixels of the image, $G_i \in \{0,1\}$ and $P_i \in (0,1)$ present the value of the i-th pixel of the ground truth and the predicted mask, respectively.

Evaluation metric. We utilized Dice and IoU, two typical metrics for semantic segmentation, to quantitatively measure the model performance. These metrics evaluate the overlap between the ground truth and the predicted mask of an image by the following formulas:

$$\text{Dice} = \frac{2\,\text{TP}}{2\,\text{TP} + \text{FP} + \text{FN}} \tag{4}$$

$$\text{IoU} = \frac{\text{TP}}{\text{TP} + \text{FP} + \text{FN}} \tag{5}$$

where TP, FP and FN stand for True Positives, False Positives and False Negatives, respectively.

B. Representative Results

We compare the segmentation quality of U-Lite and UNeXt [16] on three medical datasets: ISIC 2018, DSB 2018, and GlaS. Fig. 5, Fig. 6, and Fig. 7 show some representative sesults of testing images and their predicted masks by both models, along with the ground truths. U-Lite provides more accurate results than UNeXt, as highlighted by the red circles in the last two columns of each figure. These circles indicate the areas where UNeXt failed to segment correctly.

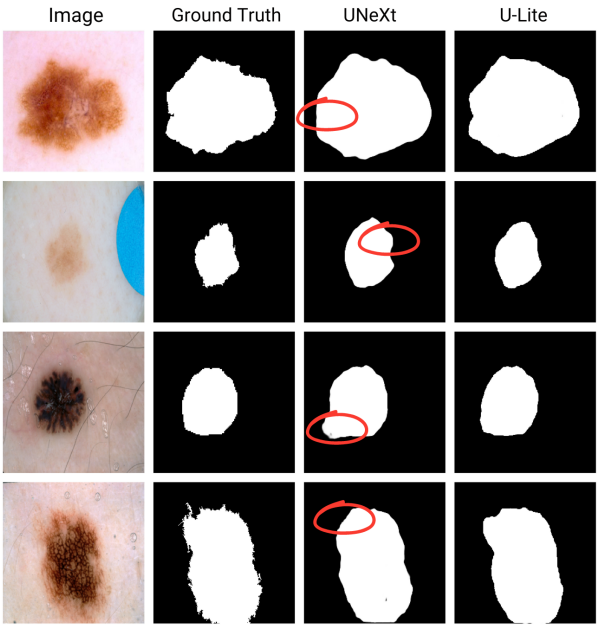

Fig. 5: Comparisons between UNeXt and U-Lite on ISIC 2018 dataset.

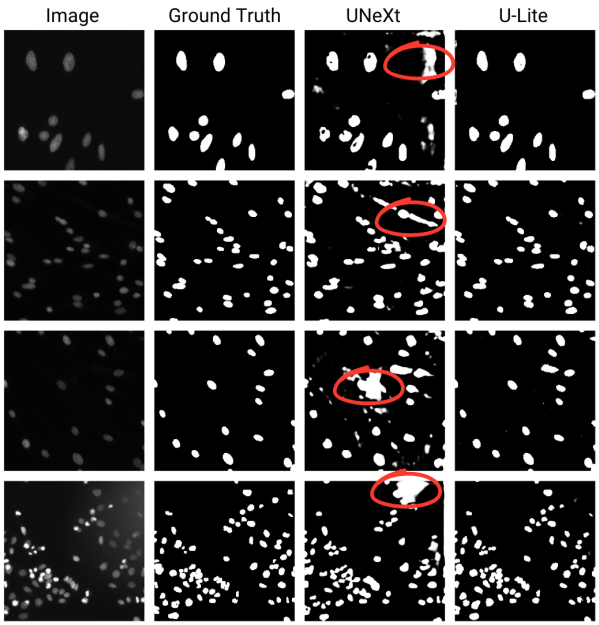

Fig. 6: Comparisons between UNeXt and U-Lite on DSB 2018 dataset.

C. Comparative Results

To prove the outstanding performance of the proposed model, we compare the performance indicators of U-Lite with other previously proposed models in the medical image segmentation task.

As shown in Table I, for the ISIC 2018 dataset, U-Lite achieves 90.39% Dice and 83.63% IoU, with the Dice

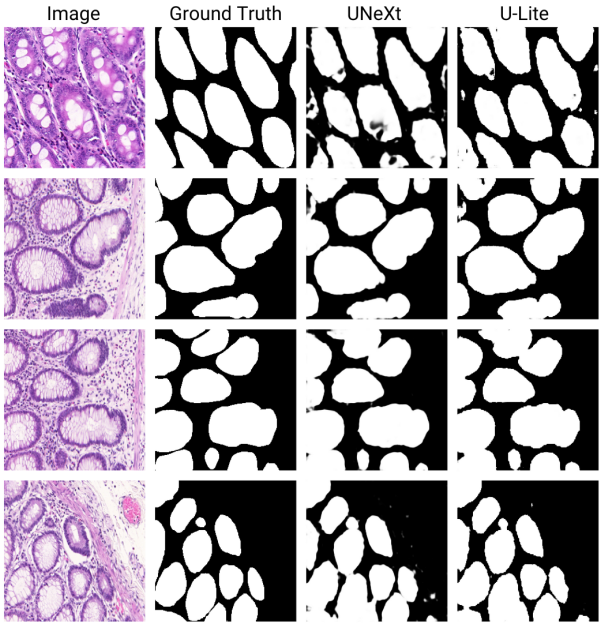

Fig. 7: Comparisons between UNeXt and U-Lite on GlaS dataset.

performing 2.02% higher than U-Net (a traditional CNNs model) and 0.53% higher than ConvUNeXt (a recent high-performing CNN-based model). The total parameters of the U-Lite model are small, only 878K parameters, 35 times less than U-Net. The number of parameters of U-Lite is also smaller than that of some recently proposed lightweight models: ConvUNeXt with 3.5M parameters, Unet++ with 9.2M parameters, and UNeXt with 1.47M parameters.

Table II and Table III evaluate the performance of U-Lite on DSB 2018 and GlaS datasets, respectively, compared to previously proposed models. On DSB 2018, our proposed model achieves 91.37% Dice and 83.63% IoU. Meanwhile, on GlaS, these indices are 86.65% Dice and 77.84% IoU. These results are all higher than the other models mentioned in the tables.

As shown in tables I, II, and III, our proposed model occupies only 3.5MB of memory for storage, much smaller than the state-of-the-art models. Thus, it can be suitable for real-time applications on mobile devices.

In the experiment, we also compared testing times per image on the CPU between U-Lite and previously proposed models. It is observed that UNeXt has the fastest processing speed, followed by U-Lite. Meanwhile, other models all give longer testing times than our model. Although U-Lite is not as fast as UNeXt, it provides more acceptable results when we prioritize the accuracy and compactness of the model, especially for medical image segmentation tasks.

V. Discussion

A. Analysis on the Axial Depthwise Convolution operator

To evaluate the performance of the proposed Axial Depthwise Convolution module, we replace the Axial Depthwise Convolution operator, in Fig. 2, with the conventional Depthwise Convolution operator and experiment with many sizes of kernel to compare their performances. The results are shown in Table IV.

Surprisingly, Axial Depthwise Convolution still performs better and again shows simplicity in parameter configuration

TABLE I: QUANTITATIVE EVALUATION RESULTS ON ISIC 2018 DATASET COMPARED TO PREVIOUSLY PROPOSED MODELS

		IoU	76.45	76.53	76.86
	Axial DW Conv	Dice	86.00	85.80	**86.85**
		IoU	77.20	76.32	**77.84**

and computational complexity. This result can be theoretically explained by the following reasons: 1) By using a horizontal filter along with a vertical filter instead of a unique Depthwise Convolution operator, the model is more focused on which interested spatial aspect to aggregate information. 2) More flexible. We give an example, for the Sobel edge detection problem, the filter $n \times 1$ can act as a vertical edge detector while the $1 \times n$ can act as a horizontal edge detector. 3) Without losing the effect on the receptive field. On the spatial area, if the pixel (a,b) wants to aggregate information from pixel (x,y), it can contact the others through the middle point (a,y) or (x,b), based on the axial mechanism.

To our knowledge, the main factors that make our Axial Depthwise Convolution module differ from the previously

proposed architecture of InceptionNet [17] are that, firstly, we use the Depthwise Separable Convolution concept to reduce the number of parameters, secondly, we take the sum of two convolutions with kernels $1 \times n$ and $n \times 1$ which leads to the cruciform receptive field (while they are connected in series in InceptionNet), and lastly, a residual connection is added through the depthwise convolution layer to retain the important information of feature maps.

B. Effect of Axial Dilated Depthwise Convolutions to the bottleneck

Table V compares the performance of U-Lite before and after integrating the model with the Axial Dilated Depthwise Convolution (ADDC) mechanism. In the case of not using ADDC, we adopt the Axial Depthwise Convolution module with the kernel size $n = 7$ only to the bottleneck of U-Lite as an alternative. Overall, this model contains 817K parameters. It is observed that ADDC boosts the performance of U-Lite in both Dice and IoU coefficients on all three datasets while not overly increasing the number of learnable parameters.

TABLE V: PERFORMANCES WHEN USING (w) AND WITHOUT USING (w/o) THE AXIAL DILATED DEPTHWISE CONVOLUTIONS (ADDC) IN THE BOTTLENECK

Dataset	ADDC	Dice	IoU
ISIC 2018	w/o	89.96	83.21
	w	**90.39**	**83.63**
DSB 2018	w/o	91.21	84.60
	w	**91.37**	**84.86**
GlaS	w/o	84.54	74.82
	w	**86.85**	**77.84**

VI. Conclusion

In this paper, we proposed a lightweight CNN-based architecture for the medical segmentation task. The suggested model U-Lite overcomes the limitation of many complex models that need a high number of parameters and thus results in much memory size and low inference speed. To this end, we proposed the Axial Depthwise Convolution module as a combination of Vision Permutator and ConvNext blocks. We further boost the performance of U-Lite by integrating an Axial Dilated Depthwise Convolution mechanism to the bottleneck of the model. Our experiments on various medical datasets show that U-Lite has a smaller number of parameters and costs less in computational complexity while also performing promising results.

***Abstract*—The ultrasound imaging method is a highly promising technique used in various fields. The utilization of ultrasound technique's backscattering could also allow humans to observe objects as small as the size of the incident wavelength. However, the employing backscattering approach requires high computational calculations and poses a significant obstacle to the production of equipment using the ultrasonic method. In this work, we utilized the pseudo-random compression sampling method in the extended DBIM model, which takes tissue density factor. This is necessary because tissue density provides quantitative information about soft tissue and serves as an image contrast source. This method combines pseudo-random measurement and compressed sensing data recovery technique. The simulation results have proved the effectiveness of the proposed CCS-DBIM method. In terms of imaging quality, at compression ratios as low as 0.5, the large difference in imaging quality is evident. After 5 iterations, the normalization error of the DBIM and CCS-DBIM methods was 0.8828 and 0.5281 respectively, i.e. a 40% reduction in normalization errors when the number of measurements was only half of the variables. The disadvantage of the proposed CCS-DBIM method is that the imaging time is significantly greater than that of the DBIM method. However, with today's parallel computing technology, large amounts of data and computational time will no longer be a big problem.**

Keywords—Ultrasonic imaging, distorted Born iterative method, pseudo-random, scattered data, Born approximation.

I. INTRODUCTION

To construct quantitative ultrasound images, the simplest method is to extract information directly from the B-mode image. The image texture analysis was performed using a number of techniques, such as first order and second parameters (mean value, standard deviation, entropy, run-length parameters) [1], contour-based statistical parameters [2], and wavelet analysis [3]. However, these quantitative parameters are not completely independent of imaging systems, and therefore, these solutions have certain limitations and are not applied in current biomedical devices. For quantitative ultrasound imaging, two of the most interesting techniques are ultrasound tomography and backscatter coefficient analysis. Ultrasound tomography is based on backscattering, where a significant portion of energy scatters in multiple directions when the acoustic wave encounters an inhomogeneous field. A variety of measurements in the scattering medium can be conducted using the wave equation. The ultrasonic tomography problem consists of the following tasks: measuring and determining the change of sound parameters in the scattering medium such as variations in sound velocity, density, attenuation, intensity and other parameters. Nevertheless, the backscattering technique used has certain limitations, which is reason tomography ultrasonic devices have not been as successful as other biomedical imaging modalities such as X-ray imaging, nuclear-based imaging, or harmonic imaging. One limitation is that backscattering encounters some problems when restoring high-contrast objects due to convergence effects. This limitation has restricted the use of backscatter imaging to breast tissue imaging, as breast tissue consists mainly of soft tissue. Some independent studies have explored imaging of bone [4], which may expand the application range of the backscatter technique to some extent. Another requirement is that backscattered data must be acquired from multiple angles ranging from 0° to 360° to achieve the best image quality. This is another reason why most backscatter research focuses on breast tissue imaging. Some approaches are proposed in order to improve imaging quality in ultrasound tomography [5], [6], [7], [8], [9].

In 2006, the compressed sensing (CS) technique was developed by works [10], [11], [12], [13], which analyzes and restores signals at a much lower sampling rate than the standard Nyquist sampling rate, but ensures accuracy. That proves that, if compression sampling is used, only a much lower amount of data is required than conventional sampling techniques, but ensures accurate signal recovery. Therefore, the amount of data required for collection and analysis will be significantly reduced, leading to a high increase in processing speed and minimizing system complexity. However, with compression sampling techniques, deploying a hardware random number generator (HRNG) or pseudorandom number generator (PRNG) to generate a random sequence will be very difficult in practice. Therefore, we propose a pseudo-random compression sampling solution to recover images in the DBIM model [14] taking into account the density parameters of the imaging object. The hardware of the pseudo-random

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

transmitter is the basic electronic circuit of the nonlinear system and is much simpler than the random transmitter [15].

II. Pseudo-random compression sampling

In traditional compression sampling techniques, measuring matrix $\bar{\Phi}$ is random. However, it can be noticed that the method of deployment on the hardware of pseudorandom systems is usually simpler than that of random systems. Therefore in this study, the matrix $\bar{\Phi}$ built using pseudo-random methods. We consider a dynamic pseudo-stochastic system of pseudo-like nature. Since the operational properties of the system are very sensitive to initial conditions, the output of the system is pseudo-random. This is presented in the study [16]. This technique ensures accuracy in recovery similar to random compression sampling, as noted in [17], [18]. In this work, we look at a logistic map based on a dynamic structure that generates a very simple pseudorandom sequence that behaves like a Gauss chain [16]. To build $\bar{\Phi}$, we use the following logical chain:

$$Hq(n+1) = \rho q(n)\big(1 - q(n)\big), \tag{1}$$

Then, convert the string using the logit transform to get the Gauss chain as follows:

$$q_G(n) = \ln\left[\frac{q(n)}{1 - q(n)}\right]. \tag{2}$$

When control parameters $\rho = 4$, the dynamicity described by Eq. (1) is pseudo-random; this means that the dynamics of Eq. (1) are very sensitive to initial conditions $q(0)$. A slight variation of $q(0)$ will cause big change $q(n)$ in a relatively short period of time. Details about the construction $\bar{\Phi}$ from $q_G(n)$ can be referenced from the work [16]. Finally, we restore the image by using a sparse approximation algorithm.

III. Proposed Distorted Born Iterative method combined with pseudo-random compression sampling technique

Suppose we have $N_t \times N_r$ probes, where N_t is the transmitter number and N_r is the receiver number (therefore, we have $N_t \times N_r$ measurements). We need to restore the ideal target function, it is divided into N pixels vertically and horizontally, i.e. N^2 is variables.

If $N_t \times N_r$ is less than N^2, i.e. the number of equations is less than the number of variables, this is an "under-determinded problem". In principle, when the number of equations is less than the number of variables, we cannot get the correct solution; we need to use approximation methods. When $N_t \times N_r$ is much smaller than N^2, we call this a case of collecting little information. We define that the ratio between $N_t \times N_r$ and N^2 is the compression ratio r:

$$r = \frac{N_t N_r}{N^2}. \tag{3}$$

It is clear that in the problem of collecting small amounts of scattered information, we have $r < 1$. When r is small, the measurement system will be simple and the data collected will be small; Therefore, system setup and calculations will be less complicated. Therefore, we focus on the case of the smallest value of r while ensuring acceptable image recovery quality.

With the traditional DBIM method [14], where the ideal target function is the input and the recovery target function is the output. This method uses measurement parameters with evenly arranged receiver and transmitter positions, and applies the Tikhonov approach to restore the ideal target function. With the CCS-DBIM proposed method, the measurement configuration is applied with uniformly distributed transmitter positions and pseudo-randomly distributed receiver positions. Then, the l_1 optimization method is used. The l_1-LSP method solves the least squares problems based on the l_1 norm using the truncated Newton interior-point method and is expressed as follows:

$$min\|\bar{A}\bar{w} - \bar{u}\|^2 + \zeta\|\bar{w}\|_1, \tag{4}$$

in which $\bar{A}$ is a data matrix in dense or sparse form with n columns and m lines; $\bar{w}$ is a vector of length n; $\bar{u}$ is a vector of length m. In the CCS-DBIM method, $\bar{A}$, $\bar{w}$, $\bar{u}$ are $\overline{M_t}$, $\Delta\bar{O}$, and $\Delta\bar{p}^{sc}{}_t$, respectively. Note that, the size of $\overline{M_t}$ depends on the number of transmitters (N_t), receiver number (N_r) and the number of variables (N^2). Therefore, it will change in different scenarios. In the CCS-DBIM method, the l_1 norm is represented as follows:

$$\Delta\bar{O} = \arg\min_{\Delta\bar{T}} \left\|\Delta\bar{p}^{sc}{}_t - \overline{M_t}\Delta\bar{O}\right\|_2^2 + \zeta\|\Delta\bar{O}\|_1 , \tag{5}$$

where ζ is the regularization parameter in the problem l_1, the object function $\bar{O}$ is defined as follows:

$$\bar{O}(\mathrm{r}) = \begin{cases} \omega^2\left(\frac{1}{v^2} - \frac{1}{v_0^2}\right) - \rho^{1/2}(r)\nabla^2\rho^{-1/2}(r) & if\ r \le R \\ 0 & if\ r > R \end{cases} \tag{6}$$

where R is the radius of the target, $\rho(r)$ is the target density, ω is the frequency of the incident signal ($\omega = 2\pi f$), v_0 is the sound speed difference of the background medium, and v is the target medium. In this paper, the pseudo-random compression sampling method is utilized in the extended DBIM model with taking account of tissue density parameter.

The normalized error between the obtained image and the initial image at every iteration is determined by using this formula:

$$\varepsilon = \frac{1}{V \times W}\sum_{i=1}^{V}\sum_{j=1}^{W}\frac{\left|m_{ij} - \hat{m}_{ij}\right|}{\left|m_{ij}\right|} \tag{7}$$

where m is a $V \times W$ initial image (i.e. hypothetical target function) and $\hat{m}$ is the obtained image.

IV. Numerical simulation

Frequency $f = 0.64$ MHz; total loops $N_{sum} = 5$; N = 10 (i.e., the number of variables equal to $N^2 = 10 \times 10 = 100$); diameter of the object = 7.3 mm; the variation in the sound contrast is 7%; signal-to-noise ratio (SNR) = 20 dB; the distance from the transmitter and receiver to the center of the object is 100 mm. The number of measurements (N_m) is defined as the product of

the number of transmitters (N_t) and receivers (N_r), i.e. $N_m = N_t \times N_r$. The number of measurements in the selected simulation scenarios is correlated with the number of variables as shown in Eq. (3).

Fig. 1 shows the measurement configuration of the traditional DBIM method with a measurement number of N_m = 100 (transmitter number of 20 is indicated by a red star, receiver number of 5 is indicated by a blue rectangle). The positions of the transmitter and receiver are evenly spaced on the measuring system. Similarly, Fig. 2 shows the measurement configuration of the proposed CCS-DBIM method with the same number of measurements, however it differs only in that the positions of the receivers are arranged pseudo-randomly on the measurement system. This is done to ensure that recovery is possible with the sparse and random signal recovery algorithm l_1. Fig. 3 shows the ideal object that needs to be reconstructed.

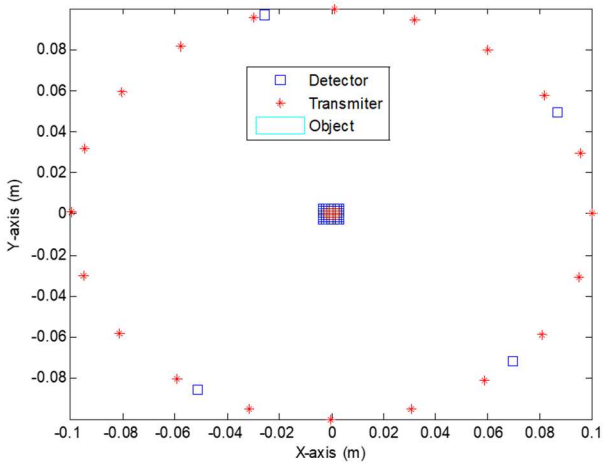

Figure 1. Measurement configuration of traditional DBIM method (N_m = 100)

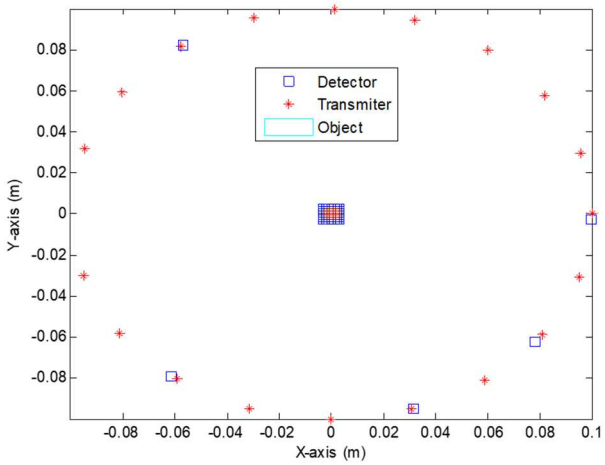

Figure 2. Measurement configuration of the proposed CCS-DBIM method (N_m = 100)

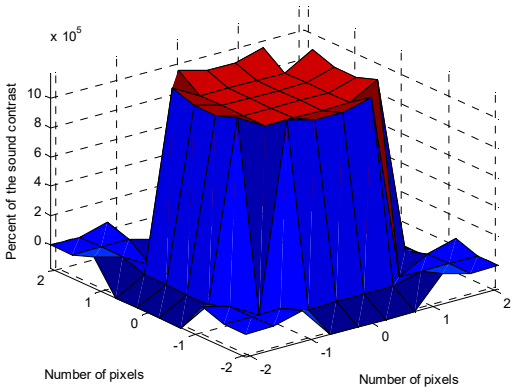

Figure 3. Ideal image that needs to be reconstructed

The image restored using the DBIM and CCS-DBIM methods in case the compression ratios r = 1, r = 0.8 and r = 0.5 in loop 1 are shown in Figure 4, 6 and 8, respectively, we see that, when the compression ratio is large (r = 1), i.e. the number of measurements equals to the number of variables, the recovery results in the first loop with the DBIM method are also quite good. However, when the number of measurements is much reduced, i.e. when the compression ratio is small (r = 0.5), the recovery results in the first loop with the DBIM method are quite poor. In particular, with the CCS-DBIM method in the first loop as well as in all other loops, the recovery results are always significantly better than the DBIM method, especially right at the first loop. In addition, the noise handling of the CCS-DBIM method is done quite well, we see that background noise in the CCS-DBIM method is significantly reduced compared to the DBIM method at the same compression ratio, and at different compression ratios, we also observe a sharp reduction in background noise.

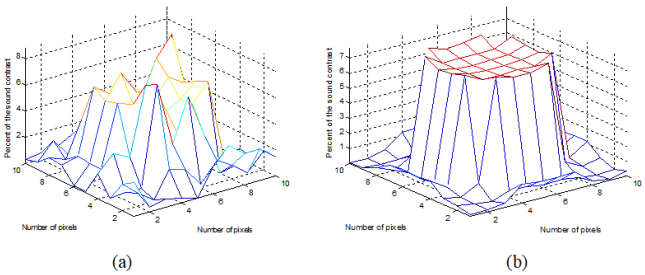

Figure 4. Recovery image results in loop 1 of DBIM using Tikhonov regularization (a) and CS-DBIM using l_1 norm (b) methods in the case of N_m = 100

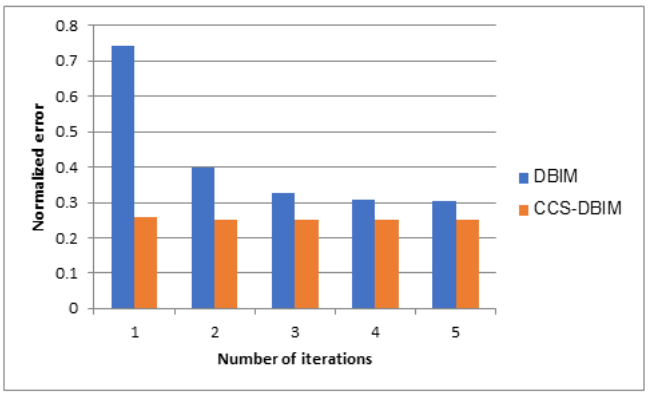

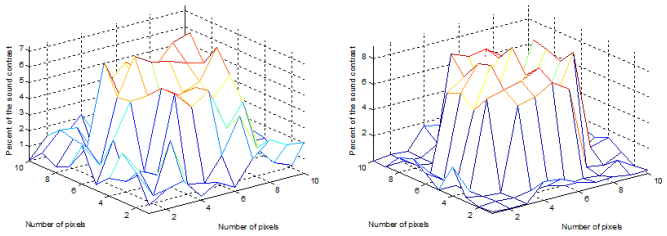

Figure 5. The normalization error result corresponds to the loop number of DBIM and CCS-DBIM methods in the case of $r = 1$

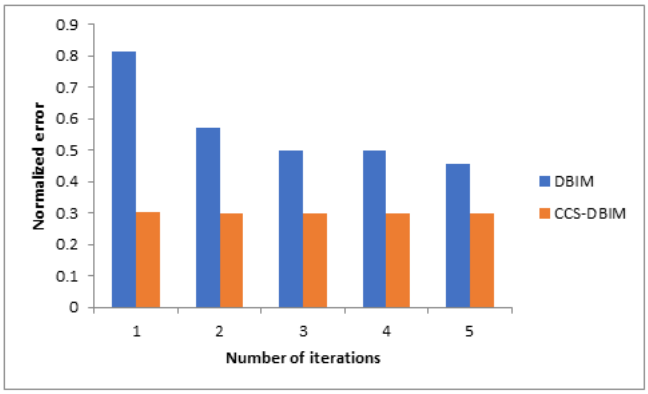
(a) (b)

Figure 6. Recovery image results of DBIM (a) and CCS-DBIM (b) methods in the case of $r = 0.8$



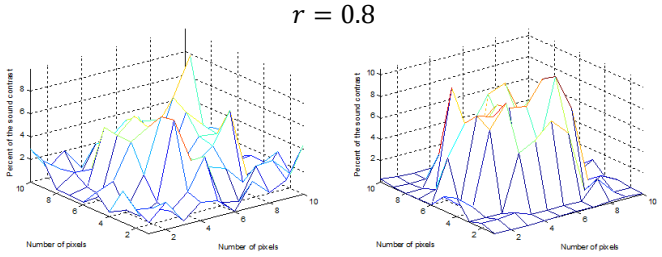


Figure 7. The normalization error result corresponds to the loop number of DBIM and CCS-DBIM methods in the case of $r = 0.8$

(a) (b)

Figure 8. Recovery image results of DBIM (a) and CCS-DBIM (b) methods in the case of $r = 0.5$

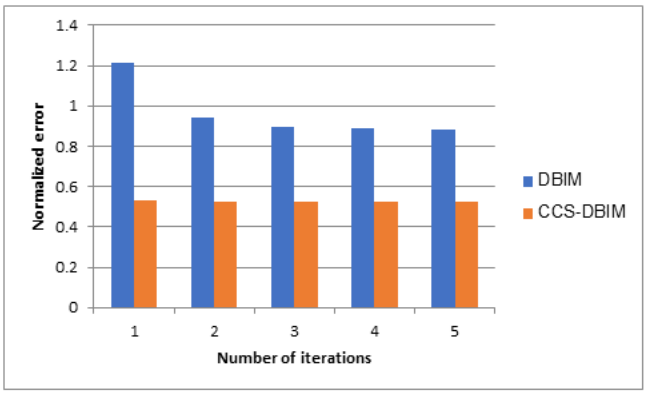

Figure 9. The normalization error result corresponds to the loop number of DBIM and CCS-DBIM methods in the case of $r = 0.5$

Figure 7 shows the normalization error result corresponding to the loop number of DBIM and CCS-DBIM methods in the case of $r = 0.8$. Although the normalized error seems not to be saturated after 5 iterations, we want to observe the convergence rate of the two methods in iterations. The CCS-DBIM method reaches saturation very quickly after the first 1-2 iterations. However, the DBIM method after 5 iterations still has not reached saturation. This shows that the convergence speed of the CCS-DBIM is much better than that of the DBIM.

Figure 10 shows the normalization error results corresponding to the different compression ratios of DBIM and CCS-DBIM methods. It can be seen that, when the compression ratio decreases, normalization errors tend to increase, this is completely normal, because the compression ratio decreases in proportion to the number of measurements decreases, so the collected data will decrease and consequently the image recovery will be reduced. However, we see that, at smaller compression ratios, especially at a compression ratio of 0.5, the greater the difference in error intervals in the 2 methods, specifically DBIM and CCS-DBIM methods have normalization errors after 5 loops of 0.8828 and 0.5281, i.e. the normalized method for the proposed method decreases by 40% when the number of measurements is half of the variables. In the case of a compression ratio of 1, the normalization error of DBIM and CCS-DBIM methods after 5 loops is 0.3024 and 0.2517, i.e. the normalization error of the proposed method decreases by 16.7% when the number of measurements is equal to the number of variables. This makes sense in practice, since when we need to create a high-resolution image of an object, i.e. a large number of variables, meanwhile, our hardware configuration is limited, so restoring the object at small compression ratios gives as accurate a result as possible.

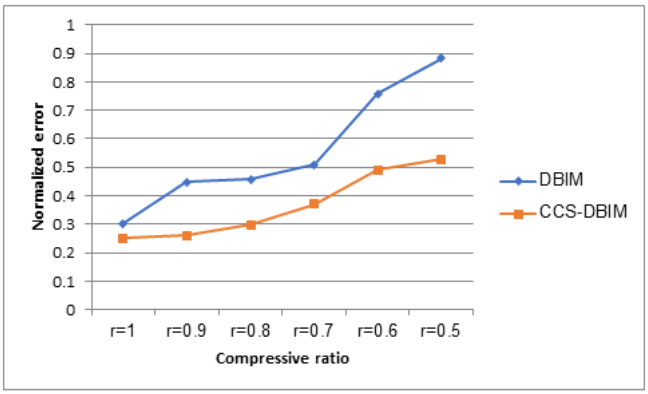

Figure 10. Normalization error results corresponding to different compression ratios of DBIM and CCS-DBIM methods

Figure 11 shows the imaging time results corresponding to the different compression ratios of DBIM and CCS-DBIM methods. We see that, the smaller the compression ratio, the smaller the imaging time, which can be explained by the fact that, when the compression ratio is small, i.e. the number of measurements is small, the amount of information to be processed and calculated will be less, therefore, the time to create the image will be less. We realize that the disadvantage of the CCS-DBIM method is that the imaging time is significantly larger than the traditional DBIM method. However, in Figures from 4 to 10, we see that the CCS-DBIM method recovers the object very well from the first loop, and the normalization error decreases after the first few loops, and then it quickly reaches a threshold and does not decrease anymore. That means, in actual image creation, with the CCS-DBIM method we only need to restore the image in the first few loops (i.e. do not have to create images in all 5 loops as with the DBIM method), if so, then the imaging time will be comparable to the DBIM method. Moreover, with today's parallel computing technology, large amounts of data and computational time will no longer be a big problem.

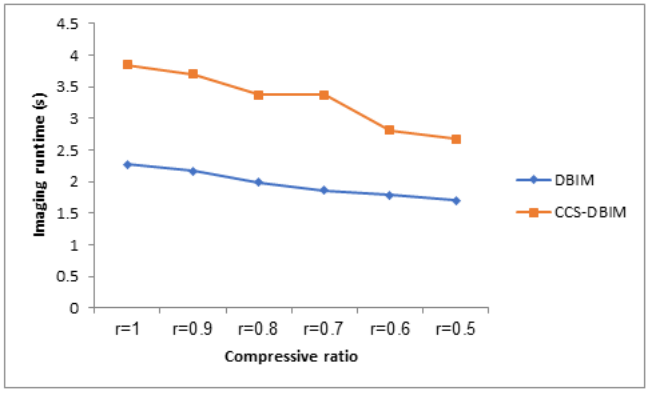

Figure 11. Imaging time results corresponding to different compression ratios of DBIM and CCS-DBIM methods

The complexity of the reconstruction system depends on the number of pixels $N \times N$, the number of iterations N_{iter}, the number of transmitters N_t and receivers N_r. With the proposed CCS-DBIM, the number of measurements and number of iterations required to reconstruct an image is greatly reduced. Therefore, this method provides much reduced computational complexity.

V. Conclusions

This paper applied pseudo-random compression sampling in an extended DBIM model that takes into account the density factor for imaging. The proposed CCS-DBIM method is easier to implement and more effective than previous methods. To prove the effectiveness of this method, many hypothetical simulation scenarios were performed. The results showed that a clear difference in imaging quality was expressed in compression ratios as low as 0.5. After 5 iterations, the CCS-DBIM method reduced normalization errors by 40% compared to the DBIM method, and with only half of the measurements. However, one of the disadvantages of the CCS-DBIM method is that the imaging time is significantly greater than that of the DBIM method. However, with parallel computing technology, the problem of large amounts of data and computational time can be solved.

***Abstract*—In recent years, there has been growing interest in using sensors worn on patients' bodies to assist doctors in monitoring and evaluating rehabilitation therapy. In this study, we toward an assisted tool that aids in the rehabilitation assessments of patients with impaired hands. The proposed method automatically spots the patient's exercises using utilizing accelerometers and displays the results on the collected video. This tool helps doctors to monitor and evaluate the patient's progress more concentrated and easily. The proposed method utilizes wavelet signal transformations, and signal segmentation by Sliding Window and Short-time Energy techniques. These techniques are not only simple calculations but also offer promising results. In the experimental results, the exercises, which are set up in real clinical situations, have been segmented with 87% of accuracy and 80% of sensitivity rate. These results confirm a potential solution to improve the efficiency and effectiveness of the rehabilitation process using the automatic assisted application.**

***Index Terms*—wearable sensor, accelerometer, rehabilitation, wavelet transform, sliding window, short-time energy**

I. Introduction

Modern medicine not only aims to treat life-threatening diseases but also to facilitate the recovery of patients' motor functions and their reintegration into society. Thus, rehabilitation is a crucial process for patients following injuries or strokes. For hand rehabilitation, patients frequently perform exercises as per the physician's prescribed regimen. Currently, wearable sensor technologies offer promising prospects for the development of innovative tools to facilitate rehabilitation assessment. These technologies allow for the capture of data from sensors such as cameras and accelerometers, which can then be analyzed and applied to create applications that assist healthcare professionals in tracking and evaluating patients' rehabilitation progress.

Automatic segmentation of the rehabilitation exercises or sessions performed by patients is the first step of an assisted tool. As shown in Fig. 1, within a rehabilitation session, the patients repeatedly practice exercises. Log activities during a session could be weak/normal hands in actions, or idle times where the patients are relaxed or in the exercises under

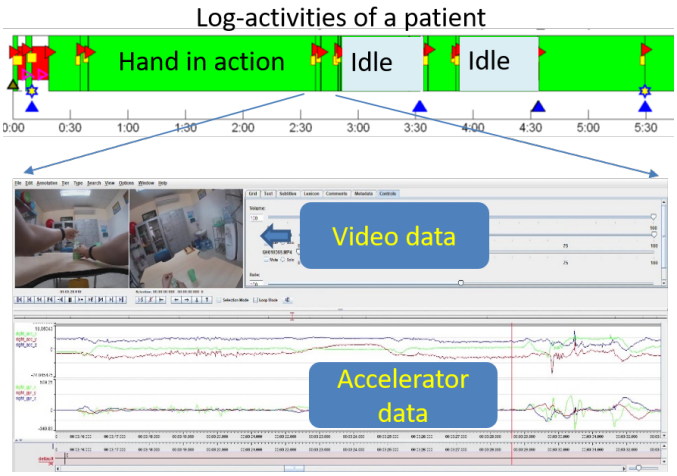

Fig. 1. An illustration of the study's purpose. Upper-panel: Log activities during a rehabilitation session. Lower-panel: The corresponding data collected by wearable devices. A spotting technique helps to segment the period when the patient's hand is in action. The idle times, therefore, can be eliminated.

construction or preparations. A signal processing technique could be applied for spotting these log activities. Based on the log activities during a session, the technical doctors are more convenient to jump and observe a certain exercise. This approach is especially critical in healthcare settings with a high patient load but limited staffing resources.

To address this issue, wearable sensors including accelerometers and image sensors are set up in rehabilitation exercises at a healthcare center. Data collected by wearable sensors are synchronized. To automatically spot each exercise, the acceleration data is analyzed by a series of signal processing techniques. Assessment of the patient's rehabilitation ability is based on the video data of each segmented period. Therefore, the proposed method handles three key issues: determining the start and end times of hand movements during exercise, identifying the hand involved in the exercise, and integrating the detected outcomes into corresponding exercise videos. The evaluation results ensure that the proposed method is able to

978-1-6654-5245-8/23/$31.00 ©2023 IEEE

healthcare professionals to rapidly assess a patient's exercise progress, measure training duration, and compare the strength and dexterity of the patient's weaker and unaffected hands.

II. RELATED WORKS

Applying wearable-sensor techniques for rehabilitation monitoring has received attention in recent years. For instance, the roles of the hand in egocentric videos such as hand detection, segmentation, localization as well as activity recognition, and hand-object manipulations in activities of daily living (ADL) have been widely explored in [1]. Researchers in [2], [3] focus on the video data collected by wearable camera only to measure meaningful information of a patient's hands such as the number and speed of hand-to-object interaction. Combining wearable sensors such as accelerator and video collected simultaneously has not been deeply attempted.

This study demonstrates the importance of accelerometer signals for applications in rehabilitation monitoring. Accelerometer signal processing has been an active research area in recent years due to its widespread use in wearable devices and healthcare applications. One commonly used technique for accelerometer signal processing is wavelet transform, which has been applied in many studies to decompose the signal into different frequency bands and extract time-frequency features. In [4] and [5], the authors used wavelet transform to decompose the accelerometer signal into frequency subbands and extract time-domain features for activity recognition. Accelerometer signal also helps divide the signal into segments based on some criteria such as amplitude, frequency, or time intervals. Segmentation is often used to detect specific activities or events in the signal. For example, Zhou, Bangwen, et al. [6] used segmentation with a multi-probability threshold on accelerometer signals for human activity recognition. Wavelet transforms and segmentation are two commonly used techniques for processing accelerometer signals and extracting meaningful features.

III. PROPOSED METHOD

A. Data acquisition setting

Patients undergoing rehabilitation are outfitted with a wearable chest camera and smartwatch featuring accelerometers on both hands. The clinical setting is shown in Fig. 2 During the exercises, they utilize both hands (the right hand and the left hand) to facilitate the comparison between the normal hand and the weak hand. We used a GoPro Hero4 camera from San Mateo, California, USA, mounted on the chest and head to collect image data (Fig. 2(a)-(c)), while the accelerometer data were obtained by a Gear S3 Frontier, a Samsung watch worn on the patient's arms. During recording, the image data and accelerometer were manually synchronized. The smartwatch Samsung Gear 3 (SG3) employs different sensors such as an accelerometer, a gyroscope, a heart rate sensor, a thermal and a light sensor. In this study, sensing signals from the accelerometer will be used as inputs of the system. The sampling frequency of the SG3 is set at 50Hz. Fig. 2(d) depicts

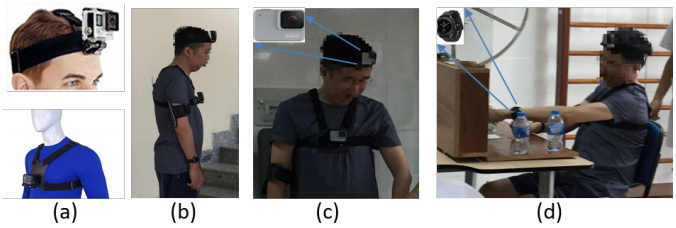

Fig. 2. Set up the wearable devices. a) Mounting wearable cameras on chest and head; b) Wearable devices see from side and frontal-view; c) a Patient wear cameras on chest and head; d) A patient doing a physical exercise wearing a smart-watch G3.

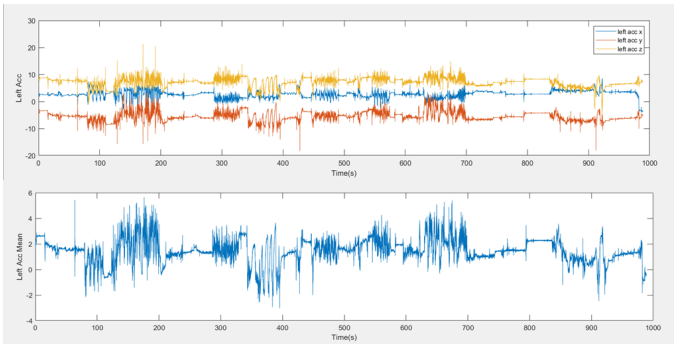

Fig. 3. Calculate the average value of the acceleration signal

actual photos of a patient wearing the sensors during a physical exercise.

B. Extract acceleration data

Acceleration data obtained from the sensor with 3 dimensions x, y, and z is averaged according to the following formula:

$$mean_{acc} = (acc_x + acc_y + acc_z)/3 \quad (1)$$

The original value and the average value of the acceleration are shown on the graph as shown in Fig.3:

C. Wavelet transform

Wavelet transforms have emerged as a widely used and effective technique for signal and image processing, particularly in the areas of noise removal and field separation, as described in references [7] and [8]. This technique, also known as multi-resolution analysis, involves decomposing a given signal into two key components: the approximation component A (also referred to as the Approximation), which corresponds to the low-frequency component, and the detail component D, which corresponds to the high-frequency component. The decomposition is achieved using two filters: a low-pass filter that is based on the scaling function $(\Psi(x))$ and a high-pass filter that utilizes the wavelet function $(\Phi(x))$. The scaling function captures the global features of the signal, while the wavelet function captures local features. By performing a wavelet transform on a given signal, it can be broken down

into its different frequency components, each of which can then be analyzed and processed independently. This makes the wavelet transform a powerful tool for processing complex signals and images, enabling more effective noise removal and signal separation. The relationship between these two functions is given by the following formulas:

$$\Phi(x) = \sum_{k=0}^{N-1} (c_k.\Phi(2x-k)) \tag{2}$$

$$\Psi(x) = \sum_{k=0}^{N-1} ((-1)^k.c_k.\Phi(2x+k-N+1)) \tag{3}$$

In order to minimize computational load, filters are applied at multiple levels. At each level, the signal is down-sampled to a factor of 2 after being passed through the filter. This results in each layer of the signal having a different resolution. The discrete wavelet transform, therefore, is known as a multi-resolution analysis (MRA).
At each filter stage, the filter expression is given by the formulas:

$$y_{\text{hight}}(n) = \sum_{k=0}^{N-1} (S(n).g(2k-n)) \tag{4}$$

$$y_{\text{low}}(n) = \sum_{k=0}^{N-1} (S(n).h(2k-n)) \tag{5}$$

whereas S(n) represents the signal, h(n) represents the impulse response of the low-pass filters corresponding to the scaling function $(\Psi(x))$, and g(n) represents the impulse response of the high-pass filters corresponding to the wavelet function $(\Phi(x))$. These two filters are related by the formula:

$$h(N-1-n) = (-1)^n g(n) \tag{6}$$

where N is the number of samples in the signal. In this work, we used a 5-level discrete wavelet transform to reduce the noise amplitude and align the signal's approximation with the horizontal axis.

D. Signal segmentation

In signal processing, there are various methods available for segmenting signals, including the Sliding Window algorithm, Top-Down algorithm, Bottom-Up algorithm, and SWAB algorithm (Sliding Window and Bottom-up). For this project, we prefer to use the Sliding Window algorithm to segment the accelerometer signal, due to its simplicity, low complexity, and ease of implementation in programming. In this study, the steps of the sliding window algorithm are depicted in Fig.4. The Sliding Window algorithm utilizes windows of varying size (initially set to 1) that move along the time axis of the signal. The algorithm begins by establishing the left boundary of the prediction segment, which also serves as the starting point for the sliding window on the right. While moving along the data points, the window size gradually increases until the mean squared error approximation of all data points within the window surpasses the user-defined maximum error threshold

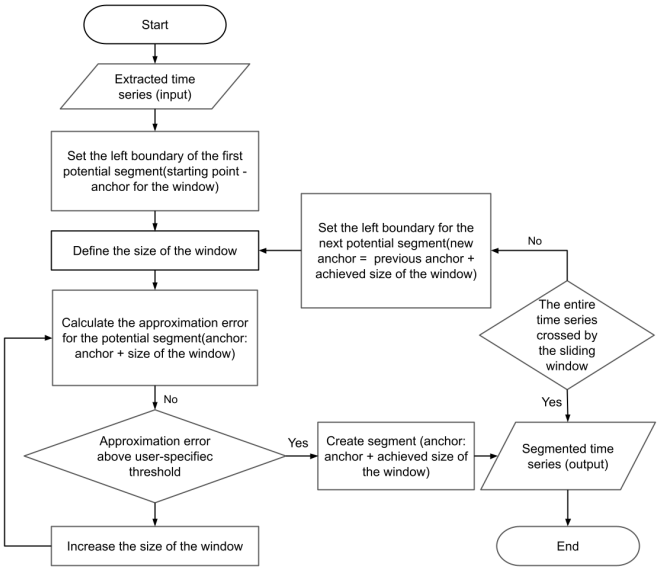

Fig. 4. Sliding Window algorithm diagram

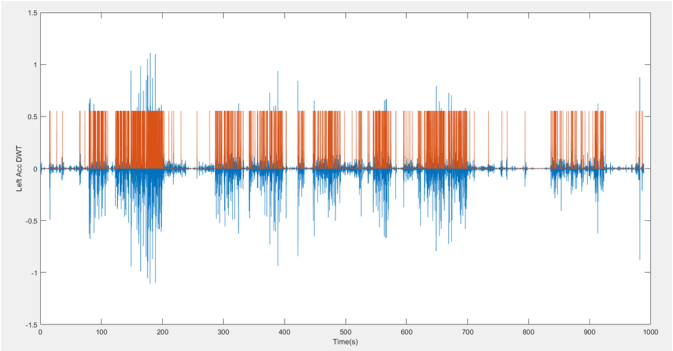

Fig. 5. Signal segmentation using Sliding Window (orange signal)

for the signal approximation. At this point, the right boundary of the window becomes the endpoint for a segment. The breakpoint of the previous segment becomes the starting point of the next segment, and the window size returns to the initial level, beginning the increment process again. This process continues until all data points are segmented. The Sliding Window method helps to segment the signal into segments with strong signal amplitude as shown in Fig.5

E. Detect time frame when hand engages activity

The energy E of a discrete signal x(n) is determined by the following expression:

$$E = \sum_{n=-\infty}^{\infty} \mathrm{x}^2(\mathrm{n}) \tag{7}$$

While energy calculation provides valuable information about the signal's amplitude, it does not provide any insight into the signal's time dependence. As we are aware, the amplitude of the acceleration signal varies over time. To account for this time-varying aspect, we calculate the short-time signal energy,

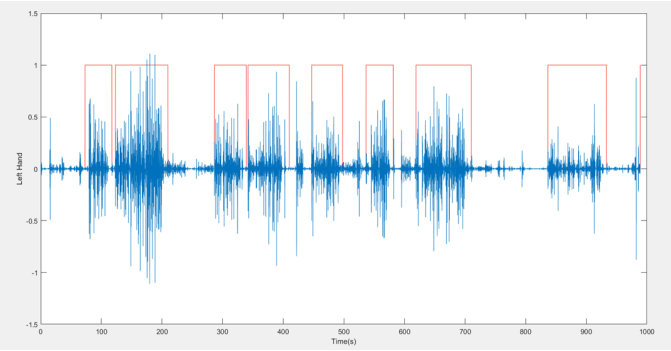

Fig. 6. Segment signal after calculating STE

commonly referred to as Short-time Energy (STE), to identify periods with high energy concentration in the signal. The STE is computed as follows:

$$\mathrm{E_m} = \sum_{n=-\infty}^{\infty} [x(\mathrm{n})\mathrm{w}(\mathrm{m}-\mathrm{n})]^2 \tag{8}$$

Once the E_m signal has been calculated, the energy threshold is applied and appropriate short time frames are eliminated to attain greater accuracy in comparison to the actual signal. Figure 6 depicts the outcome of signal segmentation during hand activity (red area).

IV. EXPERIMENTAL RESULTS

A. Dataset and Metric

The proposed method is evaluated by real situations of patient rehabilitation in which the data is collected at a Rehabilitation healthcare center. Each dataset comprises video captured by a chest-mounted camera and accelerometer data for both left and right-hand. To prepare ground-truth, the video data are utilized to denote exercise and non-exercise segments.

The performance of the proposed method was assessed using the Intersection over Union (IoU), which measures the overlap between the actual active interval and the detection interval. Furthermore, we employ two metrics including specificity and sensitivity indicators with an IoU threshold above 0.5. Two metrics are to comprehensively evaluate the performance and gain a better understanding of its capabilities and limitations.

B. Evaluation results

The results of the evaluation on four data sets with measurements for both hands are presented in Table I. In this context, the mean Intersection over Union (IoU) represents the degree of overlap between the predicted and actual time intervals. To accurately identify the rehabilitation interval, the start and end times of hand movements are recorded using accelerometers and overlaid onto corresponding exercise videos as shown in Fig. 7. The rehabilitation interval can be precisely determined by indicators (e.g., red and blue arrows for the right and left hand, respectively). The video results are made available at https://bit.ly/3laTBWg

TABLE I
EVALUATION OF THE PROPOSED MODEL'S ACTIVITY DETECTION

Data	Hand	IoU mean	Spec (%)	Sens (%)
Video 1	Left	0.79	1	1
	Right	0.78	1	1
Video 2	Left	0.7	0.92	0.92
	Right	0.43	0.55	0.4

Average	Both hands	0.64	0.87	0.80

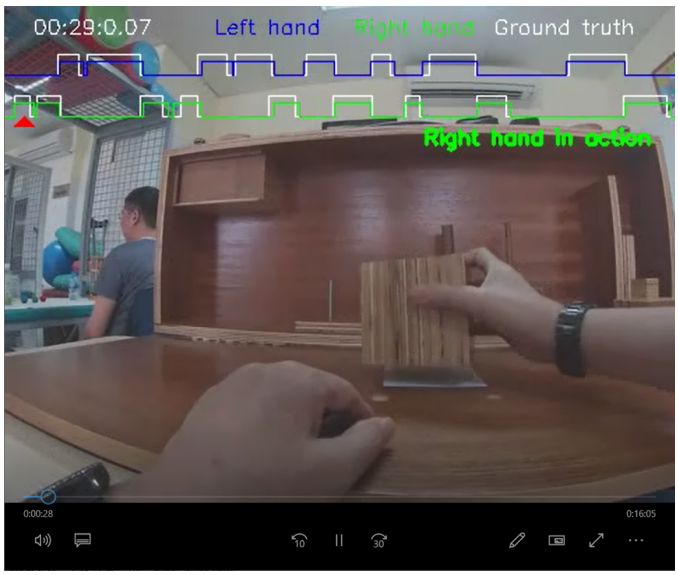

Fig. 7. Hand activity segment results on video

V. CONCLUSION

After completing the processing of the accelerometer signal received from the wearable device to obtain the results above and comparing them with the actual video of the exercises, we can see that the achieved results for the start and end times of one hand's participation in the exercise are quite good, but the accuracy for the starting and ending times of the activity is still not precise. There is still the phenomenon of wrong-hand detection in some activities. This occurs because the noise filtering process is not effective, and the error threshold at the processing steps is still done manually and cannot be automated, resulting in lower accuracy. In addition, computer vision studies should be combined to identify which exercises patients do and how often they should exercise to assess hand rehabilitation. These tasks will be our research direction in the future.

***Abstract*—Visual-guided Audio Source Separation (VASS) is the task that deals with using available visual information to guide the audio separation from the mixture signal consisting of the sounds of many simultaneous sound sources. Visual information can be images of sound sources (e.g., musical instruments) or human gestures and activities (e.g., musicians). The visual features, audio features, and the correlation between audio and visual can be used to estimate the audio mask in the audio source separation model to improve the separation performance. In this study, we introduce a new multi-modal audio separation framework to jointly train the processing blocks helping the network to find the features of the target sounds more optimally. The proposed framework is introduced with three main blocks: visual extractor, action extractor, and audio separator. They combine visual, action, and spectral features to estimate the separated sounds' spectral masks. Extensive experiments have been conducted on the MUSIC dataset containing musical performance videos to evaluate the quality of human joint estimation and gesture representation and their role in audio separation. Experimental results obtained from different settings have confirmed the effectiveness of combining an action extractor with the audio-visual separation model.**

I. Introduction

As a topic in signal processing and machine learning area, audio source separation focuses on techniques to extract individual sound sources from mixed audio signals. The goal is to separate and isolate different sources, such as vocals, instruments, or background noise, from a recorded mixture [16], [24]. Audio source separation has received the interest of the research community for many decades due to its importance in many application fields, for example, telecommunication, healthcare, robotics, entertainment, music information retrieval, etc.

Early studies used digital signal processing techniques and probabilistic statistical models, to calculate and estimate the desired audio source [14], [19]. In current years, the strong development of machine learning and deep learning models has allowed researchers to develop universal deep learning models for audio source separation in particular as well as audio processing in general. These approaches use additional information about either the sources themselves or the environmental condition in order to guide the separation process. In case the input data is video clips, including audio and visual, the exploitation of visual information to help the audio separation process in the universal models is the ideal proposed by many researchers [8], [10]. Such universal models were shown to be effective in guiding the source separation algorithm, giving a promising performance.

Inspired by this approach, some recent studies including ours have used the semantic relationship between sound information and visual information about the objects existing in the video, to support the source separation. We have introduced an empirical study on isolating the sounds of individual instruments in the video [5]. Our other one has investigated an across-modal retrieval framework for simultaneous training of the audio component and visual component, which optimizes the correlation of sound and image of the object that is the sound source [12].

In this study, we present an extension of our previous work [12], to investigate the role of human action in the visual-guide audio source separation by combining the human action extractor with our previous audio-visual model. The proposed multi-modal framework includes three main blocks: (1) a visual extractor to detect and extract the visual feature of objects in the video; (2) an action extractor, to detect and extract the action feature of humans in the video; and (3) audio separator combines visual feature, action feature, and spectral feature for estimating the spectral masks of the separated sounds.

The rest of this paper is structured as follows. We first briefly present the state of the art on audio source separation and visual-audio source separation in Section II. Section III introduces the proposed VASS framework, integrating new processing blocks for extracting the human action feature. We describe experimental settings, results, and comments in Section IV. Finally, some conclusion is shown in Section V.

II. Related works

Audio source separation is an actively researched topic with various approaches and scenarios that have been published in

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

recent years. Some of the main approaches can be mentioned as follows:

Audio-only-based approaches have usually depended on prior knowledge or assumptions about the statistical characteristics of the target sounds (such as independence, sparsity, and so on) [4]. While traditional approaches used NMF [21], [3], [4] to separate the sound, type of supervised learning can generate synthetic samples frequently including combined known sounds in training data, then training the model to extract the desired sounds from the combination [11]. In settings where separated target sources are not available, weak sound-event activity labels [13] have been proposed.

In the audio-visual-based approaches, the challenge of figuring out the relationship between the audio signal and its matching pattern in the field of visuals is considered by Audio-Visual Source Separation. Some approaches have been used for tasks including voice isolation [6], [1], acoustic instrument audio isolation [23], [8], and separation of on-screen sounds of generic objects [18]. Integrating visual information into object and action recognition systems enhances their performance and versatility. By combining visual and auditory cues, these systems can better handle challenging scenarios and improve recognition accuracy. Deep learning techniques have been instrumental in achieving this integration. Arandjelović *et al.* demonstrated the joint learning of audio and visual representations for object recognition and retrieval [2]. Recently, authors have attempted to incorporate data on movement into the visual representation using these approaches, either in the form of pixel trajectories [23] or human posture [8]. Zhao *et al.* illustrated a PixelPlayer to learn from the unlabelled videos to separate input sound in the form of pixel trajectories [23]. Gan *et al.* proposed a novel approach that utilizes music-related visual cues, specifically hand gestures, to guide the sound separation process. The authors argued that certain hand gestures performed by musicians during instrument playing can provide cues about the sound source associated with each gesture. By analyzing video data of musicians playing different instruments, they aim to infer the sound source corresponding to each gesture and use it to separate the audio sources in a music mixture [8]. In 2020, Afouras *et al.* also exploited the temporal correspondence between audio and visual modalities in videos to learn meaningful audio-visual associations without explicit supervision. They proposed a self-supervised learning approach to learn aligning audio and visual streams from different video segments. The learned audio and visual features are used to cluster video segments based on the objects present in them [1]. Nevertheless, these strategies employ a video-level "mix-and-separate" training model.

Besides exploring the correlation between objects and sound sources, it is indeed important to investigate the relationship between actions. Shlizerman *et al.* proposed a novel approach that can predict human body actions and poses based solely on the audio input. They used a neural network model on a large dataset of synchronized audio and motion capture data, where the audio signals are used as input to predict the corresponding body poses. The model is designed to learn the complex mapping between audio and body dynamics, capturing the underlying patterns and relationships [15]. By analyzing the connection between action and sound, researchers can develop models that capture the multi-modal nature of audio-visual data more comprehensively [9].

These advancements in sound source separation and the integration of visual information into object and action recognition systems have paved the way for improved audio-visual analysis and understanding. By leveraging the complementary nature of audio and visual cues, researchers have made strides in enhancing recognition accuracy, robustness, and applicability in various domains, such as surveillance, robotics, and human-computer interaction [8]. Continued research in these areas holds great potential for further advancements and innovation in audio and visual signal processing.

III. Proposed VASS framework

A. General workflow

Aiming to separate different audio sources from video, we propose a VASS system composed of three key processing components: object detection and visual feature extractor, action detection and action feature extractor, and audio-visual-pose separator, as depicted in Figure 1. These blocks work together to process input data consisting of video and single-channel audio signals of such video. The object detector's role is to identify objects in the video frames that are likely to be audio sources. Once detected, the visual feature extraction block will extract features for the identified object. To extract the action features of the musician in the video, the action feature extractor is utilized. In the audio-visual-pose separation block, we employ a convolutional neural network, which combines audio features with visual features and action features through convolutional layers to estimate the spectral masks of the audio that need to be separated.

Below, we will present more details about the processing blocks in the proposed workflow:

1) Object detection and visual feature extraction: The object detector's role is to identify objects in the video frames that are likely to be audio sources. Once identified, the visual features of such objects are extracted by the visual feature extractor. In this module, we use the same way as in our previous study [12], in which the YOLOv5 model is used to detect instruments in the video (i.e., image frames) first, then the ResNet-18 is used to exploit the visual features of the identified instruments.

2) Human joints estimation: Besides objects, the actions of musicians, while they are playing various musical instruments, may bring useful information for sound source separation. To incorporate player action in the sound source separation framework, we extract human joints from RGB images and compute action embedding features via a Graph Convolutional Network (GCN). Specifically, AlphaPose [7], a deep learning method, to harness the power of CNN for accurate and reliable estimation of human joints is used for this task. By combining the capabilities of object detection and neural networks,

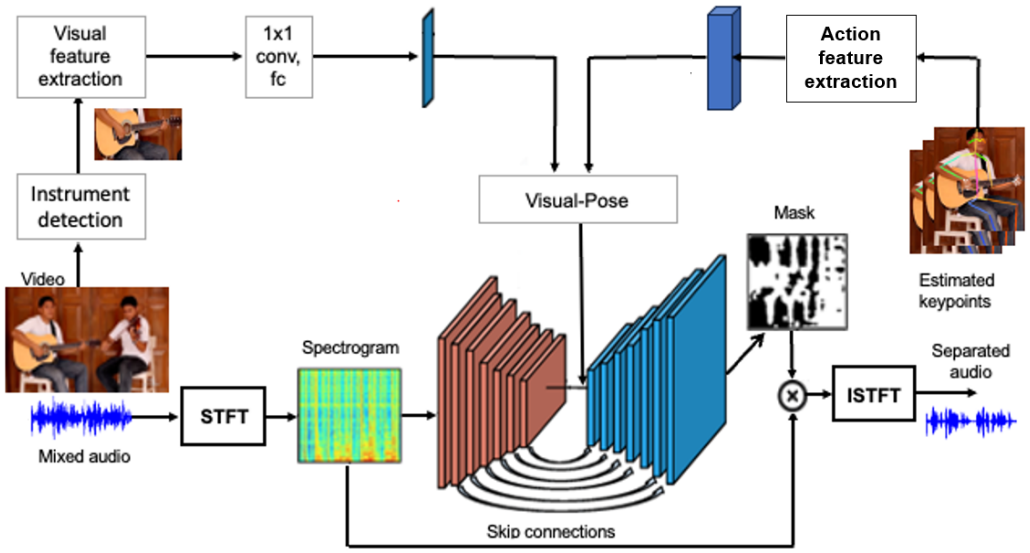

Fig. 1. The general workflow of proposed Visual-guide Audio Source Separation system.

AlphaPose provides precise estimations of the positions and actions of key joints within the human body. To ensure the system's effectiveness, AlphaPose has undergone extensive training using a large dataset. This training allows the system to learn and recognize the distinctive features and characteristics of various joints, including the shoulders, elbows, wrists, fingers, knees, and ankles. By learning from diverse examples, AlphaPose becomes capable of generalizing its knowledge and accurately estimating joints even in challenging scenarios such as occlusions and varying lighting conditions.

Figure 2 illustrates the index of 68 joints (26 joints for the body and 21 joints for each hand) of AlphaPose. We extract a sequence of skeletons with 68 joints from each 10-second clip. Each joint is represented by 2D coordinates (x, y) and its corresponding confidence score. This information will be fed to the GCN model to generate the embedding feature of the musician action.

3) Human action feature extraction and recognition: We use a Spatial-Temporal Graph Convolutional Network (ST-GCN) [22] to extract action features of musicians because compared to other approaches, this model has been proven robust in capturing human action's spatial and temporal information. The human action extraction module consists of two steps. First, an ST-GCN $G = (V, E)$ is built, where each node $v_i \in V$ corresponds to body joints of the body skeleton and each edge $e_i \in E$ represents the natural connection between those joints. We use 2D coordinates of detected body joints along with the confidence score extracted by AlphaPose as presented in the previous section as input for each node and construct a space-time graph by connecting body joints in a single frame and the joints in a sequence of frames. Then, we train the model on the training set of the MUSIC dataset to recognize the musical instrument playing gesture of the musician in the video. The main aim of the second step is to use the trained model as an action feature extractor. In this way, the framework can extract relevant features and representations specific to each instrument-playing activity. These features provide a distinctive representation of the actions performed while playing each instrument and will be used to help the model to separate sound sources better.

4) Audio separation: For audio separation, we use a U-NET convolutional network due to its proven effectiveness in audio prediction in this block. U-NET first extracts audio features of the spectrogram of the input mixed signal by applying down-sampling convolutional layers. These audio features are then conjugated with visual features and action features before being sent through up-sampling convolutional layers to estimate the spectral masks of each sound separately.

The audio-visual-pose separator is trained with a new loss function that we call the *audio-visual-pose loss function*. This loss function aims at exploiting not only audio spectral features, but also consistency between the separated spectrograms with the visual object categories, and the action categories.

B. Audio-visual-pose loss function

The proposed VASS system is implemented to separate the sound of each individual instrument from the music video. The original input data are videos and the single channel mixtures of audio of such videos. To train the audio-visual-pose separator aimed at achieving accurate audio source separation, the loss function is designed to enforce both spectral features and the consistency between the isolated spectrograms with the visual object categories, and the action categories.

Let's consider a pair of videos before mixing audio O_{v1} and O_{v2}, assuming the audio signal of each video is a mixture of individual sources as follows [5]:

$$x_1(t) = \sum_{i=1}^{N_1} s_i^1(t) \quad \text{and} \quad x_2(t) = \sum_{i=1}^{N_2} s_i^2(t), \tag{1}$$

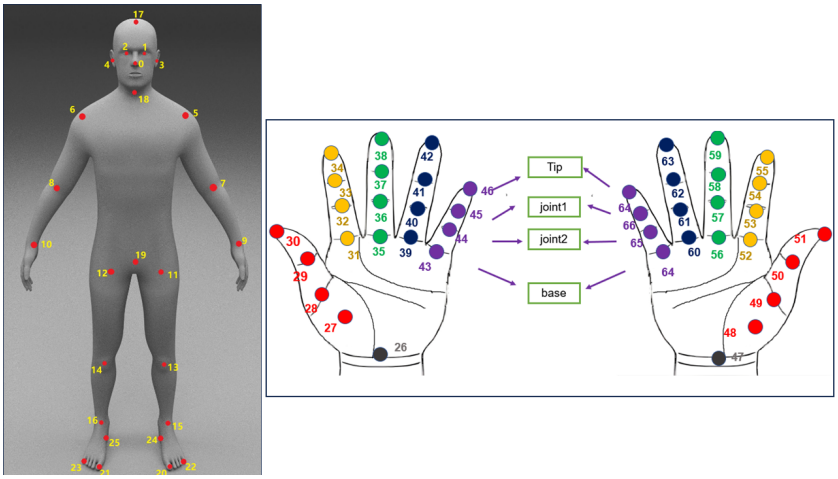

Fig. 2. Skeleton with join indexes extracted by Alphapose including 26 body joints and 21 joints for each hand.

where $s_i^1(t)$ and $s_i^2(t)$ represent the individual sources in the first and second videos, respectively.

The audio signals are transformed to the frequency domain by computing their magnitude spectrograms [5]:

$$\mathbf{X}_1 \approx \sum_{i=1}^{N_1} \mathrm{S}_i^1 \text{ and } \mathbf{X}_2 \approx \sum_{i=1}^{N_2} \mathrm{S}_i^2, \tag{2}$$

where $\mathbf{S}_i^1$ and $\mathbf{S}_i^2$ denote the magnitude spectrograms of the estimated sources $\hat{s}_i^1(t)$ and $\hat{s}_i^2(t)$ in the first and second videos, respectively. Similarly, $\mathbf{X}_1$ and $\mathbf{X}_2$ represent the magnitude spectrograms of the mixed signals $x_1(t)$ and $x_2(t)$, respectively.

The audio separation model is trained to aim for minimizing the audio separation loss component, which measures the discrepancy between the sum of separated spectrograms and the corresponding magnitude spectrograms of the mixed audio signals. Alternatively, The audio separation loss can be formulated in terms of the predicted ratio masks of the separated sound sources. The ratio mask represents the proportion of each source at each time-frequency bin. In this case, the separation loss $L_{sep-mask}$ can be approximated as [5]:

$$\begin{aligned} L_{sep-mask} = &|| \sum_{i=1}^{N_1} \mathcal{M}_i^1 - \mathcal{M}^{O_{v1}} ||_1 \\ &+ || \sum_{i=1}^{N_2} \mathcal{M}_i^2 - \mathcal{M}^{O_{v2}} ||_1, \end{aligned} \tag{3}$$

where $\mathcal{M}i^1$ and $\mathcal{M}i^2$ are the predicted spectrogram ratio masks for the sources in the first and second video, respectively. $\mathcal{M}^{Ov1}$ and $\mathcal{M}^{Ov2}$ represent the ground-truth spectrogram ratio masks for the sources in two videos, written as:

$$\mathcal{M}^{O_{v1}} = \frac{\mathbf{X}_1}{\mathbf{X}_1 + \mathbf{X}2} \quad \text{and} \quad \mathcal{M}^{Ov2} = \frac{\mathbf{X}_2}{\mathbf{X}_1 + \mathbf{X}_2}. \tag{4}$$

Realizing that the action of musicians when playing different instruments is also different, and assuming that the number of such action classes is equal to the number of instrument object classes, we introduce an object-pose-consistency loss for each predicted audio spectrogram. This loss ensures the separated spectrograms align with the visual object and the musician's action, and is calculated via cross-entropy loss as:

$$L_{obj-pose} = \frac{1}{N_1 + N_2} \sum_{i=1}^{N_1+N_2} \sum_{c=1}^{C} -y_{i,c} \log(p_{i,c}), \tag{5}$$

where N_1 and N_2 are the numbers of objects in the first and second video, respectively, and C represents the total number of classes. The binary index $y_{i,c}$ determines if class c is the correct class of the predicted spectrogram $\mathbb{S}i$, while $p_{i,c}$ denotes the prediction probability corresponding to the class c.

Finally, our overall loss function is defined as:

$$L = L_{\text{sep-mask}} + \lambda L_{\text{obj-pose}}, \tag{6}$$

where λ is the weight assigned to the object-pose-consistency loss. This weight allows us to balance the importance of separation accuracy with object consistency and action pose consistency in the overall training objective.

By optimizing this combined loss function, we aim to achieve a trade-off between accurately separating the audio sources using the predicted ratio masks and maintaining consistency between the separated spectrograms and the visual object and action categories. The parameter λ allows us to control the relative importance of the object and action poses consistency in relation to separation accuracy.

IV. Experimental Results

A. Dataset

The MUSIC dataset comprises YouTube videos collected through keyword queries. It consists of 685 video clips featuring musical duets and solos, with 536 solos and 149 duets. We used a subset that includes 536 solo videos to implement the proposed method, called *solo MUSIC*. This dataset covers a category of 11 instruments, including accordion, violin, guitar,

clarinet, tuba, acoustic cello, xylophone, flute, erhu, trumpet, and saxophone.

The original solo videos were cut into 10-second clips with various overlap ratios ranging from 50% to 70% to normalize and ensure and balanced distribution of solo clips of instrument classes. As a result, a total of 9760 10-second clips were obtained. They were allocated to training, evaluation, and testing datasets of 9260 clips, 250 clips, and 250 clips, respectively.

B. Evaluation metrics

Metrics of the human gesture recognition: We use four metrics: *Precision, Recall, F1-Score* [17] to evaluate the quality of the trained ST-GCN model for human gesture recognition.

Metrics of sound source separation: Three metrics *SDR (Signal-to-Distortion-Ratio)*, *SIR (Signal-to-Interference Ratio)*, and *SAR (Signal-to-Artifact Ratio)* are used to evaluate the quality of sound source separation. These criteria have been commonly used in the source separation community, measured in dB where the higher the better [20].

C. Implementation details

Our model is implemented using PyTorch, a popular deep-learning framework. The entire process involves several steps, including video segmentation, audio preprocessing, object detection, image feature extraction, pose estimation, pose feature extraction, and feature fusion.

1) Video segmentation: To begin with, we divide the input videos into clips of 10 seconds each. This ensures that the model can process manageable segments of the videos, facilitating better analysis and feature extraction.

2) Audio preprocessing: For the audio component, we use the STFT for converting the waveform audio signals into spectrograms and analyzing the frequency content of audio signals over time. The STFT is set up with a window size of 1022 and a hop length of 256, which enables capturing fine-grained details of the audio signals.

3) Object detection and image feature extraction: For object detection, we utilize the YOLOv5, a popular object detection algorithm. This model is trained on a comprehensive dataset consisting of 11 object categories derived from the Music dataset for fine-tuning and customizing for our specific task. Then, the ResNet18 is used to extract high-level features from the instrument images, which are crucial for further analysis and classification. The output of ResNet18 is passed through the 1x1 convolution fully connected layer to make the visual feature vector output with the size of (1, 256).

4) Pose estimation and human action feature extraction: In addition to object detection and image feature extraction, we utilize the Alpha Pose algorithm to extract skeletal joint positions from each frame of the video clips. By analyzing the action and configuration of these skeletal joints, we can infer valuable information about the musicians' poses and gestures. For each 10-second input clip, we divide it into 80 frames. These skeletal joint positions are then processed by the ST-GCN model, which has been pre-trained on our dataset. ST-GCN effectively captures temporal dynamics and encodes motion-related features from the skeletal joint sequences. It should be noted that both Alpha Pose and ST-GCN are pre-trained on our dataset. The output of this process is a vector of size (20, 68, 256), where 20 represents the 20 specific frames, 68 represents the number of skeletal joints, and 256 represents the number of corresponding features for each joint in each frame.

5) Feature fusion with Visual-Pose module: After obtaining the visual and pose features, we pass both of these features through the Visual-Pose Module to combine them. Note that the sizes of the visual features vector and pose features vector are different, so we first repeat the visual features to match the pose features' size before concatenating them to form a vector of size (20, 68, 512). Next, this vector is fed through two convolutional layers, which we refer to as spatial and temporal convolutions. The output of this process is a vector with dimensions (1, 512) used to fuse with the audio features generated by the Encoder in the U-NET. This fusion occurs at the bottleneck of the U-NET network.

6) Training setup: The model is trained for 2 epochs, with a batch size of 1. We use Adam optimizer to implement. The learning rate for the overall model was initialized as 1×10^{-4}, while for the image feature extraction component, we use a learning rate of 1×10^{-5}. This differential learning rate helps fine-tune the image feature extractor more effectively. In the loss function, the weight of object-pose-consistency loss is set $\lambda = 0.05$.

D. Results and discussion

1) Evaluation of the quality of human pose estimation: The main objective of this evaluation is to quantify the quality of human pose estimation. Given an RGB image, AlphaPose will result in 68 joints as explained in the previous section. Figure 3 shows an example of estimated joints for playing guitar, trumpet, and flute activities from RGB images while Fig. 4 illustrates a sequence of a skeleton of playing guitar.

We conducted an empirical study to examine the quality of joint estimation, focusing on three distinct activities in the dataset: guitar, trumpet, and flute playing. The dataset encompassed a wide range of guitarists and trumpeters with diverse playing styles, techniques, and skill levels.

To evaluate the confidence of the participation estimation, we calculate a threshold by analyzing the range of confidence values. This threshold serves as a reference to determine whether a joint is detected with high confidence or not. Joints with higher confidence values than the threshold are considered successfully detected, while those with lower confidence values may be deemed undetected. When setting the confidence threshold at 0.3, we observed that the pose estimation system captured more poses. However, this lower threshold also resulted in an increased likelihood of estimation errors. For example, some key points may be falsely detected or placed in incorrect positions, leading to less accurate pose representation. However, when setting the confidence threshold higher at 0.5, we observed more accurate estimations with

fewer errors. The system focused on capturing poses with higher confidence, resulting in higher accuracy and confidence levels. However, this also meant that some valid poses with lower confidence may have been excluded from the estimation.

Therefore, we have come up with a solution, by computing the average confidence values from the generated JSON result files, which provide detailed data on the estimated main joints including their corresponding confidence values, we calculate the average confidence value for each video. From the computed average confidence values, we establish a threshold that allows us to evaluate the confidence of the main joint estimations. This threshold enables us to accurately assess the performance of the pose estimation system on music-playing videos, providing reliable evaluations of joint positions and actions with higher confidence.

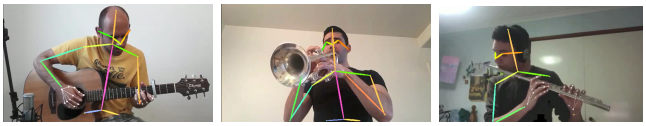

Fig. 3. The estimated joints of three musical playing activities.

Through the analysis of joint detection results during the performance of guitar, trumpet, and flute, we discovered guitar and flute playing activity exhibited consistently higher confidence scores, indicating robust and reliable joint detection. On the other hand, when trumpet playing activity, lower confidence scores were observed. This can be attributed to the occlusion of hand joints, meaning that certain parts of the hands were obstructed or hidden from view during the performance. The occlusion of hand joints in trumpet playing can occur due to the nature of holding the instrument, which may partially or fully cover some hand joints.

By aggregating the results from various videos, we generated a comprehensive report highlighting the joints that frequently go missing. This report provides valuable insights into the specific joints or body parts that present challenges for accurate estimation. Figure 5 shows the analysis results of three activities. We can observe that in guitar and flute playing activity, the bone joints were consistently and clearly detected, enabling accurate estimation of their positions and actions. Specifically, in the guitar playing activity, keypoints with ID numbers 50 (Right Thumb joint 2), 57 (Right Middle Finger joint 1), 49 (Right Thumb joint 1), 51 (Right Thumb tip), and 61 (Right Ring Finger joint 1) demonstrate the greatest occurrence of disappearances. These keypoints predominantly belong to the right hand, indicating the inherent challenges in detecting them due to the various playing techniques and hand positions involved. Furthermore, the disappearance rates of these keypoints consistently range from 8.85% to 9.69% out of a total of 58,603 frames. This implies that, on average, approximately 5186 to 5836 frames out of 58,603 frames experience the disappearance of these keypoints. This relatively low disappearance rate is advantageous in effectively monitoring the keypoint positions throughout the guitar-playing activity. These findings indicate the effective performance of the pose estimation system in monitoring the keypoints during guitar playing, enabling easier analysis and identification of guitar playing activities.

Similarly, in the flute playing activity, we achieve promising results with relatively low disappearance rates for the top 5 keypoints that experience the most frequent disappearances. The disappearance rates of these keypoints range from 6.40% - 7.78% out of a total of 64,363 frames, approximately 3750 to 4559 frames out of 64,363 frames experience the disappearance of these keypoints. The keypoints with the highest disappearance rates in flute playing are identified as ID 43 (Left Little finger base), 36 (Left Middle Finger joint 1), 9 (Left Wrist), 39 (Left Ring Finger base), and 35 (Left Middle Finger base). These keypoints primarily pertain to the left hand and predominantly represent the end joints of each finger, which is a characteristic feature observed during flute playing. Moreover, the disappearance rates of these keypoints in flute playing are the lowest among the three activities examined, indicating the exceptional performance of the pose estimation system in accurately monitoring these keypoints during flute playing.

The precise monitoring of keypoints during guitar-playing activities facilitates effective analysis and detection of guitar and flute-related actions. This capability significantly contributes to tasks such as instrument classification, enhancing our ability to identify and understand specific musical activities related to guitar and playing.

For the trumpet-playing activity, we observed significant differences compared to the previous two activities. The disappearance rates of keypoints suddenly increased, ranging from 7.98% to 15.59% out of a total of 83,698 frames, approximately 6679 to 13,048 frames out of 83,698 frames experienced the disappearance of these keypoints. The keypoints that experience the most frequent disappearances include the main keypoints with ID numbers 9 (Left Wrist), 7 (Left Elbow), 27 (Left Thumbbase), 10 (Right Wrist), and 26 (Left Palm). The disappearance rates of these keypoints exhibited a substantial deviation of up to 7.61%, whereas the discrepancy for guitar and flute playing activities was only around 0.84% and 1.48%, respectively. These keypoints encompass both sides of the hands and include larger joints in the arms, such as the Elbow. This indicates that playing the flute presents greater challenges in detecting keypoint positions compared to the previous activities. The playing techniques used in flute playing often obscure the keypoint locations, making them harder to discern. In particular, keypoints such as the elbow and wrist are frequently obstructed, making it extremely difficult to accurately determine these keypoints. The difficulty in identifying these keypoint locations significantly impedes the accuracy of the pose estimation system for flute playing. As a result, the precision of instrument recognition and performance analysis may be compromised, leading to a decrease in the quality of the results.

In summary, different playing postures in musical instrument

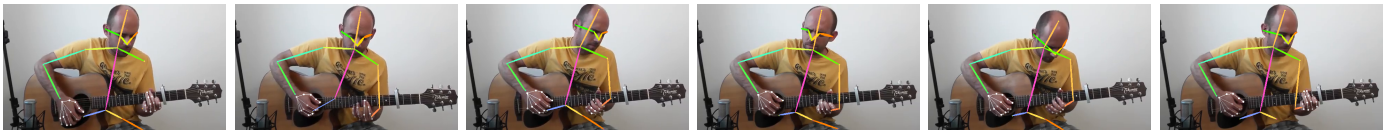

Fig. 4. Skeleton action during guitar playing

performance have a significant impact on the detection of keypoints and the determination of instrument-specific actions. This has a profound effect on the analysis and evaluation of musical instruments. The variations in hand positions, playing techniques, and instrument-specific actions make it challenging to accurately detect and track keypoints, leading to potential limitations in the analysis and assessment of musical instruments.

2) Evaluation of the human gesture recognition: Table I shows the recognition results of different activities while Figure 6 illustrates the confusion matrix. We can observe that ST-GCN is quite robust in recognizing these instrument activities. The F1-Score value for most activities is quite high, ranging from 0.86 to 0.99. The lowest F1-score (0.89) is obtained for "playing erhu" activity while the highest ones are achieved for "playing guitar" and "playing accordion". This shows that the model is capable of properly recognizing various activities based on human skeletons. Therefore, in this work, we employ the model as an extractor to compute the embedding feature for human action.

TABLE I
RECOGNITION RESULTS OF ACTIVITY RECOGNITION.

ID	Activity	precision	recall	f1-score
0	playing accordion	0.99	0.99	0.99
1	playing acoustic-guitar	0.98	1.00	0.99
2	playing cello	0.95	0.96	0.96
3	playing clarinet	0.93	0.85	0.89
4	playing erhu	0.82	0.98	0.89
5	playing flute	1.00	0.98	0.99
6	playing saxophone	0.95	0.79	0.86
7	playing trumpet	0.95	0.95	0.95
8	playing tuba	0.94	0.82	0.88
9	playing violin	0.98	0.97	0.98
10	playing xylophone	0.96	0.96	0.96

3) Evaluation of sound source separation: To investigate the effectiveness of the VASS model when exploiting more human action features, we compare the audio separation results obtained by our VASS model with three different setting cases on the MUSIC dataset:

- **Audio-Visual**: We do not perform the pose estimation, pose features extraction, and the Visual-Pose module. The output of the visual feature extraction process will have a size of 256, it was directly combined with the audio features generated by the Encoder at the bottleneck of the U-NET [5].
- **Audio-Pose**: For this case, object detection, image feature extraction, and the Visual-Pose module were not used. The output of the pose feature extractor will have a size of 512 instead of 256, it was directly combined with the audio features generated by the Encoder at the bottleneck of the U-NET.
- **Audio-Visual-Pose**: All the described activities in the proposed VASS model are performed sequentially.

The sound source separation results of our VASS model with three setting cases over the solo MUSIC dataset are shown in Table II.

TABLE II
AVERAGE AUDIO SOURCE SEPARATION RESULTS OF THE PROPOSED VASS MODEL OVER THE SOLO MUSIC DATASET.

Test case	SDR	SIR	SAR
Audio-Visual	4.92	6.54	**16.91**
Audio-Pose	3.88	6.11	15.72
Audio-Visual-Pose	**5.42**	**7.07**	16.78

As you can see, the results of the Visual-Object model are higher than those of the Visual-Pose model in both SDR and SIR, especially the most important metric SDR. This points out that using a combination of audio features and visual features of the instrument object for guiding the audio separation process gives better results than the field using a combination of audio features and musician action features.

The proposed Audio-Visual-Pose method offers the best instrument sound separation performance in both SDR and SIR when compared to the two others. Specifically with SDR, the Audio-Visual-Pose model provides 1.54 and 0.50 higher than the Audio-Pose model and Audio-Visual models, respectively. This confirmed that additional use of human action features along with audio features and object features can increase the performance of audio source separation from video.

V. CONCLUSIONS

Focus on the visual-guide audio source separation problem, this study investigates a specific task of separating different instrument sounds in the music performance video. Aiming to exploit the connection between action and sound, we proposed a novel deep learning model to jointly train the visual feature, action feature, and audio features of a multi-modal framework from the input video. Our VASS model was tested with three different setting cases: exploit audio features and visual features, exploit audio features and action features, and exploit all together audio, visual, and action features simultaneously.

Due to the limited server configuration for experimental, the audio separation results on the solo-solo MUSIC dataset were not highly competitive compared with some current studies. However, our study has confirmed the role of human action extraction in visual-guide audio source separation tasks, combining the human action extractor with the audio-visual model can increase the quality of separated sounds.

***Abstract*—The paper proposes a combination of time and frequency synchronization with Doppler compensation for coded OFDM-based UWA systems. In addition, we use a soft-decision for M-QAM schemes and Viterbi decoding to enhance the system's performance. A novel pilot arrangement scheme is proposed to mitigate inter-carrier and intersymbol interference. The simulation results show that the system performance obtained by the proposed concept significantly outperforms the state-of-the-art methods.**

***Index Terms*—OFDM, underwater acoustic (UWA), Forward Error Correction (FEC), Doppler compensation, and non-uniform FFT.**

I. Introduction

Over the last decade, researchers and industry have been interested in investigating underwater acoustic (UWA) communications using the orthogonal frequency division multiplexing (OFDM) technology [1]–[3]. The deployment of the OFDM in underwater communication offers a variety of applications for both military and commercial purposes. To communicate in the UWA channel, researchers have faced a lot of challenges. The main drawbacks of communication in underwater channels are the high attenuation, high bit error rates, large and erratic propagation delays, high Doppler shift influence, and narrow bandwidth of acoustic channels [4]. In this research, we propose some techniques to overcome these disadvantages to enhance OFDM-based UWA performance.

The main contributions and novelties are given as follows:

- To solve these problems, we combine time and frequency synchronization in coded OFDM-based UWA systems. The time and frequency synchronization has been described in [5], [6].
- We provide soft-decision in comparison to the standard approach for coded OFDM-based UWA systems with M-QAM. Using this technique, the obtained system performance has a significantly lower BER than that obtained by the hard-decision technique.

The rest of our paper is organized as follows. The architecture of the OFDM system is described in Section II. Sec. III presents the suggested soft decision for the demodulation algorithms for 4-QAM, 16-QAM, and 64-QAM. The system performance simulation results are discussed in Sec. IV. Finally, Sec. V draws conclusions.

II. The architecture of the OFDM-based UWA system

A. Transmitter achitechture

Fig. 1(a) depicts the OFDM-based UWA transmitter structure. Firstly, the bits stream will be encoded by the convolutional coder. The encoded bits will be punctured to have a desired code rate. Afterwards, these bits are modulated by using the M-QAM modulation. The pilot symbols are inserted for the purpose of channel estimation. Virtual sub-carriers are inserted before sending to the IFFT to form the OFDM signal. The guard interval (GI) is inserted in the OFDM signal to protect the received signal from multipath propagation. The modulated signal is then sent to the receiver over the UWA channel [7].

B. Receiver achitechture

The receiver performs the inverse functions of the transmitter as shown in Fig. 1(b). In order to remove out-of-band noise, the received signal is initially fed to a bandpass filter (BPF). Later, the coarse Doppler frequency shift is estimated based on a pilot carrier frequency (PCF) signal and compensated by a resampling block. The next two blocks are OFDM frame synchronization and OFDM symbol separation. The fine Doppler frequency shift is performed to compensate for the remainder of the Doppler shift. The Least Square (LS) method is used for channel estimation. The Zero Forcing (ZF) method is deployed to perform the data equalization. The M-QAM demodulation block demodulates the equalized signal. Finally, a forward error correction (FEC) decoder corrects the erroneous caused by the fading channels. To enhance the system performance, we use soft-decision in the FEC decoders.

In this paper, we use a systematic convolutional encoder structure. The encoder has a code rate of 1/2. Its constraint length is 5.

C. Description of the proposal of the transmitted OFDM signal structure

As illustrated in Fig. 2, we suggest a pilot arrangement for both channel estimation and Doppler shift estimation, where Doppler shift is estimated based on the PCF signal. Additionally, this PCF signal transmits a larger power compared to other

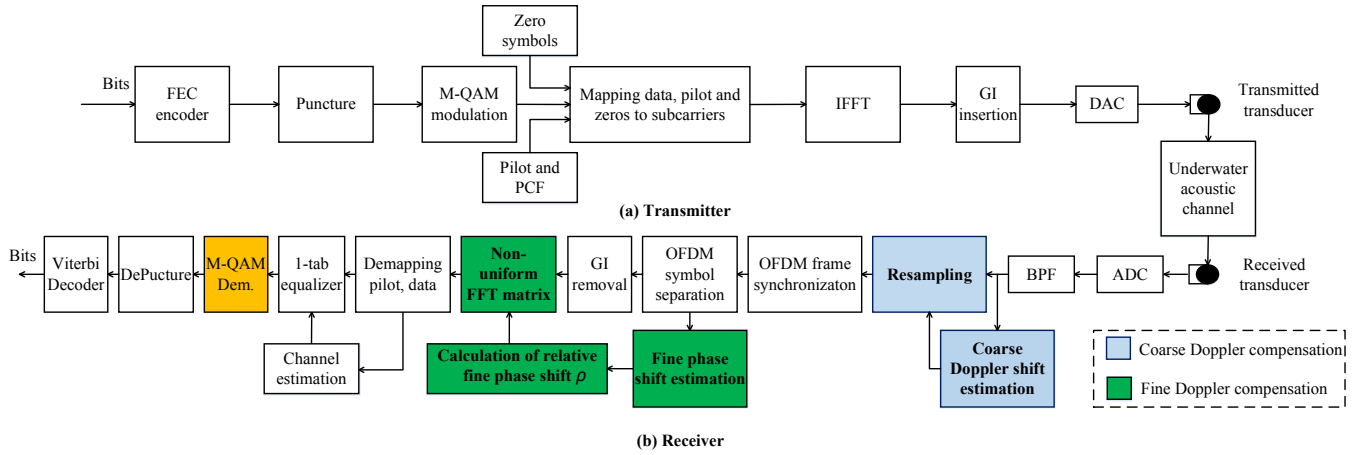

Fig. 1: The architecture of the proposed OFDM-based UWA system.

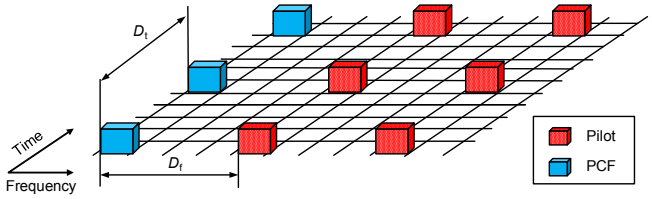

Fig. 2: Our proposal for a pilot strategy for OFDM-based UWA systems.

sub-carriers as shown in Fig. 3(a). D_t and D_f represent the pilot distance in the time and frequency domains, respectively. Moreover, we apply the Zadoff-chu sequence to create pilot value.

Let us consider the symbol $\vec{d}_{i,k}$ in the i^{th} OFDM symbol, on the k^{th} sub-carrier, then $\vec{d}_{i,k}$ can be written as

$$\vec{d}_{i,k} = [p_{i,2K}, d_{i,2K+1}[1], p_{i,2K+2}, \ldots, d_{i,3K-1}[K/2]]^T, \quad (1)$$

where $p_{i,2K}$ and $d_{i,2K+1}[n]$ represent a pilot in the i^{th} OFDM symbol, on the $2K^{th}$ sub-carrier and a data in the i^{th} OFDM symbol, on the $(2K+1)^{th}$ sub-carrier and at the index n, respectively. The index n runs from 1 to $K/2$.

Let us describe the modulated M-QAM symbols vector $\boldsymbol{s}_i$ after zeros insertion follow as:

$$\boldsymbol{s}_i = \begin{bmatrix} [0_{i,0}, \ldots 0_{i,2K-2}]^T \\ \mathrm{PCF}_{i,2K-1} \\ \vec{d}_{i,2K \to 3K-1} \\ [0_{i,3K}, \ldots, 0_{i,5K}]^T \\ \vec{d}^{*}_{i,5K+1 \to 6K} \\ \mathrm{PCF}^{*}_{i,6K+1} \\ [0_{i,6K+2}, \ldots, 0_{i,8K-1}]^T \end{bmatrix} \quad (2)$$

where $\mathrm{PCF}_{i,2K-1}$ represents the PCF signal in the i^{th} OFDM symbol on the $(2K-1)^{th}$ sub-carrier. Supposed that the FFT length is $N_{\mathrm{FFT}} = 8K$, the total number of data and pilot sub-carriers is $2K+2$, and the remaining $6K-2$ sub-carriers are zero.

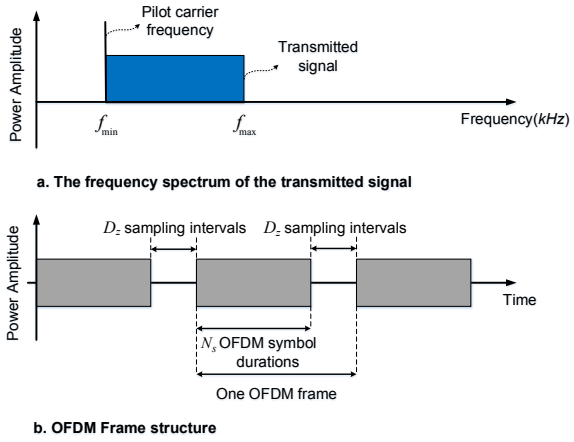

Fig. 3: (a) the frequency spectrum of the transmitted signal and (b) OFDM frame structure.

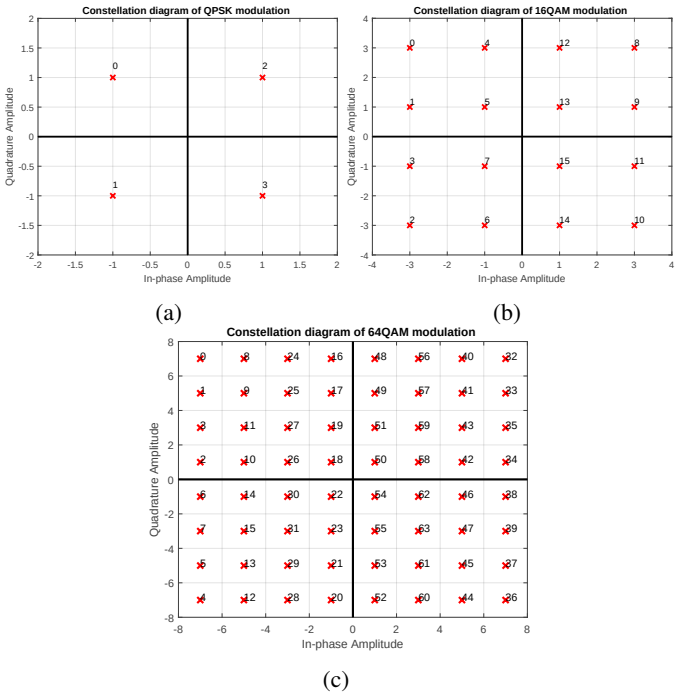
In Fig. 3(b), we can observe the structure of an OFDM-based UWA frame. Each OFDM frame is composed of a total of N_s OFDM symbols. Here, we use T_g to represent the duration of GI and T_{sub} to represent the duration of a single OFDM symbol. A pause period is created between two OFDM frames by the preamble D_z. Consequently, the duration of an entire OFDM frame, denoted as T_s, can be expressed as:

$$T_s = N_s(T_{sub} + T_g) + D_z \quad (3)$$

D. Doppler compensation by using the PCF signal

We make the assumption that the time-domain received signal, denoted as y, can be represented as $y = h*x+w$, where x signifies the transmitted signal, h characterizes the channel coefficients specific to the UWA channel, and w corresponds to the additive white Gaussian noise (AWGN).



First, to eliminate the out-of-band noise impact on the received signal, y is fed into the BPF block. Then, the coarse Doppler shift estimation and resampling will be done on the PCF signal. Based on the guard interval, the beginning of each OFDM frame is detected by using a time synchronization method described in detail in [5]. Afterward, the fine Doppler compensation for the received signal y is performed after removing the guard interval, which is clearly presented in [6]. The fine Doppler compensation is to minimize the remaining frequency offset by using a non-uniform FFT matrix, namely, $[\mathbf{G}_{\mathbb{RS}}]$, as follows:

$$\hat{\mathbf{Y}} = [\mathbf{G}_{\mathbb{RS}}]y \tag{4}$$

After the Doppler shift is compensated, we can estimate channel coefficients at the positions of the reference signals based on the pilot signal. Following the acquisition of all the channel coefficients at these points, we have to estimate channel coefficients at the positions of the data signals. The most conventional method is the interpolation technique. In terms of equalization, the signal may be easily implemented by applying the formula $\tilde{X} = \frac{\hat{Y}}{H}$ in the frequency domain. Before decoding FEC, the signal is then fed to M-QAM demodulation which is discussed in detail in Sec. III.

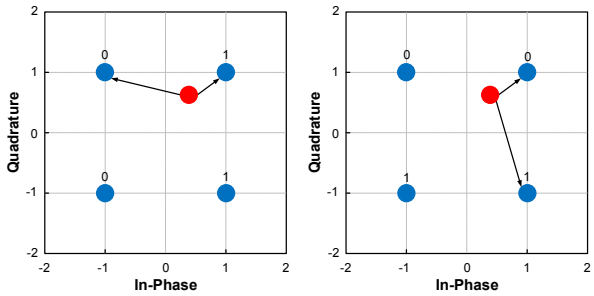
III. Proposal of a Soft-Decision Algorithm for M-QAM Demodulation

To improve the performance of our OFDM system, we propose a soft-decision detection instead of using hard-decision for M-QAM demodulation. Fig. 4 depicts the M-QAM (namely, 4-QAM, 16-QAM, and 64-QAM) constellation.

(a) (b)

(c)

Fig. 4: (a) 4-QAM constellation, (b) 16-QAM constellation, and (c) 64-QAM constellation.



Let S_{I}^{+} and S_{I}^{-} represent a set of the symbols whose I^{th} bit is 1 and 0, respectively. To make the decision on I^{th} bit according to soft output, we define the log-likelihood ratio (LLR) value calculated as follows

$$\begin{aligned} \mathrm{LLR}(\mathrm{b_I}) &= \ln \frac{\sum\limits_{\mathrm{X}\in \mathrm{S_I^-}} \mathrm{f}(\tilde{\mathrm{X}}|\mathrm{X})}{\sum\limits_{\mathrm{X}\in \mathrm{S_I^+}} \mathrm{f}(\tilde{\mathrm{X}}|\mathrm{X})} \\ &\approx \frac{1}{2\sigma^2}\left(|\tilde{X} - X_{\mathrm{I,opt}}^{+}|^2 - (|\tilde{X} - X_{\mathrm{I,opt}}^{-}|^2\right) \end{aligned} \tag{5}$$

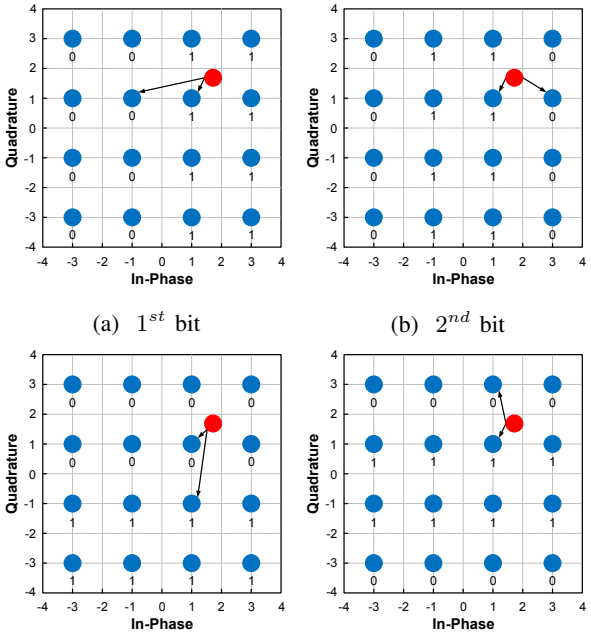
where $\mathrm{f}(\tilde{\mathrm{X}}|\mathrm{X})$ stands for the probability density function that a symbol can be received given its transmission, $X_{\mathrm{I,opt}}^{+} = \arg\min_{X\in \mathrm{S_I^+}} |\tilde{X} - X|^2$, and $X_{\mathrm{I,opt}}^{-} = \arg\min_{X\in \mathrm{S_I^-}} |\tilde{X} - X|^2$. Based on Eq. (5), we calculate the LLR values for different demodulation schemes.

A. Soft-decision for 4-QAM demodulation

Let us $b_0 b_1$ denotes two bits of 4-QAM demodulation. For each bit of the 4-QAM constellation, The calculations of LLR value are depicted in Fig. 5.

(a) 1^{st} bit (b) 2^{nd} bit

Fig. 5: The 4-QAM constellation's LLR computations for each bit: examples.



It follows from Fig. 5 that the LLR values of 1^{st} bit $\mathrm{LLR}\,(b_0)$ depend on the real part $\tilde{X}_{\mathrm{I}}$ whereas the LLR values of 2^{nd} bit $\mathrm{LLR}\,(b_1)$ rely on the imaginary part $\tilde{X}_{\mathrm{I}}$. Suppose that the red point is represented by the symbol $\tilde{X}_{\mathrm{I}}$. In terms of LLR calculates of 1^{st} bit, the real part of the 4-QAM constellation takes the value 1 when $b_0 = 1$ and -1 when $b_0 = 0$. Similar to the LLR calculation of 2^{nd} bit, the imaginary part of the 4-QAM constellation takes the value -1 when $b_0 = 1$ and 1 when $b_0 = 0$. Using the Eq.(5), two LLR values of each bit in 4-QAM demodulation are given as:

$$\mathrm{LLR}\,(b_0) = -\frac{2}{\sigma^2}\Re(\tilde{X}_{\mathrm{I}}), \quad \forall \Re(\tilde{X}_{\mathrm{I}}) \tag{6}$$

$$\mathrm{LLR}\,(b_1) = \frac{2}{\sigma^2}\Im(\tilde{X}_{\mathrm{I}}), \quad \forall \Im(\tilde{X}_{\mathrm{I}}) \tag{7}$$

B. Soft-decision 16-QAM demodulation algorithm

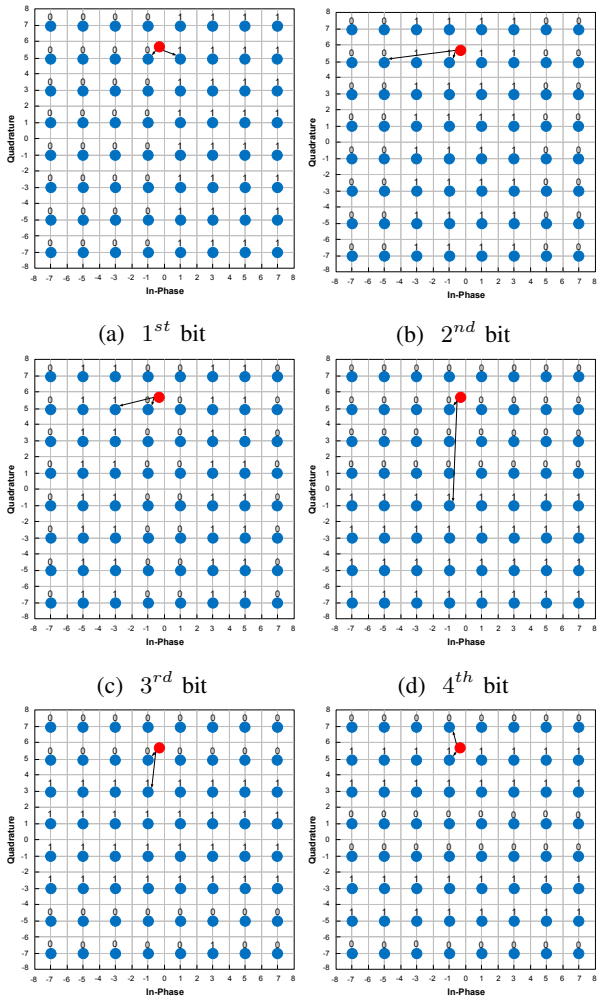
Let us $b_0b_1b_2b_3$ represent four bits of 16-QAM demodulation. From equations (8), (9), (10) and (11), it can be seen that the LLR values of the 1^{st} bit LLR (b_0) and 2^{nd} bit LLR (b_1) depend on the real part $\tilde{X}_{\mathrm{I}}$, while the values of the 3^{rd} bit LLR (b_2) and 4^{th} bit LLR (b_3) rely on the imaginary part $\tilde{X}_{\mathrm{I}}$. Fig. 6(a) shows LLR computation for 1^{st} bit. In this constellation, the real part has values of 1 and 3 when b_0 is 1, and -1 and -3 when b_0 is 0. According to the Hamming distance, the numbers -1 and 1 correspond to $b_0 = 0$ and $b_0 = 1$, respectively, which may be disregarded. Similar to the remaining bits, the LLR values can be described as follows:

(a) 1^{st} bit (b) 2^{nd} bit

(c) 3^{rd} bit (d) 4^{th} bit

Fig. 6: Examples of The 16-QAM constellation's LLR computations for each bit.

$$\mathrm{LLR}\,(b_0) = \begin{cases} -\frac{4}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) - 1], & 2 \le \Re(\tilde{X}_{\mathrm{I}}) \\ -\frac{2}{\sigma^2}\Re(\tilde{X}_{\mathrm{I}}), & -2 \le \Re(\tilde{X}_{\mathrm{I}}) < 2 \\ -\frac{4}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) + 1)], & \Re(\tilde{X}_{\mathrm{I}}) < -2 \end{cases} \tag{8}$$



$$\mathrm{LLR}\,(b_1) = \frac{2}{\sigma^2}[|\Re(\tilde{X}_{\mathrm{I}})| - 2], \quad \forall \Re(\tilde{X}_{\mathrm{I}}) \tag{9}$$

$$\mathrm{LLR}\,(b_2) = \begin{cases} \frac{4}{\sigma^2}[\Im(\tilde{X}_{\mathrm{I}}) - 1)], & 2 \le \Im(\tilde{X}_{\mathrm{I}}) \\ \frac{2}{\sigma^2}\Im(\tilde{X}_{\mathrm{I}}), & -2 \le \Im(\tilde{X}_{\mathrm{I}}) < 2 \\ \frac{4}{\sigma^2}[\Im(\tilde{X}_{\mathrm{I}}) + 1], & \Im(\tilde{X}_{\mathrm{I}}) < -2 \end{cases} \tag{10}$$

$$\mathrm{LLR}\,(b_3) = \frac{2}{\sigma^2}[|\Im(\tilde{X}_{\mathrm{I}})| - 2], \quad \forall \Im(\tilde{X}_{\mathrm{I}}) \tag{11}$$

C. Soft-decision 64-QAM demodulation algorithm

Let us $b_0b_1b_2b_3b_4b_5$ represent six bits of 64-QAM demodulation. Similar to Sec. B, the values of the first three bits (LLR (b_0), LLR (b_1) and, LLR (b_2)) depend on the real component $\tilde{X}_{\mathrm{I}}$, while the values of the last three bits (LLR (b_3), LLR (b_4) and, LLR (b_5)) depend on the imaginary part $\tilde{X}_{\mathrm{I}}$ as shown in Fig. 7. These LLR values can be obtained as follows:

(a) 1^{st} bit (b) 2^{nd} bit

(c) 3^{rd} bit (d) 4^{th} bit

(e) 5^{rd} bit (f) 6^{th} bit

Fig. 7: Examples of The 64-QAM constellation's LLR computations for each bit.

$$\mathrm{LLR}\,(b_0) = \begin{cases} -\frac{8}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) - 3], & 6 \le \Re(\tilde{X}_{\mathrm{I}}) \\ -\frac{6}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) - 2], & 4 \le \Re(\tilde{X}_{\mathrm{I}}) < 6 \\ -\frac{4}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) - 1], & 2 \le \Re(\tilde{X}_{\mathrm{I}}) < 4 \\ -\frac{2}{\sigma^2}\Re(\tilde{X}_{\mathrm{I}}), & -2 \le \Re(\tilde{X}_{\mathrm{I}}) < 2 \\ -\frac{4}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) + 1], & -4 \le \Re(\tilde{X}_{\mathrm{I}}) < -2 \\ -\frac{6}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) + 2], & -6 \le \Re(\tilde{X}_{\mathrm{I}}) < -4 \\ -\frac{8}{\sigma^2}[\Re(\tilde{X}_{\mathrm{I}}) + 3], & \Re(\tilde{X}_{\mathrm{I}}) < -6 \end{cases} \tag{12}$$

$$\mathrm{LLR}\,(b_1) = \begin{cases} \frac{4}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) - 5], & 6 \le \Re(\tilde{X}_\mathrm{I}) \\ \frac{2}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) - 4], & 2 \le \Re(\tilde{X}_\mathrm{I}) < 6 \\ \frac{4}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) - 3], & 0 \le \Re(\tilde{X}_\mathrm{I}) < 2 \\ -\frac{4}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) + 3], & -2 \le \Re(\tilde{X}_\mathrm{I}) < 0 \\ -\frac{2}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) + 4], & -6 \le \Re(\tilde{X}_\mathrm{I}) < -2 \\ -\frac{4}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) + 5], & \Re(\tilde{X}_\mathrm{I}) < -6 \end{cases} \tag{13}$$

$$\mathrm{LLR}\,(b_2) = \begin{cases} \frac{2}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) - 6], & 4 \le \Re(\tilde{X}_\mathrm{I}) \\ -\frac{2}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) - 2], & 0 \le \Re(\tilde{X}_\mathrm{I}) < 4 \\ \frac{2}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) + 2], & -4 \le \Re(\tilde{X}_\mathrm{I}) < 0 \\ -\frac{2}{\sigma^2}[\Re(\tilde{X}_\mathrm{I}) + 6], & \Re(\tilde{X}_\mathrm{I}) < -4 \end{cases} \tag{14}$$

$$\mathrm{LLR}\,(b_3) = \begin{cases} \frac{8}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 3], & 6 \le \Im(\tilde{X}_\mathrm{I}) \\ \frac{6}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 2], & 4 \le \Im(\tilde{X}_\mathrm{I}) < 6 \\ \frac{4}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 1], & 2 \le \Im(\tilde{X}_\mathrm{I}) < 4 \\ \frac{2}{\sigma^2}\Im(\tilde{X}_\mathrm{I}), & -2 \le \Im(\tilde{X}_\mathrm{I}) < 2 \\ \frac{4}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 1], & -4 \le \Im(\tilde{X}_\mathrm{I}) < -2 \\ \frac{6}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 2], & -6 \le \Im(\tilde{X}_\mathrm{I}) < -4 \\ \frac{8}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 3], & \Im(\tilde{X}_\mathrm{I}) < -6 \end{cases} \tag{15}$$

$$\mathrm{LLR}\,(b_4) = \begin{cases} \frac{4}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 5], & 6 \le \Im(\tilde{X}_\mathrm{I}) \\ \frac{2}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 4], & 2 \le \Im(\tilde{X}_\mathrm{I}) < 6 \\ \frac{4}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 3], & 0 \le \Im(\tilde{X}_\mathrm{I}) < 2 \\ -\frac{4}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 3], & -2 \le \Im(\tilde{X}_\mathrm{I}) < 0 \\ -\frac{2}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 4], & -6 \le \Im(\tilde{X}_\mathrm{I}) < -2 \\ -\frac{4}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 5], & -6 \le \Im(\tilde{X}_\mathrm{I}) < -4 \end{cases} \tag{16}$$

$$\mathrm{LLR}\,(b_5) = \begin{cases} \frac{2}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 6], & 4 \le \Im(\tilde{X}_\mathrm{I}) \\ -\frac{2}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) - 2], & 0 \le \Im(\tilde{X}_\mathrm{I}) < 4 \\ \frac{2}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 2], & -4 \le \Im(\tilde{X}_\mathrm{I}) < 0 \\ -\frac{2}{\sigma^2}[\Im(\tilde{X}_\mathrm{I}) + 6], & \Im(\tilde{X}_\mathrm{I}) < -4 \end{cases} \tag{17}$$

IV. Results and Discussions

In the following, the parameters of the experimental OFDM-based UWA system are described, where a single input and single output scenario are considered. The sampling frequency f_s is 96 kHz. The carrier frequency ranges from 12 kHz to 15 kHz. The guard interval length and the total number of sub-carriers are $GI = 1024$ and $N_{\mathrm{FFT}} = 2048$, respectively. The modulation techniques, namely, 4-QAM, 16-QAM, and 64-QAM, are applied. Regarding the simulation results, we will discuss the following issues: frame synchronization results, Doppler compensation performance, the effectiveness of the pilot strategy, and the performance of the proposed soft-decision method.

First of all, we discuss the synchronous signal. Fig. 8(a) represents the received signal after adding AWGN at SNR = 5 dB, respectively. Next, Fig. 8(b) is the synchronous signal, **SYN**, which is obtained on the basis of the designed guard interval.

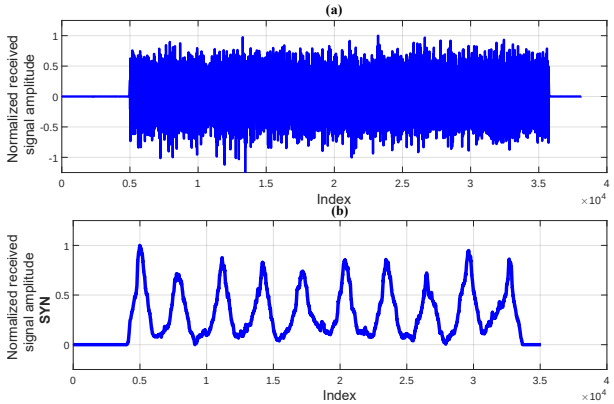


Fig. 8: (a) The received signal (**y**), (b) the synchronous signal (**SYN**)

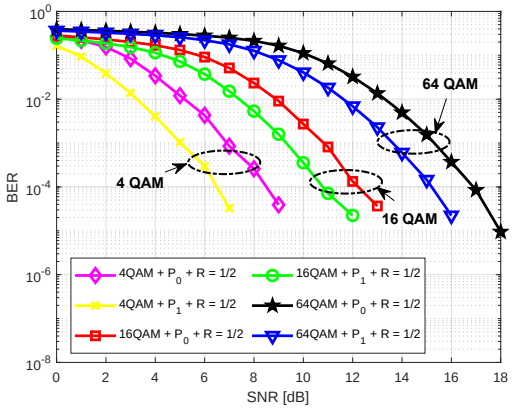

Fig. 9: BER of different pilot schemes.

Figure 9 shows the performance of the pilot strategy in our system using the convolution code $R = 1/2$. Instead of using the pilot sequence P_0 that is used in [6] for channel estimation, we employ the Zadoff-chu sequence P_1 in this article. As can be seen, our approach outperforms the method of [6] three distinct modulation schemes. Specifically, this method offers a system performance in terms of SNR gain of 2dB in the case of 4-QAM, 1dB in the case of 16-QAM, and 2dB in the remaining case.

In the following part, we discuss the performance of the Doppler compensation method. To evaluate the performance of the method in [6] when the system applies convolution codes $R = 1/2$ and soft-decision of M-QAM demodulation by adjusting the subcarrier frequency to shift it by 20 Hz. As shown in Fig. 10, the performance of the system is measured by BER. The case of without Doppler compensation is a reference. The performance of the OFDM-based UWA is clearly improved by using the proposed technique.

Finally, we discuss the performance of the proposed method if the demodulation scheme is combined with convolution code. The suggested technique performs better in both circumstances than the hard decision, as illustrated in Fig. 11(a), 11(b) as well as in 11(c). In particular, when using 4-QAM modulation, our technique outperforms other methods by 1 dB

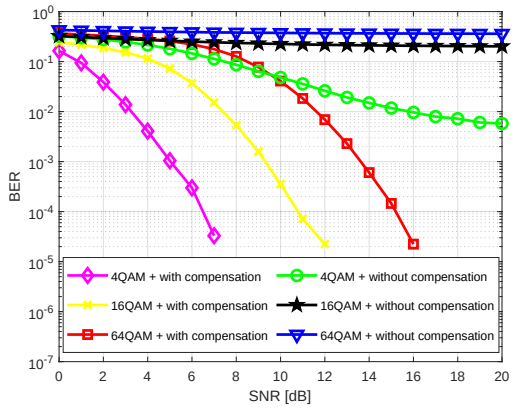

Fig. 10: BER of Doppler compensation with convolution code $R = 1/2$.

for code rates of $R = 1/2$ and 2 dB for rates of $R = 2/3$ as depicted in Fig. 11(a). According to the results shown in Fig 11(b) and 11(c), our method is better than 6 dB in the case of code rate $R = 1/2$ and 5dB in the case of $R = 2/3$ for both 16-QAM and 64-QAM.

V. Conclusion

In this paper, we propose a combination of time and frequency synchronization with Doppler compensation for coded OFDM-based UWA systems. For a given transmission scenario, the numerical simulations help us to optimize the system parameters to obtain the best performance. Numerical simulation results show also that the obtained system performance by using our proposed techniques outperforms the state of the art in terms of BER or in terms of SNR.

***Abstract*—The present study explored the possibility of using a quaternion neural network (QNN) as a prediction model to achieve optimal predictive control of non–linear systems. Computational experiments for a tracking task of a non–linear plant confirmed the promising role of QNN for control applications.**

I. Introduction

Although deep neural networks (DNNs) have been successfully demonstrated to solve intractable problems in many fields [1], high–dimensional NNs using hyper–complex numbers have been explored as an alternative for handling such problems. The present study investigated a control systems application using a quaternion NN (QNN) [2]. We focused on a model predictive control (MPC) approach [3] to achieve optimal predictive control of non–linear systems.

II. Optimal Predictive Control

An optimal control input to the objective plant is determined by minimising the objective function J at each time step k: $J = \sum_{j=1}^{N_p} \|\hat{\epsilon}_{k+j|k}\|^2 + \sum_{j=1}^{N_u} \lambda_j \|\Delta u_{k+j-1}\|^2$, where N_p is the prediction horizon for the plant output $y_k \in \mathbb{H}$, $\hat{\epsilon}_{k+j|k} \in \mathbb{H}$ is the predicted control error defined by the difference between the predicted plant output $\hat{y}_{k+j|k} \in \mathbb{H}$ and reference output $r_{k+j} \in \mathbb{H}$, N_u is the control horizon for the control input $u_k \in \mathbb{H}$, $\Delta u_{k+j-1} \in \mathbb{H}$ is the control input increment, and $\lambda_j \in \mathbb{R}$ is the weight coefficient. A multi–layer QNN was used as the model of the objective plant to estimate the predictions of the plant output for the whole prediction horizon at each time k. The external input to the network consists of the tapped delay lines of the plant's input–output. The QNN was trained offline to minimise a real–valued cost function defined by the norm of the identification error defined by the difference between the plant and network outputs using a stochastic gradient descent method extended to quaternion systems on the input–output set of the plant. We introduced a metaheuristics optimisation method, such as simulated annealing (SA), genetic algorithm (GA), and particle swarm optimisation (PSO), which allowed us to minimise the objective function J without solving the non–linear programme.

III. Computational Experiments

To investigate the capability of using the QNN in the optimal predictive control, computational experiments were conducted using the following objective plant: $y_k = 1.3y_{k-1} - 0.3y_{k-2} + 0.03y_{k-3} + u_{k-1} + 0.7u_{k-2} + 0.2y_{k-1}^2 + \zeta_{k-1} - 0.3\zeta_{k-2}$, where $\zeta_k \in \mathbb{H}$ is the random noise. The control input had an inequality constraint of $|u_{k_i}| \leq 0.5$. The QNN had a 4–16–1 network topology. The total number of training datasets was 10^4. In the objective function J, N_p and N_u were set to one and λ_1 was set to 0.1. The control task of ensuring that the plant output followed the reference output could be achieved with the acceptable accuracy (Fig. 1). The mean squares of the control error with SA, GA and PSO were 0.0245 ± 0.0015, 0.0296 ± 0.0024 and 0.0240 ± 0.0011, respectively. The Welch one–way ANOVA test with a significance level of 5% showed statistical differences between GA and SA/PSO.

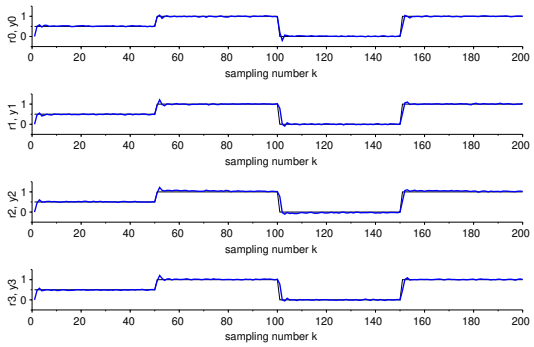

Fig. 1. Example of system responses using SA, where the reference changes 0.5, 1, 0 and 1 every 50 samples. The reference r_k and the plant output y_k are denoted using thin black and blue lines, respectively

IV. Conclusions

To achieve an optimal predictive control for non–linear systems, we applied a QNN to a prediction model in the MPC approach and an optimal control input was defined by minimising the quadratic objective function composed of the predicted control error and control input increment using a metaheuristics optimisation. Our findings confirmed that the optimal predictive control using the QNN could ensure the control task with the required performance.

Dhirubhai Ambani Institute of Information and Communication Technology (DA-IICT), Gandhinagar, India.
E-mail: {priyanka_gupta, aastha_k, hemant_patil}@daiict.ac.in

***Abstract*—This study proposes Morse wavelet-based scalogram features for classification of normal *vs.* pathological infant cry. To the best of the authors' knowledge and belief, this study is the first of its kind to exploit analytic wavelet-based features for this task. For comprehensive evaluation of the proposed feature set, two datasets have been considered in this work, namely, Baby Chillanto, and DA-IICT corpora, and a third dataset is created by the combining these corpora. Furthermore, three data augmentation techniques (namely, tempo, volume, and speed perturbation) have also been applied on these datasets, and the performance of the proposed feature set is evaluated. Our study finds that the proposed Morse wavelet-based features shows the best performance of 98.19% (94.51%) as overall accuracy without augmentation, with an absolute improvement of 6.03% (6.06%) and 0.88% (5.10%) in accuracy compared to Mel-STFT and CQT baselines, respectively, on Baby-Chillanto (DA-IICT) datasets. Further, the performance of wavelet-based features outperforms the Mel-STFT and CQT on Baby Chillanto dataset, whereas it gives comparable results on DA-IICT and combined datasets.**

Index Terms: Infant cry classification, Morse wavelet, scalogram, data augmentation.

I. Introduction

Crying is the known mode of communication for infants, which is an essential evolutionary signal that enables infants to convey discomfort. During the first three months after birth, infant cries are known to carry neurological and health status of the infant [1]. About 2.5 million infants succumb to various vaccine-preventable and other ailments within initial months of birth. Several diagnosis methods, such as magnetic resonance imaging, computed tomography scans, and head ultrasound are used to identify various pathologies. However, pathology diagnosis is costly, and also time taking, which impacts the health of the baby. For example, asphyxia is identified by pale and bluish limbs. However, by the time these visual symptoms are visible, notable neurological damage to neonate would have already been occurred [2]. Hence, the need to develop a robust assistive pathology detection algorithm to aid paediatricians in identifying such pathologies is increasing [3]. Some of the prominent causes of infant's death are asthma, Sudden Infant Death Syndrome (SIDS), and asphyxia.

The infant cry classification and analysis involves neurological, physiological, psychology, engineering, developmental linguist, and paediatrics making this field highly interdisciplinary in nature. Early, in 1960s, the preliminary analysis of infant cries for pathological cry detection was pioneered using spectrograms by *Xie et. al.* [4]. The characteristics of normal cry sounds, generally defined as "cry modes" or "cry phonemes," including vibration, dysphonation, inhalation, and hyperphonation, were investigated for both the time and frequency-domains [4]. This study was extended to the pathological cries in [5], where some of these cry modes were found to be correlated with pathology. In [6], infants are found to have melodic pattern in their cry. To that effect, a recent Constant Q Transform Cepstral Coefficients (CQCC)-based study was also explored in [7] where the *form-invariance* property of Constant Q Transform (CQT) was explored for infant cry classification. Given CWT is a type of CQT, in this study, we explore the effectiveness of Continuous Wavelet Transform (CWT) (i.e., scalogram-based features) for infant cry classification task. Furthermore, similar to Mel-Short Time Fourier Transform (Mel-STFT), and CQT, the CWT-based scalogram features are also known to have better resolution in lower frequency regions [8], [9]. In addition to the existing baselines reported in [10], [11], [12] that use spectrograms (with or without mel scale) as input to neural network-based classifiers, we use CQT-based baseline as well, and we propose Morse wavelet-based features for infant cry classification. Moreover, the spectrogram has fixed time-frequency resolution in the entire time-frequency plane and hence, it fails to preserve *form-invariance* property of Fourier transform, i.e., $F\{x(\alpha t)\} = \frac{1}{|\alpha|} X\left(\frac{\omega}{\alpha}\right)$, because the analysis window used in STFT is a function of *only* time parameter.

It should also be noted that there is existing literature which uses wavelets for infant cry classification [13], [14], [15]. However, the existing works propose the use of variants of Daubechies wavelets, which differ from our proposed work in the following 3 aspects:

- The existing approaches use **real** wavelets, whereas, our work proposes the use of **analytic** wavelets which are known to capture instantaneous frequency. Moreover, Morse wavelets show *strict analyticity* which enables **no spectral leakage** (as discussed later in this paper) and superior time localization.
- The existing approaches are based on DWT-based features, where our work is based on the analytic CWT. The analytic CWT is robust to noise and stable to perturbations and higher-order modulations, which makes it more suitable for feature extraction as compared to DWT.
- Our work additionally addresses the issue of selection of an appropriate wavelet by using *Generalized* Morse

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

wavelets as a superfamily of analytic wavelets. To the best of the authors' knowledge, this issue of selection of appropriate wavelet has not been addressed in the literature, especially for infant cry classification. Therefore, our work exhibits novelty in these three aspects.

In particular, we present the following contributions in this paper:

- We propose Generalized Morse Wavelet (GMW)-based features for pathology detection from infant cries.
- Given that Baby Chillanto, and DA-IICT datasets have utterances recorded in different acoustic conditions, performance is also evaluated on a third dataset - combined dataset.
- Three data augmentation techniques (speed, volume, and tempo perturbation) on all the three datasets.
- For all these datasets, the proposed features are evaluated for two cases (i.e., with and without augmentation).

II. Proposed GMW-based Features

Analytic wavelets are *causal* in the frequency-domain, and are of different types, including complex Shannon, log-normal, Gaussian derivative, Cauchy, and Morlet wavelets [16], [17], [18], [19]. However, as there are numerous wavelet types, selecting the most suitable one for a given task is a significant consideration. GMWs, on the other hand, are regarded as a super-family of analytic wavelets, which addresses the problem of choosing a specific type of analytic wavelet [20], [21], [22]. Moreover, infant cry is an oscillatory signal, and its zero-crossings capture important acoustic information pertaining to possible pathology. Thus, we employ Morse wavelet that is analytic and hence, it can capture the instantaneous frequency content in the cry segment.

GMWs are a set of eigenvectors w.r.t. to a time-frequency localization operator, whose details can be studied from [23]. In this work, out of these set of eigenvectors, only the 0^{th} GMW is considered because it corresponds to the *largest* eigenvalue, and is known for its *optimal energy concentration* properties [23], [24]. To that effect, we represent the 0^{th} GMW as the Morse wavelet, which is mathematically expressed in the frequency-domain as [20], [21], [24]:

$$\Psi_{\beta,\gamma}(\omega) = \int_{-\infty}^{+\infty} \psi_{\beta,\gamma}(t) e^{-j\omega t} dt = U(\omega) a_{\beta,\gamma} \omega^{\beta} e^{-\omega^{\gamma}}, \quad (1)$$

where β and γ control the *shape* and *size* of the wavelet, as shown in Fig. 1. Furthermore, $a_{\beta,\gamma}$ is a real-valued normalizing constant, and $U(\omega)$ is the unit-step function in the frequency-domain due to the causality of $\Psi_{\beta,\gamma}(\omega)$. The Morse wavelet, however, is better analyzed using its dimensionless derivatives [22]. To that effect, its 2^{nd} derivative is called the *wavelet duration* or *inverse bandwidth* and is denoted as $P^2_{\beta,\gamma}$. The significance of 2^{nd}-order derivative is discussed in detail in the Appendix of this paper. The quantity $P^2_{\beta,\gamma}/2\pi$ sets the number of oscillations in the wavelet, where $P^2_{\beta,\gamma}$ is given as [22]:

$$P^2_{\beta,\gamma} \equiv -\frac{\omega^2_{\beta,\gamma} \Psi''_{\beta,\gamma}(\omega_{\beta,\gamma})}{\Psi_{\beta,\gamma}(\omega_{\beta,\gamma})} = \beta\gamma. \quad (2)$$

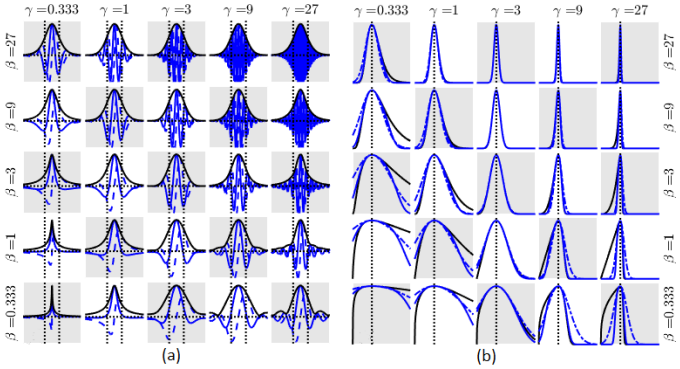

Fig. 1. Morse wavelets for varying values of β and γ in (a) time-domain, and (b) frequency-domain. After [21].

When the parameter $P^2_{\beta,\gamma}$ is kept fixed, varying the parameter γ, shifts the wavelet transform between different families of wavelets of fixed durations. Therefore, the parameter γ is termed as *family*. In this work, the Morse wavelet with parameter γ = 3 (also known as *'Airy family'*) is chosen because we get the most optimum Heisenberg area $A_{\beta,\gamma}$ for γ = 3 even for a small wavelet duration (as shown in Fig. 2) [21]. The minimum value of $A_{\beta,\gamma}$ is governed by $\sigma_t^2 \cdot \sigma_\omega^2 \geq 1/4$, where σ_t^2 and σ_ω^2 are the variances in time and frequency domains, respectively [17]. Further details of the Heisenberg's area $A_{\beta,\gamma}$ can be studied from [8], [24]. Additionally, at $\gamma = 3$,

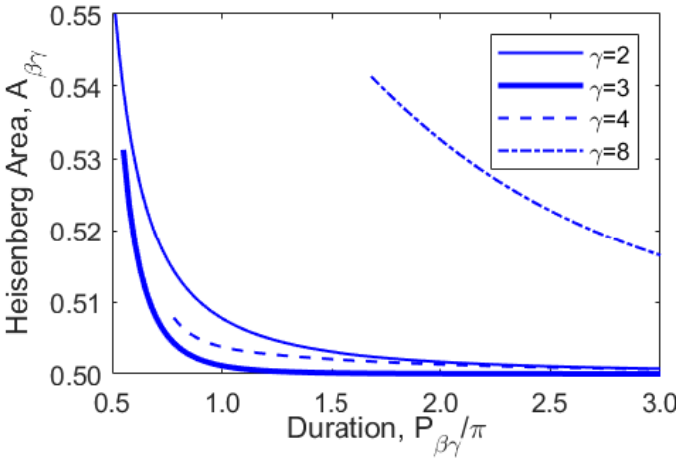

Fig. 2. Effect of γ parameter on the time-frequency Heisenberg area $A_{\beta,\gamma}$ w.r.t. wavelet duration $P_{\beta,\gamma}/\pi$. After [21].

the Morse wavelet is said to be similar to the conventional Morlet wavelet. However, the conventional Morlet wavelet defies analyticity property under special cases, but the Morlet-like wavelet achieved from by taking $\gamma = 3$ in Morse wavelet, shows *strictly* analytic behaviour. In other words, as observed in Fig. 3, a *spectral leakage* can be observed in the case of the conventional Morlet wavelet, whereas the Morse wavelet remains to be strictly analytic, i.e., its spectrum *does not leak* to the negative frequency region, i.e., it is zero in the negative frequencies as seen in Fig. 3 (d).

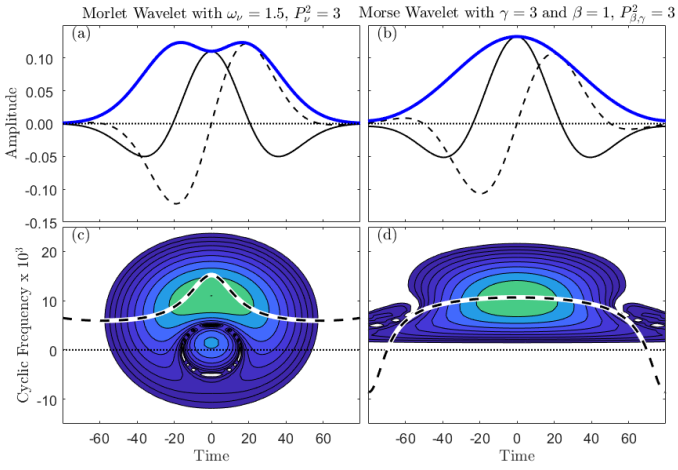

Fig. 3. Analysis of spectral leakage (a) Morlet wavelet, *vs.* (b) Morse wavelet and (c), (d) their respective Weigner-Ville distributions.

A. Morse Wavelet-Based Feature Extraction

The CWT of a signal $x(t)$ is estimated as

$$W_a x(u,s) =< x(t), \psi_{u,s}(t) >, \\ = \frac{1}{\sqrt{s}} \int_{-\infty}^{+\infty} x(t)\psi^* \left(\frac{t-u}{s}\right) dt, \quad (3)$$

where $< \cdot, \cdot >$ indicates inner product operation to compute wavelet coefficients, and $*$ denotes the complex conjugate operator. The dilation (scaling) coefficient is denoted by s, and translational (positional) coefficients are denoted by u. From Fig. 4 (a), it can be observed that the scalogram corresponding to healthy (normal) cry exhibits a *continuous* band of energy in the high frequency region (particularly near 1 kHz, as shown by the red box). However, a clear distinction can be observed in Fig. 4 (b), which shows scalogram corresponding to pathological (asphyxia) infant cry. In particular, it can be observed that there is *absence* of continuous band of energy in this case. Moreover, a *short burst of energy* (as indicated by the red box) is observed in the lower frequency region, indicating the possible presence of pathology. In this work, we extract CWT-based representations (i.e., scalograms), as described in Algorithm 1. These scalogram-based features are then fed as input to the GMM classifier.

Algorithm 1: MATLAB pseudocode for the proposed Morse wavelet-based scalogram extraction

Input: Speech signal $x(t)$
Output: scalo_image
w_name='morse' // Taking Morse wavelet
[cwt_coeffs, F] ← cwt(x(t), w_name)
/* Mapping CWT coefficients to scalogram RGB image of 512×512. */
tpoints ← time vector of $x(t)$
/* Converting to Pseudocolor image */
pcolor(tpoints, cwt_coeffs)
/* Converting scalorgram as RGB color image */
scimg=ind2rgb(rescale(cwt_coeffs), jet(320));
scalo_image← imresize(scimg, 512, 512);

III. Experimental Setup

A. Datasets Used

In this study, we use three datasets, namely, Baby Chillanto database, the DA-IICT corpus, and the combined (Baby Chillanto + DA-IICT) dataset. Baby Chillanto dataset was designed using recordings made by doctors and is the property of Mexico's NIAOE-CONACYT and its statistics can be studied from [25], [26]. The second dataset known as the DA-IICT corpus was collected by [27], [28]. The third dataset called as combined dataset consists of all utterances of Baby Chillanto dataset along with DA-IICT corpus, with 1842 utterances in the healthy class, and 1616 utterances in the pathology class. For fair experimentation, we have resampled the utterances of all the datasets to a uniform sampling frequency of 16 kHz. Experiments in this study are performed using *10*-fold cross-validation (CV) method. Table I shows the data partitioning of each of the *10*-folds.

TABLE I
Number of Utterances in Data Partitions in Each Fold

Dataset →	Baby Chillanto	DA-IICT	Combined
Train	2041	1071	3112
Test	227	119	346
Total	2268	1190	3458

B. Data Augmentation

To increase the robustness towards *realistic* scenarios, data augmentation has also been performed on all the datasets. Data augmentation is particularly useful for infant cry classification problem because of the limited publicly available datasets. The data augmentation in this work has been performed using "SOX" tool for three augmentation techniques, namely, speed, tempo, and volume perturbation. For speed augmentation, the audio is perturbed *w.r.t.* time to get the speed augmented utterance, expressed as $y(t)$=$s(b*t)$, where $s(t)$ is the input cry utterance, and b is scaling factor [29]. Tempo augmentation is a STFT-based perturbation technique where speech segment is re-positioned based on speech synthesis instants as in [30]. For volume augmentation, the utterance is scaled as $y(t)$=$b * s(t)$. The value of b takes values as 0.9 and 1.1 for speed and volume perturbation each.

C. Classifier Used

The classifier used in this work is Gaussian Mixture Model (GMM). For the case of Baby Chillanto dataset, the number of mixtures taken is 512, while it is 128 for the DA-IICT corpus. The difference in the number of mixtures for both the datasets is due to the difference in the size (i.e., the number of cry utterances) of both the datasets.

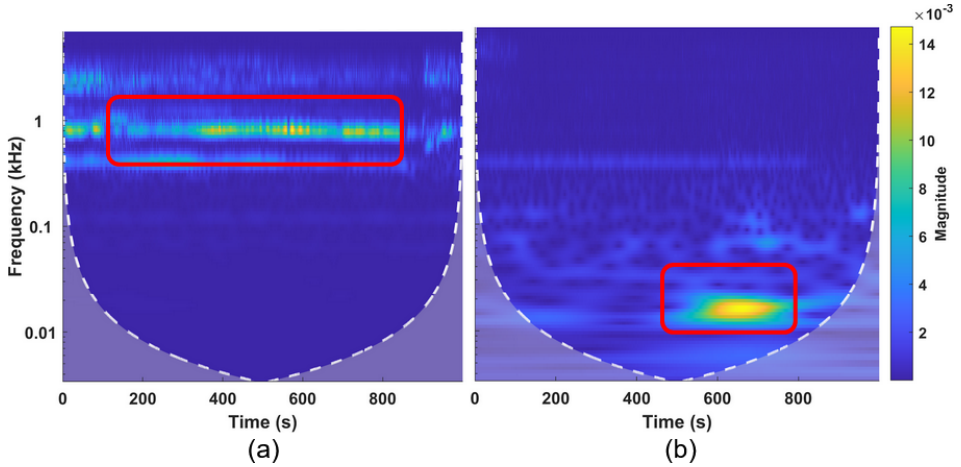

Fig. 4. Proposed Morse scalogram-based analysis for (a) healthy, and (b) pathology (asphyxia) infant cry.

Moreover, it should be noted that due to the relatively smaller test size of the dataset, neural network-based classifiers, such as CNN could not be used as it results in *overfitting*. However, we also performed experiments using SVM as the classifier to observe the effect of the classifier.

D. Baselines

Given that the proposed feature set is *non-cepstral*, in this work, for fair comparison, two non-cepstral baselines are considered, namely, Mel STFT, and CQT. Mel STFT-based features are evaluated by keeping window size of 30 ms and window shift of 15 ms, whereas the CQT-based baseline is using 96 bins and F_{min} = 100 Hz. It should be noted that both the baselines and the proposed feature set have *high* resolution in the lower frequency regions.

IV. Experimental Results

A. Effect of Classifier Structure

Given the small size of the test data, neural network based classifiers such as CNNs are not considered, to observe the effect of the classifier. Table II shows the performance of Mel STFT, CQT, and the proposed Morse wavelet-based scalogram features using SVM and GMM classifiers on the standard Baby Chillanto dataset. It can be observed that the proposed features outperform Mel STFT and CQT features for both SVM and GMM. However, since GMM gives absolute increment of 7% on all feature sets as compared to SVM, the remaining experiments in this paper are performed by considering GMM-based classifier.

TABLE II
% Accuracies using SVM and GMM

Classifier	Mel STFT	CQT	Morse Wavelet-based Scalogram
SVM	88.55	87.84	**90.75**
GMM	92.16	97.31	**98.19**

B. Effect of Wavelet Duration ($P^2_{\beta,\gamma}$)

In this sub-Section, we present the results obtained by varying the wavelet duration parameter $P^2_{\beta,\gamma}$ of the Morse wavelet. Fig. 5 shows the effect of $P^2_{\beta,\gamma}$, keeping γ fixed as 3, on the two datasets. It can be observed from Fig. 5 that the results are degraded for relatively lower values of $P^2_{\beta,\gamma}$, more so, for the DA-IICT corpus. From eq. (2), it can be deduced that for a fixed value of γ (i.e., $\gamma = 3$), a low value of $P^2_{\beta,\gamma}$ corresponds to a low value of β. Therefore, in Fig. 1, as we keep $\gamma = 3$ fixed, and move towards lower values of β (i.e., lower values of wavelet duration $P^2_{\beta,\gamma}$), poor quality subband filters (with low quality factor, i.e., with increased bandwidth) are produced. Therefore, the performance is degraded for lower values of wavelet duration for both the datasets. Furthermore,

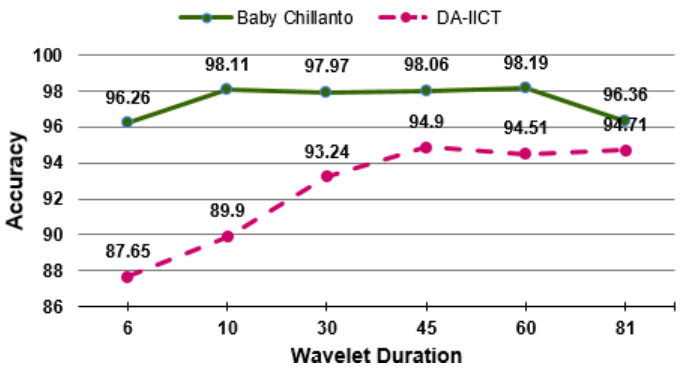

Fig. 5. Effect of the Morse wavelet parameter $P^2_{\beta,\gamma}$ on Baby Chillanto, and DA-IICT corpora.

the optimal value of $P^2_{\beta,\gamma}$ obtained is 60 for the case of Baby Chillanto dataset, and 45 for the case of DA-IICT corpus. Given that Baby Chillanto is statistically significant standard dataset for infant cry classification problem, we choose to keep $P^2_{\beta,\gamma}$ as 60, for the remaining set of experiments.

C. Overall Performance

As discussed in sub-Section IV-B, keeping the parameter $P^2_{\beta,\gamma}$ as 60, we now present the overall performance in terms

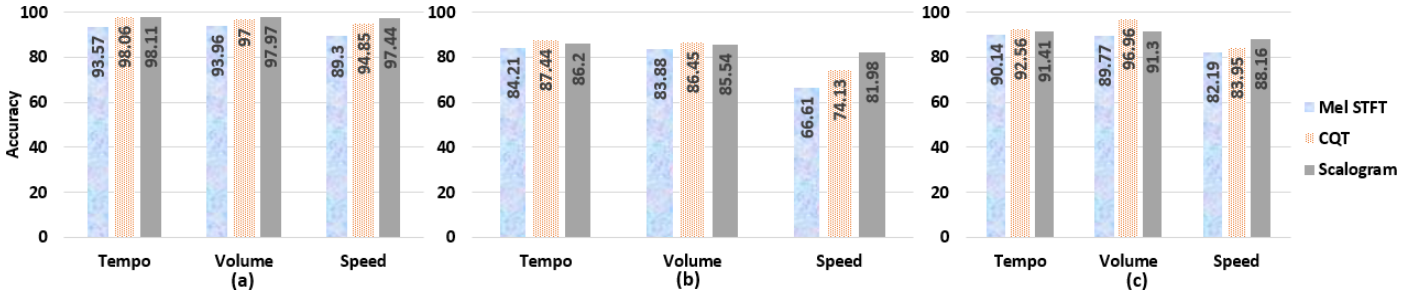

Fig. 6. Effect of three data augmentation techniques (i.e., tempo, volume, and speed perturbations), on (a) Baby Chillanto, (b) DAIICT, and (c) combined corpora. Best viewed in color.

of % accuracy, obtained on the three datasets used in this work. To that effect, Table III shows the performance of Mel STFT, CQT, and the proposed Morse wavelet-based scalogram features. It can be observed that the proposed features

TABLE III
OVERALL PERFORMANCE (IN % ACCURACY) OF BASELINES AND THE PROPOSED FEATURES ON THE THREE DATASETS

Datasets →	**Baby Chillanto**	**DA-IICT**	**Combined**
Mel-STFT	92.16	87.45	89.57
CQT	97.31	89.41	**92.05**
Morse wavelet -based scalogram	**98.19**	**94.51**	91.70

outperform Mel STFT and CQT features on Baby Chillanto and DA-IICT corpora. On the Baby Chillanto dataset, the absolute improvement in % accuracy is 6.03 and 0.88, for Mel STFT and CQT, respectively. On the DA-IICT dataset, the absolute improvement in % accuracy is 7.06 and 5.1, for Mel STFT and CQT, respectively. Furthermore, for the combined dataset, CQT still remains to be performing the best. However, the absolute difference of % accuracy of CQT and Morse wavelet-based scalogram features is only 0.35. This marginally improved performance of CQT can be due to the data partitioning effect on the combined data.

D. Effect of Data Augmentation

In this sub-Section, the results (in % accuracy) pertaining to the three data augmentation techniques are presented, namely, tempo, volume, and speed perturbation. Fig. 6 (a) shows the results pertaining to Baby Chillanto dataset, wherein the performance on three types of data augmentation techniques (tempo, volume, and speed perturbation) is shown. It can be observed that Morse wavelet-based scalogram approach outperforms the existing approaches for *all* the three augmentation techniques in the case of Baby Chillanto dataset. Furthermore, Fig. 6 (b) shows the results pertaining to DA-IICT dataset. It can be observed that CQT-based method is observed to perform the best for tempo and volume perturbation (with accuracies of 87.44% and 86.45%, respectively), whereas for speed perturbation, Morse wavelet-based features show the best performance of 81.98% accuracy. A similar trend can be observed in Fig. 6 (c), which shows the results pertaining to the combined dataset. Furthermore, volume perturbation should ideally not affect classification, however, it does have a detrimental effect based on the results shown in Fig. 6, thereby interfering with pathological markers.

It is worth noting that *all* the datasets, the performance of speed augmentation is relatively lower than tempo and volume perturbation for each of the Mel STFT and CQT-based features. However, the performance degradation is negligible for the proposed Morse wavelet-based scalogram feature set.

V. SUMMARY AND CONCLUSIONS

This study proposed the use of Morse wavelet-based scalograms features for the classification of normal *vs.* pathological infant cries. Given the form-invariance property of CQT, the proposed features are CWT-based, which is also a type of CQT. However, while dealing with CWT, choosing an appropriate wavelet function is an issue. Therefore, we proposed to exploit GMWs, which encompass most of the families of analytic wavelets. To that effect, we showed detailed analyses pertaining to the choice of Morse wavelet parameters, which are followed by experimental fine-tuning. Moreover, we evaluated the performance of the proposed system using three datasets, namely, Baby Chillanto, DA-IICT, and combined dataset. Lastly, we also show the effect of three data augmentation techniques (tempo, volume, and speed perturbation). Our results, particularly on volume perturbation, indicate that it is likely that the augmentation has interfered with pathological markers, and hence, an acceptable method of volume augmentation which does not interfere with pathological markers is a future research direction.

APPENDIX

The 2^{nd} order derivative $P_{\beta,\gamma}$ is the second-order term in the time-domain Taylor expansion of the wavelet demodulated by its own peak frequency. The following discussion derives the expression and assesses the significance of the 2^{nd} order derivative.

For a complex random variable X, the n^{th} moment is $E[X^n]$ which is estimated as [31]

$$E[X^n] = \int_{-\infty}^{+\infty} x^n f_X(x) dx, \tag{4}$$

where $f_X(x)$ is the probability density function of X. The characteristic function $C_x(t)$ is defined as

$$C_x(t) = E[e^{-itx}] = \int_{-\infty}^{+\infty} e^{-itx} f_X(x) dx, \tag{5}$$

where $f_X(x)$ is the probability density function of X. Interestingly, *the characteristic function of X is nothing but the Fourier transform of $f_X(x)$*. The moments ($E[X]$, $E[X^2]$, $\dots E[X^n]$) can be generated by differentiating the characteristic function $C_x(t)$ or by differentiating the Fourier transform of $f_X(x)$.

Now, consider $f_X(x)$ as the Morse wavelet demodulated by its peak frequency ω_ψ, and denoting it by $f(t)$ i,e.,

$$f(t) = \psi(t) e^{-i\omega_\psi t}. \tag{6}$$

Then the time-domain n^{th} order moment of the demodulated wavelet can be written as

$$m_{n;\psi} \equiv \int_{-\infty}^{+\infty} t^n f(t) dt = \int_{-\infty}^{+\infty} t^n \psi(t) e^{-i\omega_\psi t} dt. \tag{7}$$

Given the relationship between the time domain moments and the frequency domain derivatives

$$\frac{m_{n;\psi}}{m_{0;\psi}} = i^n \frac{\psi^{(n)}(\omega_\psi)}{\tilde{\Psi}(\omega_\psi)}, \tag{8}$$

where $\tilde{\Psi}(\omega_\psi)$ is the wavelet's *dimensionless derivatives* at $\omega = \omega_\psi$, and defined as [22], [24]:

$$\tilde{\Psi}_n(\omega) \equiv \omega^n \frac{\Psi^{(n)}(\omega)}{\Psi(\omega)}, \tag{9}$$

where n as superscript denotes the n^{th} derivative and $\tilde{\Psi}(\omega_\psi)$ is nothing but $\tilde{\Psi}_n(\omega)$ evaluated at $\omega = \omega_\psi$. Therefore,

$$\frac{m_{n;\psi}}{m_{0;\psi}} = i^n \frac{\psi^{(n)}(\omega_\psi)}{\tilde{\Psi}(\omega_\psi)} = i^n \frac{\tilde{\Psi}_n(\omega_\psi)}{\omega_\psi^n}. \tag{10}$$

Since the wavelet satisfies the admissibility criteria, its mean is zero; i.e., $m_{1;\psi} = 0$. Therefore, the higher-order demodulate moments can be normalized by the 2^{nd} moment, and hence, the dimensionless measure using the 2^{nd} moment is defined as

$$P_{\beta,\gamma} = \omega_\psi \sqrt{\frac{m_{2;\psi}}{m_{0;\psi}}} = \sqrt{|\tilde{\Psi}_2(\omega_\psi)|}, \tag{11}$$

where $\tilde{\Psi}_2(\omega_\psi) = -\beta\gamma$ (as shown in Appendix D of [22]).

***Abstract*—Limited-view sensor arrangement is a major concern in medical imaging as it limits the data that the sensor could acquire. However, this limitation, signal sparsity, can be exploited using compressive sensing (CS) techniques to reconstruct high-resolution images. The objective of this research paper is to develop CS-based algorithms for reconstructing images in limited-view photoacoustic tomography. Various CS reconstruction algorithms and sensor arrangements were assessed to identify the optimal approach for reconstructing images from limited-view sensor data. The results show that the split Bregman total variation (SBTV)-l_1 CS algorithm is the most efficient for all sensor arrangements. The study also reveals that the convex sensor array yields the best results among all sensor arrangements. Additionally, the implementation of SBTV-l_1 using Cholesky factorization requires less computation time and is 10 to 15 times faster than the direct implementation.**

***Index Terms*—Photoacoustic Tomography, Compressive Sensing, Split Bregman, Limited view.**

I. Introduction

Medical imaging is a technology that is crucial for the analysis of drug distribution, disease diagnosis, and therapy. Radiographic imaging systems allow to save and easily access images or videos enabling accurate disease diagnosis. Without these developments, it would be impossible to identify these diseases before they progress to a far more serious level that endangered human life. There are several imaging techniques currently in use, including X-rays, optical coherence tomography (OCT), ultrasound scanning (USG), magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET) [1]. MRI takes longer and costs more than an X-ray. In comparison to a CT scan, it exposes people to less radiation. However, X-rays are primarily employed to scan bones, and as they only provide a single image from a single angle, they cannot image tissues or give a detailed perspective of the body [2]. Photoacoustic tomography (PAT) is a novel medical imaging technique that addresses the limitations of existing methods while incorporating the desired benefits. PAT employs the principle of light absorption, which causes a localized temperature increase and generates sound waves or pressure differences. These sound waves are detected by a sensor array and used to produce images of specific tissues or regions of interest [3].

Given that an imaging system is modeled as a linear system, the least squares (LS) solution resolves it as precisely as possible [4]. However, the LS solution can suffer from being ill-posed, computationally complex, non-sparse, sensitive to noise, and non-unique. Regularization is a technique that can encourage the solution to exhibit sparsity, smoothness, or other desired structures that align with the properties of the signal by incorporating a penalty term. A common regularization technique in compressive sensing (CS) is the use of Lasso regularization, which involves adding an l_1-norm penalty to the objective function. This penalty discourages large coefficients in the solution and promotes small, sparse solutions, ultimately encouraging sparsity in the reconstructed signal [5]. Sparsity is necessary for reconstruction because it enables the reconstruction of the original signal from a small number of non-zero coefficients, resulting in less processing, less computing, and faster signal acquisition. Thus, by combining PAT and CS, the necessary signal can be reconstructed with very high contrast, good resolution, and faster computing speeds.

This paper is structured as follows: Section II presents an overview of the theory behind compressive sensing algorithms. Section III details the proposed work and the algorithms used. Section IV discusses the results obtained from the study. Finally, Section V presents the conclusions drawn from the study.

II. Theory

A. CS-PAT algorithms

In this section, a brief overview of the existing CS-PAT reconstruction algorithms is provided. In photoacoustic tomography (PAT), a laser is utilized to stimulate a specific region within a compressible medium, ensuring thermal confinement and minimal viscosity. This leads to the generation of sound waves or pressure variations [6]. The acoustic pressure can be described by the linear approximation of the wave equation, and its solution, representing the acoustic pressure at a specific location and time, is obtained through the application of the Green's function approach [7]. The Green's function corresponds to a solution of the wave equation that incorporates a localized source term at a specific point in space and time. By integrating the Green's function with the source term, the solution to the wave equation can be obtained for any arbitrary source distribution. In practice, the pressure is computed on grid points, with grid spacing adhering to the Nyquist criterion [8] to prevent aliasing. The grids are typically divided into an imaging grid and a k-space computation grid. The k-space representation of the solution involves expressing the wave equation in terms of the wavenumber (or frequency) components of the solution. By taking the Fourier transform of the equation,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

the partial differential equation is transformed into a set of ordinary differential equations in terms of the wavenumber components. These equations can then be solved numerically using techniques such as the Fast Fourier Transform (FFT). The k-space computation is particularly advantageous when dealing with problems that exhibit periodicity or translation symmetry, as the Fourier transform naturally captures these properties. Additionally, the use of Fourier-based methods allows for high accuracy and spectral convergence, similar to the pseudospectral method.

The PAT imaging system is designed as a linear system as

$$\mathbf{y} = \mathbf{M}\mathbf{x}. \tag{1}$$

Here $\mathbf{y} \in \mathbb{R}^{N_s N_t \times 1}$ is the measurement vector, $\mathbf{M} \in \mathbb{R}^{N_s N_t \times N_{in}^2}$ is the system matrix and $\mathbf{x} \in \mathbb{R}^{N_{in}^2 \times 1}$ is the image to be reconstructed (in vectorized form); N_s, N_t and N_{in}^2 are the number of sensors, number of time samples and the number of imaging grid points respectively. The system matrix arises when discretizing the partial differential equations (PDE) problem, which involves approximating the continuous solution and differential operators on a discrete grid or mesh. The discretization divides the spatial and temporal domains into a set of discrete points or elements, and the system matrix relates the values of the solution at these discrete points. Once the system matrix is formed, it can be combined with the vector representing the right-hand side of the discretized equations, which contains the source terms and boundary conditions, to form a linear system of equations. This linear system can then be solved using various numerical techniques, such as direct methods (e.g., LU decomposition) or iterative methods (e.g., conjugate gradient method), to obtain the numerical solution of the PDE problem. In recent years, CS has emerged as a relatively new field that has garnered significant attention. It concerns the retrieval of a sparse or compressible signal from a small number of linear measurements, often substantially less than the signal's dimension. However, standard least squares regression may not be the most suitable approach in this context since it necessitates more measurements than the signal's dimension. To tackle this challenge, multiple regularized least squares regression techniques have been proposed, which exploit the sparsity or compressibility of the signal to enhance the recovery performance. These techniques play a crucial role in compressive sensing since they enable us to recover the signal accurately from the limited measurements. The first and the best way to enforce sparsity is to do the l_0 norm minimization. It is formulated as

$$\mathbf{x}^* = \min_{\mathbf{x}} \|\mathbf{y} - \mathbf{M}\mathbf{x}\|_2 + \lambda \|\mathbf{x}\|_0 . \tag{2}$$

It is NP-hard and one approach to solving such a problem is to use a smoothed differentiable approximation of the l_0 norm. l_1-norm minimization-based optimization problems such as Basis Pursuit (BP) [9], and Least Absolute Shrinkage and Selection Operator (LASSO) [10] are also commonly used. The BP optimization problem is formulated as

$$\mathbf{x}^* = \min_{\mathbf{x}} \|\mathbf{x}\|_1 \ \text{s.t}\ \mathbf{M}\mathbf{x} = \mathbf{y}, \tag{3}$$

and the LASSO problem is formulated as

$$\mathbf{x}^* = \min_{\mathbf{x}} \|\mathbf{M}\mathbf{x} - \mathbf{y}\|_2^2 \ \text{s.t}\ \|\mathbf{x}\|_1 , \tag{4}$$

The formulation (4) is utilized for scenarios when the measurement data is noisy. Two of the most common approaches for solving l_1-minimization is by using the CVX tool [11] and l_1-magic [12]. Both of these methods are time-consuming and computationally expensive [13], [14].

An l_2-norm when applied as a regularizer to a least-square (LS) problem causes diagonal loading [15] and is formulation as

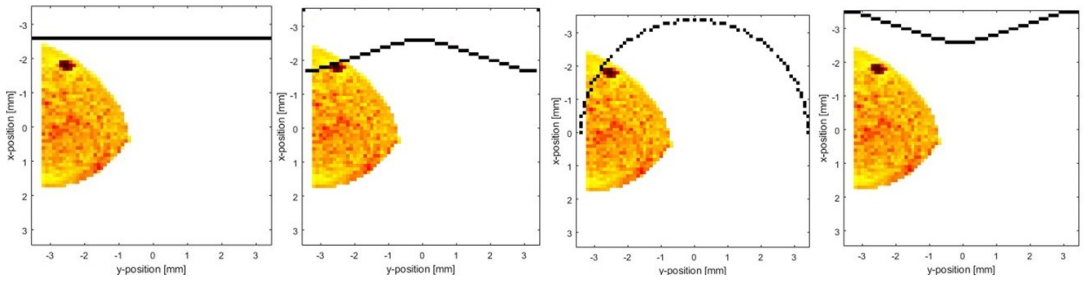
$$\mathbf{x}^* = \arg\min_{\mathbf{x}} \|\mathbf{y} - \mathbf{M}\mathbf{x}\|_2^2 + \lambda \|\mathbf{x}\|_2^2 , \tag{5}$$

where $\lambda > 0$. Alternatively, it is known as Tikhonov regularization [16]. Since it results in uniform distribution of error and a subpar reconstructed image, this kind of regularization is not preferred. To further exploit sparsity, $l_1 - l_2$ regularization which is non-convex and Lipschitz continuous is used for image reconstruction and is formulated as

$$\mathbf{x}^* = \min_{\mathbf{x}} \|\mathbf{x}\|_1 - \|\mathbf{x}\|_2 \ \text{s.t}\ \mathbf{M}\mathbf{x} = \mathbf{y}. \tag{6}$$

The two most popular techniques for implementing such a regularization are forward-backward splitting (FBS) [17], and difference of convex algorithms (DCA) [18].

The method of total variation regularization is a frequently employed technique in compressive sensing and is commonly used to preserve edges, denoising, and image enhancement. The method of total variation regularization entails augmenting the objective function of the least squares regression by introducing a penalty term. This penalty term minimizes the sum of absolute differences between neighboring pixels or samples in the signal. The introduction of this penalty term promotes sparsity in the gradient domain of the solution, resulting in improved recovery performance. It is formulated as



$$\mathbf{x}^* = \min_{\mathbf{x}} \|\mathbf{D}\mathbf{x}\|_1 \ \text{s.t.}\ \mathbf{M}\mathbf{x} = \mathbf{y}, \tag{7}$$

where $\mathbf{D}$ is a difference matrix defined as:

$$\mathbf{D} = \begin{bmatrix} -1 & 1 & & \\ & -1 & 1 & \\ & & \cdots & \cdots \\ & & & -1 \end{bmatrix}.$$

III. Proposed work

In this section two CS algorithms are proposed for the reconstruction of images from limited-view sensor arrangements. The first one is relaxed BP and the second one is l_1 regularized split Bregman (SB) TV (SBTV-l_1). The algorithms and their corresponding implementations are also discussed.

(a) (b) (c) (d)

Fig. 1: Sensor arrangement: (a) line sensor array, (b) concave sensor array (c) semicircular sensor array, and (d) convex sensor array

A. rBP-ADMM

Initially, BP-ADMM problem is formulated by introducing an auxiliary variable $\mathbf{z}$ and the augmented Lagrangian can be formulated as

$$L(\mathbf{x},\mathbf{z}) = \gamma \left\|\mathbf{z}\right\|_1 + \mathbf{u}^T(\mathbf{x}-\mathbf{z}) + \frac{\rho}{2}\left\|\mathbf{x}-\mathbf{z}\right\|_2^2 + \frac{\alpha}{2}\left\|\mathbf{M}\mathbf{x}-\mathbf{y}\right\|_2^2, \tag{8}$$

where $\mathbf{u}$ is the dual variable, ρ is the augmented Lagrangian parameter and $\alpha, \gamma > 0$. The rBP-ADMM includes a relaxation parameter r, applied to the $\mathbf{u}$-update in the $\mathbf{x}$-subproblem, which is proved to be much more efficient than its conventional BP-ADMM implementation. rBP-ADMM implementation is shown in Algorithm 1. Relaxation is necessary as the BP-ADMM is highly sensitive to modeling errors.

Algorithm 1 rBP-ADMM

Require: ρ, α, γ, r, maxiter, tol.
Initialize: $k = 0$, $\mathbf{z}^{(0)} = \mathbf{u}^{(0)} = 0$, NMSE^0 = ∞
while $k <$ maxiter $\wedge$ NMSE$^k >$ tol **do**
$\mathbf{x}^{k+1} \leftarrow \left(\rho\mathbf{I} + \alpha\mathbf{M}^T\mathbf{M}\right)^{-1}\left(\rho\mathbf{z}^k + r\mathbf{u}^k + \alpha\mathbf{M}^T\mathbf{y}\right)$
$\mathbf{z}^{k+1} \leftarrow \text{Shrink}\left(\frac{\mathbf{u}^k}{\rho} + \mathbf{x}^{k+1}, \frac{1}{\gamma}\right)$
$\mathbf{u}^{k+1} \leftarrow \mathbf{u}^k + \rho\left(\mathbf{x}^{k+1} - \mathbf{z}^{k+1}\right)$
NMSE$^{k+1} \leftarrow \frac{\|\mathbf{x}^{k+1}-\mathbf{x}^k\|_2^2}{\|\mathbf{x}^{k+1}\|_2^2}$
$k \leftarrow k+1$
end while

B. SBTV-l_1

An unconstrained TV problem after the introduction of the auxiliary variable $\mathbf{d}$ is written as

$$\mathbf{x}_{TV} = \min_{\mathbf{x},\mathbf{d}} \left\|\mathbf{d}\right\|_1 + G(\mathbf{x}) + \frac{\alpha}{2}\|\mathbf{x}\|_1 + \frac{\gamma}{2}\left\|\mathbf{d}-\mathbf{D}\mathbf{x}\right\|_2^2, \tag{9}$$

where $G(\mathbf{x}) = \frac{\beta}{2}\|\mathbf{M}\mathbf{x}-\mathbf{y}\|_2^2$, and $\alpha, \beta, \gamma > 0$. Instead of solving the optimization problem in (9) in a single step, an SB formulation is employed which allows splitting the full optimization problem in (9) into its equivalent subproblems. The advantage of this method is that it allows for exact minimization, fast convergence, and less computation time. The subproblems are solved iteratively as depicted in Algorithm 2, where $\mathbf{b}$ is the Bregman parameter.

Algorithm 2 SBTV-l_1

Require: $\alpha, \beta, \gamma > 0$, tol, maxit
Initialize: $k = 0$, NMSE^0 = ∞, $\mathbf{d}^0 = \mathbf{b}^0 = \mathbf{0}$
while $k <$ maxiter $\wedge$ NMSE$^k >$ tol **do**
$\mathbf{x}^{k+1} \leftarrow$ Shrink$((\beta\mathbf{M}^T\mathbf{M} + \gamma\mathbf{D}^T\mathbf{D})^{-1}(\beta\mathbf{M}^T\mathbf{y} + \gamma\mathbf{D}^T(\mathbf{d}^k - \mathbf{b}^k)), \frac{1}{\alpha})$
$\mathbf{d}^{k+1} \leftarrow$ Shrink$(\mathbf{D}\mathbf{x}^{k+1} + \mathbf{b}^k, \frac{2}{\gamma})$
$\mathbf{b}^{k+1} \leftarrow \mathbf{b}^k + \mathbf{d}^{k+1} - \mathbf{D}\mathbf{x}^{k+1}$
NMSE$^{k+1} \leftarrow \frac{\|\mathbf{x}^{k+1}-\mathbf{x}^k\|_2^2}{\|\mathbf{x}^{k+1}\|_2^2}$
$k \leftarrow k+1$
end while

IV. Results

This section presents a comparison of the performance of the proposed compressive sensing algorithms with existing methods. The performance evaluation is based on the following metrics:

1) Structural similarity index (SSIM): It is used to assess image quality and has a value range of -1 to 1. When the reconstructed image closely resembles the original image, its value is close to 1.
2) Peak Signal to Noise Ratio (PSNR): It is the ratio between the maximum signal power to the noise power. It is measured in decibels.
3) Number of iterations: The number of iterations is also taken into account as a metric for assessing how well iterative algorithms work.
4) Normalized mean-squared error (RMSE): It is the normalized mean-squared error between the reconstructed image and the original image defined as:
$$\text{NMSE} = \frac{\|\mathbf{x}-\hat{\mathbf{x}}\|_2^2}{\|\mathbf{x}\|_2^2} \tag{10}$$
where $\hat{\mathbf{x}}$ is the estimated image (or the reconstructed image from measurements).
5) Gini Index (GI): It reflects how sparse the signal is. The range is from 0 to 1, where 1 means highly sparse.
6) Computation time: It is the amount of time taken by an algorithm to complete the iteration and it depends on the

stopping criteria. It is used to evaluate the performance of various algorithms because it is the crucial metric for determining an algorithm's effectiveness and efficiency.

The processor used in the simulation is Intel®Core™ i7-8565U 1.8GHz with MATLAB®.

The purpose of this study is to determine the optimal sensor arrangement and compressive sensing algorithm for reconstructing images from limited-view sensor arrangements. Cholesky factorization (c) is used to implement the inverse in the iterations which can decrease the computation time. The study evaluated the performance of four different limited view sensor arrangements (linear, convex, concave, and semicircular), as shown in Figure 2, and several compressive sensing algorithms (including SBTV, SBTV-l_1, Cholesky factorized-rBP (c-rBP), $l_1 - l_2$ using DCA and FBS, BP, LASSO, regularized LS (RLS), and LS) to compare their effectiveness.

For the line sensor array, the maximum SSIM obtained is 0.938 when c-SBTV-l_1 algorithm is used. Additionally, it is demonstrated to have a maximum PSNR of 30.983 dB and a reconstruction time of under a second, which falls within the acceptable limit. The c-BP also has an SSIM of 0.905, but when comparing the computation time, SBTV-l_1 algorithm is preferable.

For the concave sensor arrangement, the SSIM for the SBTV implementation is better and the highest SSIM and PSNR of 0.962 and 33.586 dB is obtained when SBTV-l_1 is used. It is observed that the c-SBTV-l_1 has the least computation time, which makes it the more suitable algorithm for reconstruction. For the semicircular sensor arrangement, the performance of both c-rBP and c-SBTV-l_1 is comparable with both having an SSIM of 0.952 and 0.932 respectively. But the reconstruction time of c-SBTV-l_1 is the lesser and thus more preferable. When comparing the SSIM of all sensor arrangements the convex sensor array exhibits the best SSIM value of 0.97 for SBTV-

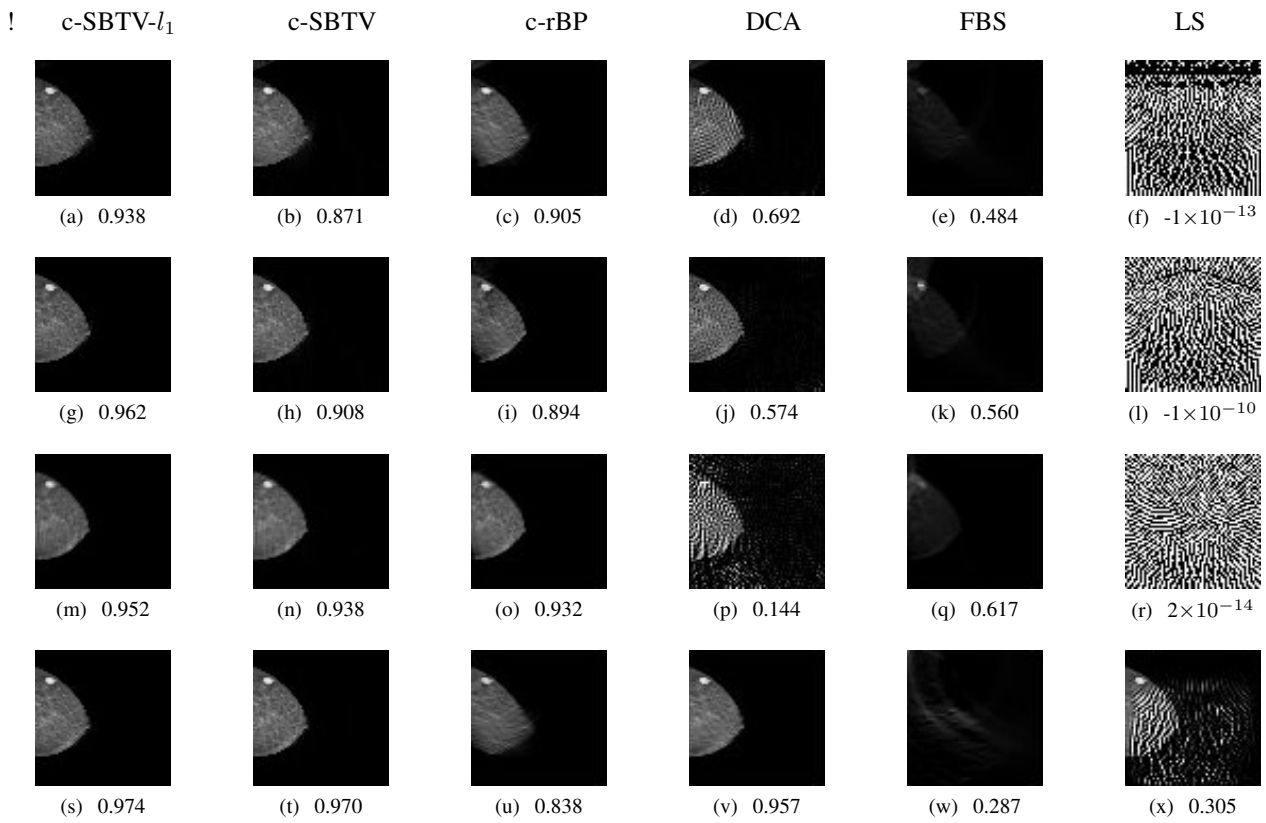

Fig. 2: Reconstructed images for different sensor arrangements: Line sensor array (a)-(f); Concave sensor array (g)-(l); Semicircle sensor array (m)-(r); Convex sensor array (s)-(x) with the corresponding SSIM's.

TABLE IV: Limited view - convex sensor array test results

Algorithm used	**SSIM**	***PSNR (dB)***	**iterations**	***NMSE***	***GI***	***time (sec)***
SBTV	0.971	35.851	15	0.003	0.770	5.35
c-SBTV	0.970	36.150	15	0.003	0.770	0.86
SBTV-l_1	0.975	36.347	10	0.021	0.770	5.37
c-SBTV-l_1	0.974	36.304	9	0.005	0.767	0.76
c-rBP	0.838	25.017	54	.065	0.756	8.68
DCA	0.957	33.299	200	0.483	0.768	17.33
FBS	0.287	16.610	101	0.743	0.707	53.96
BP-l_1-magic	0.986	38.715	8	0.002	0.845	1011.33
LASSO-l_1-magic	0.990	39.921	15	0.001	0.865	67.53
RLS	0.424	13.528	NA	0.995	0.764	48.79
LS	0.305	10.937	NA	0.503	0.756	35.57

l_1 with a reconstruction time of 0.76 seconds. Also, it can be observed that the implementation of Cholesky factorization has made the SBTV-l_1 algorithm 7 times faster for line and convex arrays and 9 and 15 times faster for concave and semicircular arrays respectively.

It is to be noted that even though the BP and LASSO implementation using l_1-magic gives good SSIM and PSNR values, the reconstruction time is very high and unacceptable for a fast image reconstruction. The non-iterative algorithms, LS and RLS have the worst results as it is highly dependent on the data availability, and it consumes more time for computation.

The results showed that convex sensor arrangement provided the best outcomes for all the CS algorithms, with the c-SBTV-l_1 algorithm being the most efficient. The SSIM and PSNR values were highest for the convex sensor arrangement in comparison to the other arrangements. The results of the different sensor arrangements for different CS algorithms are presented in Tables II - IV, and the corresponding reconstructed images are shown in Fig. 2.

V. CONCLUSION

This work aimed to identify the most efficient sensor arrangement and compressive sensing algorithm for reconstructing PAT images from limited-view sensor data. Four different sensor arrangements and several compressive sensing algorithms were evaluated. According to the findings, the SBTV-l_1 algorithm was successful in reconstructing the PAT image

for all sensor arrangements, demonstrating its superiority over other CS algorithms. Moreover, the study revealed that the use of a convex sensor array resulted in higher image quality compared to other sensor configurations. Additionally, implementing Cholesky factorization in the inverse computation stage of the SBTV-l_1 algorithm accelerated the reconstruction process by 15 times compared to the implementation without Cholesky. The results presented in the study can provide useful insights into selecting the optimal sensor arrangement and algorithm for PAT image reconstruction from limited-view sensor data in various applications.

E-mail: {sidharrth.nagappan, lim.chernhong, anuja.dharmaratne}@monash.edu

***Abstract*—Recent advancements in deep learning allowed the deployment of large, multimodal models for depression analysis, but the increasing complexity of such models resulted in slow deployment times. This work proposes multi-stream audio-only models for depression analysis, that use transformer weights attended to by low-level descriptors (LLD) through an attention-weighted sum. It operates on the hypothesis that handcrafted feature sets will ameliorate extensive transformer pre-training. Extensive experimentation on the DAIC-WOZ test dataset shows that a combination of an audio spectrogram transformer (AST) and a Mel-frequency cepstral coefficient (MFCC) based convolutional neural network (AST-MFCC) produces the highest accuracy in our suite of models, but reports marginally lower macro F1 scores than both a naive AST and pure LLD-based models, suggesting that the injection of extra feature streams adds a sensibility element to models and limits false positives. However, the naive transformer-based and LLD-based models are surprisingly more effective at flagging depressed patients, although at the cost of an acceptable number of false positives. Our work suggests in totality that the addition of extra feature streams adds a distinct and controllable discriminating power to existing models and is able to assist lightweight models in low-data, audio-only settings.**

I. Introduction

Automatic Depression Detection (ADD) is a principal research area, stemming from the need for comprehensive screening processes in clinical psychotherapy. In a preliminary stage, current medical teams require patients to self-diagnose using the Patient Health Questionnaire (PHQ), where the patient answers a series of ordinal questions that quantify the severity of depression. In later stages, trained physicians interview patients and make an official diagnosis based on the replies and behavioural patterns of the patient. The preliminary assessment attempts to quantify a phenomenon that is subjective, while the physician interview is time-consuming and may not be required in most cases [1].

To address the above-mentioned problems, ADD systems were introduced [2]. However, the growing computational complexity of multimodal depression analysis engines makes us question whether the same task can be achieved through the analysis of only speech signals. This allows lightweight model deployments, but the real question is whether the performance trade-off as compared to a full-blown multimodal video-audio-text-based engine is significant.

The state-of-the-art in audio-based analysis have either been (i) pure deep learning models, (ii) low-level feature extraction with convolutional neural networks or (iii) context-aware question-answer attention networks [1]. Each method outperformed its predecessor, but to the best of our knowledge, little research has studied the individual contributions of each component. In this work, we test different combinations of state-of-the-art audio models and low-level feature sets, to deliver a robust model that leverages the best of each feature stream and operates in production environments with limited data.

The principal contributions of our work are: (i) testing the audio spectrogram transformer for deep depression analysis in a pioneering multi-stream approach, (ii) proposing inspired attention-based multi-stream fusion for LLD-assisted audio analysis and (iii) multi-stage cooling-based training processes for multimodal transformers. To ensure that our results are reproducible, we make our code publicly available [1].

II. Related Work

In clinical environments, a variety of depression scales are used, including physician-operated instruments such as the Diagnostic and Statistical Manual of Mental Disorders (DMS), Hamilton Depresion Rating Scale (HDRS), Montgomery-Åsberg Depression Rating Scale (MADRS) and self-diagnosing scales such as the Patient Health Questionnaire (PHQ-8) and Beck's Depression Inventory [3]. The principal difference between physician-operated surveys and self-diagnosing surveys is the human element that is able to make nuanced decisions about behavioural and psychopathological tendencies observed during conversations with the patients [4]. During conversations, simple voice modulations, pauses, vocabulary choice and other fine-grained observations play a role in analysing the severity of depression. To automate screening technology, the majority of production systems have focused on distributing self-diagnosing questionnaires. However, numerically quantifying highly subjective illnesses is widely disputed as an accurate assessment [5], and the only other alternative (live clinical interviews) is blockaded by a limited supply of medical professionals.

Due to rapid developments in the macroscopic fields of speech transcription and speech emotion recognition (SER) [6] and a proven relationship between prosodic and formant voice features and the severity of depression, recent research has applied machine learning to automate the screening process [7].

Initial work fundamentally relied on low-level descriptors (LLDs) such as spectral, cepstral, formant, and energy coefficients as the only representatives of an audio signal. Such features would then be treated as input features to the standard linear discriminant machine learning classifiers, such as Gaussian Mixture Models, Hidden Markov Models, k Nearest Neighbour (kNN) and Support Vector Machines [8]. The advent of deep learning mimicked the same structure, instead using multilayer perceptrons to build decision structures [9]. Later work used the same LLDs but in combination with convolutional neural networks, that would effectively slide across feature tensors and build an understanding of the relationships between sub-groups of audio features.

A more evolved understanding of audio signals was inspired by mel-spectrograms, allowing one to convert audio signals to visual representations. As analysing the 2-dimensional spectrograms became a computer vision task, a multitude of deep image models were applied. These included Long Short Term Memory (LSTM) models, Convolutional Neural Networks (CNNs), LSTM-CNNs, question-answer attention networks and LLD-based graph CNNs [10]. However, the increased dependence on deep learning comes with a large data barrier. For example, the Distress Analysis Interview Corpus/Wizard-of-Oz (DAIC-WOZ), the most widely used depression corpus, only contains 189 patient interviews.

More recent research understood the contributing effects of both LLD-inspired learning and deep audio modelling, eventually proposing inspired methods to fuse their contributions. Newer state-of-the-art transformer-based audio models such as the audio spectrogram transformer (AST) have been released, allowing systems to comprehend global context with minimal memory overhead, even when audio streams are lengthy [11]. The AST achieves state-of-the-art performance on AudioSet, ESC-50 and Speech Commands V2. The AST's ability to process lengthy streams and understand context seems particularly useful in depression analysis, as interviews are often extensive and a range of voice modulations are observed; a medical professional takes a collective view of the entire interview before reaching a diagnosis, as should a model. In an increasingly multimodal era of deep learning, our research attempts to strike a balance by proposing lightweight, audio-based methods to understand the extent to which audio signals alone are effective at depression detection.

III. Methods

Single-stream methods employ only one model type, while multi-stream networks fuse the neural outputs of different independent models through early or late fusion. In this work, we propose a two-stream approach, consisting of a Deep Audio Model (DAM) that directly manipulates the audio signal and a tensor of low-level descriptors (LLD) working in tandem. Both feature streams are combined through an attention-weighted sum, where outputs from the DAM and LLD streams are summed before the final tensor is queried by DAM outputs. Our initial hypothesis is that the low-level nature of LLDs will alleviate the black box of deep audio models.

A. Audio Spectrogram Transformer (AST)

An Audio Spectrogram Transformer (AST) is employed as the primary deep audio-based model [12]. It outperforms existing CNN-based architectures in a variety of generic audio classification tasks, using self-attention to learn the temporal and spectral dependencies of audio signals.

The audio spectrogram is first computed through strategies such as short-time fourier transforms (STFT) and embedded into 2-dimensional patches. Each embedding records positional, spatial and temporal relationships within a spectrogram. Subsequently, embeddings are passed into a transformer encoder, constituting self-attention modules and multi-headed attention blocks. After each head attends to different input patches, the final output is concatenated and passed through fully connected layers and a classification module. The architecture is illustrated in Figure 1.

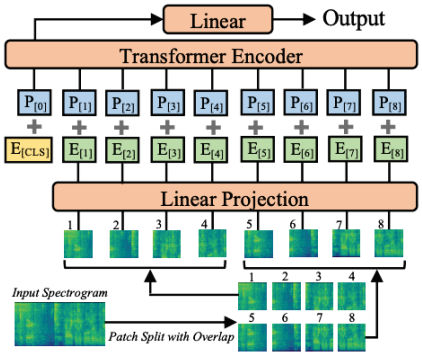

Fig. 1. AST architecture [12]

This research is the first to use the AST in the context of depression detection and also the first to use the AST in a multi-stream setting.

B. Low Level Descriptor (LLD) Convolutional Neural Network

Low-level descriptors are still stalwarts in audio processing, allowing the computationally efficient extraction of very low-level features. While they do not encompass an understanding that is as extensive as deep audio models, we hypothesise that their inclusion through attention querying will ameliorate the performance of its deep counterpart. The processing of LLDs is done through both 1-dimensional and 2-dimensional convolutional neural networks (CNNs). CNNs traverse through feature tensors, subsequently passing through pooling and batch normalization layers before returning a *batch size* $\times$ *512* tensor to be combined with other feature streams. The individual success of CNNs for LLD processing is apparent in [3]. CNNs were so predominant in the literature that several models went so far as to employ dual-stream CNNs [13], where one 2D stream would process a mel-spectogram while the other 1D stream would iterate through Mel-frequency cepstral coefficients (MFCCs).

We employ three commonly used feature sets as candidates for LLDS: IS09, eGemaps and MFCCs.

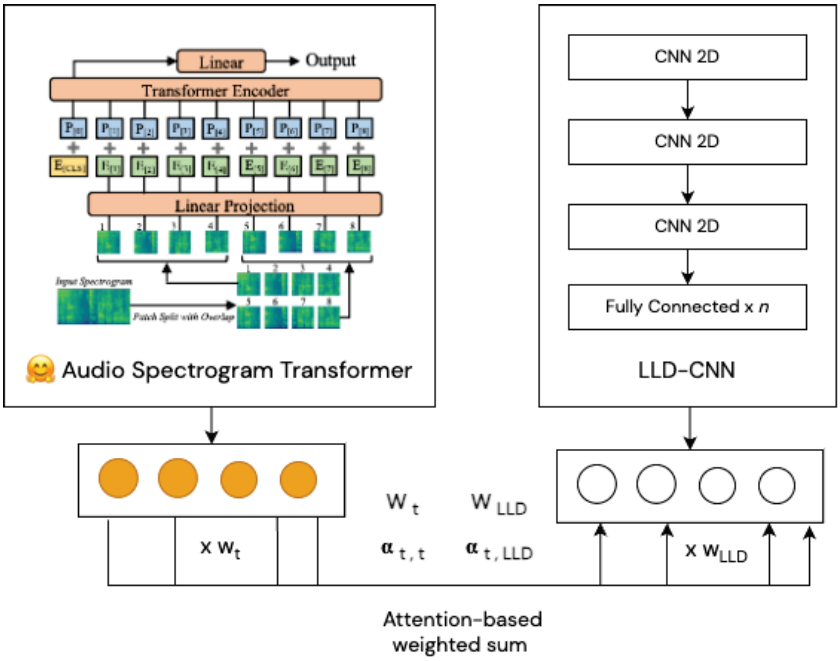

Fig. 2. Attentive AST-LLDs

1) MFCCs - 2-dimensional feature tensors that capture spectral characteristics of audio signals by converting a frequency-domain representation to a cepstral-domain representation through a combination of framing, windowing, fast fourier transforms, mel filterbanks, logarithms, discrete cosine transforms (DCT) and cepstral lifting.

2) IS09 - 348 functional units are extracted from each audio sample, encompassing fundamental frequency, frame energy, the zero-crossing rate and 12 selected MFCCs and their corresponding derivatives.

3) Extended Geneva Minimalistic Acoustic Parameter Set (eGeMaps) [14] - 88 acoustic features comprising F0-related, energy, spectral, harmonics-to-noise ratio, voice quality and prosodic features augmented with additional formant features.

C. Attention-based Tabular Combination

A distinct contribution of our research is examining unique combinations of multiple feature streams, going a step beyond standard concatenation. Early and late fusion functions ensure that stream features play a contributing role.

A weighted sum is first computed between the modalities, with the weight of each component becoming a trainable parameter. Subsequently, a $LeakyReLU$ based attention function uses transformer outputs as keys and the output of the other modalities as values. In these equations, α is the attentional matrix, F is the final feature vector, W is the weight matrix, x is the AST's audio features, while lld represents the LLD features.

$$F = \alpha_{x,x} W_x x + \alpha_{x,c} W_{lld} lld \tag{1}$$

$$\alpha_{i,j} = \frac{exp(LeakyReLU(a^T [W_i x_i || W_j x_j]))}{\sum_{k \in \{x,c,n,w\}} exp(LeakyReLU(a^T [W_i x_i || W_k x_k]))} \tag{2}$$

The dimensions of the fully connected layers in both the DAM and LLD blocks are determined by halving the number of neurons in each subsequent layer; the outputs of the final layer in each block are then passed to the fusion module. By understanding the relative weights given to each feature stream and complementing individual transformer features with their corresponding LLDs, we hypothesise that these key-value pairs will result in performance improvements [15]. The final architecture is illustrated in 2.

IV. Experiment

A. Preprocessing on the dataset

The DAIC-WOZ corpus is a set of compiled clinical interviews and ground truth depression diagnoses. It is scraped in it's entirety from the University of South Carolina's portal [16]. A total of 180 participants are available, with pre-defined train, test, and validation splits. Each participant is given a PHQ-8 score and a binary identifier of depression; often, both values are linked where a PHQ-8 score above 10 signifies depressive symptoms. Interviews are conducted by Elle, a computer agent, who asks succinct questions that are both pre-defined and conceived in real-time to logically sustain the conversation.

We use interviewer-interviewee timestamps to remove the interviewer's voice, and subsequently concatenate each participant's answers into a single audio file. Significant pauses

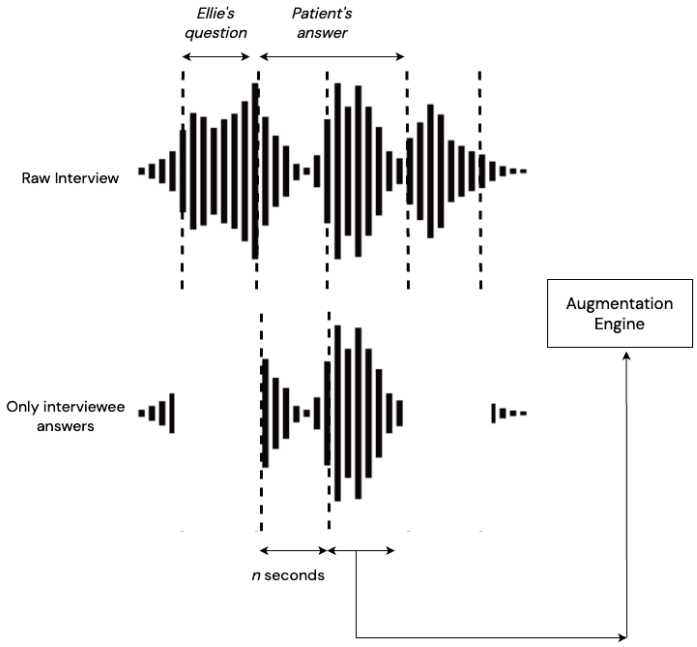

Fig. 3. Preprocessing and sampling interview data, consisting of removing the interviewer's voice, splitting the audio into n second samples and augmenting each sample through the proposed augmentation pipeline

of above 3 seconds are also removed to build more compact spectrograms and LLD feature sets, in line with the work of [1], [17]. Based on the pioneering sampling strategy of [17], we segment each participant's audio file into 5-second segments. This presents a balance between having sufficient data in an audio sample and controlling the sparsity of sample-based spectograms. The preprocessing and sampling strategy is illustrated in Figure 3.

Given the vast disparity between depressed and non-depressed samples and the possibility of overfitting, we use a random selection of augmentation strategies including Vocal Tract Length Perturbation (VTLP) [18], α-controlled white noise injection (noise factor of 0.05), semitone-based pitch adjustment (pitch factor of 1.5) and audio shifting (maximum shift of 0.2s) to augment non-depressed samples [19], culminating in a balanced training set. Manual intervention is done to ensure that the augmentation of the audio clip does not make the voice indiscernible.

Recent work that specifically studied the effects of audio augmentation strategies argued that the best performance is obtained through different combinations of augmentation methods [20], [21]. However, the literature is ambiguous about whether the augmentation strategies above are applied sequentially to signals, or chosen at random. We, therefore, test our baseline model with different combinations of augmentation strategies on the training set, while keeping our validation and test datasets untouched. All augmentation is done through a function that chooses a strategy through a temperature-based roulette wheel. We employ audio wrangling functions from *librosa* in tandem with *numpy*.

TABLE I
ABLATION STUDY BETWEEN AUGMENTATION STRATEGIES ON OUR BEST MODEL (AST + MFCC)

Strategy	Accuracy	F1 Score
No augmentation	0.7210	0.4304
VTLP [18]	0.7037	**0.4317**
Random augmentation	**0.7253**	0.4310

Our worst performance is obtained when all four augmentation strategies are applied sequentially, while our best is a random selection between noise injection, pitch adjustment and audio shifting (as shown in Table I).

B. Feature Extraction

A total of 3 different feature sets are extracted from each sample: (i) IS09, (ii) eGemaps and (iii) Mel-frequency cepstral coefficients (MFCCs). Librosa is used for (i) and (ii), while we employ the OpenSmile toolkit's audio processing binary for (iii). Hamming windows, Fast Fourier Transforms (FFT), Mel filter banks, logarithmic transformations and Discrete Cosine Transforms (DCT) are sequentially applied to each sample. All computation happens in a cached dataloader in a Linux-based high-performance cluster. Feature tensors are directly reshaped and sent to the GPU prior to modelling.

C. Cooled Training

Our architectures constitute blocks of different maturity levels; transformer weights are extensively pretrained and are capable of sensible computation out of the box, while randomly initialised convolutional neural networks and fully connected layers require significant training epochs to start producing discernible results. We, therefore, train all weights in the transformer block for 5 epochs, before freezing transformer weights, increasing the learning rate, and training the entire network for up to 30 epochs. We name this method "cooled training".

V. RESULTS AND DISCUSSIONS

All models are implemented using Pytorch, with base transformer architectures being imported from Huggingface.

The first set of experiments (as shown in Table II attempts to identify the best-performing LLD feature set for this task, where each feature set is passed in its entirety to a 1D convolutional model. The first model in this series is tuned to identify an optimal number of layers (4 CNN-BatchNorm blocks) and this configuration is carried forward. We can observe that both eGeMaps and MFCC features deliver similar performance. The efficiency of MFCC features falls in line with the findings of [3], [21], [22], although the minor performance boost obtained by eGeMaps is surprising. When testing MFCC features in tandem with a 2D CNN, we find that performance worsens further, even after hyperparameter tuning.

To understand if multi-stream additions are in-fact superior to naive transformer models, we experiment with different combinations of the AST with the top two LLDs (MFCC and

TABLE II
MODEL STREAM RESULTS WITH ACCURACY, PRECISION, RECALL, MACRO F1 SCORE AND F1 SCORES FOR POSITIVE AND NEGATIVE CLASSES

AST + eGemaps	0.6244	0.4305
AST + MFCC	**0.7037**	0.4325

eGemaps) in Table III, combined using an attention-weighted sum.

Here, we find that a naive AST model performs worse than *eGemaps-Conv1D*, which could be attributed to the transformer model's inability to completely generalise to the new problem domain of depression detection. Perhaps lower learning rates and more extensive fine-tuning can tackle this issue.

In terms of multi-stream models, we find that *AST + eGemaps* performs worse than *eGemaps* alone (by up to 4.91%). The *AST + MFCC* combination all its counterparts with a 16.83% accuracy improvement from the baseline AST model. However, it is important to note that the macro F1 score drops by 9%, indicating that additional keyed components increase the model's power to identify non-depressed samples, but hinder its ability to flag depressed samples.

We compare our multi-stream model to an LSTM-based reproduction of [20]. Their final model was an LSTM-AU model that considered MFCC features using an LSTM model in tandem with handcrafted action units from the video modality. Our reproduction only uses the LSTM component of their model, proving that the multi-stream model outperforms its LSTM-based counterpart in an audio-only context.

VI. CONCLUSION

In this work, we explored different LLD-based convolutional neural networks in tandem with state-of-the-art audio transformers, and analysed their performance limitations with regards to fully-fledged video+text+audio modality models. We find that the most complex model is not necessarily the best performant and basic LLD-based models perform unusually well in low-data, audio-only contexts. Our multi-stream model attains the highest accuracy in our suite of models, but has a diminished ability to identify depressed samples. Nevertheless, our results suggest that LLD-assisted transformers are a promising research direction since they produce comparable results in low-data settings and have discriminating powers that can be more closely controlled as compared to black-box deep learning models.

E-mail: Jinwei.Lin@monash.edu ORCID:0000-0003-0558-6699

***Abstract*—The Text Extraction of the Audio from the Video plays an important role in multimedia editing and processing. As a popular open source toolkit, Whisper performs fast in human voice recognition. However, the recognition performance is dependent on the computing resource, which makes the low computing memory running Whisper become difficult. Our paper presents an available solution to extract the human voice from the video and gain the high quality text generation from the voice. The generated voice can be used in video language translation and translated voice simulation. To improve the extraction and transform quality of human voice, we present ecVoice, a method using the idioms similarity computation and analysis to improve the quality of audio text extraction. Relative experiments are held to verify that the ecVoice can improve the idiom grammar correction rate to 90% on average. The method is simple but fast which means this method will cause less bad influence of consuming computing resources when improving the voice recognition rate. Our method and solution can significantly enhance the Whisper recognition with low computing memory.**

I. Introduction

Extracting and gaining a high quality audio text from the video is a significant application and implementation in multimedia. The text extracted from the video can be used in multiple fields of multimedia applications or research implementations, such as translated language of video playing, audio editing and internationalisation of game video design. With the technologies of super Artificial Intelligence (AI), AI assistants have more and more important roles in multimedia and computer games design. One important process or research problem of these applications is transforming the voice to text, which is also one of the most important points of our research.

However, there are still some difficulties or challenges in transforming the voice to text, for example, improving the recognition accuracy and processing speed.Usually, methods like Deep Neural Network (DNN) are used to address this issue. But the recognition accuracy may of course have a large fluctuation influence which is related to the parameter size of the neural network model. For some machines or hardware with limited gpu performance or memory, the network parameter size of the model is one of the main influence factors. For the limitation of computing hardwares, one feasible method to improve the recognition performance is using the software solutions, like improving the algorithms design and architecture. In this paper, these software methods can be summarised into three categories, the first is pre-processing methods, the second is the during-processing, the third is post-processing methods. We will focus more on the post-processing method in research of the paper.

In the paper, we will present an available solution to split the audio from the video and extract the accurate text from the audio with an efficient and prolongable algorithm to improve the performance and accuracy of audio text extraction based on idioms similarity replacement. The relative experiment code is open source in GitHub:https://github.com/JYLinOK/ecVoice.

II. Literature Review

A. Extract Text from Voice

Extracting the text from voice files is related to the research field of voice recognition. The technologies of voice recognition have been used in various fields in AI, such as using speech recognition to recognize the emotion of the speaker [1], the end-to-end automatic speech recognition [2], as well as using different methods to improve the speech recognition accuracy in normal speech recognition filed [3]. The efficiency of speech recognition is closely related to the volume of the given information from the voice and how the recognition performs a high quality recognition in limited conditions [4]. The accuracy of speech recognition can be improved by improving the process algorithms [5], or using special processes on voice data [6]. Some researchers try to improve the recognition accuracy by focusing on the text processing after the post-processing of speech recognition [7].

Our research is focused on extracting the text from the voice in the wild that includes human speech, and improving the speech text recognition by post-process of the recognized text.

B. Voice in Multimedia Editing

In this research, we focus on improving the efficiency of the voice processing in multimedia editing. Voice processing plays an important role as visual information processing in modern multimedia editing [8]. Voice processing is also an important part in video editing, and plays an important role in video text translation [9] and game design [10]. The audio from the video and then translate the speech voice to text for further multimedia processing [11], which is considered as a significant application in voice recognition. And the research of the paper is focused on how to improve the accuracy of speech recognition from the audio that was extracted from the video, by presenting an algorithm on the post-processing of voice recognition. This research work will be applied and accessed

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

in our further research on automatic intelligent multimedia editing and NeRF AI game engine design in the future.

C. Text Grammar Correction

After translating the voice to text from the audio, two factors will influence the currency of the speech recognition. One is the recognition success rate of the speech recognition model, which can only be improved by updating and optimising the design or training strategy of the recognition model [12]. The other is the pre-processing [13] or post-processing and optimization of the translated text from the recognition model. For the post-processing of the translated text, the text syntax correction process in the field of natural language [14] is to directly improve the textual expression quality of the translated text to improve the accuracy of the voice recognition.

One of the most important keys of our method to improve the quality of the audio text extracted from the video is to improve the efficiency of text grammar correction by correcting the wrong expression of the idioms with idioms similarity replacement. Our method is simple but fast, which makes it can be used in the optimising and correcting translated text extracted from the speech audio with a high speed requirement.

III. Methodology Analysis

A. Running Architecture

Optimising textual expression of the extracted text that is translated from the audio of the video is the main process and algorithm analysis of this research. Beside this, splitting the audio data from a specific video, and making the pre-processing of the voice data, are also an important part of the running architecture of the research. As shown in Figure 1, the running architecture of this research includes 7 key components: splitting audio from video, splitting speech from audio, split the main speech, speech text recognition, creating the pinyin analysis function, generating the pinyin dictionary of idioms data-set, finding the closest idioms algorithm. Following are the detailed analysis of the components mentioned above.

As shown in Figure 1, first, process splitting audio from video, is related to the item $videoAudioSplit$. The target of the process is extracting the audio files from the specific video file. Second, process splitting speech from audio, is related to the item $UltimateVocalRemover$. Because the toolkit Ultimate Vocal Remover will be used to gain the pure human speech data with a high quality from the audio files. Third, the process of splitting the main speech is related to the item $segmentation$, which means making the segmentation for the speech file to get the main useful segment data. Fourthly, the processing of speech text recognition is related to the item $useWhisper$, which means using the robust toolkit whisper to generate the accurate translated text of the speech file. Fifthly, the process of analysing pinyin and generating the pinyin dictionary is related to the item $getPinYin + genIdomPinyin$, which means creating function to get the basic information of the segments of words, and generating a pinyin dictionary with a special data format. Last, the process of finding the closest idioms algorithm is related to the item $findClosest$, which means analysing the expression of a segment of words to check if it is a normal idiom with the correct writing format or not, and get the most closest right idiom expression if the words segment is wrong.

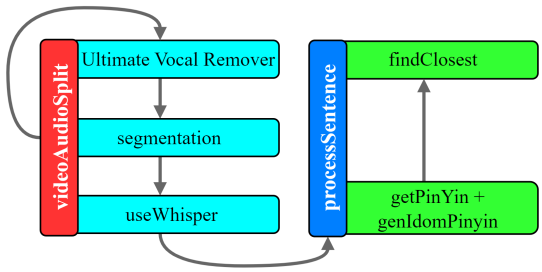

Fig. 1. Running and design architecture of this whole research.

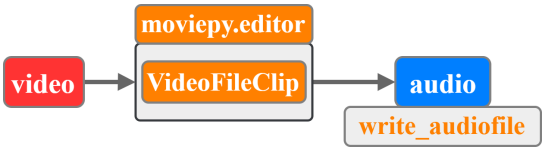

Fig. 2. Using Moviepy to splitting the audio data from video.

B. Splitting Audio From Video

If we want to implement the optimization for the text expression that is extracted from the audio file, the primary process is getting the audio files. Due to focusing on the target of multimedia processing, the audio files used in this research are all split from the video file, which is corresponding to the item $videoAudioSplit$ in Running Architecture. As shown in Figure 2, we utilise the Python library $moviepy$ to design a processing algorithm to get the split audio file from one specific video file. Using the function $mp.VideoFileClip$ to generate a video clip of an input video with the mp4 format, followed by using the function $write_audiofile$ to resave the audio data as a wav format file. Thus getting the audio file of one specific video file. The format of the extracted audio file can be custom defined in the processing code.

C. Audio Segmentation

After gaining the extracted audio file from the video file, further processing related to the voice optimization can be implemented. In our research, to ensure the high quality of the audio data before it is processed in future procedures, like splitting the human speech voice and the background audio made by other objects but not human voice, we make the process of cutting off the two ends audio segments of the previous audio that is extracted from the video. This process and design is corresponding to the item $segmentation$ in Running Architecture. As shown in Figure 3, we use the $pydub$ library to make the segmentation of the audio. Detailedly, Using the function $AudioSegment.from_wav$ to transform the audio file, for example in wav format, subsequently, using the index of list to make the segmentation of the audio file.

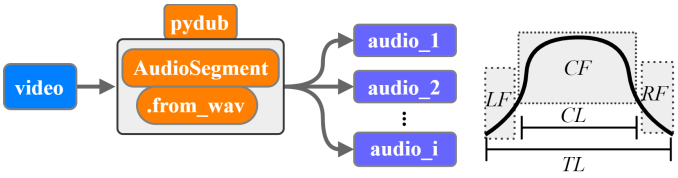

Fig. 3. Using pydub to make the segmentation of the extracted audio.

During this processing, the audio file is presented as one kind of editable data with the list format. After the segmentation edit of the audio, calling the function $export$ of the split audio. Eventually, the previous audio will be split into a specific number of segments.

As shown in Figure 3, assume the total length of audio is represented as STLS, when the audio is generated or recorded, usually the two ends of the audio are sick in recording the information, which will cause some mistakes in information representation. Therefore in this research, processing algorithm will delete the two ends of the audio to reduce the related interference, and use the middle segment of the audio as the processed audio. As shown in Figure 3, the LF represents the left end of audio length, the RL represents the right end of audio length, the CL represents the central of audio length.

D. Audio to Text

After the segmentation of audio, the next process is translating the speech audio to text, which means the process needs the speech recognition to get the text of the human speech in the audio. To ensure the quality of this process of speech recognition, we use the toolkit $UltimateVocalRemover$ to split the human speech from the audio. Except for human speech audio, the background music or voice of the previous audio will be saved for future works, like video or audio speech language translation and multimedia application editing.

Subsequently, we used whisper to implement the speech recognition. We design a custom selection function with five model parameters: t, b, s, m, l to select the five types of model of whisper by using the $load_model$ function. Each model from whisper needs a different size of Visual RAM (VRAM) to run. As shown in Figure 4. After a series of experiments, we found that the minimum practical required VRAM is bigger than the requirement provided by whisper, so we provide the recommended size parameters for this, as shown in Figure 4. The output result of this process is the text recognized from the speech audio file, which will be used in the next procedure.

E. Redundancy Removal

After getting the text that is recognized and translated from the speech audio, the next procedure is optimising the translated text. In our research, we prepared several methods to make the optimization, of which the first one is, as shown in Figure 5, the redundancy removal of the translated text. The key point of this method is that, comparing the start and end parts of two closed sentences to find the redundant words in some combined context. Because, before the speech audio

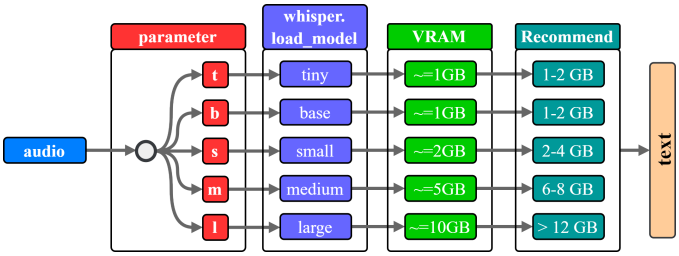

Fig. 4. Using the Whisper to get translate the speech of audio to text.

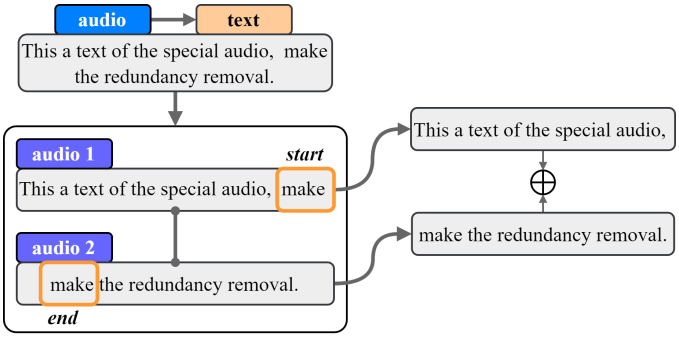

Fig. 5. Comparing two closed sentences to make redundancy removal.

is sent to make the speech recognition to get the translated text, the speech audio is gained by segment or splitting, which means some repetitive words may be represented in the start and end parts of two closed sentences. Therefore this process will be meaningful to get more accurate translated results in the further speech text processing.

As shown in Figure 5, for example, suppose there is an audio with a speech text "This is a text of the special audio, make the redundancy removal.", when this audio is recorded or split from the previous process, the audio may be split or recorded into two sentences which have the same repetitive words in the start and end parts of two closed sentences, like $audio1$ and $audio2$. Our method is to remain one side of repetitive words in one sentence, and remove the repetitive words in the other sentence. Subsequently, making the further text processing for them, before combining them to get the terminal output.

F. Data Format Conversion

After implementing the redundancy removal of the translated text of the speech audio, the next process for the audio text is building a dataset that follows the special data format with the existing idiom data files. As shown in Figure 6, the previous data format of the idioms json files is combined with:$derivation, example, explanation, pinyin, word$ and $abbreviation$. Obviously some of these items are non-useful for us to build the idioms for syntax correction. Therefore, we just selected the item$word$ as one component of our new designed idioms dataset. Beside this, the tone of the idiom word is the other required component, which is gained from the program coded by the library $pypinyin$ of Python.

As shown in Figure 6, we design a data format of key-value to store the information of the idioms and their corresponding

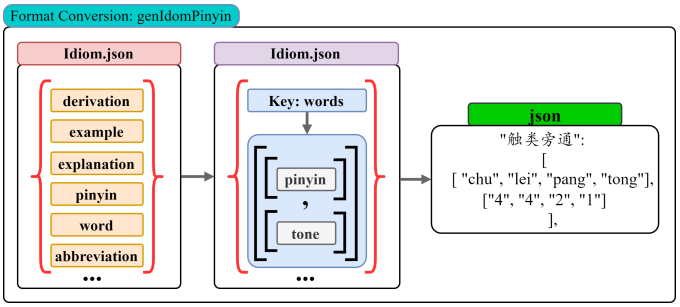

Fig. 6. Data format conversion of the idioms to make the dataset.

tones. One unit of this dataset is combined with a Chinese idiom as the kay and a list of tone information of this idiom as the value. The data format can be described as follows:

$$word: \left\{ \begin{matrix} [[pinyin_1, pinyin_2, ..., pinyin_n] \\ [tone_1, tone_2, ..., tone_n]]] \end{matrix} \right\}, \quad (1)$$

The Equation 1 can be used in the data format conversion of other languages that are similar with Chinese, and has phonetic symbols and corresponding tones. With this kind of data format, we can quickly and individually deal with the calculation and comparison between different idiom words, which will promote the further development and research.

G. Similarity Computation

After finishing the building of the dataset of idioms with the special defined format, the next process is analysing and estimating whether the idiom in the text has a correct expression or not. To address this problem, we design a comparison calculation algorithm to judge and analyse the expression of the idiom. If the expression of the idiom in the text is wrong, the algorithm will find the correct expression from the idiom dataset and replace it in the text with the right expression.

To approach this problem, there are four procedures to do. First, get the wrong idiom expression in the audio text. This process is difficult with uncertain interfering factors, for those kinds of languages like Chinese, the words are independent characters, which means it will be difficult to distinguish whether a word character is relative to the word before it or the word behind it. Therefore, a word character in a Chinese sentence, maybe can become an idiom when combining with the words before and after. For this issue, we design an algorithm to analyse the word in a Chinese sentence one by one. As shown in Figure 7, for general Chinese sentences, the character length of a classical Chinese idiom is 4, so with gradual bit positional processing, selecting the sentence segments $seg_1, seg_2, seg_3, \ldots, seg_i$ to make the positional processing $p_1, p_2, p_3, \ldots, p_i$ correspondingly. If the current process index of the sentence is i, then capture a segment of sentence with a length of 4, which will select the indexes:$i, i+1, i+2, i+3$ to combine a selected sequence $[c_i, c_{i+1}, c_{i+2}, c_{i+3}]$. The length of the idiom is set to be 4, and can also be other numbers like $n, n \in \mathbb{N}^+$.

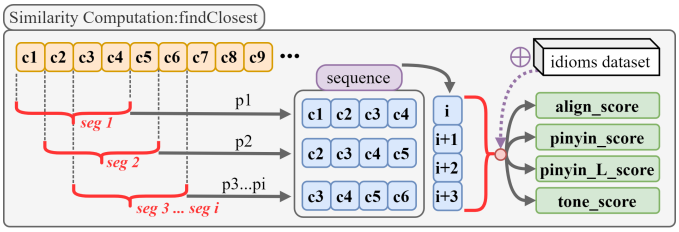

Fig. 7. Similarity computation and replacement processing for idioms.

As shown in the following code, the $word_1$ represents the sequence extracted from the sentence and $word_2$ represents the idiom selected from idioms dataset. max_L1 means the length of the sequence is bigger than the idiom. The judge criteria is relative to length of $word_2$ and parameter $align$.

```
if len(words1) >= len(words2):
    max_L1 = True
else:
    max_L1 = False

if max_L1:
    for word_i in range(len(words2)):
        if words1[word_i] == words2[word_i]:
            align_score += a

        if align_score < int(len(words2) / align):
            return_ok = False
else:
    for word_i in range(len(words1)):
        if words1[word_i] == words2[word_i]:
            align_score += a

    if align_score < int(len(words1) / align):
        return_ok = False
```

When an idiom expression with a length of $n (n \in \mathbb{N}^+)$ is gained, the next process is calculating the similarity score S_s of the idiom expression with the idiom dataset, to test whether the idiom expression is correct or wrong. We design four kinds of sub-similarity-scores to calculate the total similarity score S_a. As shown in Figure 7, the four scores are: $align_score, pinyin_socre, pinyin_L_score$ and the $tone_score$.

$$S_a = \sum_i^n \left(\begin{matrix} if\ c_{si} = c_{di} : a \\ if\ c_{si} \neq c_{di} : 0 \end{matrix} \right) \quad (2)$$

In Equation 2, there is the following relationship, the parameter $a = 1, (a \in \mathbb{N}^+)$ is the proportional control value, $c_{si} \in [c_{s1}, c_{s2}, ..., c_{sn}], c_{di} \in [c_{d1}, c_{d2}, ..., c_{dn}$, the parameter c_{si} represents the character on the index i in the $sequence$ selected from the processing sentence. The parameter c_{di} represents the character on the index i in the $idiom$ selected from the idiom dataset. This operation likes bit and operation, if parameter c_{si} equals parameter c_{di}, then the total $align_score$ which represented as S_s, will add $a = 1$, else will add 0, that means no more transformation.

Second, for each sequence selected from the sentence, we need to calculate the second evaluation score, that is $pinyin_score$, which will follow the operation idea as the $align_score$ and calculate the similarity of the pinyin character

by bit. The calculation operation is to compare and calculate the similarity between the pinyin expression of the sequence selected from the sentence and the idiom selected from the idioms dataset. Calculating the similarity between two item that all have the same expression format method in pinyin will be useful for the comparison and similarity calculation of the text correct expression, because the pinyin, as the main articulatory representation item of these languages like Chinese, is most relative expression about the pronunciation of human speech recognition. Therefore, the parameter $pinyin_score$ is useful for our similarity replacement algorithm.

$$S_p = \sum_i^n (\begin{Bmatrix} if\ cp_{si} = cp_{di} : b \\ if\ cp_{si} \neq cp_{di} : 0 \end{Bmatrix}) \tag{3}$$

In Equation 3, there is the following relationship, the parameter $b = 1, (b \in \mathbb{N}^+)$ is the proportional control value, $cp_{si} \in [cp_{s1}, cp_{s2}, ..., cp_{sn}], cp_{di} \in [cp_{d1}, cp_{d2}, ..., cp_{dn}$, the parameter cp_{si} represents the pinyin character on the index i in the pinyin expression of the $sequence$ selected from the processing sentence. The parameter cp_{di} represents the pinyin character on the index i in the pinyin expression of $idiom$ selected from the idiom dataset. This operation likes bit and operation, if parameter cp_{si} equals parameter cp_{di}, then the total $pinyin_score$ which represented as S_p, will add $b = 1$, else will add 0, that means no more transformation.

Third, besides the small-grained comparison and calculation mentioned above, we design another calculation algorithm for the large comparison and for the pinyin expression of each sequence and idiom. For each sequence selected from the sentence, we need to calculate the third evaluation score, that is $pinyin_L_score$, which will calculate the similarity of the pinyin character in the unit level of an individual word of the expression of sequence or idiom . The calculation operation is to compare and calculate the similarity between the word pinyin expression of the sequence selected from the sentence and the word pinyin expression of idiom selected from the idioms dataset. Calculating the similarity between two word items to test whether these two expressions are equal will be useful for the comparison and similarity calculation of the text correct expression, because the comparison for the word pinyin expressions between these two items will quickly get the similarity level in the big level of word. The L in $pinyin_L_score$ means the $largelevel$, this is the word level.

$$S_pl = \sum_i^n (\begin{Bmatrix} if\ cpl_{si} = cpl_{di} : c \\ if\ cpl_{si} \neq cpl_{di} : -c \end{Bmatrix}) \tag{4}$$

In Equation 4, there is the following relationship, the parameter $c = 2, (c \in \mathbb{N}^+)$ is the proportional control value, $cpl_{si} \in [cpl_{s1}, cpl_{s2}, ..., cpl_{sn}], cpl_{di} \in [cpl_{d1}, cpl_{d2}, ..., cpl_{dn}$, the parameter clp_{si} represents, in word level, the pinyin unit expression on the index i in the expression of the $sequence$ selected from the processing sentence. The parameter cpl_{di} represents, in word level, the pinyin unit expression on the index i in the pinyin expression of $idiom$ selected from the idiom dataset. If parameter cpl_{si} equals parameter cpl_{di}, then the total $pinyin_L_score$ which represented as S_pl, will add $c = 2$, else will add $-c = -2$, that means reverse transformation.

Last, after the calculation of the part of pinyin, for the other important part of the tone of idiom, we also design an algorithm to calculate the similarity between tone expressions of each sequence and idiom. For each sequence selected from the sentence, we need to calculate the fourth evaluation score, that is $tone_score$, which will calculate the similarity of the pinyin tone level number of the expressions of sequence or idiom. The calculation operation is to compare and calculate the similarity distance between the word pinyin tone level number of the sequence selected from the sentence and the pinyin tone level number of idiom selected from the idioms dataset. Calculating the similarity distance between two word items to test whether these two pinyin tone level number of items are equal or their distance will be useful for the comparison and similarity calculation of the correct pronunciation of the idiom item. A correct pronunciation is an important issue to ensure the right expression of the idioms.

$$S_t = p \cdot \frac{\sum_i^n (int(tone_{si}) - int(tone_{di}))^2)}{n} \tag{5}$$

In Equation 5, there is the following relationship, the parameter $p = 1, (p \in \mathbb{N}^+)$ is the proportional control value, $c_{si} \in [c_{s1}, c_{s2}, ..., c_{sn}], c_{di} \in [c_{d1}, c_{d2}, ..., cl_{dn}$, the parameter c_{si} represents, the pinyin tone level number of the word in the index$i$ of expression of the $sequence$ extracted from the processing sentence. The parameter c_{di} represents, in word level, the pinyin tone level number of the word in the index$i$ of expression of $idiom$ selected from the idiom dataset. We use the calculation method of square deviation to calculate the offset distance of similarity of pinyin tone of the sequence and idiom. The parameter p is used to fine-tune the effort of the calculator of the similarity distance of pinyin tone.

During the design and implementation process of similarity calculation, double for loop is usually used to make the double ergodic calculation. To ensure the correct calculation, the iteration number should be the smaller level compared with the second for loop. So $min(iteration\ number)$ should be dimension number of first for loop, the other $bigger(iteration\ number)$ should be dimension number of second for loop.

After all calculations of these four scores, the final evaluation similarity score S can be gained as follow as shown in Equation 6:

$$\begin{aligned} S = pinyin_score \times pp - tone_score \times pt \\ + pinyin_L_score \times ppl \end{aligned} \tag{6}$$

Using the S parameter of Equation 6 to evaluate the similarity degree between the $sequence$ extracted from the processing sentence and the $idiom$ selected the idioms data set. Each total calculator score S of each similarity calculation all will be saved in a list. Finally, make the operation $max(scores_list)$ to get the maximum of the total score. Subsequently, make a

judgement of the parameter S to decide whether to replace the sequence with the right idiom expression. If the total similarity score is too small, then remain the previous expression of the extracted sequence, otherwise, replace the sequence with the right expression of the idiom selected from idioms data set.

IV. Experiment and Evaluation

To evaluate the performance of our process algorithm, we design the following evaluation method to test the performance of $ecVoice$ from different dimensions.

A. Idiom Correction by Word Expression

First we make the detection experiment for the single idiom correction by using almost some pinyin tone and pronunciation but different expressions in word writing. As shown in Table I, the parameter $word$ represents the writing of the sequence extracted from the sentence. Due to the sequence word maybe having different expressions in typing or characters writing, we use the pinyin characters and the _ symbol to connect different pinyin of different words. The parameter $n, n \in \mathbb{N}^+$. represents $group_n$, which means the number of the items of a test group of sequence words. All of the items in the group of sequence words will be tested with our algorithm and count the number of correct test samples, of which number is recorded with the parameter $c, c \in \mathbb{N}^+$. The parameter $time, time \in \mathbb{N}$ represents the time in seconds of the whole implementation of the group of sequence words. The parameter $s1, s1 \in \mathbb{N}$ represents the similarity score between the correct sequence and the correct idiom, which means the score $s1$ should be the largest one among the similarity scores of the sequence group. Because the first item in the sequence group has the same typing or writing expression of the idiom from the idioms dataset. The parameters $s2, s3 (s2, s3 \in \mathbb{N})$ represent the similarity scores between two incorrect sequences and the correct idiom from the idioms dataset. Therefore parameters $s2$ and $s3$ should be never larger than $s1$. The parameter $sa, sa \in \mathbb{N}$ represents the average of the parameters $s2$ and $s3$, which represents the average of the normal similarity score of this sequence test group.

TABLE I
WORD ERROR INDEX = 1.

word	n	c	time	s1	s2	s3	sa
ri_chu_san_gan	3	3	1.207	19.0	19.0	14.0	16.5
chu_mu_cheng_song	3	3	1.18	22.0	16.0	22.0	19.0
fang_ge_zong_jiu	3	3	1.156	21.0	21.0	18.75	19.9
jing_bing_qiang_jiang	3	3	1.203	26.0	23.75	23.75	23.8
man_shan_bian_ye	3	3	1.151	21.0	21.0	21.0	21.0
po_bu_ji_dai	3	3	1.123	17.0	17.0	17.0	17.0
qing_chu_yu_lan	3	3	1.121	20.0	20.0	20.0	20.0
ren_shou_nian_feng	3	3	1.135	23.0	23.0	23.0	23.0
shi_wai_tao_yuan	3	3	1.127	21.0	21.0	21.0	21.0
wu_ti_tou_di	3	3	1.126	17.0	17.0	17.0	17.0

As shown in Table I, the word error index is 1, that means for all sequences with the incorrect expression of the test sequence group, the first character is wrong for the idiom expression. Here for convenience to represent the word site of the sequence, the number of the index starts from 1. The result shows all of the sequences with the wrong idiom expression have been detected. For different sequences, the similarity score used to judge is different. The approximate similarity score is in the range of from 17.0 to 26.0. The implementation time for each sequence group is about 1.2 seconds.

Subsequently, we implement the experiment of sequence groups that have the wrong textual expression sequences in the index of 2, which means the second characters of those sequences are in the wrong expression. As shown in Table II, the result shows all of the sequences with the wrong idiom expression have been detected. The approximate similarity score is in the range of from 17.0 to 26.0. The implementation time for each sequence group is about 1.15 seconds.

TABLE II
WORD ERROR INDEX = 2.

word	n	c	time	s1	s2	s3	sa
ri_chu_san_gan	3	3	1.149	19.0	19.0	19.0	19.0
chu_mu_cheng_song	3	3	1.166	22.0	22.0	22.0	22.0
fang_ge_zong_jiu	3	3	1.255	21.0	18.75	18.75	18.8
jing_bing_qiang_jiang	3	3	1.27	26.0	23.75	23.75	23.8
man_shan_bian_ye	3	3	1.209	21.0	21.0	21.0	21.0
po_bu_ji_dai	3	3	1.192	17.0	17.0	17.0	17.0
qing_chu_yu_lan	3	3	1.147	20.0	20.0	20.0	20.0
ren_shou_nian_feng	3	3	1.156	23.0	23.0	23.0	23.0
shi_wai_tao_yuan	3	3	1.137	21.0	21.0	21.0	21.0
wu_ti_tou_di	3	3	1.089	17.0	17.0	17.0	17.0

Next, we implement the experiment of sequence groups that have the wrong textual expression sequences in the index of 3, which means the third characters of those sequences are in the wrong expression. As shown in Table III, the result shows all of the sequences with the wrong idiom expression have been detected. The approximate similarity score is in the range of from 17.0 to 26.0. The implementation time for each sequence group is about 1.15 seconds.

TABLE III
WORD ERROR INDEX = 3.

word	n	c	time	s1	s2	s3	sa
ri_chu_san_gan	3	3	1.149	19.0	19.0	19.0	19.0
chu_mu_cheng_song	3	3	1.166	22.0	22.0	22.0	22.0
fang_ge_zong_jiu	3	3	1.255	21.0	18.75	18.75	18.8
jing_bing_qiang_jiang	3	3	1.27	26.0	23.75	23.75	23.8
man_shan_bian_ye	3	3	1.209	21.0	21.0	21.0	21.0
po_bu_ji_dai	3	3	1.192	17.0	17.0	17.0	17.0
qing_chu_yu_lan	3	3	1.147	20.0	20.0	20.0	20.0
ren_shou_nian_feng	3	3	1.156	23.0	23.0	23.0	23.0
shi_wai_tao_yuan	3	3	1.137	21.0	21.0	21.0	21.0
wu_ti_tou_di	3	3	1.089	17.0	17.0	17.0	17.0

Subsequently, we implement the experiment of sequence groups that have the wrong textual expression sequences in the index of 4, which means the fourth characters of those sequences are in the wrong expression. As shown in Table IV, the result shows all of the sequences with the wrong idiom expression have been detected. The approximate similarity score is in the range of from 17.0 to 26.0. The implementation time for each sequence group is about 1.14 seconds.

TABLE IV
WORD ERROR INDEX = 4.

word	n	c	time	s1	s2	s3	sa
ri_chu_san_gan	3	3	1.159	19.0	19.0	19.0	19.0
chu_mu_cheng_song	3	3	1.149	22.0	22.0	22.0	22.0
fang_ge_zong_jiu	3	3	1.155	21.0	21.0	21.0	21.0
jing_bing_qiang_jiang	3	3	1.259	26.0	23.75	23.75	23.8
man_shan_bian_ye	3	3	1.152	21.0	21.0	21.0	21.0
po_bu_ji_dai	3	3	1.137	17.0	17.0	17.0	17.0
qing_chu_yu_lan	3	3	1.107	20.0	20.0	20.0	20.0
ren_shou_nian_feng	3	3	1.146	23.0	23.0	23.0	23.0
shi_wai_tao_yuan	3	3	1.152	21.0	21.0	21.0	21.0
wu_ti_tou_di	3	3	1.096	17.0	17.0	17.0	17.0

The operations mentioned above is all about controlling one of the characters of the sequence to be wrong in expression, followed by detecting and calculating the similarity between the sequence with wrong expression and the idiom with correct expression. To better test the performance of our algorithm, we design the following experiments, which set two characters of the sequence to be wrong and test the similarity score. As shown in Table V, setting the first and second characters of the sequences to be wrong and then testing the similarity score, meanwhile recording the implementation time for each sequence group. As shown in Table V, the result shows all of the sequences with the wrong idiom expression have been detected. The approximate similarity score is in the range of from 17.0 to 26.0. The implementation time for each sequence group is about 1.14 seconds.

TABLE V
WORD ERROR INDEX = 1,2.

word	n	c	time	s1	s2	s3	sa
ri_chu_san_gan	3	3	1.161	19.0	19.0	14.0	16.5
chu_mu_cheng_song	3	3	1.188	22.0	16.0	22.0	19.0
fang_ge_zong_jiu	3	3	1.142	21.0	21.0	18.75	19.9
jing_bing_qiang_jiang	3	3	1.155	26.0	26.0	21.0	23.5
man_shan_bian_ye	3	3	1.168	21.0	21.0	21.0	21.0
po_bu_ji_dai	3	3	1.133	17.0	17.0	17.0	17.0
qing_chu_yu_lan	3	3	1.126	20.0	20.0	19.75	19.9
ren_shou_nian_feng	3	3	1.13	23.0	23.0	23.0	23.0
shi_wai_tao_yuan	3	3	1.143	21.0	21.0	21.0	21.0
wu_ti_tou_di	3	3	1.086	17.0	17.0	17.0	17.0

After testing the influence of the two characters in the start of the sequence to the similarity score calculation, we have also tested the influence of the two characters in the end of the sequence to the similarity score calculation. As shown in Table VI, setting the third and fourth characters of the sequences to be wrong and then testing the similarity score, meanwhile recording the implementation time for each sequence group. As shown in Table VI, the result shows all of the sequences with the wrong idiom expression have been detected. The approximate similarity score is in the range of from 17.0 to 26.0. The implementation time for each sequence group is about 1.25 seconds.

B. Idiom Correction by Tone Pronunciation

Due the pinyin tone of the sequence is another important factor for the similarity calculation for our similarity analysis and replacement algorithm, we implemented the following two kinds of experiments to test the performance of our algorithm under the influence of wrong pinyin tone. Because the tone of pinyin can make the word character, so in this condition, the textual expression of the sequence usually are different.

TABLE VI
WORD ERROR INDEX = 3,4.

word	n	c	time	s1	s2	s3	sa
ri_chu_san_gan	3	3	1.163	19.0	19.0	19.0	19.0
chu_mu_cheng_song	3	3	1.154	22.0	22.0	22.0	22.0
fang_ge_zong_jiu	3	3	1.222	21.0	18.75	18.75	18.8
jing_bing_qiang_jiang	3	3	1.24	26.0	23.75	23.75	23.8
man_shan_bian_ye	3	3	1.646	21.0	21.0	21.0	21.0

ren_shou_nian_feng	3	3	1.144	23.0	21.75	15.0	18.4
shi_wai_tao_yuan	3	3	1.114	21.0	7.75	12.75	10.2
wu_ti_tou_di	3	3	1.101	17.0	16.5	16.5	16.5

As shown in Table VIII, setting the third and fourth tone numbers of the sequence pinyin to be wrong and then testing the similarity score, meanwhile recording the implementation time for each sequence group. As shown in Table VIII, the result shows all of the sequences with the wrong idiom expression have been detected. The approximate similarity score is in the range of from 8.5 to 25.5. The implementation time for each sequence group is about 1.35 seconds.

C. Optimization for Audio Text Recognition

To test the optimization and assistance of our whole algorithm to the audio text recognition, we implemented the following comparison experiments. We use some video selected by random and use our algorithms to make the audio text recognition, comparison the output of the methods and the original output from the small size of the whisper model.

As shown in Table IX, HanLP-v1.8.4 [15] is very famous Chinese syntax correction and NLP process framework, but

TABLE VIII
TONE ERROR INDEX = 3,4.

shi_wai_tao_yuan	3	3	1.147	21.0	19.75	20.5	20.1
wu_ti_tou_di	3	3	1.102	17.0	15.75	16.5	16.1

TABLE IX
MODEL OR METHOD PERFORMANCES COMPARISON

methods	performance	useful
HanLP	60-85%	less useful
original whisper	81%	normal
our ecVoice	81-95%	useful

in special application like idiom syntax problem analysis or detection is needed more update. Our algorithm performances well in this issue, which performance good in small size model.

V. Conclusion

By the experiments analysis mentioned above, we can get this conclusion: the similarity calculator and judgement part of the whole similarity replacement algorithm has a high efficiency. The running time for each sequence group is about 1.5 seconds, which can be optimised by upgrading the search algorithm in the further research. Compared with tone wrong expression detection, the word wrong expression detection needs less implementation time and has a higher efficiency. For application situations that without non-real-time requirements, this still can provide a strong and fast process performance.

Heart Rate Acquisition and Processing Techniques for a Miniature Wearable Microphone Sensor

Yi Yang Ang*, Kirish Boodhoo*, Wee Ser*, and Rex Xiao Tan*
*R&D Group, Aevice Health Pte Ltd, Singapore

***Abstract* — This paper presents an adaptive windowing approach to advanced heart rate vital estimation from cardiovascular acoustic captured using the recently proposed miniature wearable microphone sensor. The sensor is sufficiently light to securely attach to the user's chest with a medical silicone adhesive and can now estimate vitals beyond the upper and lower limits previously identified. The proposed approach consists of acquiring an initial vital estimate from its spectrogram and then deriving an optimal window length based on the frequency resolution and physical limits of vitals to refine the estimation. Finally, we proposed an estimation correction step if the current estimates differ from past estimates' trends using a 1-step autoregressive model. The proposed approach was verified experimentally in a practical context of overnight vital sign monitoring with healthy volunteers against a medical gold-standard device commonly used in healthcare settings. The proposed approach achieved an accuracy of ± 2.8 beats per minute (bpm) for heart rate measurement against a heart rate measurement reference of ± 3 bpm accuracy.**

Keywords- wearable acoustic sensor, IoT system, heart rate estimation, FDA-cleared

I. INTRODUCTION

World Health Organization (WHO) and Centers for Disease Control and Prevention published a fact sheet identifying cardiovascular diseases as one of the leading causes of death worldwide [1], [2]. Accordingly, in recent years the number of wearable devices has grown tremendously to address this market demand [3]–[5] as early detection of cardiovascular diseases through continuous monitoring of heart rate (HR), followed by early interventions, can help alleviate mortalities.

When compared to the wearable single-lead ECG monitoring device [6], wearable acoustic sensors have demonstrated their potential in continuous monitoring of HR [7]–[12], respiration rate (RR) [11], [13], and the detection of anomalies in the heart [14], [15] and lung sounds [16], [17]. Still, a wearable device that measures multiple features or serves multiple functions tends to face hardware limitations of memory and battery capacities, further complicated or worsened by computational complexity and cost.

One cardiac cycle of heart acoustics consists of two sounds (commonly annotated as lub-dub corresponding to the first, S1, and second, S2). The first and second heart sounds are due to the closure of atrioventricular values at the beginning of systole and semilunar valves during diastole, respectively [18]. Recently, our group developed a miniature wearable acoustic sensor for continuously monitoring vitals [19]. Then, we further showed that the HR estimates perform well in most of the HR ranges [20]; however, the performances were challenged in the extreme ends of HR (i.e., HR<60 bpm and 120 bpm<HR).

One of the primary shortcomings of the previous HR estimation algorithm was using a fixed window size in the peak detection of the autocorrelation function, which poses the risk of under- and over-estimation of HR in the two extreme HR ranges.

In this work, we advanced the prior art by proposing an adaptive peak detection approach to improve the HR algorithm performance in the lower and higher ends of HR. Further, we proposed including an estimation correction step using a 1-step autoregressive (AR) model to filter away any predicted miscalculation due to poor signal-to-noise ratio (SNR). Finally, we analyzed the performance of the proposed HR estimation against a non-acoustic-based United States Food and Drug Administration *(*FDA) cleared medical heart rate monitoring device MightySat® Rx (Masimo, United States).

II. METHODS

The proposed algorithms were implemented in a wearable acoustic microphone sensor, AeviceMD (Aevice Health Pte Ltd, Singapore). The wearable weighs approximately 10 g and securely attaches to a user's chest with a medical silicone adhesive. Since the paper's contribution is the proposed approach to enhance HR estimation robustness, we direct interested readers to the device's design and other algorithms

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

besides the HR estimation algorithms to our other works [19]–[22].

A. Overview of HR Estimation Algorithm

AeviceMD has a sample rate of 4000 Hz to enable capturing of adventitious auscultation, $\mathbf{x} \in \mathbb{R}^L$, where L is the total number of samples in 5.12 s [21], [22]. However, since heart sound typically spans a much lower frequency [23], the acoustics were down-sampled to 250 Hz before estimation. Down-sampling serves as a low pass filter [24] and reduces the memory allocation and processing needed in the wearable to perform the task of HR estimation. Next, the time-domain acoustic is peak-enhanced to emphasize the S1-S2 before acquiring the principal frequency of its autocorrelation for peak-interval detection. Fig. 1 illustrates the proposed approach for HR estimation for our miniature wearable microphone sensor.

B. Adaptive Windowing for Peak Detection

Our previous work found that HR estimation based on peak detection from a fixed window interval was not optimal for robustly estimating HR of extreme ends. This is because the earlier fixed window interval prevents the algorithm from identifying S1-S2 peaks with larger or smaller systolic periods corresponding to the lower and upper HR limits, respectively. As part of the effort to advance the signal processing, we proposed to utilize an adaptive window interval to segment the acoustic prior to peak detection at the two extreme ends, as illustrated in Fig. 1. The proposed adaptive window intervals are designed based on the reported systolic period range of 0.2 to 0.4 s [23]–[26].

Concretely, each auscultation, $\mathbf{x} \in \mathbb{R}^L$, S1 and S2 are first enhanced from the down-sampled, $\mathbf{x}_d \in \mathbb{R}^{L_d}$, acoustic by peak thresholding to arrive at $\mathbf{x}_t \in \mathbb{R}^{L_d}$ before estimating the frequency of the smoothed autocorrelation, $\boldsymbol{\gamma}_t \in \mathbb{R}^{L_d}$, from its spectrogram. Here, we proposed to use $N = 1024$ to achieve a frequency resolution of $r_f = 0.244$ Hz/bin, corresponding to approximately $r_b = 14$ beats per min (bpm). Notice because L_d corresponds to 5 s of auscultation, an r_b of 14 bpm can theoretically resolve at least one pair of S1-S2 in each 5 s acoustic.

It is clear from the above that HR estimates that are based solely on frequency estimation of autocorrelation, $\boldsymbol{\gamma}_t$, cannot differentiate S1-S2 and resolve the ambiguity of ± 14 bpm; hence, peak detection is an essential step to arrive at an accurate estimate [12].

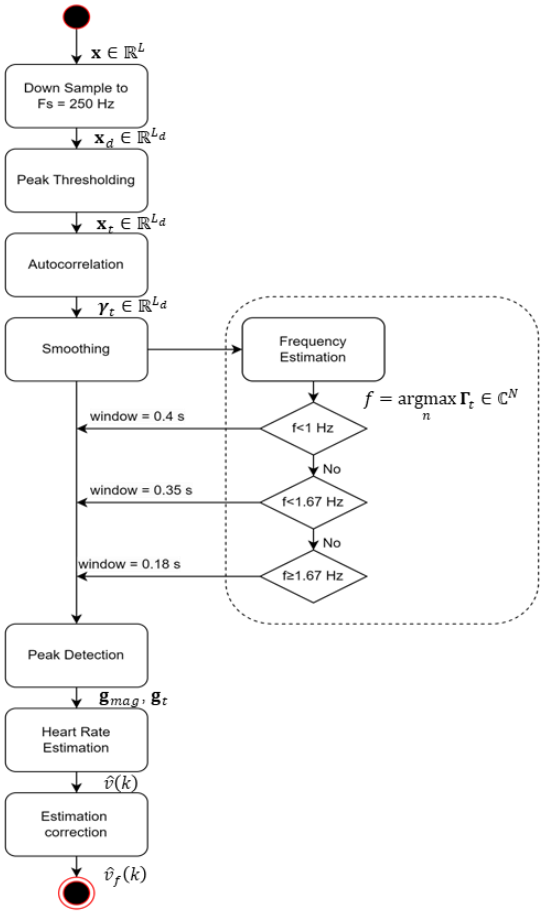

Fig. 1: The proposed HR estimation algorithm based on acoustics from the miniature wearable microphone sensor

The main objective of peak detection is to identify the occurrence of S1 or S2 events. Accordingly, from the frequency estimation, $\boldsymbol{\gamma}_t \in \mathbb{R}^{L_d}$ is segmented into $\boldsymbol{\gamma}_{t,w} \in \mathbb{R}^{\lfloor L_d/W \rfloor}$, where $w = [1, \cdots, W]$ and W is the total number of window segments. Note that $\lfloor . \rfloor$ The local peak magnitude, $\mathbf{p}_{mag} \in \mathbb{R}^W$, and their relative time position, $\mathbf{p}_t \in \mathbb{R}^W$, within each window segment are identified. Lastly, the global peak, $\mathbf{g}_{mag}$, and the global peak's relative time position, $\mathbf{g}_t$, corresponding to the S1 events, can be localized by finding all the stationary points in $\mathbf{p}_{mag}$, i.e., localizing the sign changes from the 2nd-order difference of $\mathbf{p}_{mag}$.

With the global peak magnitude and relative position ($\mathbf{g}_{mag}$ and $\mathbf{g}_t$) corresponding to all the S1 events identified, the kth instance HR, $\hat{v}(k)$, is estimated from the averaged interval difference of $\mathbf{g}_t$.

.

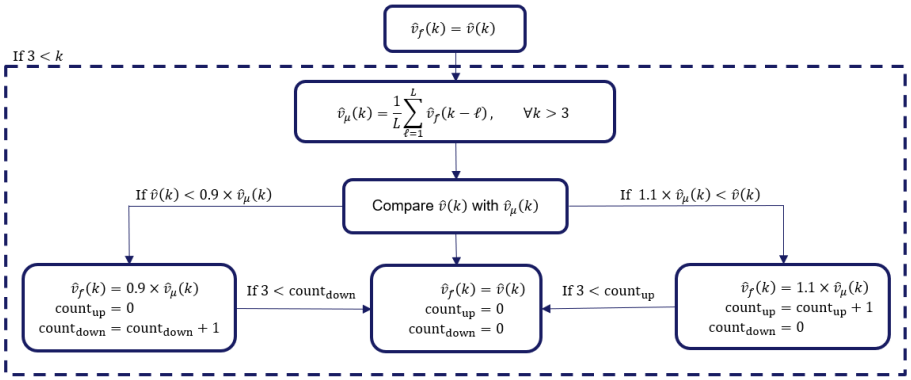

Fig. 2: The proposed process for estimation correction with 1-step AR model when $k < 3$.

C. *Estimation Correction with 1-step AR model*

The estimation correction approach aims to predict the upward or downward trend of the HR estimation algorithm after estimating $3 < k$ HR estimates. By comparing the current estimate, $\hat{v}(k)$, with its previous average HR estimation, $\hat{v}_\mu(k)$, this reduced the occurrence of displaying an instantaneous spike or dip in HR value due to the poor SNR to arrive at the final HR estimation, $\hat{v}_f(k)$. A summary of the approach is presented in Fig. 2. To address the shortcoming of updating an actual high and low HR, we proposed the following conditions if there are three consecutive downtrends (e.g., $3 < \text{count}_{\text{down}}$) or uptrends (e.g., $3 < \text{count}_{\text{up}}$) detected, the current HR will be replaced by the latest computed HR.

D. *Algorithm Performance Evaluation*

The algorithm was evaluated in two stages to demonstrate the improvements attributed to the adaptive peak detection and estimation correction approaches.

In the first stage, we analyzed the HR estimation results of AeviceMD with and without the proposed approaches. In the second stage, we analyzed the results from a main group of 26 healthy subjects and a secondary group of 15 healthy subjects. The performance of the HR estimation from the AeviceMD was compared against MightySat® Rx (Masimo, United States), a gold standard medical heart rate monitoring device.

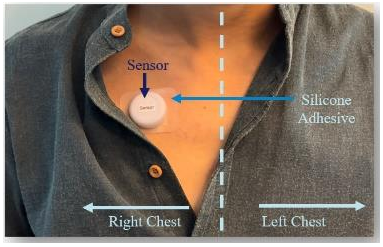

Fig. 3: Placement of the sensor on the right side of the chest wall

The main group has an age distribution between 21 to 80 (40% of the main group is male) with a Cohort body mass index (BMI) of $23.8 \pm$ kg/m.

The participant age distributions are as follows:

- 21 - 29 years old: six subjects
- 30 - 39 years old: five subjects
- 40 - 49 years old: five subjects
- 50 - 59 years old: five subjects
- 60 - 69 years old: three subjects
- 70+ years old: two subjects

On the other hand, the secondary group age distribution is between 20 to 35, where the subjects' HR was analyzed after intense exercise to elevate their heart rate.

All participants were seated on a reclining chair throughout the validation study with AeviceMD attached to their right upper chest using a silicone adhesive, as depicted in Fig. 3. The reference device was fitted to the left index finger of the subjects.

The HR of each participant was first recorded for ten minutes at rest, followed by another five minutes post-movement. At the onset of the tenth minute, the subjects were requested to simulate a tossing scenario that may happen if the device was to be worn throughout the sleep cycle of the subject. The tossing scenario involves turning the body side way (left-to-right and right-to-left). The subjects could adjust their body position for comfort during the recording session. For the secondary group recruited, the participants were asked to perform 2 minutes of jumping jacks to accelerate their HRs. The HR output of AeviceMD is updated every five seconds, whereas the HR reference device's HR is updated every second. Therefore, the data points of the HR reference device were averaged to produce five-second-average data in the validation study.

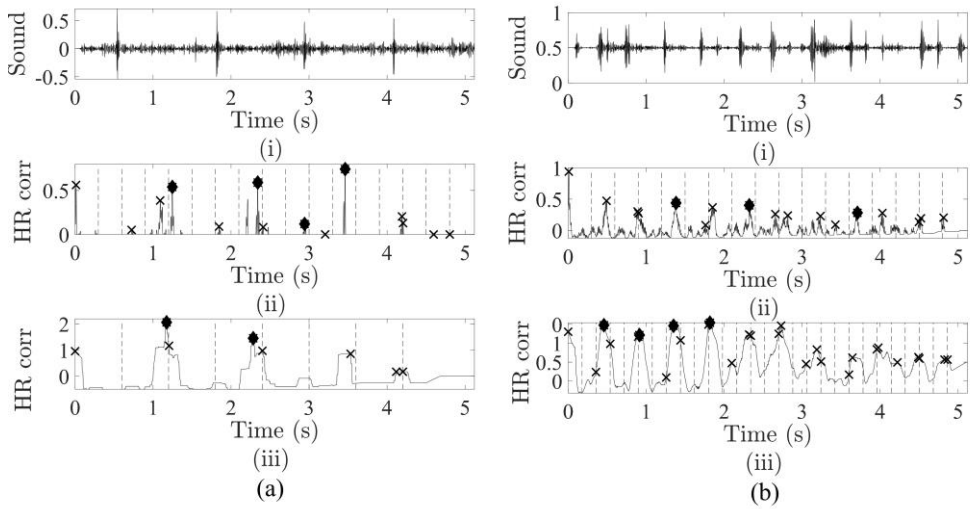

Fig. 4. Comparison in the results of HR estimation algorithm with the (ii) non-adaptive and (iii) adaptive windowing approach employed in the peak detection of HR algorithm. Two scenarios were evaluated: (a) low HR and (b) high HR. HR: Heart rate, HR corr: HR autocorrelation output, marker 'x': local peaks, marker '♦': global peaks.

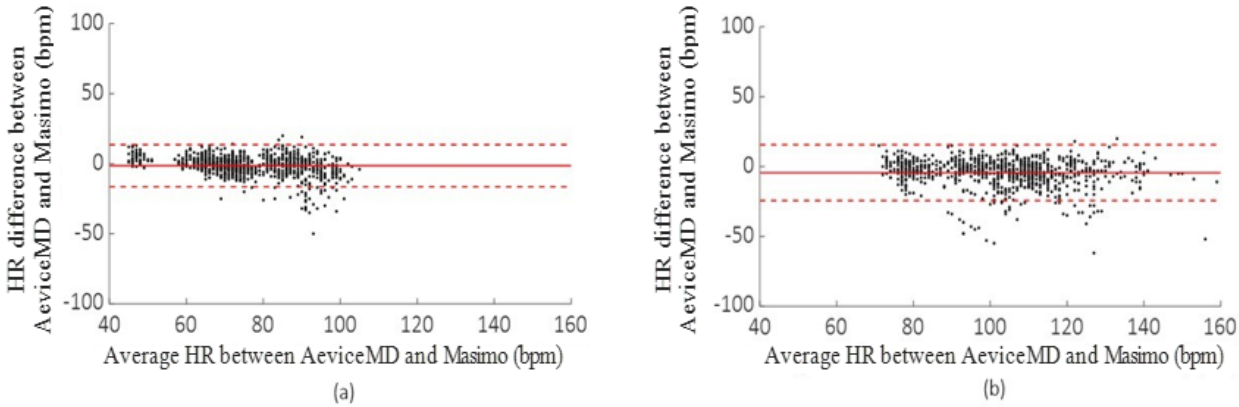

Fig. 5. The Bland-Altman heart rate distribution at (a) rest, main group, and (b) post-exercise, secondary group.

Table 1: Mean Bias and Standard Deviation of the AeviceMD HR Measurement

	Main Group		Secondary Group	
	Rest	Post Movement	Rest	Post Exercise
Mean Bias (bpm)	2.8	3.0	-1.4	-4.4
Standard Deviation (bpm)	8.3	8.1	7.5	10.0

III. Results

Because the heart rate measurement reference has an accuracy of ± 3 bpm, the mean bias of AeviceMD should also be within ± 3 bpm of the reference device, i.e., the maximum acceptable bias is ± 6 bpm of the reference. Overall, we found that the AeviceMD HR estimates' mean bias is within the acceptable range.

Specifically, the result from the first stage HR estimation analysis is depicted in Fig. 4. In the case of lower reference HR (i.e., 47 bpm in Fig. 4(a)), the estimated HR without and with the adaptive peak detection was 90 bpm and 53 bpm, respectively. The adaptive peak detection has reduced the error from 43 bpm to 6 bpm. While in the high reference HR (i.e., 129 bpm in Fig. 4(b)), the estimated HR without and with the adaptive peak detection was 54 bpm and 133 bpm, respectively. Likewise, the adaptive peak detection significantly reduced the error from 75 bpm to 4 bpm.

Table 1 tabulates the results from the second stage study. Here, we report a mean bpm bias of 2.8 and 3.0 for subjects at rest and post-movement, respectively, for the main group. While the second group reports a mean bpm bias of -1.4 and -4.4 at rest and post-exercise, respectively. The bland-Altman plots of the second stage HR estimation analysis result for at-rest and post-exercise are depicted in Fig. 5a and Fig. 5b, respectively.

IV. Conclusion

An adaptive window interval and estimation correction approach for a miniature wearable microphone sensor has been proposed and implemented on the measured heart acoustic signal for HR estimation. The proposed approach results were benchmarked against an FDA-cleared HR monitoring device, MightySat® Rx, in two extreme HR ends. In the first stage, the adaptive window interval for peak detection and estimation correction approach reduced the error from 75 bpm and 43 bpm to 4 bpm and 6 bpm, respectively. In the second stage, the maximum reported mean absolute bias was 2.8 bpm, 3.0 bpm, and 4.4 bpm for at-rest, post-movement and post-exercise, respectively. Even though the post-exercise scenario was not the intended use case of the AeviceMD, the maximum mean was still within ±6 bpm of the reference device. The purpose of including the post-exercise test was to validate the higher HR range, which was unavailable in the resting HR of healthy subjects. Overall, this work advances the HR estimation algorithm for a miniature wearable acoustic microphone sensor to estimate the HR of the upper and lower extreme ends.

***Abstract*—This paper proposes a counter-movement detection method for dumbbell curl using a convolutional autoencoder in the frequency domain. Specifically, using an inertial motion capture system, we make an acceleration dataset of dumbbell curl without counter-movement and with counter-movement. Then, we convert the counter-movement-free dataset to 3D spectrograms and train a convolutional autoencoder model using them as inputs. Anomaly score statistics are calculated using the counter-movement-free motion test data, and based on them, a threshold value is set to detect counter-movement. Experiments confirmed that the proposed method can detect counter-movement with the highest accuracy compared to the comparison methods.**

***Index Terms*—Weight training, counter-movement detection, spectrogram, convolutional autoencoder.**

I. Introduction

Free weight training with dumbbells is helpful to compensate for the lack of physical activity because it is easy to do at home. However, weight training with counter-movement forms can increase the risk of muscle, tendon, and joint injury. This problem is severe for beginners not supervised by a trainer with expertise or experience [1]–[4].

Recently, "activity recognition" using machine learning approaches has attracted much attention. Activity recognition research analyzes motion data, such as coordinates and acceleration, to recognize what kind of activity a person is engaged in. Research interest is also shifting from "activity recognition" to "activity quality analysis," which is expected to be used for digital healthcare and improving the performance of athletes.

Velloso et al. proposed a model that estimates wrist, elbow, and shoulder joint angles from data captured by Microsoft Kinect and measures the range of motion of joint angles and repetitive movements [3]. A rule-based algorithm can classify some weight-lifting exercises using the motion features extracted by their model. Moreover, they provided a user interface system that provides real-time activity quality and error feedback. Kowsar et al. measure unilateral biceps curl exercises using an accelerometer attached to glove, upper arm, dumbbell, and belt, mathematically model and extract features of normal motion from these measured data, and threshold them to propose an algorithm for detecting anomalies in which the motion is partially different from the correct motion [4]. These methods predict and detect incorrect form movements in weight-lifting exercises. Therefore, they did not explicitly consider the detection of counter-movement during the use of heavy weights with high loads on the human body.

In this paper, we propose a counter-movement detection method for a dumbbell curl based on a convolutional autoencoder (CAE). The acceleration data of dumbbell arm curl movements with and without counter-movement are measured by inertial motion capture to make a dataset. A CAE model is trained using only the counter-movement-free dataset. Then, we input test acceleration data with and without counter-movement to the trained CAE and detect counter-movement by thresholding the reconstruction error.

II. Proposed Method

A standard dumbbell curl is a single-joint exercise primarily involving elbow joint movement. When using an appropriate weight, the dumbbells can be raised and lowered slowly without needing additional movement. This is considered the correct form. However, it becomes challenging to maintain a slow and controlled movement when attempting to perform the exercise with heavy dumbbells. In such cases, a slight counter-movement may be necessary to generate enough force to lift the weight. This is considered the incorrect form of this exercise because it deviates from the original purpose of stimulating only the targeted muscles. We aim to detect this counter-movement based on the acceleration data measured by the inertial motion capture system. The procedure of the proposed method is briefly described below.

A. Dataset

Inertial sensors were attached to four locations: the back of the hand, the proximal end of the forearm, the proximal end of the upper arm, and the middle trapezius of the subjects. We measured the acceleration data when the subjects performed dumbbell curls for 10 repetitions at regular intervals according to a metronome. The motion data without counter-movement was obtained by measuring the arm curl with a 2kg dumbbell. On the other hand, the following three types of motion data with counter-movement were measured based on the base weight that each subject could barely lift for 10 repetitions without counter-movement.

1) 10 repetitions with a dumbbell of the base weight +2kg.
2) the first five of 10 repetitions with the base weight +4kg.
3) the last five of 10 repetitions with the base weight +4kg.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

TABLE I: Counter-movement detection results: (I)-(III) the comparison methods and (IV) our method.

Method	Input	Model	Recall (%)
(I)	1D time-series signal	AE	16
(II)	1D power spectrum	AE	46
(III)	1D spectrogram (3D $\rightarrow$ 1D)	AE	78
(IV)	3D spectrogram	CAE	88

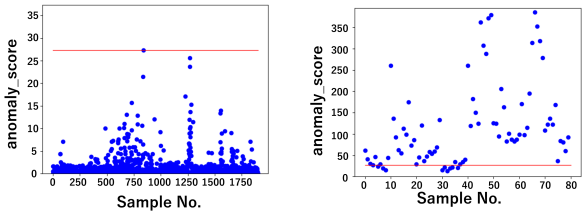
The lifting and lowering motion in the dumbbell curl was defined as one repetition with the signal length T, and a total of 6899 samples of data without counter-movement and 80 samples of data with counter-movement were collected from five subjects, respectively.

B. Training the CAE Model

The data without counter-movement were considered normal data, and the data with counter-movement were considered anomalies data, and only the normal data were used to train the proposed CAE model consisting of encoders and decoders in the 6 layer. Note that 5899 of the data without counter-movement was used as training data and 1000 as test data. Each acceleration data was converted into a 3D spectrogram and input into the CAE using the following procedure. Each time series signal from the four measurement locations along the X-axis was transformed by STFT with 64 blocks and 80% overlap, generating a 2D spectrogram. Then, four 2D spectrograms were horizontally concatenated. We performed the same process on the Y- and Z- axis acceleration data, concatenated the spectrograms in the three-dimensional direction, and normalized them to their maximum value.

We used MSE (mean squared error) as the loss function of the CAE.

C. Counter-movement detection



We assume that the distribution of the MSE (mean squared error) of the correct dataset not used for training the CAE can be approximated by a normal distribution with mean μ and variance σ, the anomaly score α is calculated by

$$\alpha = \frac{(\mathrm{MSE}(\mathbf{x}, \mathbf{y}) - \mu)^2}{\sigma^2}, \tag{1}$$

where $\mathbf{x}$ and $\mathbf{y}$ are the N-dimensional vectors of the input and output of the CAE, respectively. In the experiments, we calculated the anomaly score of the K normal data not used for training and set the maximum value of them as the threshold value $\alpha_{\mathrm{th}} = \max\{\alpha_1, \ldots, \alpha_K\}$. When the acceleration data with or without counter-movement is input into the trained CAE, if the reconstruction error is less than the threshold α_{th}, it is classified as counter-movement-free. In contrast, if the error is higher, it is classified as counter-movement.

III. Experiments

To verify the effectiveness of the proposed method, we compared our method with three methods based on autoencoder (AE) (for details, see Method (I)-(III) in Table I). We trained the comparison methods using the same dataset as the proposed method and followed the same procedure to set the threshold value for counter-movement detection (see Section II-C).

(a) (b)

Fig. 1: The anomaly scores of the proposed method calculated from the test data (a) without and (b) with counter-movement, where the red line indicates the threshold value.

Figures 1 (a) and (b) show the calculated anomaly scores for the test data without and with counter-movement, respectively, and the red line indicates the threshold value (where $\alpha_{\mathrm{th}} = 27.3$). A recall ratio was calculated from these anomaly scores and the threshold value, indicating the proportion of those labeled counter-movement predicted to be an anomaly. The same procedure was used to calculate the recall ratio of the comparison methods.

The fourth column in Table I shows the recall ratio of all the methods. The proposed method has the highest counter-movement detection accuracy of 88% in all methods, which is about five times more accurate than that of the AE method with 1D time-series acceleration signals as input.

IV. Conclusion

This paper proposed a counter-movement detection method for dumbbell curl based on a CAE model. We applied STFT to the acceleration data and obtained a 3D spectrogram. Then, we trained the CAE using the counter-movement-free dataset. Anomaly score statistics were calculated using the counter-movement-free test data, and based on them, a threshold value was set to detect counter-movement. We confirmed that experiments showed the superiority of the proposed method compared with the comparative method based on AE.

***Abstract*—Non-alcoholic fatty liver disease (NAFLD) is a fatty liver disease without a history of excessive alcohol intake. We aim to identify the causal factors contributing to the onset of NAFLD by analyzing medical data with a causal discovery approach. The linear mixed causal model (LiM) is a causal discovery method applicable to mixed data containing both continuous and discrete variables and thus suitable for medical data analysis. However, the computational time of LiM increases substantially when the number of variables reaches dozens. To solve this problem, we improved the optimization procedure used in LiM in this study. Furthermore, we applied this improved model to a causal analysis of medical data involving physical examination and blood test results. As a result, alanine aminotransferase (ALT), triglyceride (TG), gamma-glutamyl transpeptidase (γ-GTP), uric acid (UA), high sensitive C-reactive protein (hs-CRP), body fat mass (BFM), body mass index (BMI), and fecal hemoglobin (F-Hb) were estimated to be factors for the accumulation of fat in the liver.**

I. Introduction

Non-alcoholic fatty liver disease (NAFLD) is a type of fatty liver disease that develops without a clear history of alcohol consumption, and the number of patients with this disease has been increasing [1]. Previous studies have reported correlations between many medical examination items and the onset of NAFLD [2], [3]. However, few studies have focused on analyzing the causal relationship between these indicators and the NAFLD development [4]. We aim to identify causal factors of NAFLD by analyzing medical data.

The method of discovering causal relationships from data is called causal discovery. One of the causal discovery methods that can be applied to data containing both continuous and discrete variables is the linear mixed causal model (LiM) [5]. LiM has the problem of being computationally expensive when applied to data with dozens of variables. In this study, we extend LiM so that it can be applied to data with dozens of variables. We then estimate the causes of NAFLD by applying our proposed method to medical data.

II. Method

The LiM model estimates the adjacency matrix $\boldsymbol{B}$ representing causal relationships between variables by minimizing the negative log-likelihood. Zeng [5] employed a two-stage optimization process involving `GlobalSearch` and `LocalSearch` to determine $\boldsymbol{B}$. In the first stage, `GlobalSearch` estimates the causal skeleton, and in the second step, `LocalSearch` searches the space of causal relationships having the estimated skeleton to obtain the one with the best log-likelihood score. `LocalSearch` was introduced to avoid falling into local optima, but requires a computational complexity of $\mathcal{O}(2^{P^2})$, where P is the number of variables. The conventional LiM model therefore increases the computational time significantly when the number of variables reaches dozens.

To reduce the computational time, we use `GlobalSearch` with Monotonoic Basin Hopping (MBH) instead of the two-stage optimization process. MBH is a stochastic optimization algorithm that involves iteratively performing a sequence of actions, which include randomly perturbing the current local optimum and conducting optimization with the point after perturbation as the initial value. We adopt the L-BFGS-B method [6], which is an optimization method used in the original LiM. During each iteration k of L-BFGS-B, the computational complexity for computing the Hessian matrix $\boldsymbol{H}_k$ and updating the current solution $\boldsymbol{B}_k$ is $\mathcal{O}(MNP^2)$. Here, N denotes the number of samples, and M represents the parameter within L-BFGS-B that determines the number of saved BFGS corrections, typically ranging between 3 and 20 [7]. Consequently, this method can be applied to data consisting of dozens of variables, where causal discovery is not feasible within a realistic time using LiM.

III. Analysis of Medical Data

The proposed method is applied to medical data provided by Kyoto Prefectural University of Medicine, involving physical examination and blood test results from 323 males aged from 65 to 101 years and 523 females aged from 65 to 99 years. The presence of fatty liver was determined based on computed tomography (CT) scan data, considering liver-to-spleen CT attenuation values ratio (L/S ratio) below 1.0 as indicative of fatty liver [8]. The number of test items is 42, with only the presence or absence of fatty liver being a binary variable,

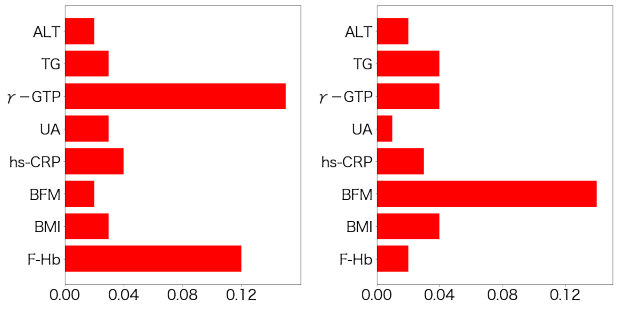

TABLE I: The number of persons with fatty liver.

Sex \ Fatty liver	Negative	Positive	Total
Men	328	27	355
Women	485	38	523
Men (oversampled)	328	328	656
Women (oversampled)	485	485	970

while the others are continuous variables. To address missing values within the medical data, collaborative filtering [9] was employed for imputation. Notably, the number of persons with fatty liver is significantly lower than those without it, necessitating measures to rectify this imbalance. To tackle this issue, the data of persons with fatty liver were oversampled using SMOTE [10]. Table I presents the counts of persons with and without fatty liver before and after oversampling in male and female datasets. Data collection and analysis received approval from the Research Ethics Committee of the Hospital.

IV. Results and Discussion

Figure 1 illustrates the onset factors of fatty liver estimated by our method for each gender and their causal effects on the development of fatty liver. In both genders, alanine aminotransferase (ALT), triglyceride (TG), gamma-glutamyl transpeptidase (γ-GTP), uric acid (UA), high sensitive C-reactive protein (hs-CRP), body fat mass (BFM), body mass index (BMI), and fecal hemoglobin (F-Hb) were estimated to have a positive effect on the accumulation of hepatic fat. This result shows the contributory role of indicators associated with metabolic syndrome, such as TG, BMI, and BFM, in fostering fatty liver onset. Previous studies have reported the link between metabolic syndrome and NAFLD development [11]. Therefore, the outcome of our estimations aligns with existing research, suggesting the involvement of TG, BMI, and BFM in liver fat accumulation. A previous study, which followed 4,138 healthy men for seven years, reported that relatively high levels of hs-CRP increase the risk of developing NAFLD [12]. The results of this analysis corroborate the claims of this preceding study. Furthermore, a preceding study that tracked 4,954 participants for five years reported that high uric acid levels increase the risk of developing NAFLD [13], and the findings of this analysis support this assertion. Correspondingly, prior research has also documented a correlation between elevated levels of ALT and the NAFLD presence [14]. Based on these results, the factors indicated in Fig. 1 were estimated to be the causes of hepatic fat accumulation.

(a) Male **(b)** Female

***Abstract* — We investigated the neuromodulation effect of transcutaneous vagus nerve stimulation (tVNS) on brain activity using electroencephalography (EEG). We measured resting-state EEG from ten participants before, during, and after tVNS. The power spectral density (PSD) was estimated in alpha band (8 – 13 Hz) and it was confirmed that significantly increased in frontal and right temporal areas during and after tVNS than before tVNS application. These results demonstrated that the tVNS could modulate the electrical brain activities during and this brain modulation effect was maintained even after tVNS application.**

I. INTRODUCTION

The vagus nerve was known as a parasympathetic branch of the autonomic nervous system. Recently, some previous studies have been conducted to induce symptom relief of neurophysiological diseases such as epilepsy by stimulating the autonomic nervous system using a vagus nerve stimulation (VNS) [1].

VNS was one of the invasive brain stimulation methods to modulate neural activity by applying a weak electric current to the vagus nerve. VNS was known to be effective in improving various neurological disorders such as epilepsy, headaches, and Alzheimer's disease. In addition, VNS could minimize drug-induced side effects and can be an effective treatment option for patients who are resistant to drugs [2]. However, VNS has a limitation in that used only in cases of high severity because stimulation electrodes and generator must be directly implanted into the human body through a surgical operation [3].

To overcome this limitation, recently non-invasive vagus nerve stimulation (transcutaneous VNS: tVNS) has been proposed, and some previous studies conducted to confirm the neuromodulatory effect of tVNS [4]. Some Previous studies reported the clinical effects of tVNS and other studies mainly used the functional magnetic resonance imaging (fMRI) to confirm the neural mechanism of tVNS. However, the different effects of tVNS have been reported depending on the experimental group and stimulation parameters, and previous studies on the neural mechanism of tVNS were still lacking. In particular, studies about the effects of tVNS on neural activity based on electroencephalography (EEG) are lacking compared to studies based on fMRI.

Therefore, we tried to investigate the effect of tVNS on neural activity based on EEG. To this end, resting-state EEG data were measured before, during, and after tVNS application, and we confirmed changes in EEG patterns during each stimulus condition.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

II. METHOD

A. Data and data acquisition

Ten participants took part in the experiment, and resting state EEG was measured before, during, and after tVNS application. EEG data were recorded at a sampling rate of 1000 Hz through 31 scalp electrodes based on the international 10-20 system (Figure 1).

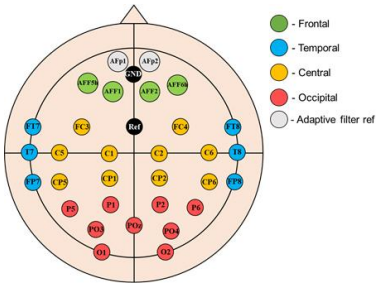

Fig. 1 The montage of EEG electrodes

tVNS was applied to the antihelix of both ears to stimulate the auricular branch of the vagus nerve (Figure 2-a, b). tVNS was applied for 1 minute and then applied through an on/off method in which stimulation was not applied for 1 minute. The corresponding process was repeated 20 times, and stimulation was applied for a total of 40 minutes.

tVNS was applied at 30 Hz with a pulse width of 200 μs. Moreover, tVNS intensity was individually determined from level 1 to 10, depending on the presence of the pain for each participant. In addition, the participants who presence the pain even at the minimum intensity of level 1 were excluded from the experiment (see Table I).

Table I. Intensity of tVNS

Level	Maximum output voltage (Vpp)	Output current ch1 (mA)	Output current ch2 (mA)
1	11.0	0.464	0.558
2	19.6	0.850	0.976
3	22.4	1.014	1.153
4	25.7	1.154	1.293
5	28.2	1.262	1.415
6	30.2	1.370	1.522
7	32.4	1.453	1.619
8	34.0	1.540	1.695
9	36.2	1.161	1.776
10	37.4	1.136	1.827

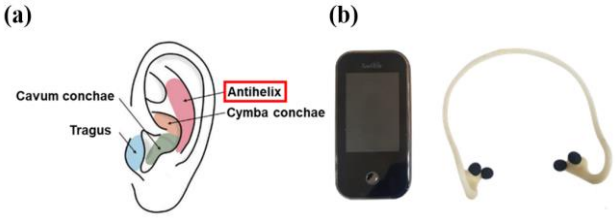

Fig. 2 (a) Location of the tVNS application and (b) tVNS device (Neurive Co., Ltd.)

B. Paradigm

All participants maintained their eyes open (EO) and eye closed (EC) state for 1 minute before and after tVNS application, respectively. In addition, they only maintained the EO state at during tVNS. To compare the EEG changes in before, during, and after stimulation, only EO data was used for further analysis. In particular, only tVNS off data was used to further analysis because of the tVNS on data was contaminated by electrical noise induced from the tVNS (Figure 3).

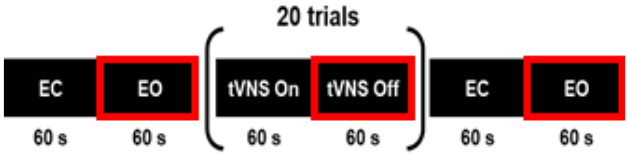

Fig. 3 The experimental paradigm

C. Preprocessing

The recorded EEG raw signals were downsampled to 200 Hz to reduce computational load. The common average reference (CAR) and a band-pass filter (1 – 50 Hz) were performed to remove the noise components. In addition, an adaptive filter applied using the AFp1 and AFp2 electrodes to remove the electrooculography (EOG) components. EEG data in before, during and after tVNS were segmented at 1-second intervals. Moreover, segmented data containing values exceeding ± 75 (μV) excluded from the analysis. Alpha band (8 – 13 Hz) power spectral density (PSD) was estimated using the fast fourier transform (FFT) to confirm the neuromodulation effects on resting state EEG. In addition, to investigate the effects of tVNS according to brain areas, the EEG data was divided into five regions of interests (ROIs). Each alpha band power of before, during and after tVNS application were statistically evaluated using the Wilcoxon signed-rank test with the false discovery rate (FDR) correction.

III. RESULT

Figure 4 shows the average alpha band frequency power topography in the before, during and after tVNS for all participants. It shows the alpha band PSD was increased in the whole brain areas at during tVNS. Moreover, the alpha band PSD was increased in the central and occipital areas at after tVNS.

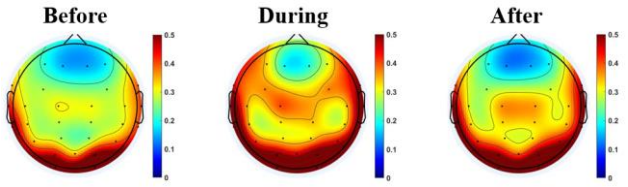

Fig. 4 Topography of the alpha band before, during and after tVNS

Further analysis was performed to precisely compare the differences between before tVNS and during and after tVNS (Figure 5). Figure 5-a shows the differences in average of alpha band PSD during and after tVNS compared to before tVNS for whole participants. Figure 5-b shows the topographic map of -values for the differences in alpha band PSD between during and after tVNS compared to before tVNS, for each channel. Channels exhibiting statistically significant differences ($p < 0.05$) were indicated by red circles in Figure 5-b. As a results, alpha band PSD significantly increased in the frontal and right temporal areas at during tVNS than before tVNS. Especially, significantly increased of alpha band PSD in right temporal area was maintained even after tVNS.

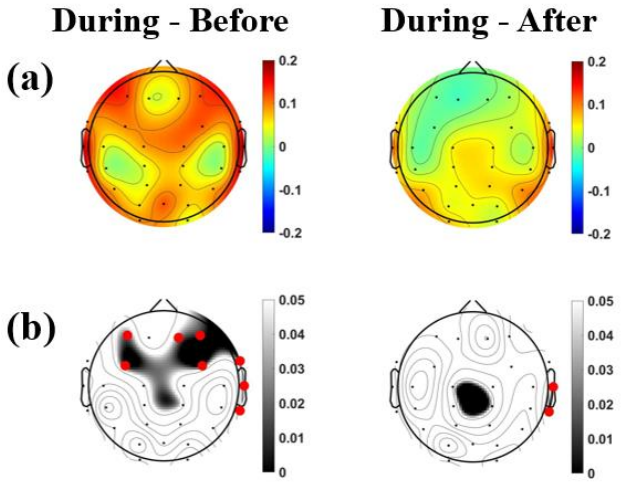

Fig. 5 Differences in alpha band PSD during and after tVNS compared to before tVNS.

Figure 6 shows the alpha band PSD for the ROIs across individual participants. Alpha band PSD was generally increased during tVNS than before tVNS in the frontal and right temporal areas. However, alpha band PSD was decreased during and after tVNS than before tVNS in few participants. These results show that tVNS may not cause the same neuromodulation effects in whole participants.

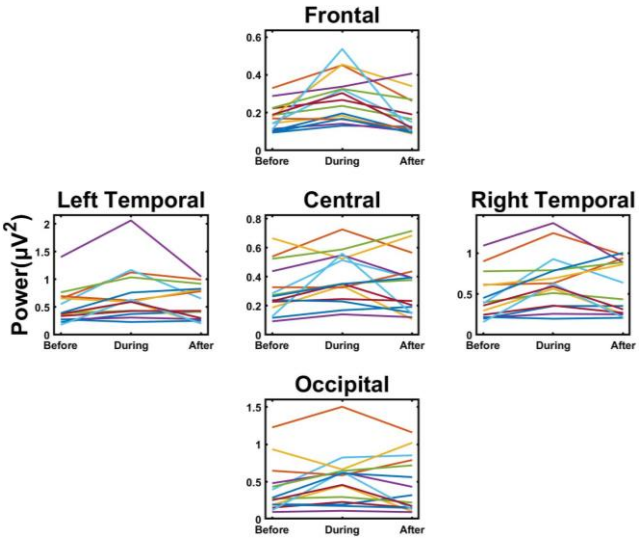

Fig. 6 Changes in individual alpha band PSD according to tVNS condition for each ROIs

Figure 7 shows the average alpha band PSD at the each ROIs for whole participants. As a results, alpha band PSD significantly increased during tVNS than before tVNS in frontal and right temporal areas. In addition, significantly increased of alpha band PSD in right temporal area was maintained even after tVNS than before tVNS (* $p < 0.05$, ** $p < 0.01$).

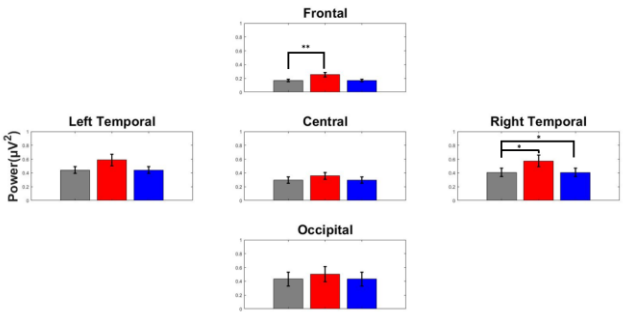

Fig. 7 Changes in mean alpha band PSD according to tVNS condition for each ROIs

IV. Conclusions

In this study, we investigated the neuromodulation effects of tVNS using the resting state EEG data measured before, during, and after tVNS. We could confirm that the alpha band PSD was significantly increased across frontal and right temporal areas during tVNS than before tVNS. Especially, these effects were found to maintained even after tVNS in right temporal area. However, we confirmed the neuromodulation effects of tVNS only on the alpha band. Therefore, in further study, will investigate the neuromodulation effects of tVNS on various frequency bands.

***Abstract* — Machine-learning-based computer-aided diagnostic (CAD) systems using neurophysiological data could complement conventional interview-based diagnostic method for major depressive disorder (MDD). In particular, gender-specific and medication-controlled EEG-features can improve the diagnostic performance of CAD system because electroencephalography (EEG) features of MDD patients are influenced from both factors. In this study, we developed a machine-learning-based CAD system using gender-specific and medication-controlled EEG features for MDD patients to improve diagnostic performances. To this end, we used eyes-closed resting-state EEG data recorded from 30 male MDD patients and 30 male healthy controls (HCs). Power spectral density (PSD) was computed to use as EEG-based features and a support vector machine (SVM) classifier with a leave-one-out cross-validation method was used to differentiate two groups. The best diagnostic accuracy of 93.33 % was obtained when 43 PSD features.**

I. INTRODUCTION

After COVID-19 pandemic, mental problems, such as depression, anxiety, and stress, have been increased due to social isolation. Among various mental disorders, the patients with major depressive disorder (MDD) have been increased by approximately 30.00 %, compared to before COVID-19 [1]. Since MDD is the most common mental disorder and is considered less severe disorder compared to other mental disorders like schizophrenia, some MDD patients do not actively treat their symptoms. However, MDD is also a severe mental disorder because that can lead to suicide if not treated in a timely manner.

Fortunately, a recovery rate of MDD is over 54 % higher than other mental disorder. However, if not treated promptly, the recovery rate is decreased until 16 %. Therefore, it is important that MDD patients should be diagnosed and treated in timely manner. Conventionally, mental disorders, including MDD, are diagnosed by interview with clinical experts. Even though it conducted under the well-organized diagnostic criteria, the conventional interview-based diagnosis might be contaminated by subjective interpretation of experts or deception of patients [2].

To assist accurate diagnosis of mental disorders, researchers have been striving to develop the machine-learning-based computer-aided diagnosis (CAD) systems using objective physiological data, like electroencephalography (EEG). When developing EEG-based CAD system for MDD patients, both gender and medication should be controlled because the EEG-features of MDD patients are influenced from those of two factors [3, 4, 5]. In terms of gender, male MDD patients showed the increased long-distance connectivity between the left parieto-occipital and frontal areas regardless of hemispheres, while female MDD patients showed the short-distance connectivity between the left posterior and central areas [6]. Moreover, treated MDD patients under the medications, such as fluoxetine or venlafaxine, showed reduced prefrontal cortex activity, as compared to unmediated MDD patients [7]. Therefore, it is necessary to develop a gender-specific and

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

medication-controlled EEG features-based CAD system for MDD patients to ensure an accurate and precise diagnosis.

In this study, we developed a machine-learning-based CAD system using gender-specific and medication-controlled EEG-based neurophysiological features. Furthermore, we investigated spatial distributions of selected features when achieving the best classification performance to improve the understanding of what neurophysiological traits affect on the diagnostic performance of male MDD patients.

II. METHODS

A. Data acquisition

In the present study, 30 drug-naïve male MDD patients and 30 male healthy controls (HCs) were recruited. To evaluate the symptoms of depression and anxiety in MDD patients, the Hamilton Depression Rating Scale (HAM-D) and Hamilton Anxiety Rating Scale (HAM-A) were used, respectively. Demographic data are summarized in Table 1. This study was approved by the Institutional Review Board of Inje University Ilsan Paik Hospital [2015-04-316/2016-08-017] and conducted in accordance with The Code of Ethics of the World Medical Association (Declaration of Helsinki), and all participants submitted written informed consent before the experiment.

Table 1. Demographic data of drug naïve male major depressive disorder (MDD) patients and healthy controls (HCs). All participants are male. Abbreviations: HAM-D – Hamilton Depression Rating Scale; HAM-A – Hamilton Anxiety Rating Scale

	MDD	HC
Cases (N)	30	30
Age (years)	36.73±12.37	30.07±7.82
Education	14.97±1.10	15.13±0.97
HAM-D	22.93±5.81	
HAM-A	27.83±6.47	

B. Data analysis

Eyes-closed resting-state EEG data were recorded for 5 minutes using a NeuroScan SynAmps2 (Compumedics USA El Paso, TX, USA) from 64 Ag/AgCl scalp electrodes evenly mounted on a QuikCap according to the extended 10-20 international system. Since two channels were used for references (M1 and M2), only 62 electrodes were used for further analysis. To eliminate artifacts of recorded resting-EEG data, band-pass filtering was conducted based on frequency ranges from 1 Hz to 55 Hz. Then, independent component analysis (ICA) was performed to remove various external artifacts, such as eye blinks and eye movements.

Artifact-free EEG data were down-sampled from the original sampling rate of 1,000 Hz to 200 Hz to reduce the computational cost of a deep-learning model. Then, EEG data was segmented into the length of 35,945-time points (about 3 minutes).

C. Feature extraction

Power spectral density (PSD) was used for neurophysiological features to differentiate MDD patients and HCs. To this end, a Short-time Fourier transform (STFT) method, which can compute spectral power across both time and frequency, was used. Computed spectral powers were averaged across the all-time and across the specific frequency bands. In this study, PSD were quantified for seven different frequency bands [delta: 1-4 Hz; theta: 4-8 Hz; low-alpha: 8-10 Hz; high-alpha: 10-12 Hz; low-beta: 12-22 Hz; high-beta: 22-30 Hz; gamma: 30-55 Hz]. Therefore, the size of extracted PSD-based features was [60 (subjects) x 434 (62-channels x 7 frequency bands)].

D. Classification

Since too many features can hide accurate classification performances occurring bias when using machine-learning algorithms, feature selection method was used to select important features in this study. Among various feature selection methods, an independent *t*-test was used, and features were selected based on *t*-values. We evaluated classification performances sequentially using the selected features from 1 to 50. To differentiate MDD patients from HCs, a support vector machine (SVM) classifier with leave-one-out cross-validation was used.

Based on the classification performances, we investigated the spatial distribution of selected features. To this end, we represented the selected channels and frequency bands to topographical map when achieving the best classification performance.

III. RESULTS

A. Classification performances

Table 2 represents the classification performances between MDD patients and HCs (accuracy, sensitivity, and precision). The best classification accuracy of 93.33 % was achieved when using 43 features.

Table 2. Classification performances (units: %)

Accuracy	Sensitivity	Specificity
93.33	93.33	93.33

B. *Identification of features used for diagnosis*

To evaluate what frequency band plays an important role when differentiating MDD patients and HCs, we investigated the characteristics of 43 features selected when achieved the best classification. As a results, four frequency bands (delta, low-beta, high-beta, and gamma) were used, and the largest number of features was selected from gamma frequency band (the number of features: delta – 11, low-beta – 1, high-beta – 7, and gamma – 24). Fig. 1 represents the characteristic of selected features in terms of number.

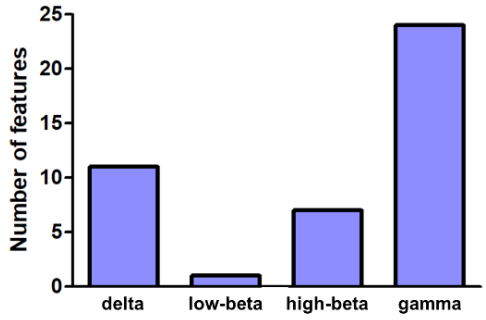

Fig. 1 Features used for classification for each frequency band (delta band: 11, low-beta band: 1, high-beta band: 7, gamma band: 24)

We also investigated the spatial distribution of selected 43 features where is the important brain locations when differentiating MDD patients from HCs. Most of selected channels were located in central area regardless of frequency bands. Fig. 2 represents the location of selected features, red color indicates the selected channels and blue color represents the not-selected channels.

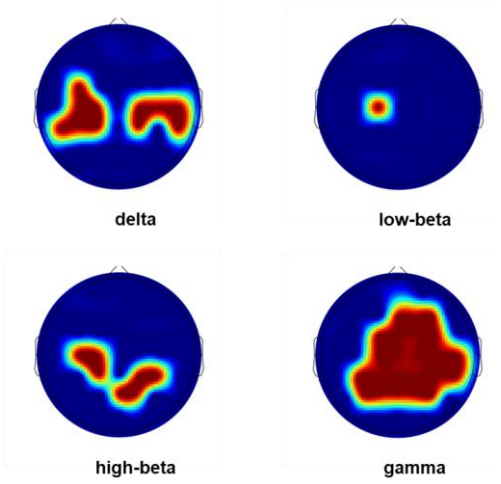

Fig. 2 Topographical map to represent selected 43 features when achieving the best classification performance.

IV. Conclusions

In the present study, we developed a machine-learning-based diagnostic tool utilizing the EEG-based PSD features to assist accurate diagnosis for drug-naïve male MDD patients. The best classification accuracy of 93.33 % was obtained when using 43 PSD features, and the more than half of selected features were allocated in high-frequency bands, such as low-beta, high-beta, and gamma. Moreover, the selected features were predominantly located in the central area of the brain.

Even though the developed EEG-based CAD system showed the high diagnostic performances, there were limitations. First, in this study, only male MDD patients were recruited. To improve the feasibility, the generalized EEG-based CAD system, which can be used regardless of gender, by recruiting female MDD patients. Moreover, in this study, EEG-based features were extracted by hand-craft engineering, which cause low computation efficacy and human-related diagnostic error. Therefore, to improve efficacy and minimize human-related error, the semi-automatic diagnostic tools should be developed by using deep-learning techniques.

In conclusion, we developed the machine-learning-based CAD system using gender-specific EEG-based features to assist accurate and objective diagnosis of drug-naïve male MDD patients and achieved the high diagnostic accuracy. Our developed machine-learning-based CAD system can be a promising diagnostic tool to timely diagnose the male MDD patients.

***Abstract* — The near-infrared spectroscopy (NIRS) measures changes in brain signals which quantify the concentration changes of oxygenated hemoglobin and deoxygenated hemoglobin. Previous studies mainly focused on developing models that can learn the characteristics of NIRS signals to improve the performance of classification models. In this study, we investigate to optimize the input data shape in order to extract the relevant features from NIRS signals using Shallow ConvNet, a deep learning model in a brain-computer interface research.**

I. Introduction

A brain-computer interface (BCI) is a technology that reads neural signals from the brain using invasive and non-invasive devices, processes the signals, and interprets them using computers. In BCI research, two commonly used brain neural signals are electroencephalography (EEG) and near-infrared spectroscopy (NIRS) signals. EEG is measured the electrical activity in the brain, while NIRS is measured changes in the concentrations of oxygenated hemoglobin (HbO) and deoxygenated hemoglobin (HbR) in the cerebral region.

Reference [1] showed that a mental arithmetic task can be interpreted using BCI. During mental calculations of simple math problems, the subjects' brain activity was measured. Based on the brain signals, it was determined whether or not the participants had successfully performed the task. Reference [1] reported classification accuracy for NIRS data using a machine learning model called shrinkage linear discriminant analysis (sLDA). Recent research has been actively conducted not just on machine learning models, but also on deep learning models. Because deep learning models have the advantage of being able to automatically learn features from data and effectively capture complex patterns or abstract features with their hierarchical structures. In particular, researchers have focused on developing deep learning models to enhance classification performance.

However, the purpose of this study is to find optimal input data for effective learning rather than developing complex models. To be specific, we identify the optimal input data that enables effective learning of the signal's characteristics in a deep learning model, Shallow ConvNet, using NIRS signals.

We also test the model with two different input data used in NIRS signals to investigate its applicability on NIRS data.

II. Method

A. Used Deep Learning Model

Shallow ConvNet is a deep learning model inspired by the filter bank common spatial patterns (FBCSP) pipeline [2]. It contains temporal and spatial convolutional layers, each of which learns information about time and channels, respectively (see Fig. 1). Therefore, for the above reasons, this model has been widely used for EEG data analysis.

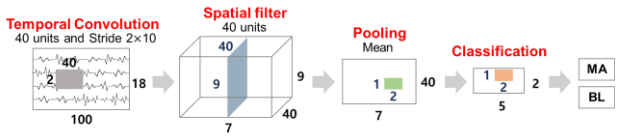

Fig. 1 Shallow ConvNet architecture with hyperparameters adjusted through a cross-validation.

We adjusted the hyper-parameters specifically for NIRS since the data size is small using the inner loop of nested cross-validation. Additionally, we modified the kernel size and stride in the pooling layer to address the issue of the kernel size being larger than the data size. Several other hyper-parameters were also fine-tuned, such as dropout rate, learning rate, and batch size.

TABLE I

HYPER-PARAMETER SETTINGS

Hyper-parameter	Hyper-parameter setting
Kernel size in temporal	40
Stride in temporal	10
Kernel size in pooling	2
Stride in pooling	1
Kernel size in final	2
Drop out	0.5
Learning rate	0.1
Batch size	2

Temporal: Temporal layer. Pooling: Pooling layer. Final: Final layer.

B. *Experimental procedure*

An open dataset for an EEG and NIRS hybrid BCI was used in this study [1]. We only used NIRS data of twenty-nine subjects which were measured while the subjects performed mental arithmetic (MA) and resting-state (RS) tasks. The experiment consisted of three sessions, and each of which consisted of 10 trials for the MA and RS tasks, respectively; a single trial consisted of an instruction period of 2 s, a task period of 10 s, and a rest period of between 15 to 17 s (see Fig. 2).

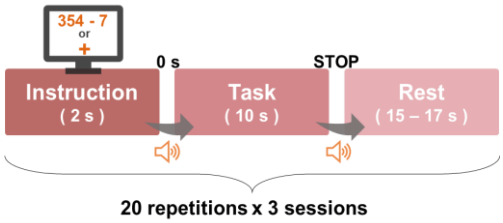

Fig. 2 Schematic sequence diagram of the experimental paradigm.

C. *Data collection and processing*

The NIRS signal was collected from thirty-six channels and and one channel consists of a pair of source-detectors. However, we used nine NIRS channels in the prefrontal cortex, which are well known to be associated with cognitive tasks (see Fig. 3).

The data was collected at 12.5 Hz sampling rate. The collected data were downsampled at 10 Hz, meaning that 10

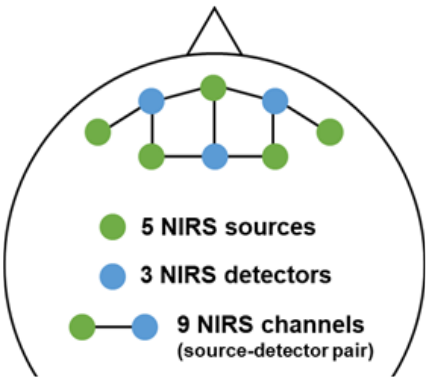

Fig. 3 Placement of NIRS sources and detectors. Gray solid lines are NIRS channels.

data samples exist per second. Concentration changes of the HbO and HbR were estimated using the modified Beer-Lambert law [3]. High-frequency instrument noise, as well as low-frequency components such as heartbeats and respiration, were removed from the HbO and HbR signals using bandpass filtering with cutoff frequencies of 0.01 and 0.1 Hz. The filtered data were epoched from -5 to 10 s based on the onset time, and baseline correction was performed using average values of -5 to -2 s for each epoch.

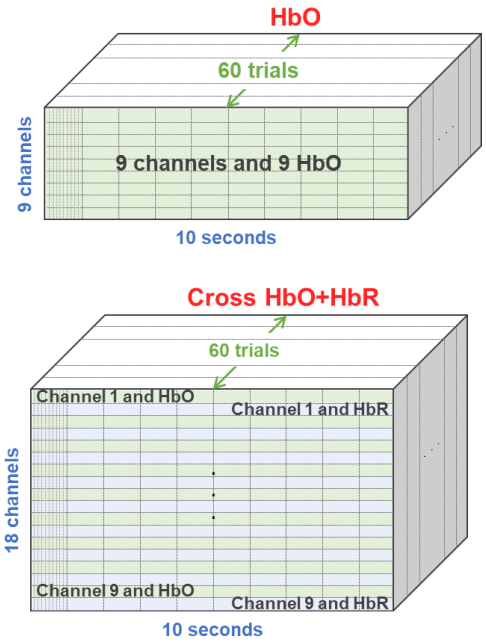

Fig. 4 Input data shape of Shallow ConvNet

After performing baseline correction, we generated two types of input data: HbO data and Cross HbO+HbR data (see Fig. 4). The latter involves concatenating the HbO and HbR

data for each channel, column by column. Each type of input data was used as input for the Shallow ConvNet.

In order to find hyper-parameters for NIRS data, cross-validation was performed using the input data. Nested cross-validation involves an outer loop and an inner loop. In the outer loop, a 5-fold cross-validation was performed to evaluate the performance of the model. In the inner loop, a 4-fold cross-validation method was used to determine the optimal hyper-parameters.

III. Results

We examine the performance of the Shallow ConvNet model to determine which data type, HbO or Cross HbO+HbR, better captures the information present in the NIRS data.We present the classification accuracy for each subject when HbO and Cross HbO+HbR are used. When using HbO, and Cross HbO+HbR data, the classification accuracies were 74.94 ± 10.43% and 76.26 ± 11.68%, respectively (See TABLE II).

TABLE II

Classification Accuracy per Subject in The Shallow ConvNet

Sub: Subject, Avg: Average.

The classification accuracy was relatively higher when using both HbO and HbR as input data compared to using them independently. Furthermore, we confirmed that the fNIRS-PreT, a newly proposed deep learning model in previous studies, achieved a maximum classification accuracy of 78.53% using the same dataset as our study (see Figure 5).

Therefore, when comparing it with the results of previous research, we confirmed that optimizing the input data of existing deep learning models alone can achieve similar classification performance to developing complex algorithms.

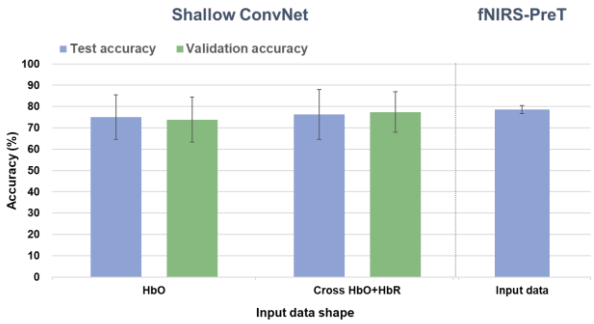

Fig. 5 The average classification accuracies in Shallow ConvNet,and fNIRS-PreT

IV. Conclusions

EEG signals contain temporal and spatial information, while NIRS signals provide temporal, spatial, and hemodynamic response information. Many researchers have conducted numerous studies, including proposing new models, to improve the classification performance of deep learning models using these signals, and this research has continued until recently. Among them, Shallow ConvNet is a widely used model for classification using EEG data, as it is considered effective in extracting temporal and spatial features. However, if NIRS signals are used as input data for this model, it is possible that the effective learning of hemodynamic response information in the signals cannot be guaranteed.

Therefore, it is necessary to develop a new model that can effectively capture the characteristics of these signals or find an input data shape that enables existing models, such as a shallow ConvNet, to extract the features of NIRS signal, in order to enhance the classification performance of the deep learning model using NIRS signals. However, we have confirmed in previous studies that the structure of the newly developed model is complex. Therefore, in this study, our aim was to find the optimal input data shape that enables the existing model to effectively learn the hemodynamic information contained in NIRS signals, without the necessity of developing complex models. We used NIRS data collected during MA and RS tasks, which underwent pre-processing to generate two different shapes of input data. These data shapes were subsequently fed into the Shallow ConvNet, and their performances were compared to determine the optimal input data shape.

As a result, we confirmed that optimizing the input data of the deep learning model, we can achieve classification performance comparable to developing complex algorithms.

In future works, we aim to enhance the classification performance by utilizing a more diverse combination of HbO and HbR, as well as optimizing the deep learning model.

***Abstract*—This study proposes a method for detecting and correcting defective data read from drifted humidity sensors used in the greenhouse, leveraging a nested Kalman filter approach with two components: an inner Kalman filter and an outer Kalman filter. The inner Kalman filter is built using data from neighboring sensors. It serves as the prediction for the outer Kalman filter, where its measurement is the data from the sensor of interest (in a defective data case) or from interpolation of neighbor sensors (in a severely defective data case). Analysis based on the standard deviation value of sensor data is used to classify the data into three cases: normal, defect, and severe defect. In the first case, the sensor data are considered trustable. In the last two cases, the data are corrected accordingly using the nested Kalman filters. Experimental results demonstrated significant improvement in accuracy. The mean absolute deviation (MAD) and the root-mean-square error (RMSE) between the corrected data and ground truth reduced when applying the proposed method. The experiments were conducted in two scenarios. The first scenario involves a sensor of interest that exhibits all three data cases: normal, defective, and severely defective data. The second scenario focuses on a sensor that mainly experiences two cases: normal and defective. The MAD decreased by approximately 75.71% and 50.93% in the former and the latter, respectively. Likewise, the RMSE dropped by about 66.41% and 41.80%, respectively. Therefore, the proposed method provides an effective and reliable technique for defective data detection and correction in humidity sensors where accurate and stable humidity measurement is critical.**

I. Introduction

Intelligent agriculture has emerged as a vital factor in improving the quality and quantity of farm products [1]. The main objective of intelligent farming systems is to supervise and manage the environmental conditions essential for the well-being and growth of plants and animals [2][3]. Temperature, humidity, and light intensity are among the critical environmental factors that play a crucial role in various applications, including agriculture, horticulture, and environmental monitoring [4]. In this study, the primary focus is on maintaining optimal conditions in orchid greenhouses, where the quality of the orchids heavily depends on precise humidity control. Humidity is a crucial parameter that significantly influences the health and growth of orchids, and any deviation from the required levels could adversely affect their well-being. Despite its importance, monitoring humidity poses a significant challenge for automated systems. Humidity sensors, particularly when exposed to high humidity environments like orchid greenhouses for prolonged periods, often degrade over time [5]. This degradation can lead to incorrect values over time, adding another layer of complexity to the precise maintenance of the desired humidity levels. Consequently, data from humidity sensors can become defective, leading to inefficient control and decision-making in intelligent farming systems. In order to address the challenges associated with defective data, farmers must regularly inspect the status of sensors installed in greenhouses and the quality of the collected data. Intelligent farming systems can support farmers in identifying defective data, potentially caused by drifting sensors or other factors, and automatically correcting the data to enhance the overall performance and accuracy of the system. Therefore, the scope of this work is focused on developing methods to detect and correct defective humidity data in high-stakes environments, such as orchid greenhouses, where the maintenance of humidity sensors is of paramount importance. Consequently, data from humidity sensors can become defective, leading to inefficient control and decision-making in intelligent farming systems. In order to address the challenges associated with defective data, farmers must regularly inspect the status of sensors installed in greenhouses and the quality of the collected data. Intelligent farming systems can support farmers in identifying defective data, potentially caused by drifting sensors or other factors, and automatically correcting the data to enhance the overall performance and accuracy of the system.

Various techniques for detecting and correcting sensor drift

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

have been proposed [6][7][8]. For instance, Dheeraj *et al.* proposed a spatial kriging and Kalman filtering-based automatic drift detection and correction approach [6]. Their method proved resilient to drift and surpassed traditional average interpolation techniques [6]. However, kriging interpolation faces accuracy limitations when dealing with a few data points. Zhan *et al.* adopted a clustering method and a Kalman filter to address the same challenge [7]. Their strategy did not rely on heavy assumptions or prior data model knowledge, and the results demonstrated improved data reliability and robustness in noisy situations [7]. However, the method's singular value decomposition (SVD) led to considerable computational time complexity. Therefore, it is not suitable for real-time applications. Zenisek *et al.* used a machine learning approach for drift detection to forecast maintenance needs for industrial equipment [8]. They applied three machine learning algorithms, i.e., linear regression, random forest regression, and symbolic regression, to assess the machine's state and generate alerts if data began to drift into unknown territory [8]. However, while such machine learning techniques can offer valuable solutions, they also present certain challenges. Primarily, the performance of these algorithms heavily relies on the quality of the training dataset. Furthermore, ensuring that the employed dataset genuinely represents the complete range of potential data variations is another challenge. If the dataset lacks representativeness, the effectiveness and reliability of the machine learning model could be compromised.

In our preliminary research, we focused on enhancing the accuracy of humidity sensors using nested Kalman filters. This approach significantly improved the precision of the sensor readings [9]. However, that approach lacked a detection mechanism. It showcased the potential of nested Kalman filters for addressing drift in humidity sensors, indicating that further improvement could be achieved by incorporating a detection component. In another previous work, we proposed a method that utilized a Kalman filter with an artificial neural network to detect sensor drift and correct humidity data obtained from drifting sensors [10]. The method demonstrated a significant reduction in accumulated mean absolute deviation. However, the detection process required daily data samples to classify the sensor's status, and the neural network relied solely on time as input. This led to the Kalman filter use a single prediction value for each sample every day, resulting in an unreliable outcome due to its inability to fully capture the complexities of sensor drift. Additionally, a parameter relating to the variance of the process noise of the Kalman filter was fixed daily, which is an unrealistic assumption concerning the dynamic nature of sensor drift. Therefore, in this study, we propose a new method that focuses on analyzing and detecting data status every 4 hours, providing a more adaptive approach to correcting defective and severely defective data in drifting humidity sensors. This method aims to address the limitations of previous approaches by leveraging the strengths of the nested Kalman filter. Our current work incorporates two main components for correcting defective and severely defective data: the inner Kalman filter, which is built using data from neighboring sensors and serves as the prediction state for the outer Kalman filter, and the outer Kalman filter, which uses the inner Kalman filter's prediction state and measurements from the sensor of interest or bicubic interpolation of neighbor sensors to correct the inaccurate humidity value. By focusing on fixing defective data and refining the nested Kalman filter approach, our method aims to accurately identify and rectify the distorted humidity readings, restoring the data to its appropriate values and maintaining the sensor's accuracy and reliability.

The rest of this paper is structured as follows: Section 2 offers a concise overview of the essential background information and concepts relevant to our proposed framework and an outline of the monitoring system and the one-dimensional Kalman filtering algorithm employed in our experiments. In Section 3, we delve into the specifics of the proposed method. Section 4 presents the experimental results and performance evaluation of the proposed method. Section 5 discusses our findings and interprets the outcomes, highlighting the strengths and potential limitations of the method and its implications for future research and practical applications. Finally, Section 6 summarizes the work presented in this paper.

II. Background

This section provides an overview of our monitoring system implemented to gather the data utilized in this study. Additionally, a brief introduction to the one-dimensional Kalman filter is also included in this section.

A. Overview of a monitoring systems

Our monitoring system is implemented in greenhouses at NECTEC, NSTDA, Thailand, spanning an area of 6×20 square meters. This system is comprised of 21 humidity sensors with two data loggers (logger (a) and logger (b)). Each humidity sensor is responsible for monitoring a 2×2.5 square meter area, as illustrated in Fig. 1. Data from the humidity sensors is transmitted to a data logger, which reformats and forwards the information to the gateway. The data from all the loggers is periodically transmitted to a database via a GPRS network using the gateway. This allows users to access the data through a web browser. Digital SHT31 humidity sensors from Sensirion are used in this greenhouse, which operate by measuring capacitance. Over time, the collected humidity data may become defective due to factors such as sensor aging, environmental changes, or manufacturing defects. Inaccurate measurements lead to the generation of defective data and can adversely affect the efficiency and effectiveness of greenhouse operations.

B. One-dimensional Kalman filtering

The Kalman filtering algorithm encompasses two primary stages: prediction and measurement update [11]. The fundamental assumption of this algorithm is that a linear system can

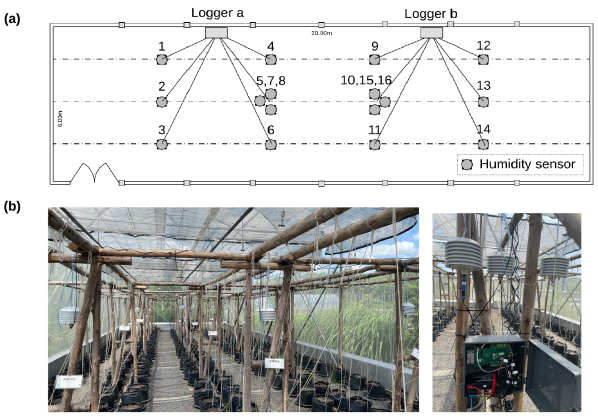

Fig. 1. Sensor location inside the greenhouse in NECTEC, NSTDA, Thailand: (a) diagram of the locations in association with the dataloggers and (b) image of the inside environment.

be delineated using one state equation and one measurement equation. These equations are as follows:

$$x_k = Ax_{k-1} + Bu_{k-1} + w_{k-1}, \tag{1}$$

and

$$y_k = Cx_k + v_k, \tag{2}$$

where x_k denotes the state at time k, u_{k-1} is an input at time $k-1$, w_{k-1} is process noise with a mean of zero and a variance of Q at time $k-1$, y_k represents a measured output at time k, v_k is measurement white noise with a variance of R at time k, and A, B, and C are factors associated with the state transition, control input, and the correlation between the measurement and the state, respectively.

The prediction stage involves two steps. Initially, the algorithm utilizes the previous state estimate $\hat{x}_{k-1}$ to predict the *a priori* state estimate $\hat{x}_k^-$ through the equation:

$$\hat{x}_k^- = A\hat{x}_{k-1} + Bu_{k-1}. \tag{3}$$

Note that for $k=1$, $\hat{x}_0$ is an the initial state.

Subsequently, the *a priori* error variance P_k^- is calculated using:

$$P_k^- = AP_{k-1}A + Q, \tag{4}$$

Here, P_{k-1} represents the *a posteriori* error variance, which is defined as the expectation of a posteriori estimate error, $x_k - \hat{x}_k$, times its transpose. For $k=1$, P_0 is an initial error variance.

The measurement update stage is composed of three steps. Initially, the algorithm computes the Kalman gain K:

$$K = \frac{P_k^- C}{CP_k^- C + R}. \tag{5}$$

Then, it estimates the predicted state estimate $\hat{x}_k$:

$$\hat{x}_k = \hat{x}_k^- + K(y_k - C\hat{x}_k^-). \tag{6}$$

Finally, the state error variance is updated:

$$P_k = (1 - KC)P_k^-. \tag{7}$$

III. Proposed Method

The proposed method, as illustrated in Fig. 2, is divided into two main stages: detection and correction. In the detection stage, data from the sensor of interest are compared with the standard deviation (SD) values of humidity readings from neighboring sensors over a four-hour period. This allows us to identify if the data significantly diverges from its neighbors. The thresholds of mean - $2\cdot$SD and mean + $2\cdot$SD are selected based on our observation and the fact that approximately 95% of the data in a normally distributed dataset falls within these boundaries. Here, the mean refers to the average of the neighboring humidity sensor. If the data point is outside these boundaries, the data is considered defective; if it's within, the data is deemed normal. If the data point lies beyond mean - $4\cdot$SD or mean + $4\cdot$SD, it is classified as severely defective. The $4\cdot$SD thresholds are chosen based on our observation and the understanding that the probability of observing a data point beyond these boundaries in a normally distributed dataset is less than 0.00006, indicating a highly unlikely deviation. The primary task of the first stage is to categorize the data into three groups: normal, defective, and severely defective.

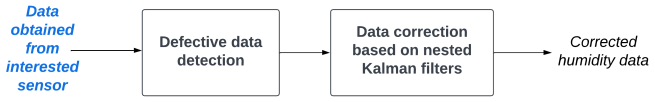

Fig. 2. Framework of proposed method.

The second stage, correction, depends on the classification of the data obtained in the first stage. If the data is normal, it remains unchanged and is used as is. If the data is defective, a nested Kalman filter is employed, structured as shown in Fig. 3(a). For severely defective data, the nested Kalman filter is also used with the structure depicted in Fig. 3(b). The difference between Fig. 3(a) and Fig. 3(b) is the use of bicubic interpolation in the latter. Bicubic interpolation estimates missing data using values and derivatives of humidity values from neighboring sensors. Performed on a 3×3 grid of data points, it considers the 8 nearest neighbor sensors, providing a smooth and continuous estimation of severely defective humidity data. Furthermore, this approach ensures the accurate estimation of severely defective values even in challenging scenarios, as it takes advantage of both the prediction and measurement states. In defective data and severely defective data cases, nested Kalman filters are employed to correct the humidity values. The outer Kalman filter uses the following state and measurement equations:

$$x_k = x_{k-1} + w_{k-1}, \tag{8}$$

and

$$y_k = x_k + v_k, \tag{9}$$

where x_k is the estimated humidity value at the location of interest at time k, w_{k-1} is the process noise at time $k-1$, y_k is the data read from the sensor at the location of interest at time

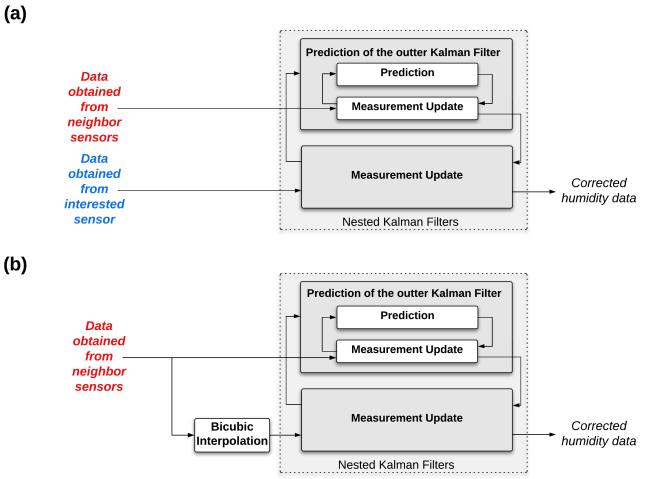

Fig. 3. Block diagrams of proposed method: (a) defective case and (b) severely defective case.

k in the *defective data* case, and y_k is the data obtained from the bicubic interpolation at time k in the *severely defective data* case. Lastly, v_k represents the measurement noise at time k.

The inner Kalman filter serves as the predictive model for the outer Kalman filter. Let N be a set of indices representing the neighbor sensors to understand this relationship. The proposed method considers a sequence y_l^p for $l = 1$ to $n(N)$, where $n(N)$ is the cardinality of N. Each y_i in the sequence corresponds to the data read from the neighbor sensor with index i for $i \in N$. Furthermore, the initial state estimates x_0^p are assumed to be the average value of the humidity values of y_i for all is. With these assumptions, the inner Kalman filter employs the following state and measurement equations:

$$x_l^p = x_{l-1}^p + w_{l-1}^p, \tag{10}$$

and

$$y_l^p = x_l^p + v_l^p, \tag{11}$$

where x_l^p is the estimated humidity value at the neighboring sensor at time l, w_{l-1}^p is the process noise at time $l-1$, y_l^p is the data read from the neighboring sensor at time l, and v_l^p is the measurement noise at time l.

The Q values for the inner and outer Kalman filters are set to 0.01 and 1, respectively, obtained through trial and error. These values represent the process noise covariance for each filter, reflecting the uncertainty in the model and the correction process.

IV. Experiment and Results

This section presents the experimental setup and results of the proposed method for detecting and correcting defective relative humidity data in greenhouse environments. First, the experimental setup is described, including the data collection process, sensor arrangement, and parameters used in the study. Next, the experimental results are discussed, highlighting the method's performance in detecting and correcting defective data. Finally, the analysis of the results demonstrates the effectiveness of the proposed method.

A. Experimental Setup

In this study, humidity data are collected from sensors placed in a greenhouse and transmitted to the database every 5 minutes, resulting in 288 data points per day. The experiment is divided into two scenarios to demonstrate the effectiveness of the proposed method in handling varying sensor conditions. Each scenario utilizes humidity data gathered from distinct sensor locations within the greenhouse, as illustrated in Fig. 4.

The first scenario involves a sensor of interest that exhibits all three data cases: normal, defective, and severely defective data. The second scenario focuses on a sensor that mainly experiences two cases: normal and defective. This distinction between scenarios allows for a comprehensive evaluation of the proposed method's ability to detect and correct the defective data issues read from drifted humidity sensor, improving the accuracy and reliability of the sensor readings across different situations.

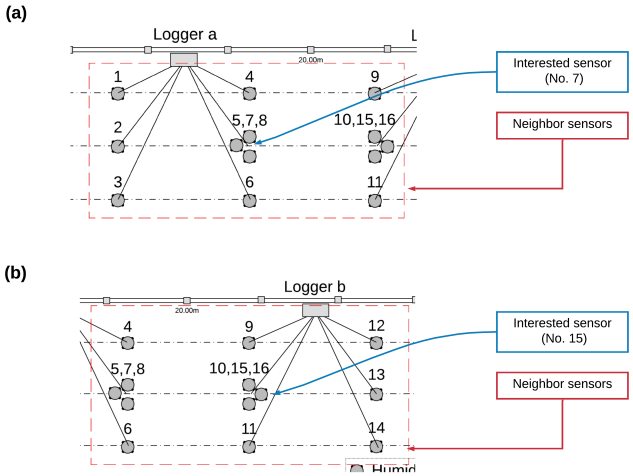

Fig. 4. Positions of sensors used in this experiment: (a) first scenario and (b) second scenario.

Since N is the set of indices of the neighbor sensors in the correction part, in this experiment,
$N = \{1, 2, 3, 4, 6, 9, 10, 11\}$, for the first scenario, and
$N = \{4, 5, 6, 9, 11, 12, 13, 14\}$, for the second scenario.

The humidity data in the NECTEC greenhouse were used. The duration for data analysis is about 61 days, i.e., from 1 June 2021 to 31 August 2021. This experiment aims to apply the proposed method to estimate the actual humidity value read by sensor No. 7 for the first scenario or sensor No. 15 for the second scenario, which is the location of interest. In other words, sensors No. 7 and No. 15 are somehow defective or drifted.

To evaluate the proposed framework, we use accumulated mean absolute deviation (MAD) and the root mean squared error (RMSE) to evaluate this experiment. In the first scenario,

sensor No. 5 serves as the reference for evaluating MAD and RMSE, as it provides readings close to sensor No. 8, which is well-maintained and installed to read values only during specific periods of certain days (to minimize sensor drift). Thus, sensor No. 5 is the reference sensor for this scenario. Similarly, in the second scenario, sensor No. 10 serves as the reference for MAD and RMSE, as it is positioned closely and provides readings close to sensor No. 16, which is also installed and maintained in the same manner as sensor No. 8. Therefore, in both scenarios, the reference sensors (No. 5 for the first scenario and No. 10 for the second scenario) are used to compare the outputs of the proposed method and calculate MAD and RMSE values.

The following equation defines the MAD:

$$\text{MAD} = \frac{1}{n}\sum_{k=1}^{n} |x_k - z_k| \,. \tag{12}$$

The following equation defines the RMSE:

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{k=1}^{n}(x_k - z_k)^2}, \tag{13}$$

where n is the number of data points, and z_k is humidity value from reference sensor No. 5 for the first scenario, or sensor No. 10 for the second scenario at time k.

B. Experimental Result

Upon applying the proposed method for detecting and correcting defective and severely defective data read from drifted humidity sensor, a substantial reduction in accumulated mean absolute deviation with reference to the sensor was observed. For the first scenario, the decrease was approximately 75.71%, while for the second scenario, it was approximately 50.93%. Similarly, the RMSE for the first and second scenarios dropped by approximately 66.41% and 41.80%, respectively, as shown in Table I. In comparison, the results from the previously proposed method, which utilized two nested Kalman filters without the detection part [9] (mentioned as *previous* in Table I), showed lower reductions in RMSE and MAD. This significant improvement in the accuracy of humidity measurements in both scenarios highlights the effectiveness of the proposed method in detecting and correcting issues related to defective and severely defective data in humidity measurements.

TABLE I
COMPARISON OF RMSE AND MAD REDUCTION BETWEEN THE PREVIOUS AND PROPOSED METHODS FOR BOTH SCENARIOS.

Sc.	Method	RMSE reduction	MAD reduction
1	Previous [9]	42.87%	43.18%
	Proposed	66.41%	75.71%
2	Previous [9]	30.24%	31.78%
	Proposed	41.80%	50.93%

The simulations were conducted on an ASUS ROG STRIX G17 laptop equipped with an AMD Ryzen 7 6800H processor, 16 GB DDR4 RAM, and GEFORCE RTX3050. The computational time for simulating the proposed method for a single day is approximately 5-7 seconds.

Preliminary experimentation with adjusting thresholds for detecting defective data has revealed a pattern when broadening or narrowing the thresholds. It was found that excessively widening the detection range leads to an inability to distinguish severely defective data in certain instances. This implies that the detection process predominantly identifies only moderately defective data, consequently impacting the overall performance of the subsequent defective data correction steps. On the other hand, setting the detection threshold too narrowly results in the identification of mainly severely defective data. This implies that each instance of correcting defective data necessitates extensive interpolation, increasing computational time, i.e., an increase of up to around 30% was observed when setting the threshold too narrowly to the point where all data were detected as severely defective.

V. DISCUSSION

In both scenarios, the proposed method demonstrated significant improvements in the accuracy of humidity sensor readings, effectively detecting and correcting defective and severely defective data issues. Fig. 5 shows the example results in one day. The enhanced reliability and consistency of the sensors' measurements are crucial for various applications in agriculture, meteorology, and environmental monitoring. Notably, the proposed method showed a considerable improvement compared to the past work when the sensor was in a very bad state, having both defective and severely defective data. Furthermore, the method's superior performance in the more challenging first scenario, where the sensor experienced all three statuses (normal, defective, and severely defective), indicates its effectiveness in handling complex and varying sensor conditions.

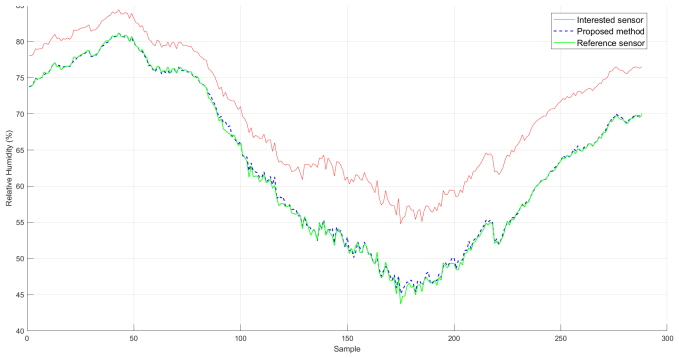

Fig. 5. Applying the proposed method to correct the defective data in the interested sensor.

The second scenario also demonstrated the method's adaptability and robustness in dealing with less severe drift issues, where the sensor exhibited mainly normal and defective statuses. In this scenario, the interested sensor was not very bad, leading to a lower percentage improvement. Nevertheless, this versatility suggests the potential applicability of the proposed

method to other types of sensors and situations where similar data issues may arise, making it a valuable tool in sensor data correction with possible applications beyond humidity sensors in various domains.

The chosen positions for the interested sensor placement influence the performance of the proposed method. A higher density of neighboring or surrounding sensors with normal reading capabilities enhances the performance of the proposed method. Acknowledging that accurate corrections cannot be achieved if most neighboring sensors cannot provide normal readings is crucial.

In the current study, the inner and outer Kalman filter's Q values were fixed based on trial and error, similar to our previous work. Although this approach yielded significant improvements in the accuracy of humidity sensor readings, there is still room for further investigation in optimizing the Q values. Adapting the Q values dynamically or exploring alternative optimization techniques could enhance the performance of the proposed method, leading to even better results in detecting and correcting defective and severely defective data. Exploring these possibilities in future research could contribute to developing more robust and efficient solutions for fixing drift and malfunction issues in humidity sensors, ultimately benefiting various agriculture, meteorology, and environmental monitoring applications.

VI. Conclusions

In conclusion, this research has presented and evaluated a novel method for detecting and correcting defective and severely defective data in humidity measurements using nested Kalman filters and bicubic interpolation. The proposed method combines standard deviation-based detection nested Kalman filters. The experimental results have demonstrated significant improvements in the accuracy of humidity measurements across two different scenarios, with varying degrees of defective and severely defective data.

***Abstract*—The popularity of autonomous driving and advanced driver assistance systems can potentially reduce thousands of car accidents and casualties. In particular, pedestrian prediction and protection is an urgent development priority for such systems. Prediction of pedestrians' intentions of crossing the road or their actions can help such systems to assess the risk of pedestrians in front of vehicles in advance. In this paper, we propose a multi-modal pedestrian crossing intention prediction framework based on the transformer model to provide a better solution. Our method takes advantage of the excellent sequential modeling capability of the Transformer, enabling the model to perform stably in this task. We also propose to represent traffic environment information in a novel way, allowing such information can be efficiently exploited. Moreover, we include the lifted 3D human pose and 3D head orientation information estimated from pedestrian image into the model prediction, allowing the model to understand pedestrian posture better. Finally, our experimental results show the proposed system provides state-of-the-art accuracy on benchmarking datasets.**

I. Introduction

Automotive technologies are developing toward autonomous driving. Autonomous driving or ADAS (Advanced Driver Assistance Systems) can significantly improve safety by reducing accidents caused by human mistakes or careless driving behaviors. Pedestrian Crossing Intention Prediction is a crucial task in this type of system. It tries to predict the pedestrian's intention of crossing the road by analyzing pedestrian images, postures, behaviors, and information about the surroundings of pedestrians.

In recent years, research in this field has considerably increased. The introduction of JAAD [1] and PIE [2] datasets has enabled researchers to develop pedestrian trajectory, behavior, and crossing intention prediction tasks more effectively. A model using CNN and RNN architectures for pedestrian crossing intention and trajectory prediction was proposed in the paper of PIE dataset, which demonstrates the RNN model's ability to process sequence information in this task. Other methods [3] [4] [5] [6] [7] have started to introduce a series of information related to pedestrians, such as human pose and trajectory. Besides, surrounding environment data has also been introduced, such as ego-vehicles speed, surrounding environment images, and traffic status.

However, there are still more additional information that has not be exploited into this task. Both datasets provide quite rich road environment information that has not been fully utilized. In addition, with the introduction of the Transformer [8], it becomes a more suitable model architecture for predicting pedestrian crossing intention because of the advantage of being parallelizable for real-time computation and the ability to model the temporal information of sequential data.

A benchmark for evaluating pedestrian action prediction [9] has also been released. This evaluation standard solves the problem of inconsistent standards for comparing previous methods. However, we have observed that the testing environment in several previous works may not necessarily follow the benchmark settings.

In this paper, We focus on exploring different data and model structures to find a solution that could handle more complex scenarios and provide reliable performance while following the Benchmark [9] settings. The main contributions of this paper are summarized as follows:

- We propose a multi-modal method based on Transformer architecture and use nine different types of input data for predicting pedestrian crossing intention, and it achieves state-of-the-art performance.
- We are the first to combine Traffic light, Crosswalk, and Road Sign data into new Traffic Perception Data. This strategy has been demonstrated to improve the accuracy of our method through experiments.
- Our method uses lifted 3D human pose and 3D head orientation information to provide 3D pedestrian information for the model, which allows it be adapted to a wide variety of scenarios.

II. Related Work

Pedestrian crossing intention prediction is an important part of ADAS systems and self-driving cars, so there have been many related studies in the past. Initially, some methods directly analyze the possibility of pedestrians crossing through a single image [1] [10] [9]. However, because only a single image was used for analysis, there was insufficient contextual information to infer pedestrian behavior accurately.

A. Sequential Modeling

Some methods that use sequential data as input have also been proposed [2] [3]. These methods consider the changes

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

in various features of pedestrians over a period of time. The model can analyze pedestrians' motion which is related to its possible future location. RNN models were introduced to process these sequential data. They can handle the temporal information at different time steps in contextual data. Compared with those based on single-time information, this approach brings breakthroughs and accuracy improvements to this field.

B. Exploration of Novel Inputs

Since then, many representative trajectory-based methods have been developed [11] [12]. These methods determine the likelihood of a pedestrian crossing by analyzing the pedestrian's trajectory, thus enhancing the reliability of the model in predicting the crossing intention through explicit future trajectories of pedestrians. Previous works have also tried to utilize more information about pedestrians from different angles of pedestrian images. For example, in [13] [11], they attempted to determine pedestrians' trajectories, appearance, or social states from an eagle-view perspective, which can prevent pedestrians from being blocked by other objects on roads.

However, pedestrian trajectories, i.e., pedestrian motion, are extremely diverse and unpredictable. For example, when a pedestrian is stationary or has minimal movement, there is almost no "trajectory" for the pedestrian to predict their future movement. Furthermore, eagle view data is difficult to obtain in real-world scenarios.

Some works enhance the prediction accuracy through the visual aspects. First, [3] [2] [7] [9] used the image of the pedestrian itself and also considered the surrounding images of the pedestrian. These data show the interaction between pedestrians and surrounding objects and supplement information about the environment in which the target pedestrian is located. Some methods introduced semantic segmentation information [7] [4] so that the model can analyze the road appearance and traffic conditions where the target pedestrian is located. However, relying only on visual information is easily affected by the diversity of training data and the quality of images. In addition, semantic segmentation information may bring adverse results when computing in real-time scenarios because of its large amount of computation.

Therefore, some literature turned their attention to pedestrians themselves and introduced human pose information due to the posture and behavior of pedestrians are closely related to whether they will cross the road. For example, pedestrians often use gestures to communicate with drivers to express their desire to cross. However, we believe there is room for improvement in these methods, as most of the methods lack 3D information on pedestrian posture. This 3D information would provide information on pedestrian orientation, hand movements, and potential crossing behavior in such tasks.

Pedestrians also will swing their heads to look both ways to confirm whether cars are coming and interact with the vehicle driver with eye contact and nods. Thus, the pedestrian head pose is valuable for reference. Head orientation is less mentioned in this field than the human pose. In [6] [4], they segment the pedestrian's head or body orientation into eight discrete directions as input. However, they only focus on a single dimension of the horizontal rotation of the pedestrian. In [14], they introduced 3D head orientation including the dimensions pitch, roll, and yaw, and used the head rotation angle as a scale. But this method relies mainly on the head direction to determine pedestrian intention and does not consider other pedestrian features, which is still unreliable.

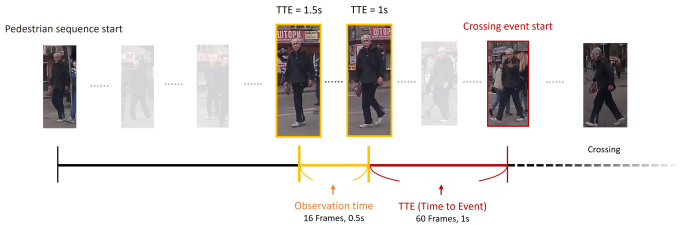

Fig. 1. Definition of TTE and observation time. The yellow part indicates the range where the model can observe and make predictions. This range must be prior to the time "TTE" before the pedestrian starts to cross the road.

In addition, the environment around pedestrians and traffic-related information are also very critical. In [2], they included ego-vehicle speed as an input to their prediction model and mentioned that vehicle speed critically influences whether pedestrians cross the road. Since then, vehicle speed information has become common in most literature. Another paper [5] used the presence of traffic lights or crosswalks and the distance between the pedestrian and vehicle to calculate a value as input information. Although the PIE and JAAD datasets provide a wealth of information about the traffic environment above, much of the previous methods did not consider this, and this information would be worth exploring.

III. Proposed Method

A. Problem Statement

According to the definition of the benchmark, pedestrian crossing intention prediction is defined as a binary classification problem. Various information related to pedestrians is used as model input data. The model will give a prediction result of "crossing" or "non-crossing," which corresponds to the "1" or "0" of the output.

A pedestrian crossing in front of the ego-vehicle is defined as crossing, while any pedestrian that does not cross the path of the ego-vehicle is defined as non-crossing, e.g., a pedestrian walking in the same direction as the ego-vehicle.

The model needs to complete the prediction in advance before the pedestrians start to cross within the time that model can observe the input sequence. This advance is called TTE (Time-To-Event), which refers to the interval between the last frame of model observation time and the start of the pedestrian crossing. The concept of TTE and observation time can refer to Figure 1.

B. Module Architecture

The overall architecture of the proposed pedestrian crossing intention prediction system is illustrated in Figure 2. The

proposed system consists of two parts – the Feature Pre-processing Module and the Prediction Module. More details on these two modules will be described in the following sections.

*1) **Feature Pre-processing Module**:* To predict the pedestrian crossing intention, we rely on several different types of data as a basis for model prediction. Each data has a different relationship with the target pedestrian and can be used to determine whether the pedestrian wants to cross the road under different circumstances. The Feature Pre-processing Module is responsible for converting or extracting the original input data so that various types of data can be used to help the model train in the most effective way.

Traffic Perception Data: In our method, the Traffic Perception Data can help the model understand the surrounding traffic conditions in which the pedestrian is located. It consists of three different types of information: The traffic light state for the lane where the ego-vehicle is located, the presence of specific signs, and the presence of crosswalks in the current frame. These three data types are represented in a unique way to provide road environment traffic information.

*a) **Traffic Light**:* Based on the observations of failure cases, we found that many samples can preliminarily infer the possibility of a pedestrian crossing through the status of traffic lights for the lane in which the ego vehicle is traveling. In this method, we directly use the traffic light status provided by the dataset and transform the representation into a 3-dimensional array as training data. Where [1,0,0] represents a red light, [0,1,0] represents a yellow light, and [0,0,1] represents a green light, [0,0,0] represents no traffic light in the current frame. The values of each dimension have two states - 1 or 0, representing whether the corresponding light is on or off.

*b) **Road Sign**:* Road signs provide information on the right-of-way and the order of passage among road users. Pedestrians or passing vehicles will refer to the road signs to take corresponding and appropriate actions. This information can also be found in the dataset, which provides detailed information on the type of road signs in the current frame. However, the training results using detailed road sign types as training data were unsatisfactory due to redundant and divergent information.

Instead, we select the signs directly related to the pedestrian crossing and use the existing state of these signs in the current frame as input data. For example, When a stop sign appears, vehicles on the road will tend to slow down or stop. Or, if a pedestrian sign is present, vehicles will tend to yield to pedestrians. Therefore, we represent the information of specific road signs as a 1-dimensional array. When the array is [1], it represents a stop sign or pedestrian sign in the current frame; when the array is [0], it is the opposite.

*c) **Crosswalk**:* : From the perspective of pedestrians, they are more willing to cross the road in places with crosswalks, which is also a factor to consider as needed. The 1-dimension array [1] represents when the crosswalk is present in the current frame and [0] when it is not.

Traffic Perception Data Fusion: After experimenting with the above three data types, we found that performing an early fusion on these data is more effective for training than feeding the data into the model separately because the model can learn the correlation between different data. Therefore, we fuse these three data by concatenating them into a 5-dimension array.

Pedestrian Behavior Data:

*d) **3D Head Orientation**:* From the discussion in the previous chapter, we can found that knowing whether the target pedestrian is looking at the driver or noticing the vehicle can help the model to analyze pedestrians' behavior. Since head orientation is not provided in the dataset, we need to apply a head orientation detector to obtain this information.

We choose "6DRepNet" [15] as our method to generate the 3D head orientation. It can provide the orientation in three dimensions, i.e., pitch, roll, yaw of the subject's head rotation. Furthermore, the detection angle of pitch and roll covers the range [-90°, +90°], and yaw covers the range of [-180° , +180°]; these ranges cover the full range of human head rotatable angles. The final data format is a 3-dimensional array, e.g., [-10, 23, 128], which represents the current head pitch, roll, and yaw angles, as if a person were tilting their head a bit to the side and lowering their head slightly.

*e) **3D Pedestrian Human Pose**:* The 2D human pose data generated by OpenPose [16] is provided in the dataset. However, as 3D pose information can provide richer information for the model, we use the method proposed by [17] to lift 2D pose data to 3D. The original 2D pose sequence must be converted to the Human3.6M representation the lifting model uses before processing.

Therefore, we interpolate the coordinates to calculate the missing keypoints, such as head, spine, and middle of the hip in Openpose, then convert the pose representation to the format of human3.6M. The lifted format will become 17 joints with three dimensions x, y, z. The final pose data will be represented by a 51-dimensional array like [x1, y1, z1 … x51, y51, z51].

*f) **Pedestrian Bounding Box**:* The pedestrian bounding box coordinates allow us to know the location of pedestrians and the direction of pedestrian movement. The bounding box in the dataset is a 4-dimensional array of [x1, y1, x2, y2], where x1 and y1 correspond to the coordinate points at the top left-hand corner of the bounding box, and x2 and y2 correspond to those at the bottom right-hand corner.

Driving Behavior Data:

*g) **Ego-Vehicle Speed**:* Pedestrians often judge whether it is appropriate to cross the road based on the vehicle's speed. For example, fast-approaching vehicles may cause pedestrians to decide against crossing. The ego-vehicle speed data are available in the datasets and represent as a 1-dimension array. The data in PIE dataset is the GPS speed value of the vehicle driving. In JAAD, it is represented by text labels of the vehicle's motion state, such as [0] represents the stationary state, [1] is moving slow, [2] is moving fast, [3] is decelerating, [4] is accelerating.

Pedestrian Appearance Data:

*h) **Pedestrian Bounding Box Image**:* Pedestrians' appearance information can provide many details and complement other input data, such as pedestrians' behavior and

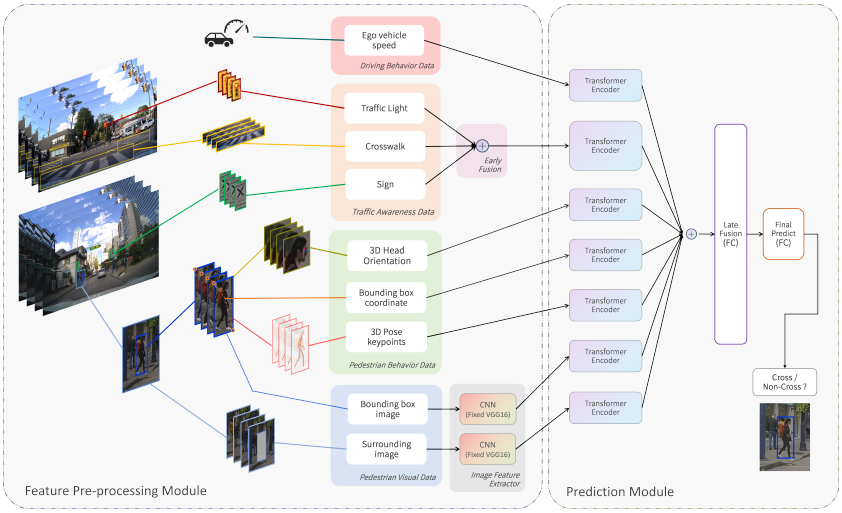

Fig. 2. The overall architecture of proposed pedestrian crossing intention prediction system.

orientation. The pedestrian bounding box image is generated by cropping the pedestrian bounding box coordinates provided by the dataset from the complete image where the pedestrian is located. The size of the image will change according to the pedestrians' location and distance in the image.

i) ***Pedestrian Surround Image****:* Besides the pedestrian appearance information, the surrounding environment around pedestrians is also vital information, which can provide a lot of additional information, such as the location where pedestrians stand, the interaction between pedestrians and surrounding objects, or whether specific objects are around them. The way to generate this information follows the setting of the benchmark dataset. It is cropped and obtained by expanding 1.5 times according to the size of the pedestrian bounding box and filling the original pedestrian bounding box area with gray pixels to present a rectangle with a hollow center. This makes the model pay more attention to visual information in the surrounding environment and avoid being disturbed by pedestrians' appearance.

The above two types of visual information will be pre-processed by a pre-trained VGG16 convolutional neural network for feature extraction same, as in the datasets. The image feature extractor does not participate in the training process. It is only used to generate and extract Image Features for subsequent model training and does not include the top layer part used as a classification. The pedestrian bounding box image and the surround image are fed to the feature extractor to generate a 512-dimensional image feature as training data.

2) ***Prediction Module****:* The Prediction Module is responsible for the part of performing pedestrian intention prediction.

a) Prediction Model Flow: Here, we introduce the model flow for the Prediction Module. The process diagram can refer to the Prediction Module part on the right side of Fig. 2.

After the Data Pre-processing Module generates all the data we need, it will first enter different branches of the Transformer Encoder to encode temporal information and extract features in each sequence. So that it can observe pedestrians' possible crossing intentions within different time steps. The output of the encoder blocks then enters the Late Fusion stage. It will merge data from different branches, comprehensively referencing changes in different data under different conditions and further extracting these features for the final prediction. The fusion stage has two main steps: integrating different features through concatenation, then reducing dimensionality and extracting through a FC(Fully Connected) layer. In the Final Prediction layer, a fully connected layer and a Sigmoid activation function will help to give the final prediction result.

b) Transformer Encoder: The Transformer Encoder block is mainly used in the proposed model. The transformer is released by [8]. One of its major features is that it can analyze and model the information from different time steps in a sequence through a novel architecture and the power of self-attention. Moreover, Transformer has a computational advantage that can be parallelized for processing. Such characteristics and advantages are particularly suitable for use in the pedestrian crossing intention prediction task.

Note that we use only the encoder part of the original Transformer and modify the input embedding layer to a learnable fully connected layer. For the weighted output of the Transformer encoder, we perform a 1D convolutional neural network to integrate the output from different time steps.

C. Loss Function

We use the Focal loss [18] as our loss function instead of Cross Entropy which is commonly used in this field. Focal loss can deal with the fact that models tend to bias towards easy samples in training data and ignore hard samples. This will cause the model to make mistakes when more complex or uncommon data appear.

Focal loss [18] reduces the weight of easy samples and forces the model to pay more attention to hard samples. To be

more specific, the focal loss is given in the following equation.

$$FocalLoss(p_t) = -\alpha_t(1-p_t)^{\gamma}\log(p_t) \tag{1}$$

$$\alpha_t = \begin{cases} \alpha & ,y=1 \\ 1-\alpha & ,y=0 \end{cases} \qquad p_t = \begin{cases} p & ,y=1 \\ 1-p & ,y=0 \end{cases} \tag{2}$$

where $\gamma \geq 0$. The parameter α can reduce the effect of imbalanced positive and negative samples. We adjust the unbalanced data using the same strategy in [9] with class weights, so the α_t here is kept at 1, which means no adjustment is applied. The parameter γ controls the importance of easy and hard samples in training. With the larger value of γ, the more the influence of the loss of the positive samples, which are the easy samples here, will be weakened. This achieves the purpose of controlling easy samples and hard samples' influence on the overall training goal. Here we set 2 for the parameter γ after the experiment.

IV. Experiments

A. Experimental Setting

In accordance with the benchmark for predicting pedestrian crossing intentions, two datasets are included in the evaluation of the model.

1) Joint Attention Autonomous Driving (JAAD) Dataset: JAAD [1] is a pedestrian crossing and behavior annotation dataset launched by A. Rasouli et al. earlier in 2017. It contains 391K of the pedestrian sample and was collected from urban scenes in North America and Europe under several weather conditions. The 80% of the sample video resolution is 1280x720 and 20% is 1920x1080. It has two subsets JAAD Beh and JAAD All. The former focused on pedestrians' behavior while they cross the road and annotated with pedestrian behavior. The majority of this subset of samples are crossing samples, so the imbalanced and rare samples along with the lower video quality, cause most methods to perform poorly. The latter adds 2100 noncrossing samples with similar characteristics to the former. Therefore, this subset is highly skewed towards the noncrossing samples, resulting in most of the methods being able to improve their performance over a large number of non-crossing samples.

2) Pedestrian Intention Estimation (PIE) Dataset: In 2019, the author of JAAD launched the PIE dataset [2]. There are 740K pedestrian samples with bounding box annotations in this dataset, all at 1920x1080 resolution and recorded in downtown Canada in clear weather. Although it is still imbalanced and the number of noncrossing samples is larger than the crossing samples. The more diverse pedestrian samples, higher resolution, and more uniform weather conditions, most methods perform better on PIE. The model performance characteristics described above can be observed in the subsequent evaluation experiments.

3) Metrics: Our method follows the five metrics used by the benchmark as our evaluation criteria. These include Accuracy, AUC (Area Under Curve), F1-Score, Precision and Recall.

B. Implementation Details

The adjustment of hyperparameters can significantly affect the training results. In our implementation, there are two types of parameter settings to be aware of - Data sampling parameters for the data interface and the model training hyperparameters based on the Transformer encoder.

1) Data Sampling Parameters of Pedestrian Crossing Prediction: The model is sensitive to parameters like "observation time" and "TTE", the impact of these two parameters on model training has been investigated in previous papers [9] [3]. These two constraints must be strictly defined and set for a fair comparison. According to the benchmark, TTE here is set to 30 to 60 frames in this paper, i.e., 1 to 2 seconds, and the observation time is 16 frames, about 0.5 seconds for 30 frames per second videos.

2) Training Details and Hyperparameters: We are primarily concerned with the following four hyperparameters in Transformer Encoder. The one controls the dimension of input embedding and output of multi-head self-attention, the dimension in the feed-forward network, the number of layers of the transformer encoder, and the number of heads of the multi-head self-attention. The hyperparameter settings we apply to each data branch are listed below in the order mentioned above. Bounding box and surrounding image: 128, 128, 1, 4. 3D pose: 128, 64, 2, 4. 3D head orientation: 128, 64, 1, 4. Bounding box: 128, 128, 1, 4. Ego-vehicle speed: 128, 128, 1, 4. Traffic perception data: 128, 128, 1, 4.

The hyperparameters that are relevant to the training process are listed below. The batch size is set to 128, and the learning Rate is set to 0.001 in our experiments. The output dimensions of the two FC layers for fusion and final prediction are 128 and 1, respectively. Furthermore, we use Adam optimizer and apply the same class weights as in the benchmark method[9] to mitigate the problem of imbalance between crossing and non-crossing samples.

C. Evaluation of the Proposed Model

The comparison of the evaluation results of our proposed method with other state-of-the-art baselines on the benchmark[9] is presented in Table I. Our proposed method achieves the best accuracy results in all evaluation datasets. Although not all of the remaining evaluation metrics are best achieved by our method, it can be claimed that our method achieves better balance across the three datasets.

The best results for different metrics are generally achieved by different methods. Some methods have achieved a significant lead in specific metrics but at a relative cost. For example, in the PIE comparison, I3D achieves a recall of 0.9 but a precision of 0.6, compared to 0.85 and 0.84 from our method which has a better balance. This is reflected in the AUC and F1.

For JAAD beh, our method outperforms all the methods that provide JAAD beh scores. Only the recall did not reach the 0.91 obtained by TrouSPI-Net, but its precision was reduced to 0.65 compared to ours. Our method maintains better accuracy,

TABLE I

COMPARISON WITH OTHER METHODS. WHERE "-" INDICATES THAT THE METHOD DOES NOT PROVIDE THESE METRICS.

Method	PIE					JAAD all					JAAD beh				
	ACC	AUC	F1	Precision	Recall	ACC	AUC	F1	Precision	Recall	ACC	AUC	F1	Precision	Recall
SFGRU[3]	0.82	0.79	0.69	0.67	0.7	0.84	0.84	0.65	0.54	**0.84**	0.51	0.45	0.63	0.61	0.64

while the model is more precise in discriminating different situations, and the difference between precision and recall is also smaller. In JAAD All, our method leads in accuracy and precision but does not perform as well on other metrics as on other datasets. It might be the problem of significant gaps between crossing and non-crossing samples and can be observed in the decreasing Recall of our method. Reducing the impact of imbalanced samples will be an area that our method needs to consider carefully in the future.

Despite this, our approach strikes a balance performance between the three datasets. This is valuable when all three datasets have their own significant bias and unbalanced data and can be observed in the ablation study.

V. ABLATION STUDY

A. Importance of Input Data

Table II shows how the different input data combinations impact the training results of our method. Due to space limitations, we have selected several representatives or more significantly varied test results to present in Table II.

Many previous studies [24] [21] [9] have pointed out that the PIE and JAAD datasets are more sensitive to specific input data. This means we can achieve good baseline results with only certain input data. For example, as shown in rows B, S and B, S, TP in Table II. The performance on PIE improved significantly after using bounding boxes and speed. Even after fusing our proposed traffic perception data, the score surpassed our proposed method and was ahead of other methods.

However, as mentioned previously, we incorporated more information to support the stability and balance of the model in a variable scenario. This ensures that the scores on the PIE are comparable to other methods and also cover the performance in other datasets.

Then, as shown in the lower third of the table, a significant performance drop occurs after removing any of the TP, H, or P data. We conclude that these three types of data complement each other, allowing the model to adapt to more scenarios and proving the validity of these data.

TABLE III

COMPARISON OF DIFFERENT FUSION METHODS. WHERE THE ABBREVIATION "CH ATT" IS CHANNEL ATTENTION.

Fusion Method	PIE					JAAD all					JAAD beh				
	ACC	AUC	F1	Precision	Recall	ACC	AUC	F1	Precision	Recall	ACC	AUC	F1	Precision	Recall
Hierarchical	**0.91**	**0.89**	**0.84**	**0.84**	0.83	0.88	0.75	0.62	**0.72**	0.54	0.67	0.58	**0.77**	0.67	0.91
Eearly Fusion	0.86	0.81	0.73	0.79	0.68	0.87	0.78	0.63	0.62	**0.64**	0.64	0.54	0.76	0.64	**0.93**
Late Fusion + CH Att	0.90	0.88	0.83	**0.84**	0.82	0.88	**0.79**	**0.66**	0.68	0.63	0.64	0.56	0.75	0.66	0.87
Late Fusion + FC	**0.91**	**0.89**	**0.84**	**0.84**	**0.85**	**0.89**	0.78	**0.66**	**0.72**	0.61	**0.68**	**0.63**	0.76	**0.71**	0.81

B. Comparison of Different Fusion Methods

We performed an experiment to verify the effectiveness of our model architecture and fusion methods. In addition to the Late Fusion method used in our method, we compare three different solutions. The results are shown in Table III.

The first is a hierarchical fusion method inspired by [3], which integrates the input information by progressively fusing different inputs in every layer. In the second method, Early fusion is used to fuse data before it enters the Transformer encoder block. Finally, based on the proposed method, we replace the Fully connected layer of late fusion with channel attention mechanism, hoping that the channel attention mechanism can automatically adjust the weights of different input information to optimize the training results.

Among these four fusion schemes, the scheme of combining Late fusion with the fully connected layer gives the most satisfactory results. In the hierarchical and channel attention scheme, these two more complex models tend to overfit as they rapidly converge to the training set during training. Early fusion, on the other hand, gives poor results because the input data is fused before the feature extraction. It is also not able to learn complex scenes well due to the lack of model complexity, which can be observed in the reduced accuracy on PIE dataset.

TABLE IV

COMPARISON OF DIFFERENT TRAFFIC PERCEPTION DATA FUSION STRATEGIES. "T" IS TRAFFIC LIGHT, "S" IS SIGN, "C" IS CROSSWALK. WHERE "NO FUSION & NO TRANSFORM" MEANS NO FUSION AND FORMAT TRANSFORM IS APPLIED. "T+SC" MEANS T IS A SINGLE BRANCH WITHOUT FUSION, WHILE S AND C ARE FUSED. THE OTHER TWO FOLLOW THIS PATTERN. "TCS EARLY FUSION" IS THE PROPOSED METHOD WITH THREE DATA FUSIONS.

TP Fusion Strategy	PIE					JAAD all					JAAD beh				
	ACC	AUC	F1	Precision	Recall	ACC	AUC	F1	Precision	Recall	ACC	AUC	F1	Precision	Recall
No Transform & Fusion	0.89	0.85	0.81	0.84	0.78	0.87	0.76	0.61	0.65	0.58	0.65	0.56	0.77	0.66	0.92
No Fusion	0.90	0.87	0.83	0.85	0.80	0.88	0.77	0.64	0.70	0.59	0.66	0.56	0.77	0.66	**0.94**

TS + C	0.90	0.87	0.82	0.85	0.78	**0.89**	0.72	0.59	**0.79**	0.47	**0.70**	0.66	**0.78**	0.73	0.83
TC + S	0.90	0.86	0.82	**0.87**	0.77	0.88	0.77	0.64	0.69	0.60	**0.70**	**0.67**	0.76	**0.75**	0.78
TCS Early Fusion	**0.91**	**0.89**	**0.84**	0.84	**0.85**	**0.89**	**0.78**	**0.66**	0.72	**0.61**	0.68	0.63	0.76	0.71	0.81

Fig. 3. The input features introduced in our method will help the model to predict more accurately in specific situations and improve the cases that are easily misclassified in the figure. Green bounding boxes indicate pedestrian samples that cross, while Red ones indicate those that do not.

C. Comparison of Traffic Perception Data Fusions

We represent the traffic lights, signs and crosswalks in a special format and integrate them using concatenant operations, so that this information brings a visible improvement to the model training. Here, we test six different fusion strategies. Without the format transformation and fusion, such data's contribution almost negligibly to the training results, i.e. the "No Transform & No Fusion" row in Table IV.

Compare to other fusion strategies, our final solution TSC Eealy Fusion, demonstrates the best results, maintaining a decent level of performance in all three datasets, but was not clearly biased towards certain datasets. For example, the TS+C and TC+S fusion strategies show excellent results in JAAD beh, but they did not provide improvement in PIE.

D. Qualitative Justification

Figure 3 shows the visualization prediction results of this method. The model can correctly predict complex samples. The addition of traffic perception data, 3D pedestrian head orientation, and 3D human pose helps the model improve the misclassification in many cases before.

E. Discussion of Failure Case

Among the failed cases, we found a condition that confuses the model and repeatedly occurs in incorrect cases. As shown in Figure 4, these cases occur when the vehicles are about to turn and the directions of the vehicles are changed after the observation. For example, the original direction of the vehicle is parallel to the pedestrian, and it does not change in the observation time. When a vehicle turns after observation and

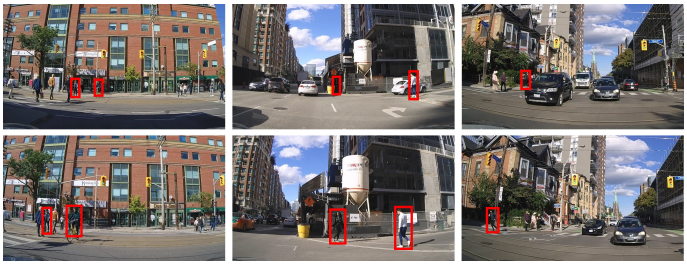

Fig. 4. These cases illustrate the impact of ego-vehicle turning after the model observation. Where Green bounding boxes indicate pedestrian samples that cross, while Red ones indicate those that do not.

a pedestrian starts to cross the road at the same time, the route of the vehicle turns to intersect with the pedestrian.

This case is confusing to the model because the model naturally defines such pedestrians as non-crossing since there is no overlap between pedestrian and vehicle trajectories during the model observation time. Such a condition would contradict with the sample of vehicles going straight because there is no significant difference between the two cases in the model observation condition, but the ground truth shows two opposite results. Therefore, we suggest that future datasets could include this kind of information, which would be beneficial for related research.

For other failures such as extreme situations where the pedestrian appearance is not visible or when there is no motion information available due to minimal pedestrian and vehicle movement. We believe that image processing or restoration models can be used to try to cope with the first case, while the second case can be aided by obtaining more accurate and rich information about pedestrian posture to predict the scene.

VI. CONCLUSIONS

In this paper, we proposed a multi-modal Transformer-based approach to predict the intention of a pedestrian crossing the road. In this work, we explore how people determine the crossing intention of pedestrians from the perspective of human drivers and pedestrians themselves and integrate the pieces of critical information to help the model make accurate predictions.

To the best of our knowledge, we are the first to represent traffic lights, road signs, crosswalks in a novel way and consider the lifted 3D human pose and 3D head orientation information to help the model better understand the traffic environment and the behavior of pedestrians. Our experimental results demonstrated that the proposed model achieves state-of-the-art performance across the three benchmark datasets. In addition, we performed several experiments to verify the effectiveness of various components and different input data of our method.

***Abstract* —Artificial intelligence (AI) has been extensively studied in science, technology, engineering, and mathematics (STEM), but there is a disparity between AI-generated and human-written scientific content. To bridge this gap, a prototype utilizing Natural Language Processing (NLP) techniques and a large language model (LLM) generates assessment questions and evaluates student answers. This formative assessment system offers a user-friendly and scalable solution for higher education educators. It tailors' assessments to individual students, accommodates varying capabilities, and facilitates performance analysis. Through rigorous evaluation and benchmarking, the prototype ensures alignment with High-Level Performance (HLP) standards. This AI-assisted formative assessment system enhances efficiency and efficacy by providing accurate and timely feedback. It has the potential to significantly improve STEM education through scalable and personalized formative assessment experiences. AI and NLP enable educators to access tailored assessment options, enhancing learning outcomes and the overall educational experience.**

I. INTRODUCTION

Formative assessment is a fundamental process in the provision of feedback to students regarding their learning progress. It constitutes a vital component of effective teaching and learning practices in the fields of science, technology, engineering, and mathematics (STEM). This approach enables students to identify areas requiring additional support and make necessary adjustments to their learning strategies. Historically, formative assessment has been undertaken by educators utilizing diverse methods such as quizzes, tests, and classroom discussions. Nonetheless, these approaches can be time-consuming, labor-intensive, and challenging to implement on a larger scale. The advent of artificial intelligence (AI) presents an opportunity to revolutionize formative assessment in STEM disciplines by providing a more efficient and scalable feedback mechanism to students.

AI-powered formative assessment systems have the potential to automatically evaluate student work, pinpoint areas necessitating further support, and deliver personalized feedback aimed at enhancing learning outcomes. In this paper, we introduce a prototype AI-assisted formative assessment system leveraging natural language processing (NLP) techniques. Our system is specifically designed for implementation in STEM courses and has the capability to assess short-answer questions, essays, and other types of student assignments. We conducted an evaluation of our system involving a group of STEM educators. The results demonstrated that our system was capable of delivering accurate and timely feedback to students, leading to improvements in their learning outcomes. We firmly believe that our system possesses the capacity to enhance the quality of STEM education by providing a more efficient and scalable approach to formative assessment. Our ongoing efforts involve further development of the system, with the aim of making it accessible to a wider audience in the future.

II. LITERATURE REVIEW

A. Digital Formative Assessment

The inclusion of digital formative assessment has become an essential component of contemporary education, enabling educators to collect immediate feedback and effectively monitor student progress. This literature review aims to examine the concept of digital formative assessment and emphasize the range of tools and technologies available to facilitate its integration into educational environments. Formative assessment involves gathering data on students' learning advancement to offer prompt feedback and adjust teaching strategies accordingly. Digital formative assessment leverages technology to enhance this process, creating

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

opportunities for interactive, personalized, and instantaneous feedback. Research indicates numerous advantages of implementing digital formative assessment in classrooms. Firstly, it fosters active student engagement by incorporating interactive elements like quizzes, polls, and discussions. Secondly, it enables teachers to efficiently track individual student progress and identify areas requiring improvement. Thirdly, digital formative assessment supports differentiated instruction, enabling educators to tailor their teaching to meet each student's specific needs. Lastly, it delivers timely and constructive feedback to students, cultivating a growth mindset and enriching their learning experience. In the pursuit of enhancing support for the development of adaptive learning environments, the interdisciplinary field of learning science has attracted the attention of computer scientists for over a decade. Researchers from the education and computer science domains have been working together to optimize the complex and time-consuming design of adaptive learning environments through the utilization of advanced techniques such as data mining, machine learning, and deep learning. Their objective is to enhance the capabilities of Intelligent Tutoring Systems (ITS) in order to provide more effective assistance to students. Numerous endeavours have been witnessed in the development of ITS for various subjects such as mathematics [1], [2], programming [3]–[6], languages [7]–[10] and more. Efficiently and effectively guiding students in their learning process remains a recurring topic in educational research of the 21st century.

B. Tools for Digital Formative Assessment

Learning Management Systems (LMS): LMS platforms like Moodle, Canvas, and Schoology offer features for creating online assessments, tracking student performance, and providing feedback. These systems often include built-in grading tools, discussion boards, and analytics, enabling teachers to monitor student progress comprehensively [11], [12].

Quiz and Polling Tools: Tools like Kahoot, Quizizz, and Mentimeter facilitate the creation of interactive quizzes and polls. These tools engage students in a gamified learning experience, encouraging participation and enabling instant feedback [13].

Online Survey Tools: Survey tools such as Google Forms and Microsoft Forms provide educators with the means to collect data from students, gauge their understanding, and assess their learning progress. These tools offer a variety of question types and data analysis features [14].

Digital Whiteboarding Tools: Whiteboarding tools like Jamboard, Miro, and Explain Everything enable collaborative and interactive formative assessment. Teachers can create visual presentations, interactive exercises, and virtual whiteboards to facilitate student engagement and feedback [15].

Video Assessment Tools: Video assessment tools, such as Flipgrid and Edpuzzle, allow students to record their responses, presentations, or explanations. Teachers can review and provide feedback on these videos, promoting self-reflection and communication skills [16]–[18].

C. Artificial Intelligence as a tool for formative assessment

There has been a growing interest in the use of AI for formative assessment in recent years. Several research studies have been conducted to evaluate the effectiveness of AI-assisted formative assessment systems [19], [20]. The findings from these studies have yielded varied results, but on the whole, they indicate that AI-supported formative assessment systems have the potential to enhance student learning outcomes. Incorporating AI into formative assessment poses certain challenges, including the difficulty of developing accurate and reliable systems. Additionally, the development and implementation of AI-assisted formative assessment systems can be costly. Despite these obstacles, the potential benefits of AI in formative assessment are substantial. AI-supported formative assessment systems have the capacity to enhance the efficiency and scalability of assessment practices, while providing personalized feedback to students, thereby aiding their learning progress. Although the use of AI in formative assessment is still in its early stages, it holds the potential to revolutionize the evaluation methods employed for students. As AI-assisted formative assessment systems continue to advance, they can significantly improve the efficiency, scalability, and personalization of assessment processes, consequently leading to notable enhancements in student learning outcomes. Below are a few instances showcasing the application of AI in formative assessment:

- **Grading student work:** AI-assisted formative assessment systems can automatically grade student work, such as essays and short-answer questions. This can free up teachers' time so they can focus on providing feedback to students.
- **Identifying areas of need:** AI-assisted formative assessment systems can identify areas where students need additional support. This information can be used to provide targeted interventions to help students improve their learning.

- **Providing personalized feedback:** AI-assisted formative assessment systems can provide personalized feedback to students. This feedback can help students to identify their strengths and weaknesses, and to develop strategies for improving their learning.

D. Large language models (LLMs)

Large language models (LLMs) are large neural networks trained on enormous amounts of text data, sometimes at the petabyte scale. They could generate text that's far more fluent and coherent than previous language models, and they can also be used as a strong foundation for other NLP tasks. LLMs represent a major advancement in AI, with the promise of transforming domains through learned knowledge [21]. A bibliometric review of LLMs research has shown that LLMs are a class of language models that have demonstrated outstanding performance across a range of natural language processing (NLP) tasks and have become a highly sought-after research area, because of their ability to generate human-like language and their potential to revolutionize science [22]. Large Language Models (LLMs) are sophisticated computer programs that introduce new possibilities for text comprehension and generation within software systems like Google Search and Bing. These models undergo extensive training on vast amounts of text, enabling them to learn intricate relationships between terms. Once trained, LLMs have the capability to produce text that closely resembles human-written content. Numerous large language models have been developed, including OpenAI's GPT-3 and GPT-4, Meta's LLaMA, and Google's PaLM2. These models possess language understanding and text generation capabilities. For instance, GPT-3, with its 175 billion parameters, can comprehend and generate text across more than 95 natural languages and 12 programming languages. Google's BERT, with 340 million parameters, can understand and generate text in 104 languages through its multilingual model. BigScience's BLOOM, with 176 billion parameters, can handle text comprehension and generation in 46 natural languages and 13 programming languages. NVIDIA's NeMo LLM, with 530 billion parameters, specializes in English text understanding and generation exclusively. LLMs have been used for various applications such as chatbots, machine translation, question answering systems, summarization systems, sentiment analysis systems, speech recognition systems, image captioning systems, among others. In this context, is believe that LLMs can be used in assisting educators in formative assessment by providing feedback to students and modifying their teaching based on the information derived from assessments [23].

Table. 1 Comparison of Different Large Language Models.

Model (Year Founded)	**Type of license**	**Supported features**	**Limitations**	**Advantages**
MarianMT (2017)	Open Source	Language translation	Limited support for other NLP tasks	Free and open source
BERT (2018)	Open Source	Language understanding, text classification	May require large amounts of labelled training data	Strong performance in various NLP tasks
Megatron LM (2019)	Open Source	Text generation, language translation, Q&A, chatbots	Requires significant computational resources	Optimized for training large-scale models
RoBERTa (2019)	Open Source	Language understanding, text classification	Limited support for fine-grained text generation	Pretrained on large corpus for improved accuracy
CTRL (2019)	Open Source	Text generation, language translation, Q&A, chatbots	Less optimized for large-scale language tasks	Fine-tuned for content creation and chatbots
T5 (2020)	Open Source	Text generation, language translation, Q&A, chatbots	Less emphasis on model customization and fine-tuning	Unified architecture for diverse language tasks
GPT-2 (2019)	Proprietary	Text generation, language translation, Q&A, chatbots	Limited fine-grained control over model behaviour	Strong text generation capabilities
Turing-NLG (2021)	Open Source	Text generation, language translation, Q&A, chatbots	Limited availability and support	Innovative model architecture
GPT-Neo (2021)	Open Source	Text generation, language translation, Q&A, chatbots	Less optimized for commercial	Open-source alternative to GPT models

			deployment	
GPT-3 (2020)	Proprietary	Text generation, language translation, Q&A, chatbots	Limited fine-grained control over model behaviour	State-of-the-art performance in various tasks
GPT-4 (2022)	Proprietary	Text generation, language translation, Q&A, chatbots	Limited fine-grained control over model behaviour	Improved performance and capabilities
OPT (OpenAI) (2022)	Proprietary	Text generation, language translation, Q&A, chatbots	Limited fine-grained control over model behaviour	Latest model with enhanced features and quality

III. METHODOLOGY

In this section, we will provide a detailed explanation of the methodology employed in developing the AI-assisted prototype, which utilizes NLP techniques to enhance educators' capabilities in the context of formative assessment (as illustrated in Figure 1). The proposed solution incorporates the utilization of the OpenAI API key. The OpenAI API is an Application Programming Interface (API) that provides access to advanced AI models developed by OpenAI. It empowers our proposed system to comprehend natural language and generate responses that closely resemble human-like outputs (Odunayo, 2023).

OpenAI provides a diverse array of models, each catering to specific application requirements and offering varying degrees of capabilities. The primary function of OpenAI API are:

Understanding Educator Input. The OpenAI GPT API takes the input provided by the educator as a starting point. This input can include prompts, questions, or specific instructions.

Contextual Understanding. GPT (Generative Pre-trained Transformer) models, such as GPT-3, are designed to understand and generate text in a contextual manner. They analyse the input provided and use the context to generate meaningful responses.

Question Generation. If the educator's input contains prompts or instructions to generate questions, the OpenAI GPT API can generate a series of questions based on the given

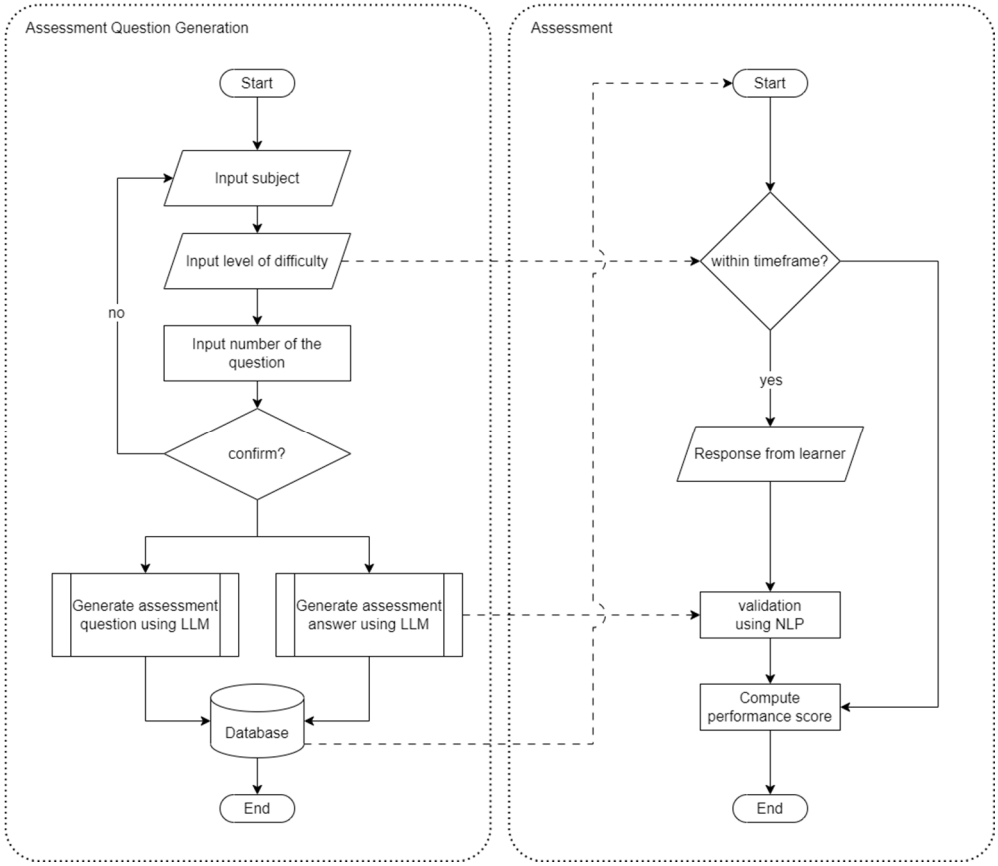

Fig. 1 Proposed solution architecture.

context. These questions are designed to be coherent and contextually relevant.

To facilitate effective preprocessing and enhance the overall functionality of our solution, we have integrated the Natural Language Toolkit (NLTK), a robust Python library designed explicitly for efficient and proficient natural language processing tasks. With NLTK, our system can effectively process human language, ensuring optimal performance:

Text Tokenization. NLTK is used for breaking down the text into smaller units such as words or sentences. Tokenization is an important step in understanding and processing text data.

Lowercasing. NLTK can be used to convert all text to lowercase. This standardizes the text and ensures that the processing is not case-sensitive.

Removing Stop Words. Stop words are common words (e.g., "the," "and," "is") that do not carry significant meaning. NLTK provides tools for removing these stop words from the text, which can improve the accuracy of text analysis.

Stemming and Lemmatization. NLTK offers stemming and lemmatization techniques that reduce words to their base or root forms. This helps in standardizing variations of words (e.g., "running" becomes "run") and improves text analysis accuracy.

Additionally, we leverage the Twinword Text Similarity API to facilitate a comparative analysis of learner responses against correct answers. This API serves as a semantic keyword research tool, employing a ranking mechanism that assesses keyword relevance to user-defined topics. This functionality empowers our system to compute the degree of similarity between learner-provided responses and the corrected answers generated by OpenAI GPT-3. Consequently, our solution streamlines the automated grading of open-ended questions, as it can objectively assess a learner's response by comparing it to the correct answer and assigning a score based on their similarity. This streamlined process saves valuable time for educators, provides learners with immediate feedback, and delivers a more objective evaluation of their performance.

IV. Result And Discussion

Table 3 shows the sample assessment question generated by the proposed framework with its sample marking scheme.

Table. 2 Sample Output.

	Assessment Question	**Sample Marking Scheme**
1	What is an algebraic expression?	An algebraic expression is a combination of numbers, variables and operations that are written out in a mathematical statement.
2	What is the difference between an equation and expression?	An equation is a statement that two expressions are qual, while an expression is composed of numbers and symbols that represents a mathematical statement.
3	How do you solve an algebraic equation?	To solve an algebraic equation, isolate the variable on one side of the equation then use inverse operations to get the variable alone on the on the other side of the equation. Once the variable is isolated, substitute the value for the variable into the equation.

Evaluation and benchmarking of the assessment system can be conducted by comparing its automated grading system, which utilizes AI and Natural Language Processing (NLP) with the Twinword semantic similarity feature, against the standard of Human Level Performance (HLP). HLP (as shown in Table 3) serves as a reference point, representing the level of grading accuracy and understanding achieved by human assessors. is employed to validate the questions generated by the proposed system, ensuring their validity, accuracy, and relevance. Additionally, it is utilized to verify that the sample answers generated align correctly with the corresponding questions. Through this evaluation, the system's performance can be assessed by comparing its grading results with those of human assessors.

Table. 3 Sample Data with Benchmarking with HLP.

Test Plan				**Performance**	
Subject	Level	Question Generated	Suggested Answer	HLP on Question Generated (Validity)	HLP on Answer Generated (Accuracy)
Mathematics	Easy	Q1. What is Algebra?	A1. Algebra is a branch of mathematics that uses symbols and equations to represent numbers, relationships, and objects.	Yes	Yes
		Q2. What are variables in Algebra?	A2. Variables are letters or symbols that stand for a particular number in an equation.	Yes	Yes
		Q3. What is an equation?	A3. An equation is a mathematical statement expressing the equality of two expressions. It is the statement of equality between two expressions that have the same value.	Yes	Yes
	Moderate	Q1. What is a Linear Equation?	A1. A linear equation is an equation of a straight line, written in the form ax + b = 0;	Yes	Yes

		where 'a' and 'b' are constants and 'x' is a variable.		
	Q2. How do you solve a System of Linear Equations?	A2. A system of linear equations can be solved using various methods such as Substitution Method, Elimination Method, and Gaussian Elimination.	Yes	Yes
	Q3. What is the Quadratic Formula?	A3. The Quadratic Formula is a method used to solve a quadratic equation, written in the form ax2 + bx + c = 0; where 'a', 'b', and 'c' are constants and 'x' is a variable. The formula is x = [-b ± √(b2 - 4ac)] / 2a.	Yes	Yes
Hard	Q1. Solve for x in the equation: 3x - 6 = 12	A1. x = 8	Yes	Yes
	Q2. Divide the polynomial 4x^3 + 27x^2 - 73x + 60 by 2x + 5	A2. 4x^2 + 17x - 43	Yes	Yes
	Q3. Find the product of polynomials (2x^2 + 3x)(5x + 4)(x - 1)	A3. 10x^3 + 31x^2 - 23x - 4	Yes	Yes
Extreme Hard	Q1. Prove that the product of two odd numbers is always an odd number.	A1. Let a and b be two odd numbers. This means a = 2n + 1 and b = 2m + 1, where n and m are integers. Thus, their product a*b = (2n+1)*(2m+1) = 4nm + 2(n+m) + 1. Since n and m are both integers, the whole expression is an integer plus one - thus it is always an odd number.	Yes	Yes
	Q2. Prove that (2x^2 -5x + 3) is a prime number for any integer value of x.	A2. Let x be any integer. Then, 2x^2 - 5x + 3 can be written as (2x - 3)(x + 1). Since at least one of the factors is always a non-zero integer, the expression 2x^2 - 5x + 3 is not prime for any integer value of x.	Yes	Yes
	Q3. Find the value of x in the equation x^3 + 3x -2 = 0.	A3. Using the cubic formula, x = (∛(-2 + √48) + ∛ (-2 - √48))/3. Therefore, the value of x is approximately -1.9021.	Yes	Yes

The AI and NLP algorithms employed in our system employ advanced techniques to analyze and evaluate student responses. Utilizing the Twinword semantic similarity feature, the system measures the degree of similarity between student answers and the correct answers. By benchmarking the system's performance against Human-Level Performance (HLP), we can assess the system's accuracy and proficiency in automated grading. This evaluation approach holds immense value in determining the effectiveness and reliability of the system. It offers valuable insights into the system's capacity to comprehend and accurately assess student answers, comparable to human assessors' expertise. Furthermore, it facilitates the identification of areas where the system excels or requires further improvement.

By subjecting the assessment system to evaluation against HLP using AI and NLP techniques, educators and developers gain crucial insights into its performance. This process enables them to refine and enhance the system's automated grading capabilities, aligning it with human-level grading standards while harnessing the power of AI and NLP technologies. It is worth highlighting that the proposed solution successfully satisfies all the criteria and test scenarios for the HLP evaluation. The assessment system demonstrates its ability to achieve grading accuracy and understanding at a level comparable to human assessors. This significant achievement attests to the system's effectiveness and reliability in automated grading, instilling confidence in its capacity to deliver high-quality assessments.

V. CONCLUSIONS

In conclusion, formative assessment holds a pivotal role in effective teaching and learning, particularly within STEM

fields, by offering students invaluable feedback on their progress. However, conventional assessment methods like quizzes and tests are often plagued by time constraints, resource demands, and scalability challenges. The integration of artificial intelligence (AI) has emerged as a transformative solution, revolutionizing formative assessment in STEM education by presenting a more efficient and scalable approach to delivering feedback. This paper introduces a prototype AI-assisted formative assessment system enriched with natural language processing (NLP) techniques, underscoring its potential to elevate formative assessment practices.

Through rigorous evaluation involving STEM educators, this system has demonstrated its prowess in providing accurate and prompt feedback, culminating in tangible enhancements in learning outcomes. By automating the grading process, identifying areas necessitating additional support, and delivering personalized feedback, the system optimizes the efficiency and efficacy of formative assessment, adeptly catering to individual student requirements. A cornerstone of this system's success lies in the incorporation of large language models (LLMs) and NLP techniques, which amplify its proficiency in comprehending natural language and generating coherent responses. Furthermore, the integration of supplementary technologies like the Twinword Text Similarity API bolsters the system's capacity to objectively assess student responses, juxtapose them against correct answers, and assign precise scores. This empowerment equips educators with time-saving features, grants students' immediate feedback, and institutes a more objective performance evaluation process.

The utilization of LLMs, such as GPT-4 and OPT (OpenAI), signifies a strategic advantage, harnessing their language understanding and text generation capabilities, as showcased in Table 1. These models have evolved as powerful tools with varying strengths and weaknesses. For instance, models like BERT excel in language understanding and text classification, while GPT-3 and GPT-4 exhibit strong text generation capabilities. MegatronLM, on the other hand, is optimized for training large-scale models, making it suitable for extensive natural language processing tasks. Each model offers a unique set of features, limitations, and advantages, enabling educators to tailor their formative assessment strategies to specific needs. While challenges persist, encompassing aspects like development and deployment costs, the potential merits of AI-assisted formative assessment systems are substantial. Their scalability and personalization capabilities hold the promise of revolutionizing education, affording educators comprehensive insights into student progress, and facilitating tailored interventions. Ongoing development endeavours aim to hone and broaden the system's capabilities, with the overarching objective of rendering it accessible to a wider audience and magnifying its impact on STEM education. By harnessing AI and NLP technologies, educators and developers can incessantly refine the system's accuracy, reliability, and alignment with human-level grading standards. This iterative approach guarantees that the system remains at the forefront of advancements in formative assessment practices, ultimately fostering enhanced student learning outcomes within STEM disciplines.

In summary, the fusion of AI and NLP techniques in formative assessment signifies a paradigm shift in STEM education. The presented AI-assisted formative assessment system underscores its capacity to furnish precise and timely feedback, thereby heightening the efficiency and effectiveness of formative assessment practices, while strategically leveraging advanced large language models like GPT-4 and OPT (OpenAI) and considering the unique features of various LLMs, as highlighted in Table 1. As further strides are made, this system possesses the potential to profoundly ameliorate the quality of STEM education by delivering scalable and personalized formative assessment experiences.

A Biased Mixed-Precision Convolution Engine for Hardware-Efficient Computational Imaging CNN

Hao-Jiun Tu*, Yu-Feng Ou, Yong-Tai Chen, and Chao-Tsung Huang
Department of Electrical Engineering
National Tsing Hua University, Hsinchu, Taiwan
* E-mail: tuj0419@gapp.nthu.edu.tw

***Abstract*—Mixed-precision networks have demonstrated significant advantages in CNN acceleration for edge inference. They can achieve high throughput and energy efficiency while maintaining quality in resource-constrained environments. However, existing high-performance accelerators for bit-flexible computation suffer from significant hardware overheads due to the extra sign extension in bit-level decomposition, severely confining the performance enhancement in mixed-precision networks. In this paper, we aim to facilitate efficient inference for mixed-precision networks in computational imaging applications. First, we propose a biased multiplier to optimize hardware performance for bit-flexible architectures. Unlike the conventional bit-level decomposition, the proposed biased representation (BR) avoids sign extension to enhance hardware efficiency. On top of that, we build 4/8-bit biased mixed-precision networks and convolution engines with highly-parallel eCNN accelerator for evaluation. We implement convolution engines with three types of multipliers, uniform-precision, sign-extended, and biased multipliers, on TSMC 40 nm technology to support advanced super-resolution and denoising at 4K UHD 30fps, FHD 60fps and FHD 30fps. Compared to the sign-extended counterpart, synthesis results show that our biased mixed-precision convolution engine can provide area overhead and energy reduction by 50%. At the same level of image quality, it can also deliver 33% energy reduction on average over the uniform-precision method.**

I. Introduction

Convolutional neural networks (CNNs) have demonstrated exceptional capability in computational imaging applications, such as super-resolution (SR) [13], [15], [17] or denoising (Dn) [5], [25], [26]. The CNN-based methods aim to generate latent images from given low-resolution or noisy images by well-learned filters, and can deliver superior quality than traditional algorithms. However, high computational demands and energy burden for CNNs make it hard to deploy on edge devices. Therefore, reducing model complexity while maintaining quality becomes a critical issue for edge CNN inference.

Depth reduction and quantization are commonly adopted to reduce complexity for CNNs. Recent evidence [7], [9], [23] indicates that the model depth has a great impact on the performance of both recognition and image restoration tasks. As a result, sufficient depth for a compact model is essential to maintain quality on edge devices. As for quantization, early works [2], [11], [12], [27] employ uniform-precision quantization for all parameters/activations across CNN layers to further reduce complexity. However, computational imaging CNNs aim to render fine-textured and high-precision feature maps. In this case, the precision of MAC operations could be at least 8-bit for representing a sufficient dynamic range. For example, hardware accelerators optimized for computational imaging use 8-bit precision to maintain image quality for hardware implementation, such as eCNN [10], RingCNN [9] and DepFiN [14]. Other frameworks like Diffy [19] and IDEAL [18] employ higher precision configurations. Thus, uniform-precision quantization restricts the potential for complexity reduction in computational imaging applications.

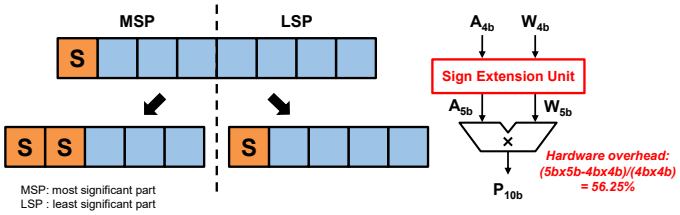

Fig. 1. Conventional bit-level decomposition with sign extension for two's complement 8-bit data (left). Hardware overheads of a sign-extended multiplier in 4-bit granularity (right).

An alternative for addressing this issue is to utilize mixed-precision quantization. Previous studies [4], [20] have shown that parameters/activations exhibit distinct properties and distributions across layers. Each layer may vary in quantization level and accordingly require different precision allocation. By exploiting the different quantization sensitivity [3], [16], [24] of each layer, the precision can be further reduced while mitigating quality degradation for non-sensitive layers within the network. This approach enables better tradeoffs between complexity and quality for mixed-precision networks.

Recently, advanced bit-flexible architectures have been developed to support various bitwidth configurations for energy-efficient inference. However, most bit-flexible accelerators, such as Bit Fusion [22], Bitblade [21] and HNPU [6], suffer from significant hardware overheads due to the conventional bit-level decomposition method as shown in Fig. 1. Since two's complement data after the decomposition is either signed or unsigned, a sign extension unit is required for signed MAC operations. The increased bitwidth on the most significant bit (MSB) of the decomposed data could produce significant hardware overheads on multipliers, as well as the subsequent accumulators and pipeline registers. These overheads defy the

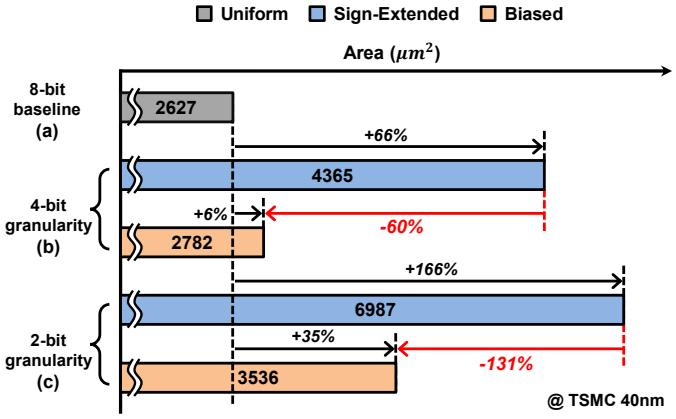

Fig. 2. Area comparison for three types of multipliers: uniform-precision, sign-extended, and the proposed biased multiplier. The computing capacity of above multipliers is the same as an 8-bit multiplication but with different granularity. (a) Baseline 8-bit. (b) Coarse-grained 4-bit. (c) Fine-grained 2-bit.

advantage of improved computational efficiency for mixed-precision networks. Therefore, an efficient hardware structure and decomposition method is crucial to facilitate optimizations of hardware performance.

In this work, we propose a biased multiplier to optimize hardware performance for bit-flexible architectures. Specifically, the proposed bit-level decomposition method, called biased representation (BR), converts the unsigned decomposed data into the signed one to fully utilize the dynamic range of two's complement input data. It can thus avoid sign extension to eliminate bitwidth-increasing overheads. Then, we build coarse-grained 4/8-bit biased mixed-precision networks and convolution engines for evaluation. We adopt eCNN [10], the state-of-the-art accelerator for computational imaging, as our engine backbone. With TSMC 40 nm technology, we implement convolution engines with three types of multipliers, uniform-precision, sign-extended, and biased multipliers, to show effectiveness on SR and Dn tasks at 4K UHD 30fps (UHD30), FHD 60fps (HD60), and FHD 30fps (HD30). Compared to the sign-extended counterpart, our biased mixed-precision convolution engine can provide area overhead and energy reduction by 50%. Moreover, it can also deliver 33% energy reduction on average over the uniform-precision method at the same level of image quality.

II. Preliminaries

A. Hardware Overhead

To accurately examine hardware overheads physically, we synthesized three types of multipliers, uniform-precision, sign-extended, and the proposed biased multiplier, on TSMC 40 nm technology as shown in Fig. 2. In comparison with an 8-bit uniform-precision multiplier, the conventional sign-extended multiplier in 4-bit granularity incurs 66% area overhead. However, our proposed biased multiplier only has 6% area overhead, providing a reduction of the area overhead by 60%, as illustrated in Fig. 2 (b). In addition to fine-grained 2-bit in Fig. 2 (c), the biased multiplier can further reduce the area overhead by 131%. This demonstrates that the biased multiplier can provide a more hardware-efficient computation for bit-flexible architectures. The key idea and details of the biased multiplier will be elaborated in Section III.

B. Bit-Level Complexity

Since the custom precision is allocated for parameters/activations across layers in mixed-precision networks, the number of MAC operations fails to exactly reflect the model complexity. Therefore, UNIQ [1] proposed the BOPs metric quantifying the number of bit operations for MAC units. Given that multiplications substantially dominate the hardware resources in MAC units, we define the metric $bitOps$ that quantifies the bit-level complexity focusing on multiplications:

$$bitOps = \sum_{l} (b_W^{(l)} h_W^{(l)} w_W^{(l)} ch_W^{(l)}) \times (b_A^{(l)} h_A^{(l)} w_A^{(l)} ch_A^{(l)}), \quad (1)$$

where l denotes the index of the layer. b_W and b_A denote the bitwidth of weight and input activation. h_W, w_W and ch_W denote the height, width and channel of weight. h_A, w_A and ch_A denote the height, width and channel of output activation.

Section I describes that the conventional bit-level decomposition induces significant hardware overheads, which can be evaluated by the metric $bitOps$, as illustrated in Fig. 1. For a 4-bit multiplier, the bit-level complexity is the product of the bitwidths of two operands ($b_{A_{4b}} \cdot b_{W_{4b}}$). The same calculation is applied to a 5-bit multiplier ($b_{A_{5b}} \cdot b_{W_{5b}}$). Therefore, a sign-extended multiplier in 4-bit granularity can exhibit 56.25% complexity overhead. In addition to 2-bit granularity, the complexity overhead increases to 125%. In the following sections, we will use the metric to evaluate the model complexity.

III. Biased Multiplier

In this section, we elaborate on the hardware-software co-design strategy for the biased multiplier. We first demonstrate how the proposed biased representation (BR) decomposes the data into two bit-slices, and how it is mapped to the hardware for reconfigurable computation. Then, we devise a BR-aware training process to optimize the model to fit the biased multiplier.

A. Biased Representation

The conventional bit-level decomposition method splits the data into the signed most significant part (MSP) and the unsigned least significant part (LSP) as shown in Fig. 1. To support reconfigurable computation, the sign extension is typically applied on the MSP and LSP of data for signed MAC operations. In contrast, the proposed BR decomposes the data without the extra sign extension as shown in Fig. 3. For example, the two's complement 8-bit data 10001100_2 (-116_{10}) can be divided into the MSP 1000_2 (-128_{10}) and LSP 1100_2 (12_{10}). Since the original unsigned bit $(+8)$ in the LSP is replaced by the sign bit (-8), it is required to compensate the offset $(+16)$ in the MSP when the sign bit of the LSP is 1_2. The MSP of data is then converted from 1000_2

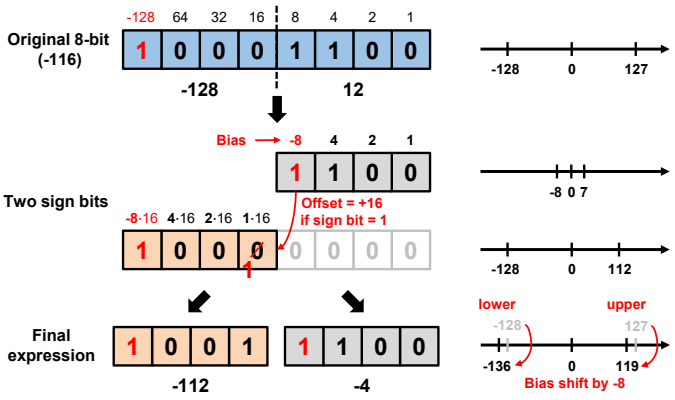

Fig. 3. Biased representation (BR) for decomposing two's complement 8-bit data into two 4-bit bit-slices (left) and the corresponding dynamic range (right).

to 1001_2 by adding 1_2. Thus, the 8-bit data 10001100_2 can be decomposed into the MSP 1001_2 (-112_{10}) and LSP 1100_2 (-4_{10}). By utilizing the BR, 8-bit data can be fitted into 4-bit signed multipliers because both decomposed MSP and LSP are signed.

However, the BR introduces a bias shift by -8 in signed 8-bit dynamic range, as illustrated in Fig. 3 on the right. With the sign bit replaced in the LSP of data, the dynamic range shifts from the original range of $[-128, 127]$ to $[-136, 119]$. As a result, the overflow issue occurs within the original range of $[120, 127]$, making it fail to represent the data in the BR. To address the issue, we propose the BR-aware training strategy, which will be discussed in Section III-C.

In general, the BR can apply to any two's complement data. The two's complement representation of an N-bit integer A can be defined as follows:

$$A = -a_{N-1}2^{N-1} + \sum_{i=0}^{N-2} a_i 2^i, \tag{2}$$

where $N \mid 2 \in \mathbb{N}$, $a_i \in \{0, 1\}$ for $i = N-1, N-2, \ldots, 0$, and a_{N-1} denotes the sign bit. To decompose A into two $N/2$-bit integers,

$$\begin{aligned} A = &- a_{N-1}2^{N-1} + a_{N-2}2^{N-2} + \cdots + a_{N'}2^{N'} \\ &+ a_{N'-1}2^{N'-1} + a_{N'-2}2^{N'-2} + \cdots + a_0 2^0, \end{aligned} \tag{3}$$

where $N' = N/2$. Equation (3) is extended by adding and subtracting $2a_{N'-1}2^{N'-1}$:

$$\begin{aligned} A = &\underbrace{-a_{N-1}2^{N-1} + a_{N-2}2^{N-2} + \cdots + a_{N'}2^{N'}}_{Most\ Significant\ Part} + \underbrace{a_{N'-1}2^{N'}}_{Offset} \\ &\underbrace{-a_{N'-1}2^{N'-1} + a_{N'-2}2^{N'-2} + \cdots + a_0 2^0}_{Least\ Significant\ Part}. \end{aligned} \tag{4}$$

Therefore, the BR can decompose an N-bit signed integer into two $N/2$-bit signed integers with the additional offset in the MSP integer.

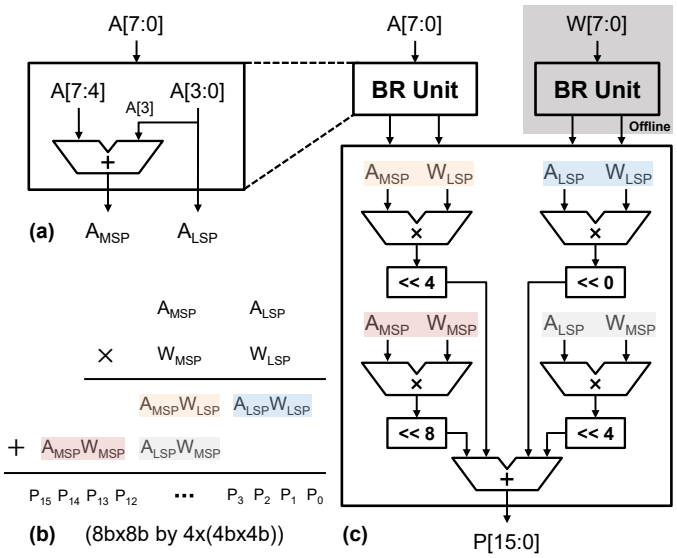

Fig. 4. Concept and structure for reconfigurable biased multiplication. (a) Schematic of a BR unit. (b) Column method for an 8-bit multiplication by using four 4-bit multiplications. (c) Overall structure for an 8-bit multiplication through biased multipliers.

B. Reconfigurable Computation for Biased Multiplication

To illustrate how biased multipliers compose the multiplication operation with 4/8-bit mixed-precision, the following discussion uses an 8-bit multiplication as an example. Fig. 4 presents the concept and structure for reconfigurable biased multiplication between two operands weight (W) and activation (A). First, a BR unit is responsible to convert the representation in bit-level decomposition, and it only consists of an adder for the 4-bit $A[7:4]$ and 1-bit $A[3]$ operands to generate the MSP of data A_{MSP}. In particular, the representation conversion for weight can be calibrated offline to reduce the hardware cost. In addition, Fig. 4 (b) also illustrates the mathematical method for an 8-bit multiplication, which can be decomposed into four 4-bit multiplications. These decomposed multiplications are then mapped to biased multipliers to generate partial products. The final result is obtained by summing all partial products through shift-and-add operations. Similarly, we can also perform 4-bit $\times$ 8-bit and 8-bit $\times$ 4-bit multiplications by using 4-bit multiplications through similar approaches as described above. Therefore, we can construct the reconfigurable biased mixed-precision convolution engine.

C. BR-Aware Training

Section III-A mentions that the BR introduces a bias shift by -8 in signed 8-bit dynamic range, leading to the overflow issue within the original range of $[120, 127]$. To avoid degrading the dynamic range through direct clipping, we propose the BR-aware training strategy to maintain quality. Fig. 5 illustrates an example of a 4/8-bit biased mixed-precision model. The dynamic range alignment is performed to preserve the full dynamic range. First, the signed 8-bit model input is shifted by -8 to align with the dynamic range of $[-136, 119]$ for the

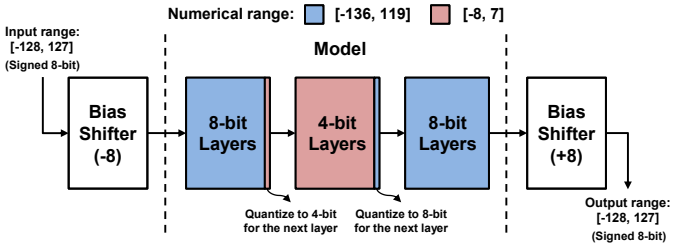

Fig. 5. An example of BR-aware training strategy for a 4/8-bit biased mixed-precision model. Assume that the activation precision is 4-bit in the middle of the model, while the rest of the model remains at 8-bit.

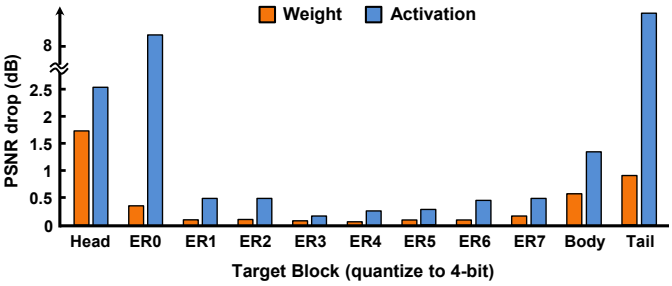

Fig. 7. PSNR drop of quantizing SR4ERNet-B8R3N6 weight and activation individually of each target block. The target block is quantized to 4-bit, while the others remain at full-precision.

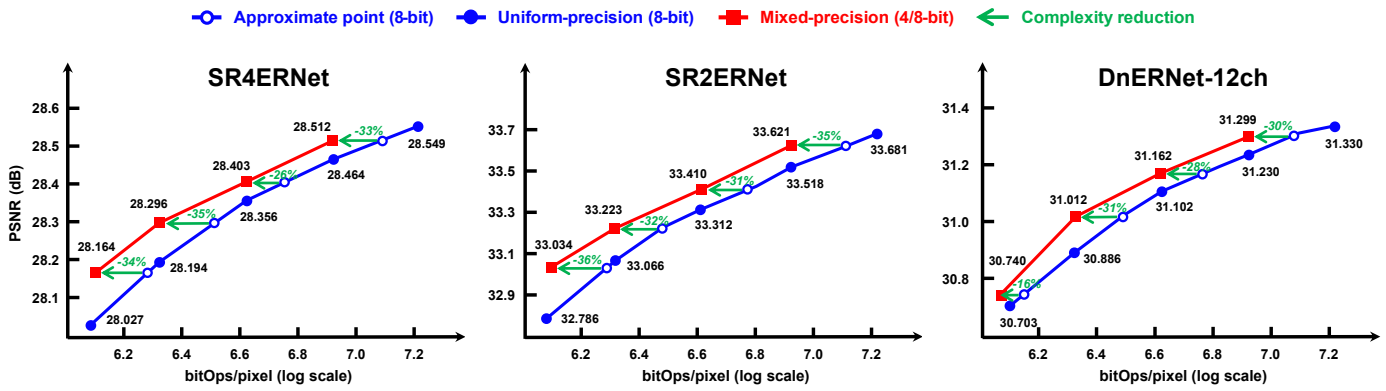
BR. In addition, the numerical range for dynamic fixed-point quantization must be guaranteed within $[-8, 7]$ for 4-bit and $[-136, 119]$ for 8-bit in each layer during quantization-aware training. Note that the numerical range in Fig. 5 only focuses on activation layers, while the numerical range for parameters must also be considered. In the end, the model output data is shifted back by $+8$ to restore the original dynamic range. With the BR-aware training, a biased mixed-precision model can be optimized to fit the biased multiplier.

IV. Evaluation

The hardware configurations of our implementation are listed in Table I. The computation for three real-time specifications, UHD30, HD60, and HD30, aims to constrain the model complexity of uniform/mixed-precision networks. In the following, we will present our approaches for building mixed-precision networks and determining layerwise precision with a heuristic-based method. Then, we will show extensive evaluations for image quality and hardware performance on 4/8-bit mixed-precision networks with our proposed biased multipliers.

A. Experiment Setup



Model structure. For high-quality computational imaging, we adopt the advanced ERNets for eCNN [10] as backbone models. They can provide similar image quality compared to the well-known SRResNet [15] for SR and FFDNet [26] for Dn, and possess additional advantages on hardware implementation [10]. Fig. 6 shows the ERNet model SR4ERNet for SRx4 and its corresponding notation for each block. There are three hyperparameters for model construction in ERNet: ERModule number B, base pumping ratio R, and additional pumping layer number N. The basic building block, ERModule, expands the model width by R times by a CONV3x3 layer and reduces the width back by a following CONV1x1 layer. We use the similar model structure to build SR2ERNet and DnERNet-12ch [10] for SRx2 and Dn, respectively.

Sensitivity-Aware Layerwise Precision. In this work, we provide a heuristic-based method to determine layerwise precision for coarse-grained 4/8-bit mixed-precision networks. We employ post-training quantization for the pretrained floating-point model to sequentially quantize the weight and activation of the target block into 4-bit, while the others remain at full-precision as shown in Fig. 7. Note that the model input and output activation remain at 8-bit to approximate. Empirically, the performance drop of Head, ER0, Body and Tail in ERNets are higher than the others. Therefore, we define these four blocks as quantization sensitive blocks and maintain the weight and activation at 8-bit in the following experiments. For clarity, the uniform-precision 8-bit for weight and activation is denoted by W8A8, while the mixed-precision 4/8-bit is denoted by W4A8, W8A4, or W4A4.

Hardware Implementation. For hardware performance comparisons, we implement three types of multipliers, uniform-precision, sign-extended, and the proposed biased multiplier, on eCNN [10] accelerators. We implemented eCNN convolution engines in Verilog HDL and performed bit- and cycle-accurate simulation for functional verification. The verified design was then synthesized with Synopsys Design Compiler on TSMC 40 nm technology. Finally, we conducted power estimation on the synthesized design using Synopsys PrimeTime PX with signal switching activity from RTL simulation.

B. Quantitative Comparisons

Table II lists the hyperparameters used in our experiments. We train ERNet models on two datasets DIV2K and Waterloo for SR and Dn tasks. We consider three throughput targets for hardware acceleration: UHD30, HD60, and HD30. For each throughput target and application scenario, we adopt

(a) SRx4 (b) SRx2 (c) Dn

the compact ERNet configuration for model evaluation as shown in Table III. Note that the quality difference between biased and "unbiased" mixed-precision models is minimal at the same level of model complexity, so we only show the latter in Table III. The mixed-precision models demonstrate significant gains over the uniform-precision models. Specifically, SR4ERNet-W4A8 and DnERNet-12ch-W4A8 models outperform the W8A8 models by 0.11 and 0.12 dB at UHD30, respectively. In general, the W4A8 models can show clear advantages over the W4A4 models because the activation are more sensitive to quantization than the weight as shown in Fig. 7. But for extremely low-complexity scenarios, the W4A4 models yield superior quality than the W4A8 models for SRx2 and Dn at near UHD60 due to the deeper layers. In addition, we compare quality-complexity tradeoff curves in Fig. 8. Based on the same image quality of the uniform/mixed-precision models, the mixed-precision models can provide the complexity reduction by 31%, 33%, and 30% on average for SRx4, SRx2, and Dn, respectively.

C. Hardware Performance

We evaluate the hardware performance of three types of multipliers on eCNN accelerators for comparison. Table IV summarizes the design configurations and synthesis perfor-

(a) Area (b) Energy

Fig. 9. Area and energy comparison for three eCNN convolution engines corresponded to Table IV. The eCNN convolution engines consist of convolution, pre-/post-processing units and local register files for parameters. The energy of both sign-extended and biased mixed-precision engines is based on the power consumption listed in Table IV and the complexity reduction with respect to uniform-precision counterpart in Fig. 8. It is then averaged over real-time inferences and normalized with the energy of the uniform-precision engine.

mance for three eCNN convolution engines. The eCNN convolution engines can run at 200 MHz and achieve up to 524.3 TbitOps of inference performance. Fig. 9 shows the area and energy comparison for the design. Compared to the uniform-precision counterpart, the sign-extended and biased mixed-precision convolution engines bring 60% and 10% area overhead, respectively. The proposed biased multipliers can provide the area overhead reduction by 50%. And the remaining overhead mainly arises from the datapath control and post-processing units to enhance the design throughput. On the other hand, we perform energy comparison among three engines, as shown in Fig. 9 (b), at the same level of image quality. The experiments are conducted on SR and Dn tasks in three real-time specifications: UHD30, HD60, and HD30. Based on the results, our biased mixed-precision convolution engine demonstrates higher energy efficiency than the other two engines. More specifically, our biased mixed-precision convolution engine can deliver 33% and 50% energy reduction on average over the uniform-precision and the conventional sign-extended methods.

V. Discussion

A. Mixed-Precision Quantization

There have been extensive explorations on mixed-precision quantization to achieve additional optimizations for model quality. HAWQ [3] introduces a sensitivity metric to systematically allocate quantization precision across CNN layers during quantization-aware training. HAQ [24] leverages a learning-based method that can automatically search the optimal quantization policy under different constraints. These approaches can further enhance model quality but require more computation and time. In this paper, we provide a heuristic-based method to determine layerwise precision for mixed-precision networks. It employs the post-training quantization to determine the precision according to PSNR drop of each target block, and we fix the precision during quantization-aware training to save the computation and time. Despite the non-optimal performance, the method is fast and effective to evaluate the model quality for mixed-precision networks.

B. Performance on Recognition Tasks

Unlike computational imaging CNNs, recognition CNNs demonstrate exceptional tolerance for low-precision conditions. Recent work [2] shows that 2-bit ResNet50 can even achieve less than 3% accuracy degradation on ImageNet dataset. Several bit-flexible accelerators, such as Bit Fusion [22] and Bitblade [21], are then dedicatedly optimized for recognition CNNs. Most of them employ the conventional sign-extended multipliers to construct the convolution engine. Due to the significant complexity reduction for recognition tasks, they can achieve great energy efficiency in spite of the hardware overheads. In this paper, the proposed biased multiplier can be applied on these bit-flexible accelerators to further enhance the hardware performance. Particularly in 2-bit granularity, our biased multiplier has only a 35% area overhead, whereas the sign-extended multiplier results in 166% area overhead, as illustrated in Fig. 2.

VI. Conclusion

In this paper, we present a bit-flexible convolution engine to achieve near-maximum hardware efficiency for dense CNN acceleration. The proposed biased multiplier contributes to hardware efficiency while maintaining quality for two key reasons. First, unlike the conventional sign-extended method, the BR avoids sign extension through the replaced sign bit in the unsigned decomposed data to significantly reduce hardware overheads in bit-level decomposition. Second, the BR-aware training strategy preserves the dynamic range of input data and enables model optimizations to fit the biased multiplier. Finally, we implement three eCNN convolution engines for verifying practical effectiveness. Synthesis results show that our biased mixed-precision convolution can further reduce the area overhead by 50%. Moreover, it can also deliver 33% and 50% energy reduction over the uniform-precision and sign-extended methods, respectively, for high-quality computational imaging at real-time applications. Based on these results, we believe that the biased multiplier demonstrates exceptional capability in hardware-efficient CNN inference for bit-flexible architectures.

***Abstract*—In this paper, we investigate lightweight models for automatic speaker verification (ASV) that can be feasibly implemented on edge devices. The proposed model architecture includes an improved and re-parameterized VGG-based front-end stem (RepVGG) and an ECAPA-TDNNLite-like backbone. We refer the proposed model by IM ECAPA Rep-TDNNLite. We further apply the decoupled knowledge distillation approach to improve the performance of the lightweight model. On the open VoxCeleb1-O test set, the proposed IM ECAPA Rep-TDNNLite achieves 1.76% equal error rate (EER) and 0.13 minimum decision cost function (minDCF) with 1.31M model parameters and 1.45G FLOPs. The performance can be improved to 1.66% EER and 0.12 minDCF by a different RepVGG front-end with 1.46M parameters and 2.67G FLOPs. Thus, the proposed lightweight model is capable of providing good performance on edge devices with limited computation resources.**

I. Introduction

Automatic speaker verification (ASV) is an identity authentication technology that has been receiving increasing attention in recent years. Modern ASV systems often convert the acoustic features of speech into the corresponding speaker embeddings for reliable verification. It can protect personal data from being forged and stolen by comparing the pre-enrollment speaker embedding with an unknown one.

Effective recognition models from the image processing field can be applied in the field of spoken language technology. In particular, such models have made very strong impact on ASV recently. With 1-D convolution (TDNN) as the backbone, ECAPA-TDNN [1], which introduced the multi-branch structure [2] and attention mechanism [3], has occupied top rankings in many competitions since its launch [4]–[6]. With 2-D convolution, ResNet [7] and RepVGG [8], [9] also work well in several ASV evaluations [9]–[11]. As both model architectures are capable of performing well in competitions, models combining the two architectures have been developed. ECAPA CNN-TDNN [12] connects the ResNet structure to ECAPA-TDNN as a front-end module, further improving system performance. CS-Rep [13] incorporates the re-parameterization method [8] and adjusts the fusion operation, and lets VGG-like TDNN structures achieve state-of-the-art performance.

Since the above models were introduced to ASV competitions, many variants have been introduced by adding or modifying different structures. Most of these models were, however, enhanced through the use of more complex convolution operations or deeper neural networks. In practice, these models are too complex to deploy on edge devices such as mobile phones. As a result of the hardware limitations on edge devices, it is important to design models with low complexity while maintaining sound performance level.

In this paper, we begin with IM ECAPA CNN-TDNN [14], which is an improved version of ECAPA CNN-TDNN, as baseline. We design a lightweight model by combining the baseline with dimensionality reduction and separable convolution [15]. Variants of RepVGG-Blocks [9] are applied to replace the original convolution layers inside the front-end module. We call this model IM ECAPA Rep-TDNNLite. Furthermore, we experiment knowledge distillation approaches to further improve the performance of the lightweight model. After training with knowledge distillation, the performance of the model on each dataset is further improved. Note that knowledge distillation is a key component as the final system outperforms other recent works without the assistance of teacher models.

The remainder of this paper is organized as follows. Section II introduces our complex and lightweight models in detail. Section III describes the knowledge distillation employed in our experiments. Section IV specifies the experimental setup and evaluation protocol. Section V presents the experimental results and associated discussion. Concluding remarks are summarized in Section VI.

II. Models

A. IM ECAPA CNN-TDNN

IM ECAPA CNN-TDNN is an improved version of ECAPA CNN-TDNN that we developed in previous study [14]. The model architecture is shown in Figure 1. The refinements are summarized as follows.

- **Adjust the neural networks of residual blocks in 2D-CNN stem to the pre-activation version.** According to the study in [16], any operation on the shortcut connections of residual blocks would lead to diminished performance of neural networks; on the other hand, switching the neural networks' sequence of residual blocks from

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

post-activation to pre-activation could increase the generalization ability of models and improve its training speed.

- **Replace Res2Block in ECAPA-TDNN with SC-Block.** SC-Block is the convolution block of Self-Calibration Network (SCNet) [17], which integrates the concepts of Res2Net and SKNet [18]. With its own self-calibration mechanism and segmentation convolution similar to Res2Block, SC-Block obtains a large receptive field and captures spatial information. This enables SC-Block to extract more detailed feature information than Res2Block.
- **Add an aggregation layer after every SC-Block.** These aggregation layers concatenate the previous output of different scales to perform feature reconstruction. They are combined with the multi-layer aggregation method in the original ECAPA-TDNN to create a hierarchical aggregation structure. At the network head (top), more features of different scales would be fused to extract speaker embeddings with more detailed information.
- **Change the attention mechanism from SE to CBAM.** SE is an attention mechanism module from Squeeze-and-Excitation Network (SENet) [3]. It only focuses on the channel dimension, while the spatial dimension still has significant information to exploit. Therefore, we introduce CBAM (convolution block attention module) [19] as a replacement for SE. Comparatively to SE, CBAM also takes spatial attention into account. By integrating channel attention and spatial attention, the 2D CNN stem could reconstruct the audio features in a more detailed manner.

IM ECAPA CNN-TDNN is a complex model with high model capacity. A trained IM ECAPA CNN-TDNN model is used as a teacher model in knowledge distillation for the proposed lightweight model, which is introduced next.

B. IM ECAPA Rep-TDNNLite

The proposed lightweight IM ECAPA Rep-TDNNLite model is based on the complex model aforementioned in Section II-A. The complete network topology is shown in Fig. 2. The modified parts are described as follows.

- **Reduce the number of convolution channels in the backbone structure.** Since this is a lightweight model, it is very intuitive to reduce the number of parameters and floating point operations (FLOPs) by reducing the number of convolution channels. Furthermore, we set the stride of the first convolution layer in the backbone structure to 2 according to ECAPA-TDNNLite [15]. This setting reduces computation by 50% while decreasing performance only slightly.
- **Replace SC-Block to separable Res2Block.** Based on ECAPA-TDNNLite, we replace the convolution blocks SC-Block inside the backbone structure with a separable Res2Block to further reduce the number of parameters.
- **Replace the 2D-CNN stem to a RepVGG-based front-end module.** As the front-end module of the complex model in Section II-A uses only the basic residual block structure, we replace it with RepVGG-Block [8]. With RepVGG, the model takes advantage of multi-branch convolution during training. In the inference stage, the model could switch to one-way convolution through re-parameterization, reducing parameters and FLOPs effectively while maintaining performance. The structure of RepVGG-Block has been experimented on speaker verification tasks [9]. Two of the RepVGG-Block variants designed in [9], RSBA and RSBB (Rep Speaker Block A & B), are implemented and evaluated in our experiments. These two structure are shown in the III part of Fig. 2.

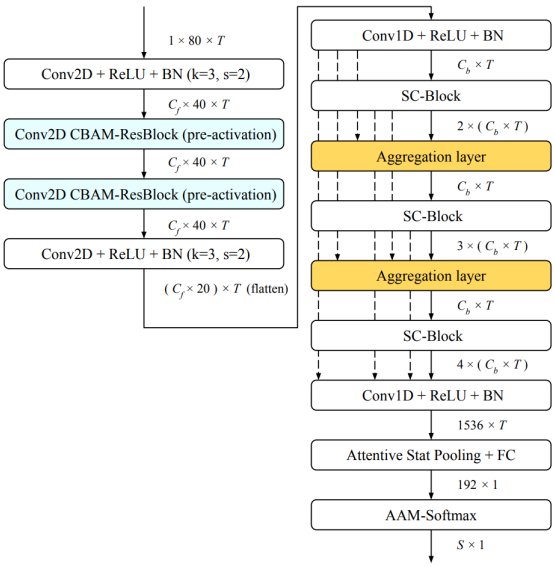

Fig. 1. Network topology of IM ECAPA CNN-TDNN. The left half is front-end module, and the right half is backbone structure. k represents kernel size, s represents stride. C_f and C_b denote the number of channels in the front-end module and the backbone structure respectively. T and S are the number of frames and speakers. Lines with dashes ignore the middle layer of the path and send the data directly to the specified layer.

In our experiments, we compare training alone and training with knowledge distillation on this lightweight model to investigate the impact of distillation on model performance.

III. Knowledge Distillation

Knowledge distillation is a well-known method for model compression. With the assistance of dark knowledge extracted from pre-trained complex model, the output of lightweight model would be as close as possible to the output of complex model. There are two mainstream knowledge distillation methods in the speaker verification task. One is the embedding-based distillation, another is the logit-based distillation. The simplified knowledge distillation diagram in speaker verification task is illustrated in Fig. 3.

In our experiments, we use the logit-based distillation. During the training phase of speaker verification systems, the output of the classification head consists of the posterior probability for the specified set of speakers. We let the output posterior of the student model imitate the output posterior of the teacher model. Our implementation of knowledge distillation includes the traditional Kullback-Leibler divergence loss

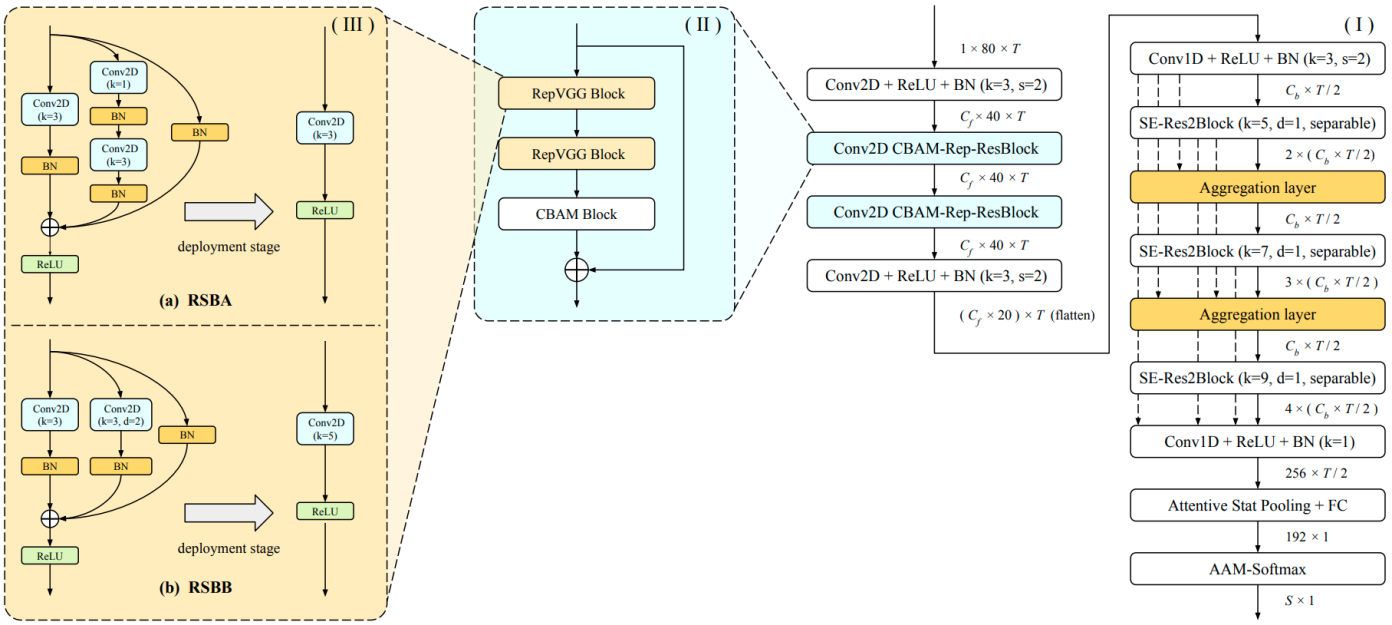

Fig. 2. Network topology of IM ECAPA Rep-TDNNLite. We expand the structural details in three levels: (I) Architecture of IM ECAPA Rep-TDNNLite, (II) Details of Conv2D CBAM-Rep-ResBlock, and (III) Details of two variant structures of RepVGG-Block. The "separable" in SE-Res2Block of (I) means we use depthwise separable convolution layers in SE-Res2Block. C_f and C_b denote the number of channels in the front-end module and the backbone structure respectively. k, s, d denote kernel size, stride, and dilation spacing. T and S correspond to the number of frames and the number of speakers. $\oplus$ denotes as element-wise addition. RSB denotes the RepSpk block from [9], and we choose two variants A & B to implement in our experiments.

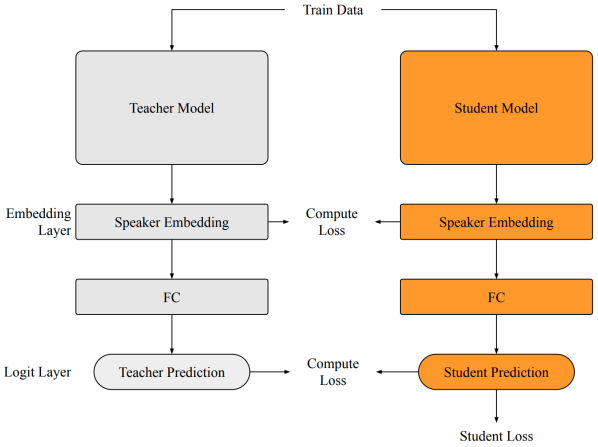

Fig. 3. Diagram of knowledge distillation for speaker verification systems. Embedding-based distillation means using the embedding layer output to compute consistency loss, while logit-based distillation uses the logit layer.

and the recently proposed decoupled knowledge distillation loss. In training stage, the distillation loss is a soft loss combined with the original student model loss (hard loss)

$$L = L_{\text{hard}} + \alpha L_{\text{soft}} \tag{1}$$

where α is a hyper-parameter for the weight of the soft loss.

A. Kullback-Leibler Divergence Loss

Kullback-Leibler divergence (KLD) measures the difference between two probability distributions. In the well-known study of knowledge distillation [20], KLD is used to calculate the distillation loss. Specifically

$$L_{\text{KLD}} = \sum_{i=1}^{N} D_{\text{KL}}\left(\tilde{\mathbf{p}}^i || \mathbf{p}^i\right) = \sum_{i=1}^{N}\sum_{j=1}^{C} \tilde{p}_j^i \log\left(\frac{\tilde{p}_j^i}{p_j^i}\right) \tag{2}$$

where N is the number of samples, C is the number of classes, $\tilde{\mathbf{p}}^i, \mathbf{p}^i$ are probability vectors, and $\tilde{p}_j^i, p_j^i$ are the probability of class j for sample i.

B. Decoupled Knowledge Distillation Loss

We also investigate decoupled knowledge distillation [21]. The loss L_{KLD} can be decomposed to two terms. One term is a binary logit loss for target classification knowledge distillation (TCKD). The other is a multi-category logit loss for non-target classification knowledge distillation (NCKD). Specifically

$$\begin{aligned} L_{\text{KLD}} &= \sum_{i=1}^{N} \text{TCKD}_i + (1 - p_t^T)\text{NCKD}_i \\ &= \sum_{i=1}^{N} D_{\text{KL}}(\mathbf{b}_t^i || \mathbf{b}_s^i) + (1 - p_t^T) D_{\text{KL}}(\hat{\mathbf{p}}_t^i || \hat{\mathbf{p}}_s^i) \end{aligned} \tag{3}$$

where s and t indicate student or teacher models, $\mathbf{b}^i$ is the binary probabilities for target classification, $\hat{\mathbf{p}}^i$ is the multi-category probabilities for non-target classification, and p_t^T is the probability of the target class predicted by teacher model.

The results of ablation experiments in [21] indicated that NCKD is the major cause affecting the distillation effect. However, the reformulated KLD in Eq. (3) shows that NCKD is constraint by weight $(1-p_t^T)$. As the teacher model predicts more accurately, i.e. the larger the p_t^T, the lower the impact of

NCKD. As a result, it is difficult to distill knowledge from the high performance model using the traditional KLD method. In order to resolve this issue, a simplified and effective method called decoupled knowledge distillation (DKD) is proposed

$$L_{\text{DKD}} = \sum_{i=1}^{N} \text{TCKD}_i + \gamma \text{NCKD}_i. \quad (4)$$

That is, $(1 - p_t^T)$ in Eq. (3) is replaced by hyper-parameter γ to simplify the balance between TCKD and NCKD.

IV. Experiments

A. Datasets

We use the development part of the VoxCeleb2 [22] dataset as our training data, which contains 1,092,009 utterances from 5994 speakers. Musan [23] corpus (additive speech, music, and noise) and RIR [24] corpus (reverb) are employed for online data augmentation. Each training step would randomly select one method for data augmentation.

B. Training Details

The input features are 80-dimensional log Mel-filterbank energies with a window length of 25 ms and a 10 ms frame-shift. In addition, the extracted features are mean-normalized without the application of voice activity detection (VAD). The features are cropped into 2-second segments and 256 segments form a mini batch. The RSBA structure can only be trained using 200 segments in a mini batch because of hardware limitations. The channel C_f is set to 64 in all front-end modules, and the channel C_b is set to 512 and 144, separately, in the backbone of complex models and lightweight models. All models are trained with an initial learning rate of 0.001, which is reduced by 25% every 10 epochs with Adam optimizer. AAM-softmax is chosen as the loss function of hard loss with a margin of $m = 0.2$ and a scale of $s = 32.0$. A weight decay of 2e-05 was applied during training to prevent the model from overfitting. The hyper-parameter α, β and γ are set to 1, 1 and 8. The temperature parameter in KLD-based loss is set to 4. The training phase of lightweight models terminates after 100 epochs.

C. Evaluation Protocol

In the experiment, the clean trials of VoxCeleb1 [25] are used as test sets. The features of test audios are cropped into 4-second segments. Equal error rate (EER) and minimum detection cost function (minDCF) are used as our evaluation metrics for measuring the performance of the systems. The computation of minDCF uses the same setting as VoxSRC 2022, with parameters $C_{\text{miss}} = 1, C_{\text{false}} = 1$, and $P_{\text{target}} = 0.05$. We did not implement any score normalization methods.

V. Results

We first present the ablation experiment results in our previous paper [14] to show the performance of IM ECAPA CNN-TDNN. After that we compare our proposed models with other recent works on lightweight models. Finally, we discuss the impact of different methods of knowledge distillation on model performance.

A. Performance of IM ECAPA CNN-TDNN

Our previous paper compared the performance of IM ECAPA CNN-TDNN composed of different attention mechanisms. The simplified experimental results are shown in Table I. We only present the evaluation results of the simplest and most complex test sets. Note that some training details and evaluation protocol in the previous paper are different from this paper, this leads to differences in performance results of models. According to the experimental results, the IM ECAPA CNN-TDNN with CBAM module performed better on the complex test set. This shows that the model has better generalization ability, which is why we use this model as our baseline model and teacher model.

B. Performance of IM ECAPA Rep-TDNNLite

Table II compares the performance of our lightweight models and other recent lightweight models for speaker verification. The EER values were taken from the reported values in the reference papers. We first experiment with IM ECAPA CNN-TDNNLite, the lightweight version of our baseline model. It has the same backbone structure as IM ECAPA Rep-TDNNLite.The results show that this model has outperformed most other recent models. On the other hand, due to the multi-branch convolution design of the RepVGG structure, the performances of two IM ECAPA Rep-TDNNLite are even better than IM ECAPA CNN-TDNNLite. This shows that

TABLE III
PERFORMANCE OF OUR PROPOSED LIGHTWEIGHT MODELS WITH DIFFERENT KNOWLEDGE DISTILLATION METHODS. REPA (REPB) DENOTES RSBA (RSBB) STRUCTURE FOR REPVGG-BLOCKS IN FRONT-END MODULES.

Architecture	#Params	FLOPs	VoxCeleb1-O		VoxCeleb1-E		VoxCeleb1-H	
			EER(%)	minDCF	EER(%)	minDCF	EER(%)	minDCF
IM ECAPA CNN-TDNN (teacher)	10.04M	3.16G	1.0318	0.0786	1.2494	0.0816	2.3402	0.1447

+ KLD Loss	-	-	1.7864	0.1200	1.9731	0.1300	3.3519	0.2046
+ DKD Loss	-	-	**1.7551**	0.1303	**1.7682**	**0.1246**	**3.2755**	0.2134
IM ECAPA RepB-TDNNLite	1.46M	2.67G	1.7658	0.1215	1.9700	0.1242	3.2419	0.1979
+ KLD Loss	-	-	1.7658	**0.1124**	1.9024	0.1244	3.2092	**0.1918**
+ DKD Loss	-	-	**1.6647**	0.1194	**1.7175**	**0.1232**	**3.1784**	0.2112

using RepVGG-Block to replace the basic convolution layer in the front-end module can improve performance. However, the number of parameters and FLOPs also increases due to the use of multi-branch convolutions. This is where the reparameterization operation of RepVGG comes into play. By reparameterizing RepVGG-Blocks in the models, the model with the front-end module composed of RSBA structures managed to reduce 10.8% of the parameters and 48% of the FLOPs while maintaining the same performance, making the resource consumption close to other recent lightweight models. Note that it achieves better EER than the lightweight versions of ResNet-34 with a smaller model size. Using RSBB version of the front-end module will improve EER performance by over 6% in comparison to RSBA version. Note that RSBB will increase the parameters and FLOPs after reparameterization because it transforms into a 5×5 convolution layer. Therefore, RSBB should preserve its original structure and require more computing resources than RSBA.

C. Comparison between Knowledge Distillation Methods

The results of proposed systems under different knowledge distillation methods (KLD, DKD) are summarized in Table III. IM ECAPA CNN-TDNN is the teacher model, while IM ECAPA RepA/RepB-TDNNLite without knowledge distillation are two student model baselines. Comparing to baselines, both distillation methods we applied could boost the performance of the models to a certain extent. However, even though the traditional KLD method made a slight improvement on several test sets, the RepA model performed poorly than the baseline on VoxCeleb1-H. The results show that the KLD method fails to improve model generalization consistently. On the other hand, the DKD method brings significant enhancements to lightweight models. Particularly in terms of EER, the systems trained with the DKD method showed a clear reduction of EER from the simplest VoxCeleb1-O to the most complex VoxCeleb1-H. Based on our hyper-parameter settings during training, the result shows that the inference in [21] that NCKD is the major factor affecting the distillation effect is correct. Meanwhile, this also means that DKD can also be applied in the audio signal processing field in addition to being used in the image processing field.

VI. CONCLUSION

We propose IM ECAPA Rep-TDNNLite model, consisting of lightweight backbone of IM ECAPA CNN-TDNN and RepVGG-based front-end module, for automatic speaker verification. It achieves an EER of 1.77% on VoxCeleb1-O with only 1.46M parameters, outperforming other recently proposed lightweight models. The performance can be further improved by 7% on average across multiple test sets with knowledge distillation from complex models. Thus, the proposed model can be implemented within the computational resources of edge devices while maintaining sound performance levels.

Efficient Incremental Text-to-Speech on GPUs

Muyang Du*, Chuan Liu*, Jiaxing Qi*, Junjie Lai*
* NVIDIA, Beijing, China
E-mail: {myrond, riverl, jqi, julienl}@nvidia.com

***Abstract*—Incremental text-to-speech, also known as streaming TTS, has been increasingly applied to online speech applications that require ultra-low response latency to provide an optimal user experience. However, most of the existing speech synthesis pipelines deployed on GPU are still non-incremental, which uncovers limitations in high-concurrency scenarios, especially when the pipeline is built with end-to-end neural network models. To address this issue, we present a highly efficient approach to perform real-time incremental TTS on GPUs with Instant Request Pooling and Module-wise Dynamic Batching. Experimental results demonstrate that the proposed method is capable of producing high-quality speech with a first-chunk latency lower than 80ms under 100 QPS on a single NVIDIA A10 GPU and significantly outperforms the non-incremental twin in both concurrency and latency. Our work reveals the effectiveness of high-performance incremental TTS on GPUs.**

I. Introduction

With the recent blossoming in deep learning, speech synthesis methods have switched from traditional concatenation-based[1] and HMM-based[2], [3] statistical parametric methods to neural network based methods and have been widely used in various application scenarios. Compared with traditional methods, neural networks can produce more natural and high-fidelity speech at the cost of more computing power and larger latency. Therefore, reducing the latency of the speech synthesis is vital to improve the user experience of applications that require instant response, such as the virtual agents of call centers, especially in the case of highly concurrent requests during peak periods. With such needs, incremental synthesis shows its benefits. Instead of synthesizing the entire speech audio before responding, incremental synthesis can produce speech chunk-by-chunk to provide a lower response latency. Once the first audio chunk is generated, the synthesis time of the subsequent audio chunks is hidden within the playback time of the preceding chunks.

Speech synthesis pipelines deployed in production environments typically comprises three major components: a frontend for extracting linguistic features from the text, an acoustic model for synthesizing acoustic features such as the Mel spectrogram, and a vocoder for converting acoustic features into waveform samples. The frontend typically performs text normalization, grapheme-to-phoneme[4] conversion, prosodic structure prediction, and named entity recognition. BERT[5], a transformer-based pre-training language model for natural language processing, has been applied in several unified TTS frontend research efforts[6] and has been proven capable of effectively extracting a wide range of linguistic features for realistic speech synthesis. Acoustic models can be grouped into two major types: autoregressive and parallel. Among them, the autoregressive model Tacotron2[7], [8] and its variants have dominated the acoustic models used in industry for many years due to their outstanding and stable synthesis quality. In recent years, parallel models, such as FastSpeech[9], [10] and FastPitch[11], have dramatically improved the controllability of speech, and are widely in personalized synthesis and singing synthesis. Parallel speech synthesis models often have architecture based on Transformer[12] and Convolution. They have higher throughput compared with autoregressive models for non-incremental synthesis. However, the synthetic speech quality of parallel models is highly dependent on the visibility of the entire feature sequence. In the case of incremental synthesis, the perceptual field is usually limited to the size of the chunk resulting in quality degradation of parallel models. In comparison, the hidden state of autoregressive models passed over time carrying contextual information ensures speech quality unharmed. Meanwhile, Samsung's study[13] also pointed out that incremental synthesis using an autoregressive model has a more stable latency when the text length increases, which is evident as the latency is positively correlated with the computational overhead.

Similar to acoustic models, there are autoregressive and parallel vocoders. Autoregressive vocoder models such as WaveNet[14], WaveRNN[15], and LPCNet[16] synthesize audio sample-by-sample based on the acoustic features and previously generated samples. Parallel vocoders such as Flow-based WaveGlow[17], GAN-based MelGAN[18], and HiFi-GAN[19] directly map the entire acoustic feature sequence to the waveform. Unlike acoustic models, autoregressive vocoders needs to perform an enormous number of regressions to generate a chunk of audio. Although the number of regressions can be reduced using the multi-band mechanism[20], further model compression may still be required to obtain real-time. In contrast, parallel vocoders can perform chunk-by-chunk generation for incremental TTS, which is friendly to GPUs.

With more applications relying on low latency speech synthesis in recent years, several studies[21]–[23] have been proposed to optimize the quality and naturalness of incremental TTS. However, previous studies have disregarded the performance of incremental TTS on GPUs, which should be worthy of attention, especially under high concurrency scenarios. To the best of our knowledge, many incremental TTS pipelines deployed in production are CPU-based, which typically requires reducing the computational cost by compressing[24], sparsi-

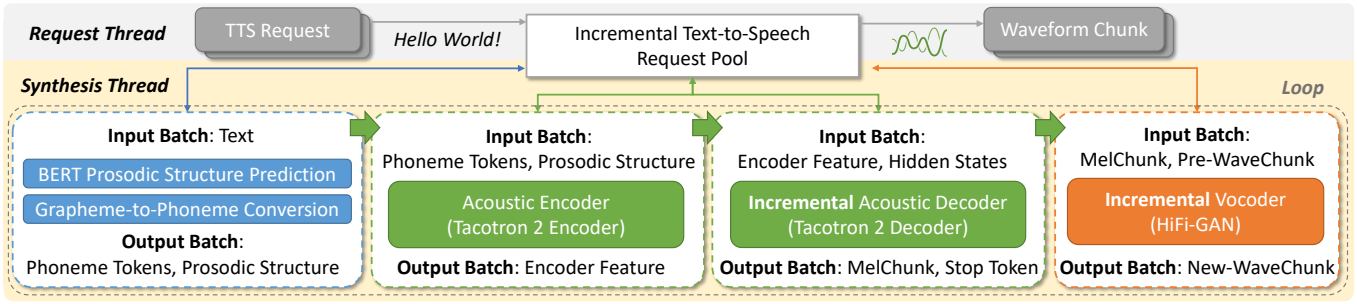

Fig. 1. Architecture of the proposed highly efficient incremental text-to-speech pipeline running on GPUs.

fying[25], and distilling[26] the model to obtain real-time. During inference, each TTS request is processed by one or more CPU cores, and batching is not involved. The additional optimization efforts for real-time on the CPU are usually time-consuming and may negatively impact the synthetic speech quality. Furthermore, the concurrency that each CPU server can handle is strictly limited by the number of CPU cores. In comparison, GPUs are better suited to computationally-intensive tasks and easier to scale. Despite the fact that GPUs have been widely used in TTS training and non-incremental synthesis as they are naturally friendly to batching, more needs to be investigated about efficient incremental TTS on GPUs.

To fill the research void, we propose an efficient approach for incremental text-to-speech synthesis on GPUs. The proposal contains a BERT-based frontend, a Tacotron 2-based acoustic model, and a HiFi-GAN-based vocoder. Furthermore, we propose the use of Instant Request Pooling and Module-wise Dynamic Batching strategies, which are vital for efficient incremental synthesis on GPUs. In the experiments, we make pressure and listening tests on the pipeline running on NVIDIA A10 GPU. Experiments prove that our approach can produce high-fidelity speech with ultra-low latency under high QPS.

II. Methods

A. Modules

*1) **Frontend**:* The frontend consists of a grapheme-to-phoneme (G2P) conversion unit and a BERT-based prosodic structure prediction model. G2P first converts the text into a Chinese pinyin sequence using the forward maximum matching algorithm based on a pronunciation dict of Chinese phrases, then converts the pinyin of each Chinese character into its phoneme tokens based on a mapping table to get the final phoneme sequence pho. During the G2P conversion, the number of phoneme tokens for each Chinese character $char_i$ is recorded as $count_i$. The prosodic structure of text can be divided into three levels: pw (prosodic word), pph (phonological phrase), and iph (intonational phrase). In order to predict the prosodic structure token sequence of each level, the text is first passed through a shared BERT backbone to extract hidden prosodic features h_i of each character using multi-head attention blocks. Then three separate linear layers are used to predict the prosody token (beginning **B** or inside **I**) of each level for $char_i$ based on h_i. Finally, the prosodic structure token sequences are regulated to have the same length as the phoneme token sequence using $count_i$.

*2) **Acoustic Encoder**:* The acoustic encoder is based on the Tacotron 2 encoder, which contains a token embedding layer, three stacked convolutional layers with batch regularization and ReLU activation, and a bi-directional LSTM layer. We refer to it as the CBRL network. In addition, three embedding layers are introduced to encode three prosodic structure sequences. The prosodic structure embedding sequence E_{pw}, E_{pph}, E_{iph} are first summed with the phoneme token embedding sequence E_{pho} then passed to the CBRL network to generate the encoded feature sequence F_{enc}.

$$\begin{aligned} E_{all} &= E_{pho} + E_{pw} + E_{pph} + E_{iph} \\ F_{enc} &= CBRL(E_{all}) \end{aligned} \tag{1}$$

*3) **Acoustic Decoder**:* The acoustic decoder is based on the auto-regressive Tacotron 2 decoder. It contains an information bottleneck PreNet, a location-sensitive attention module LSA, two stacked unidirectional LSTM layers, two linear layers for predicting Mel spectrogram and stop token, and a PostNet for improving the Mel reconstruction. Unlike the decoder used in non-incremental TTS that generates the entire Mel before vocoding. The decoder used in incremental synthesis auto-regressively generates only a chunk of Mel frames at each time, then the Mel chunk is passed directly to the vocoder for waveform chunk generation. In order to maintain the transfer of contextual information across chunks, the final decoder LSTM hidden states of the last chunk need to be explicitly cached to be used as the initial decoder states of the current chunk. These states are the last Mel frame M_{last}, the attention context A, the attention weight of the last Mel frame W_{last}, the accumulated attention weights W_{acc}, the hidden states H_{att}, H_{dec} and the cell states C_{att}, C_{dec} of the two LSTM layers.

$$\begin{aligned} H_{att}, C_{att} &= LSTM_{att}([Pre(M_{last}), A], H_{att}, C_{att}) \\ A, W_{last} &= LSA(H_{att}, F_{enc}, W_{acc}) \\ H_{dec}, C_{dec} &= LSTM_{dec}([H_{att}, A], H_{dec}, C_{dec}) \\ W_{acc} &= W_{acc} + W_{last} \\ M_{last} &= Linear(H_{dec}, A) \end{aligned} \tag{2}$$

*4) **Vocoder Model**:* The vocoder is a HiFi-GAN-based generator G that contains multiple transposed convolution and multi-receptive field fusion (MRF) blocks. In incremental TTS,

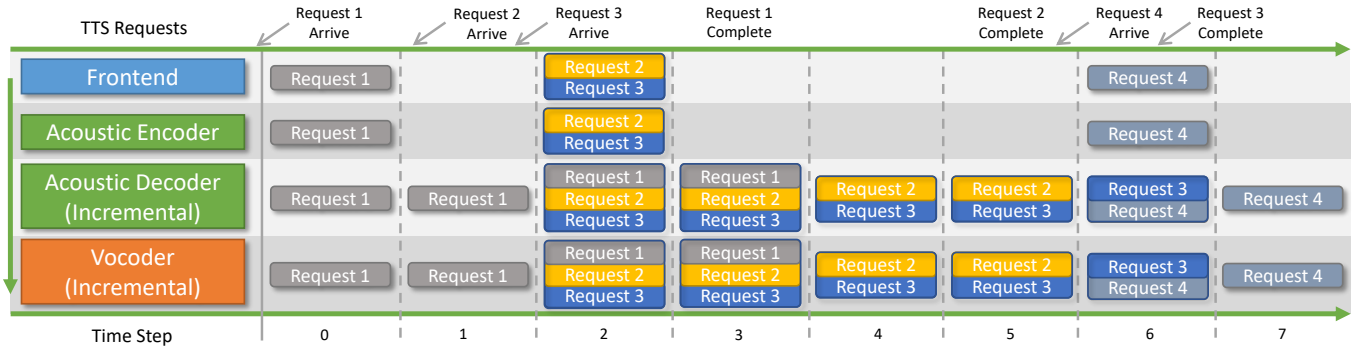

Fig. 2. Incremental synthesis timeline with the proposed instant request pooling and module-wise dynamic batching strategies.

the vocoder synthesizes one waveform chunk at a time based on a chunk of Mel frames. In order to provide a smooth articulation between two adjacent waveform chunks, we splice multiple frames from the tail of the previous Mel spectrogram chunk M_{pre} to the head of the current Mel spectrogram chunk M_{cur} and then pass it through the vocoder. Finally, the overlap areas between the current waveform chunk S_{cur} and the previous waveform chunk S_{pre} are fused by applying fade-in and fade-out coefficients α, β from equal power cross-fade, as illustrated in Equation 3.

$$\begin{aligned} S_{cur} &= G([tail(M_{pre}), M_{cur}]) \\ head(S_{cur}) &= \alpha \odot head(S_{cur}) + \beta \odot tail(S_{pre}) \end{aligned} \tag{3}$$

B. Incremental Synthesis

1) ***Incremental Synthesis of a Single Text****:* In order to achieve ultra-low latency, the proposed approach generates one short audio chunk at a time. In practice, each request contains a single text (sentence) corresponding to multiple responses. Each response carries an audio chunk of several hundred milliseconds in duration, depending on the configurable size of the chunk. The synthesis of each request involves four modules, the frontend (F), the acoustic encoder (E), the acoustic decoder (D), and the vocoder (V). The frontend and acoustic encoder modules are non-incremental and run only once per text to generated the encoded feature. On the other hand, the acoustic decoder and vocoder modules are incremental, running multiple times for each text. Each iteration produces a Mel chunk and a waveform chunk, respectively. The stop token output by the acoustic decoder exceeding threshold 0.5 flags the end of the synthesis.

2) ***Incremental Synthesis under High Concurrency****:* Incremental synthesis under high concurrency faces two challenges. Firstly, scheduling numerous requests while ensuring that each request is processed as soon as it reaches the server. Secondly, synthesizing multiple requests simultaneously while keeping low latency. As shown in Figure 1, we introduce two strategies, Instant Request Pooling and Module-wise Dynamic Batching, to guarantee new requests are synthesized instantly, together with all the other incomplete requests in the server.

■ **Instant Request Pooling**. Conventional approach to handle the incoming TTS requests while the server is processing the ongoing requests is to keep the new requests waiting inside a queue to be processed when the ongoing requests are complete. However, this approach can hardly meet the requirement of low-latency incremental TTS because the waiting time can be long under high concurrency. Therefore, we introduce an additional request pool to hold all the ongoing and new requests. We use an infinite loop to handle the incremental synthesis. Each loop iteration consistently generates one audio chunk for each ongoing request in the pool. Once a new request arrives, it is immediately added to the pool as a new pool item and available for synthesis. New requests received during the current iteration only need to wait for the next iteration to be processed, regardless of the number of ongoing requests in the pool. For each request, its pool item caches the following variables, including the model states and a module indicator:

1. Model states, including the phoneme and prosody token sequence extracted by the frontend, encoder output F_{enc}, decoder states M_{last}, W_{last}, A, W_{acc}, H_{att}, H_{dec}, C_{att}, C_{dec}, and vocoder states M_{pre}, M_{cur}, S_{pre}, S_{cur}.
2. Module indicator, indicating which module should process this item in the current loop iteration. Initialized to 0 for F, E, then changed to 1 for D, V when E completes.

■ **Module-wise Dynamic Batching**. Batching is an essential strategy to fully utilize GPU's parallel computing capability for both training and inference. For incremental TTS, we propose to use a dynamic batch size for each module. In each loop iteration, all the modules are executed sequentially, and the batch size of each module is determined by the number of items in the pool that each module should process. Specifically, each module first retrieves the pool items it should process based on the module indicator saved in each pool item. Then, it constructs an input batch for each model state from the retrieved items and performs a batched inference. Finally, it splits the output batch of each state and saves the updated state back to its corresponding pool item. Take the vocoder V as an example (F, E, D modules follows the same process), suppose N pool items are retrieved for the vocoder in the current iteration. Their states $[M^1_{pre}, M^2_{pre}, ..., M^N_{pre}]$, $[M^1_{cur}, M^2_{cur}, ..., M^N_{cur}]$, and $[S^1_{pre}, S^2_{pre}, ..., S^N_{pre}]$ are constructed to input batch M^B_{pre}, M^B_{cur}, and S^B_{pre}. After inference, the output batch S^B_{cur} is split

into $[S^1_{cur}, S^2_{cur}, ..., S^N_{cur}]$ and we update each retrieved item i:

$$M^i_{pre} = M^i_{cur},\ S^i_{pre} = S^i_{cur} \tag{4}$$

For each pool item, its F, E states keep unchanged after its first inference iteration, while its D, V states are constantly updated in the following iterations. Finally, if a request completes, its item is removed from the pool immediately.

*3) **Timeline and Latency Analysis**:* Figure 2 elaborates on the timeline of incremental synthesis with the proposed pooling and batching strategies. Each time step corresponds to one incremental synthesis iteration. In short, a new request can be processed in step t if it arrives before the start of the frontend module in step t. Request 1 arrives right before step 0 and is processed in step 0. Requests 2, 3 arrive during the execution of step 1 and are processed in step 2 in dynamic batches along with request 1. Request 1 is completed and removed immediately from the pool in step 3. Requests 2, 3 are processed together in dynamic batches in steps 4, 5. Request 2 is then completed and removed in step 5. Request 4 arrives at the end of step 5 and is processed in dynamic batches in step 6 with request 3, which is completed and removed in step 6.

Define the execution time of time step t as T_t. If a request arrives at step t, the maximum first audio chunk latency is $T_t + T_{t+1}$ (arrives right after the start of the frontend in step t), the minimum latency is $min(T_t, T_{t+1})$ (arrives right before the start of the frontend in step t, or right before the end of step t), and the expectation of the latency is $\mathbb{E} = T_t/2 + T_{t+1}$.

III. Experiments

A. Settings

All the models in our experiments are trained with the Chinese Standard Mandarin Speech Corpus (CSMSC)[27] open-sourced by Databaker. The corpus has 10,000 audio clips and a total duration of about 12 hours, each audio clip contains a short sentence of 4.27 seconds on average. We kept 100 clips for validation, 100 clips for test, and the rest for training. The Bert used in the frontend contains 12 Transformer layers with each layer 12 heads and 768 hidden units. The Tacotron 2 has the same model parameters as the original proposal with three additional 512-dim prosody embedding table. The HiFi-GAN vocoder with 128 upsample initial convolution channels and upsample factors of [8,8,2,2] is used to synthesize 22.05kHz 16bit PCM audio. All the models are trained on NVIDIA Tesla V100 GPU, and the inference pipelines are tested on NVIDIA Ampere A10 GPU. The proposed incremental pipeline is implemented in C++ as a NVIDIA Triton custom backend and the models are accelerated with TensorRT.

Since there is no publicly available performance benchmark for incremental TTS on GPU under high concurrency, we compare the proposed approach with a self-developed non-incremental pipeline using the exact same models. For the non-incremental twin, the TTS requests received over a short period are constructed into a batch for inference. The size of the batch keeps unchanged for all the models within each inference round. New requests received during the current round need to wait in the queue for the next round to be processed. Moreover, TensorRT and Triton are also applied for a fair comparison.

In the experiments, a fixed chunk size of 32 (∼372ms) Mel frames is used with an overlap (OL) of 4 and 8. We test both the incremental and non-incremental pipelines with three lengths of text (TL) and their mixture. The average audio duration (DUR) for each text type are Short (2.64s), Medium (4.08s), Long (7.00s), and Mixed (4.54s). For incremental synthesis (INCR), we measure the first-chunk latency (FCL) (between the request being sent and the first chunk being received), the last-chunk latency (LCL) (between the request being sent and the last chunk being received), and real-time factor RTF (LCL/DUR). For non-incremental synthesis (Non-INCR), we measure latency and RTF. Finally, we measure the mean opinion score (MOS) of the INCR, compared with the Non-INCR and the ground truth recordings. The MOS test is carried out by native Mandarin speakers hired from Amazon Mechanical Turk. A total of 50 fixed samples are selected from the test set for evaluating each experimental configuration. Each sample was listened by 10 evaluators and each evaluator was asked to give an opinion score from 1 to 5.

B. Discussion

TABLE I
Latency and RTF Comparison at 70 QPS

TL	OL	DUR(s)	FCL(ms)	LCL(ms)	RTF
Short	4	2.64	32.04	168.60	0.064
Medium		4.08	38.16	295.36	0.072
Long		7.00	77.05	1002.56	0.143
Mixed		4.54	44.47	400.32	0.087
Short	8	2.64	32.26	170.41	0.064
Medium		4.08	39.38	305.88	0.075
Long		7.00	91.42	1190.83	0.170
Mixed		4.54	46.29	418.37	0.091
Short	-	2.64	227.66		0.086
Medium		4.08	451.67		0.109
Long		7.00	1405.51		0.202
Mixed		4.54	1253.25		0.313

*1) **Response Latency and Real-Time Factor**:* We pressure-test the proposed approach using QPS (Queries-per-Second) from 10 to 100. Each test lasts 200 seconds. Requests sent to the server are evenly distributed within a second. Full performance metrics and samples can be found on our Github page[1]. Figure 3 shows the latency of mixed-length texts at different QPS and overlaps, which is more comparable to the real-world scenario. In the figure, we omit the data with a latency of more than 1s. For INCR, the first-chunk latency can be kept within 40 ms, and the last-chunk latency within 400 ms if the QPS does not exceed 60. In contrast, Non-INCR has a latency of more than 200 ms at 10 QPS and more than 800 ms at 60 QPS. The response latency of INCR has a 95.4%, 91.2% and 89.3% deduction compare with Non-INCR at 60, 30, and 10 QPS, respectively. At 100 QPS, INCR can synthesize in

[1]https://muyangdu.github.io/Efficient-Incremental-TTS-on-GPUs

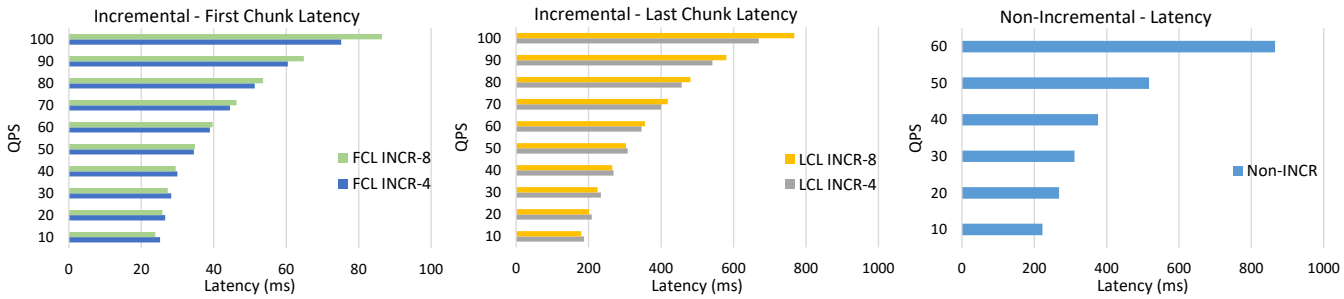

Fig. 3. Response latency of the incremental and non-incremental synthesis pipline under different QPS using mixed-length input.

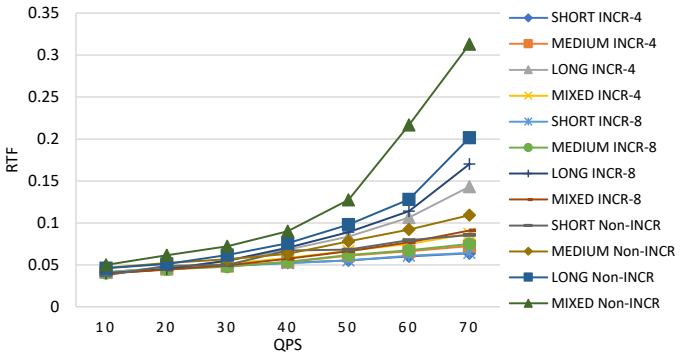

Fig. 4. Real time factor under different QPS.

real-time and provide a response latency of less than 100ms, while Non-INCR is not real-time and its latency already far exceeds 1s. In regard to the overlap, using 8 frames for overlap has slightly higher latency than 4 under high QPS.

Figure 4 shows the variation of RTF with QPS up to 70, below which all the configurations can synthesize in real-time. INCR of short, medium, and mixed text maintains a smooth RTF below 0.1 within 70 QPS. In comparison, the RTF of Non-INCR on the mixed text has a dramatic increase after 50 QPS. This proves the effectiveness and stability of the proposed strategies. Table 1 shows the performance details at 70 QPS. We observe that the mixed LCL is comparable to the medium LCL for INCR. In contrast, the mixed latency is only comparable to the long latency for Non-INCR. Similar observation is also shown in the RTF figure, in which the mixed RTF is even greater than the long RTF for Non-INCR. We attribute this observation to the redundant padding introduced for batched inference of all the modules in Non-INCR. Although padding to the maximum sequence length within a batch is still required for the F and E in INCR, the redundant padding of the D and V has been greatly reduced, leading to more efficient synthesis on GPUs.

*2) **Evaluation of Speech Quality**:* Table 2 indicates the MOS of INCR compared with Non-INCR and ground truth. The proposed approach can synthesize comparable speech quality with the non-incremental synthesis[1]. Moreover, a weak trade-off can be observed between the incremental speech quality and overlap length. Combined with the performance analysis that larger overlap only introduces slightly higher latency under high QPS on GPU, we believe it's worthwhile to use a larger overlap to achieve a better speech quality.

TABLE II
MOS WITH 95% CONFIDENCE INTERVALS

Type	Overlap	MOS (CI)
INCR	4	4.213 ± 0.120
INCR	8	4.237 ± 0.127
Non-INCR	-	4.362 ± 0.143
	Recording	4.625 ± 0.053

IV. LIMITATIONS AND FUTURE WORKS

One limitation we have identified is the use of an auto-regressive decoder, which requires multiple regressions to generate a chunk of Mel frames. Replacing it with a transformer-like parallel decoder could further speedup chunk generation. However, transformer lacks time-domain hidden states for transferring contextual information if it is used for chunk-by-chunk generation. Simply limiting the input of parallel decoder to an encoded feature chunk can result in discontinuity artifact between adjacent Mel chunks. Therefore, a potential future direction is exploring methods to use a parallel decoder for Mel chunk generation while maintaining Mel quality unharmed. Another limitation we have identified is the quality degradation caused by the overlap areas of the vocoder. While employing a larger overlap can alleviate the impact, it also reduces the ratio of valid payload of each chunk, leading to a marginally increased latency. Therefore, a potential future direction is to investigate a better streaming strategy for the parallel vocoder.

V. CONCLUSIONS

In this paper, we introduce a highly efficient approach for performing incremental text-to-speech synthesis on GPUs. Our approach allows for ultra-low latency TTS even in application scenarios with high concurrency by utilizing two important strategies: Instant Request Pooling and Module-wise Dynamic Batching. We show the effectiveness of our proposal through extensive experiments and timeline analysis. Furthermore, we offer a comprehensive performance benchmark of a complete incremental TTS system on GPUs. This benchmark can serve as a valuable reference and starting point for researchers and developers in this field. Future work will be focused on further enhancing efficiency while upholding synthetic quality.

***Abstract*—The reversible grayscale to color recovery is a challenging task due to its ill-posed inverse nature. The recovered color image produced by the color-embedded-greyscale process commonly does not have mesmerizing quality because of color distortion and checkerboard artifacts. To tackle this problem, we propose a Dual-Path Residual Attention Convolution Network (DPRACNet) to improve the quality of recovered color image. This method implements dual-path convolution network and residual attention as the building block. As reported in the Experiment Section, the DPRACNet provides best performance among the previous methods with Peak Signal to Noise Ratio (PSNR) and Structural Similarity Index (SSIM) is 31.62 and 0.934, respectively.**

Keywords—color-embedded-grayscale, dual-path convolution network, image reconstruction, residual attention

I. INTRODUCTION

A color image with three channels (RGB) can be constructed into greyscale image, cited as color-embedded-greyscale image (de Queiroz & Braun, 2006). The term color-embedded means the greyscale image contains the color information (de Queiroz & Braun, 2006). Therefore, it is achievable to revert the greyscale image back to its color version. However, the recovered color image is not as good as the initial color image. Numerous methods have been proposed to tackle this issue such as swarm intelligence (Prasetyo & Suryani., 2019) and pseudo inverse (Bjerhammar, 1951). The development of Convolutional Neural Network (CNN) enable to overcome this problem using CNN based model. CNN model achieve outstanding results compared to traditional model. For instance, CorNet (Bagaskara et al., 2020) apply CNN model to fix the information distortion of recovered color image. RecovNet (Bagaskara, 2020) introduce the use of CNN end-to-end model for color-embedded-greyscale problem. CVT (Jannah, 2022) combine the transformer and CNN model. Residual Attention Network (Deann, 2023) utilize attention mechanism.

Deeper convolutional layer grant the network to learn more advance feature so it increase the ability to learn (Wu et al., 2023). However, deeper network means more computation complexity and slower to train. The performance of the network will not make a huge impact and even decline if the network too deep (He et al., 2016). To overcome this problem, He et al. (2016) proposed residual learning concept and succeed to increase the performance of the deep network. On the other side, wider network tend to train faster, but wider network has more parameters (Zagoruyko & Komodakis, 2016). Based on these problems, many researcher propose dual convolution to expand the network width but keep the parameters low. The dual-path convolution widely used in image denoising problem such as DualCNN (Pan et al., 2018), DudeNet (Tian, 2021), and DRANet (Wu et al., 2023). These method is reported to yield good performance.

As the CNN based model grow rapidly, various architecture has been proposed to tackle different computer vision problems. U-Net (Ronneberger et al., 2015) is one of the architecture that commonly used in segmentation problems. It contains encoder and decoder. U-Net achieves state-of-the-art performance and currently adopted in other computer vision problem such as image restoration (Liu et al., 2018) and image denoising (Gurrola-Ramos, 2021). More evidence of CNN growth is attention-based models. The attention framework has widely used in numerous problems, such as image classification (Hu et al., 2018), image segmentation (Oktay et al., 2018), image denoising (Wu et al., 2023), and many others. It has been verified that attention framework achieve remarkable performance.

Motivated from several concepts as mentioned above, in this paper, we present Dual-Path Residual Attention Convolution Network (DPRACNet) for color-embedded-greyscale. DRACNet divided into two sub networks, which is upper-network and lower-network. The upper-network has a u-shaped network, which use downsampling and upsampling. The lower-network consists dilated convolution to widen the receptive field of convolution. Each sub-networks is facilitated with skip connection to enhance the network training. The feature of upper-network and lower-network is concatenated and 1×1 convolution is applied to produce the recovery color image.

The remaining section of this paper are structured in the following manner. Section II provide the relevant studies about color-embedded-greyscale image and all proposed method. Proposed method is explained in Section III. Section IV report the experiment result. Finally, the experiment concluded in Section V.

II. RELATED WORKS

A. Color embedding process

Let I be a color image of size $H \times W$ in Red-Green-Blue color space. Image I can be defined as $I \in \{Ir, Ig, Ib\}$ or $I \in \mathbb{R}^{h \times w \times 3}$. The method in (de Queiroz & Braun, 2006) begins with transforming image I into Chrominance-Luminance space or YCbCr. The transformation is formulated as:

$$\{Y, C_b, C_r\} = C\{I_r, I_G, I_b\}, \quad (1)$$

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

where $C\{\cdot\}$ represents the transformation operator from RGB to YCbCr color space. The notation Y is luminent element, while C_b and C_r is chrominance element. The process continues with decomposing luminance element Y use Discrete Wavelet Transform (DWT) as follows:

$$\{Y_\theta|(\theta = LL, LH, HL, HH)\} = \Im\{Y\}, \quad (2)$$

where Y_θ state the DWT subbands of Y element. $\Im\{Y\}$ is DWT operation. Four image sub-bands of size $\frac{H}{2} \times \frac{W}{2}$ for each image are acquired from this process. The chrominance element, $\{Cb, Cr\}$ are downsampled with factor 0.5 as depicted bellow:

$$\{c_b, c_r\} = \phi(C_b, C_r), \quad (3)$$

$\{cb, cr\}$ is the downsampled product from downsampling operator $\phi\{\cdot\}$. Each size of cb and cr become $\frac{H}{2} \times \frac{W}{2}$.

The subsequent process insert the color information by replacing the luminance elements $\{LH, HL\}$ with chrominance elements $\{c_b, c_r\}$. The other DWT elements remain the same. The embedding procedure performed by following formula:

$$\tilde{I} = \Im^{-1}\{Y_{LL}, c_b, c_r, Y_{HH}\}, \quad (4)$$

$\tilde{I}$ is color-embedded-greyscale image of size HxW. The image obtained by inverse of DWT operator $\Im^{-1}\{\cdot\}$.

Due to possible pixel values of image I may beyond the range [0, 255], we perform the clipping and rounding process. The process can be formulated as follow:

$$\tilde{I}^* = Q(\tilde{I}), \quad (5)$$

where $\tilde{I}^*$ is corrupted color-embedded-greyscale image by clipping-arounding opeartor $Q(\cdot)$.

B. Residual learning

The evolution of CNN allows it to compose a very deep network. A deeper network should capture more detailed features as the layer increases. However, the more layers stacked to the network, the more performance exhibits a progressively deteriorating trend (He et al., 2016). This issue is referred to as a degradation problem (He et al., 2016). In order to overcome this problem, a residual learning concept is proposed (He et al., 2016). The main idea of residual learning is to solve learn residual mapping which is more manageable than learning original mapping (He et al., 2016). This concept enables to build a very deep network without worrying about the degradation problem. The residual learning concept has been used in many computer vision problems, such as ResNet (He et al., 2016) for image recognition, ResU-Net (Zhang et al., 2018) for image segmentation, Residual Attention Network (Deann, 2023) for color-embedded-greyscale, DRANet (Wu et al., 2023) for image denoising and many others.

C. Dilated Convolution

Widen the receptive field of convolution can lead the network to use more context to extract global feature information (Peng et al., 2019). This can be done by increasing the filter size of convolution. However, increasing the filter size will increase the network parameters and computational complexity. To overcome this problem, dilated convolution is utilized. Dilated convolution expands the receptive field without additional parameters (Peng et al., 2019). In dilated convolution, there is dilated rate, which means the spacing between the kernel. Dilated convolution-based model has been used in various computer vision problems. Some of them are image segmentation (Chen et al., 2017), object detection (Qiao et al., 2021), and image denoising (Wu et al., 2023).

D. Squeeze-and-excitation network

One of the crucial aspects of image processing is capturing and filtering proper features. The behavior of how the model captures the features affects the output produced. However, there is a possibility some feature maps produce less useful information (Hu et al., 2018). Thus, the squeeze-and-excitation network (Hu et al., 2018) was proposed to focus on informative features and suppress the less useful ones. The gating function and sigmoid function take a big part to determine the importance of the feature map (Hu et al., 2018). Because the Squeeze-and-excitation investigates the relationship of the feature map channel, it is also called channel attention. Squeeze-and-excitation network has been widely used in image classification (Hu et al., 2018), image denoising (Wu et al., 2023), image segmentation, (Mou et al, 2019), and many other fields.

E. Dual path network

A wide network is preferable to a deep network due to vanishing or exploding gradient descent as the network is deeper (Zagoruyko et al., 2016). A wide network has a downside in the aspect of network parameters. To tackle those issues, a dual path network is used. This strategy uses two parallel sub-networks to optimize the learning ability of the model (Wu et al., 2023). These sub-networks usually has different structure so it captures different features. Dual path network has been used in various problems, such as image denoising (Wu et al., 2023), object detection (Zhou et al., 2022), image segmentation (Lai et al., 2023), and image completion (Shamsolmoali et al., 2023).

III. Proposed Method

In this section, we present the overview of DPRACNet. Subsequently, we elaborate on the detailed structure of sub-networks.

A. Network architecture

The overview of DPRACNet architecture can is displayed in Fig. 1. The model is divided into two sub-networks: upper-network and lower-network. The upper network is inspired by U-Net, which consists of downsampling and upsampling. The Max Pooling is utilized to downsample the feature maps and for the upsampling, bilinear interpolation is used. The building block of the upper network is the residual block. The U-Net structure can capture multi-scale features. The lower network contains stacked dilated residual blocks. The dilation rate is shown by the number at the dilation residual block. Skip connections are employed in both sub-networks to improve the model performance. To fuse the extracted features from each sub-networks, a concatenation operation is used. The fused features passed to 1×1 convolutions to produce the recovery-colored image. The filters of all convolutional layer are set to $3 \times 3 \times 32$.

B. Upper Network

The upper network consists stacked residual block (ResBlock) with a U-shaped structure shown in Fig. 1. The structure of ResBlock is presented in Fig. 2. Each ResBlock contains two convolutions. The first convolution is followed by non-linearities. After the last convolution, we assign

channel attention to find the inter-channel correlation of extracted features. The shortcut connection is located after channel attention and followed by non-linearity. The sign '⊕' represent element-wise summation. The use of non-linearity will be determined by experimenting with several popular non-linearity, such as ReLU, Leaky ReLU, SiLU, and GeLU. The upper network is facilitated with a symmetric skip connection. A symmetric skip connection will help convolution to reconstruct the upsampled features after the spatial information loss because of downsampling.

C. Lower-Network

The lower network is composed of several ResBlock with dilated convolution. The dilated ResBlock is displayed in Fig. 3. The lower network is also facilitated by a symmetric skip connection like the upper network. Different from the upper-network, the lower network does not have a U-shaped structure. The structure of dilated ResBlock is similar to ResBlock except it uses dilated convolution. The dilation rate span from 2 to 4. The dilated convolution will widen the receptive fields so the captured features give more context and global information. The sign '⊕' denotes element-wise summation. Channel attention is also assigned in the dilated ResBlock. The non-linearity will follow the upper network and determained via experiment.

D. Channel attention

The channel attention design is inspired by the squeeze-and-excitation block. The main purpose of using channel attention is to find the correlation of the feature maps channel. Channel attention can boost the model performance and help the model to converge when training. The composition of channel attention can be viewed in Fig. 4. To get the relationship of inter-channel, first, we squeeze the dimension of feature maps by global pooling. Squeeze-and-excitation block uses Global Average Pooling, but CBAM (Woo et al., 2018), also uses Global Max Pooling. To find out the best global pooling, we will determine it by experiment. The squeezed features are then passed to two convolutions with the first convolution followed by non-linearity. The convolution will learn the global information from squeezed features. Subsequently, the learned features are sent to the sigmoid function to generate channel weight. Finally, the reweighted feature maps are obtained by element-wise product between the input features and channel weight. This produced feature map will highlight more useful features and diminish less useful ones.

E. Loss function

Mean squared error (MSE) is implemented as the loss function for DPRACNet. MSE is widely used for the image reconstruction problem. We try to reconstruct the color-embedded-greyscale image back to color image, so MSE will be suitable for the problem. The loss function can be expressed as:

$$MSE = \frac{1}{2N}\sum_{i=1}^{N}\left\| f_{\mathrm{DPRACNet}}\left(I_G^i\right) - I_C^i \right\|^2, \quad (6)$$

where N denotes the total data, $f_{\mathrm{DPRACNet}}(\cdot)$ is the prediction produced by feed-forward of DPRACNet with a color-embedded-greyscale image I_G^i as the input. I_C^i is the ground truth of the color image.

IV. Experimental Results

This section provides the full experiment environment and result. The evaluations used to measure the network performance are Peak Signal Noise Ratio (PSNR) and Structural SIMilarity (SSIM) index.

A. Dataset

The Div2K (Agustsson & Timofte, 2017) was used to train DPRACNet. We use 800 high-resolution images for training data and 100 high-resolution images for validation data. To uniform the size of all images, we resize them to a size of 512x512 pixels. Each image is patched into non-overlapping patch images size of 128x128 pixels. The train data is reproduced by image augmentation techniques, such as horizontal flip, vertical flip, and random rotation. The total number of images in train data after image augmentation is 12800 images. The model performance is evaluated using test data, containing 24 images from the kodak image dataset (Franzen, 1999).

B. Experimental setup

For this experiment, we use TensorFlow v2.11.0 framework. The model is trained in Google Colab which facilitated with GPU T4, Intel(R) Xeon(R) CPU @ 2.20GHz, 12GB RAM. We use adam optimizer with initial learning rate is 1e-3. We use default value for adam optimizer beside the learning rate. The batch size is set to 8. For network architecture tuning, the network is trained for 40 epochs. After obtaining the final architecture, the network is trained for 70 epochs with learning rate scheduler. For 1st-30th epochs, the learning rate is 1e-3. The learning rate of 31th-60th epochs is 1e-4. For the last ten epochs, the learning rate is set to 1e-5.

C. Network architecture tuning

In this experiment, there are two parts of network to tune. These are global pooling for channel attention and non linearity for the whole network. First, we find the best global pooling for channel attention. To conduct the first experiment, we try global average pooling, global max pooling, and combination of two of them. For the combination pooling, the convolution share the used weigth, so there is no addition parameters. We determine the result based on the loss in validation data. The result of global pooling experiments is reported by fig 5. This figure shows that using Global Max Pooling achieve lowest loss compare to other global pooling. Based on the reported result, we will use Global Max Pooling in channel attention.

Using Global Max Pooling, we held the second experiment. The second experiment is finding suited non-linearity for the whole network. We use some popular non-linearities, such as ReLU, Leaky ReLU, SiLU, and GeLU. The various loss decline on different non-linearities depicts in Fig. 6. As illustrated in this figure, the most suited non-linearities to implement for the whole network is ReLU. This can be considered based on the lowest loss value when the network uses ReLU as non-linearity.

Using Global Max Pooling as the global pooling in channel attention and ReLU as non-linearity, we train the final architecture. The final architecture is trained for 70 epochs with a learning rate varying from 1e-3 to 1e-5 using a learning rate scheduler. The training progress can be seen in Fig 7.

D. Performance comparisons with previous method

To discover how good DPRACNet is compared to the previous method, we evaluate the PSNR score and SSIM. The summarization of the comparison with the previous method is represented in Table 1. As shown in this table, DPRACNet has the highest PSNR and SSIM score among previous methods. It validates that DPRACNet is better than other methods by producing the recovery color image closer to its color version.

DPRACNet also has a relatively lower number of parameters compared to other deep learning methods. Although having a relatively lower number of parameters, DPRACNet has significant performance improvement compared to other previous methods.

E. Visual Investigation

The visual investigation of DPRACNet is shown in Fig 8. This figure shows how well the performance of the purposed method. As observed in this figure, we can conclude that DPRACNet has the best recovered color image compared to the previous method based on the PSNR.

V. Conclusion

In this paper, we present Dual-Path Residual Attention Convolution Network for color-embedded-greyscale images. The network consists of two sub-networks arranged in parallel. The upper network has U-shaped and ResBlock as the building block. Meanwhile, the lower network is composed of dilated ResBlock. Each sub-networks is facilitated by a symmetric skip connection to boost the performance and network training. Using dual-path convolution, the proposed method can capture more various features and achieve promising performance. Based on the experimental result, the proposed method yields the highest performance compared to the previous method based on PSNR and SSIM 31.62 and 0.9341, respectively. The proposed method also has a relatively low number of parameters so it has less complex computation.

***Abstract* — Due to the rapid technology scaling and complexity increasing in modern IC designs, a chip often contains thousands of macros and millions of standard cells. In the back-end physical design, the placement becomes a significant challenge in the presence of large number of macros nowadays. To swiftly obtain low-power, high-efficiency, and low-cost chips, design factors such as total wirelength is usually considered as an important matric during placement stage. Conventionally, the position of the macro in initial placement is roughly determined by minimizing the wirelength at prototyping stage. After that, at macro placement stage, the location of each macro is adjusted to form a legal placement solution without increasing total wirelength. Finally, standard cells are placed based on the macro placement result. Among all three stages, the macro placement stage is crucial since the macro placement result will seriously impact the quality of standard cell placement as well as total wirelength. Therefore, in this paper, we propose a novel macro placement framework with the concept of "double contour" to find legal placement result of macros with minimum total wirelength. Specifically, our framework can be divided into two stages, the legal placement stage and optimization stage. In legal placement stage, we apply two contours which macro can be align with so the solution space is increased and the better legal placement result could be obtained. In optimization stage, we propose a simulated annealing based (SA-based) approach to further optimize the result by flipping and fine-grained moving macros. Experimental results show that our method can reduce total wirelength up to 12.5% compared with conventional single-contour-based method.**

1. INTRODUCTION

In modern IC design procedure, Intellectual Property (IP) modules and embedded memory [1] have been widely used in integrated circuit manufacturing processes to reduce design complexity and shorten time to market. Since such circuits usually contain millions of macros and standard cells, finding the appropriate position of each component is extremely difficult. The process of placing all the macros and standard cells into the chip is called mixed-size circuit placement design [2]. Currently, the most common adopted mixed-size circuit placement process can be divided into three stages: mixed-size prototyping, macro placement, and standard cells placement, as shown in Fig. 1. In mixed-size prototyping stage, we consider wirelength as the major factor to determine the initial spread of macros and standard cells on the chip, which is called the initial placement. The better initial placement should contain minimum total wirelength so that the circuit performance can be improved. In this stage, overlapping of components is allowed in order to find better solutions. In Macro placement stage, we only focus on legalization and optimization of macros based on the initial placement. In the standard-cell placement stage, macros will not be moved, and standard cells are placed in the remaining space.

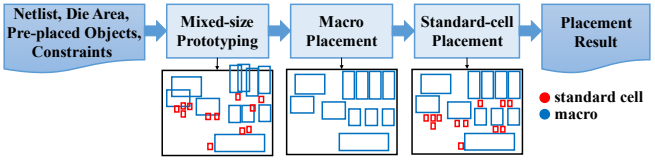

Fig. 1 Mixed-size circuit placement process.

Unlike standard cells have the same height, the size of each macro may be variant. Besides, macros are much larger than standard cells. If we place macros inappropriately, it may not only lead to longer total wirelength but also make the standard cells placement stage difficult to be implemented. Therefore, macro placement is especially important, and developing a comprehensive framework for automatically placing macros to obtain optimal macro placement efficiently is in demand. The primary goal of macro placement is to obtain a legal solution for macro placement. The solution should reserve enough space for standard cells and minimize total wirelength. Since the initial placement of macro at prototyping stage has given the wire length as the factor, it implies that in macro placement stage we should avoid increasing wirelength by minimizing the displacement of macro.

There are several papers concentrated on macro placement problems, and various data structure and algorithm such as MP-tree [3], CP-tree [4], B*-tree [5], Chang *et al.* [6], XDP [7], and ePlace-MS [8] are proposed. Among them, tree-based methods are most widely used since they are easily applied to represent the relative position of each macro in contrast of other methods. Moreover, MP tree and CP tree are inclined to reserving the center space of the chip by placing macros to the four boundaries of the chip. However, they have restriction in the case of non-boundary fixed macros. The circular-contour-based approach [9] can solve such case. Also, it usually leaves more room for standard cells than tree-based method. Nevertheless, the circular-contour-based approach will make the displacement of some macros from its original position increase, since it tends to pull the macro closed to the center to near the boundary of the chip. This may lead to longer total wirelength, and cause routing congestion at the boundary which limits the placement of standard cells.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

In this paper, we propose the concept of double-contours method to take this issue into account. We use an example to illustrate our idea. Fig. 2(a) shows the initial illegal macro placement. The macros (m1~m7) inside the gray dashed rectangle are placed closed to the center of the chip. Comparing their final position after macro placement by circular-contour-based and our proposed double contour method respectively, as shown in Fig. 2(b) and (c), it can be observed that the circular-contour-based method only use single contour to decide the position where macros to be placed. Since it is limited to only a single contour, the next macro to be placed can only choose from the current contour to place. Thus, its placeable position is relatively limit and extremely close to the boundary of the chip. On the other hand, the novel concept of the double contour is shown in Fig. 2(c). Instead of single contour, we construct a second-layer contour according to the distribution positions of m1~m7 from Fig. 2(a). The second-layer is used to provide inner space for macros. In this way, the macro whose initial position is near to the outside can be placed based on the outer contour. Furthermore, the macros whose initial position is closer to the inside can be placed based on the inner contour, which will no longer be confined to the outer contour. It can be seen that our method can lead to wider solution space. Therefore, it can effectively reduce the displacement, and thus further avoid longer wirelength.

The major contributions of this paper are as follows:

- We propose a novel double contour data structure to provide a second layer of contour for macro placement Each macro can deserve more choice of placement, so that better legal placement can be found.
- We improve simulated annealing (SA) [10] which is combined with greedy algorithm to obtain optimal placement solution efficiently. Consequently, it can focus on solution quality based on HPWL by flipping and moving macros.
- Experimental results show that our algorithm is effective and robust. The proposed algorithm can achieve the better solutions from the view of routed wire length on average, compared with single contour.

2. PREVIOUS WORKS

Since our method refers to Slicing tree [11], contour, and SA [10], here we first introduce them below.

2.1. *Slicing tree-based approaches*

Its purpose is to divide the chip into some blocks. The method is to divide a rectangular region into two rectangles with vertical or horizontal lines each round. That is, the Slicing tree is a binary tree composed of internal nodes representing vertical or horizontal lines and leaf nodes representing rectangular domains. Its advantage is to avoid macros in a certain area to be put far from the original region. Therefore, the total displacement of the macros can be effectively reduced, and the complexity of routing is also reduced.

2.2. *Contour-based placement approaches*

There are some previous algorithms that use the concept of the contour, such as MP-tree [3], CP-tree [4], B*-tree [5], MDP-tree [12], and so on. These packing trees use only a contour in one direction (ex: horizontal contour or vertical contour). Their contour is defined as the surface that can be irradiated by imagining parallel light in the specified direction. It will cause great restrictions in the process of placing the macros. Furthermore, there will be some wasted area. Another paper proposed the concept of circular contour [9] which improves the disadvantages of the single-direction contour just mentioned above. However, the macro is limited to be put along the frame. Hence, we propose a double-contours structure, so that the macro can also be placed in the middle area of the frame to solve the above problems.

2.3. *Simulated Annealing (SA)*

SA [10] will find a new solution based on the current solution. Also, it has a chance to accept a poorer solution instead of being limited to the current best solution and stop. Hence, it may find a better solution. The probability of acceptance will decrease along with the gradually reduced temperature, so eventually it converges to a better solution. Therefore, in this paper, after we find the initial legal solution, we will use the SA to further optimize our placement.

3. PROBLEM FORMULATION

This paper targets the macro placement problem in the three-stage mixed-size placement, as shown in Fig. 3. Specifically, we assume the initial placement result is given, and our mission is to adjust the macros by moving or flipping. For the purpose that the placement result can meet all the constraints and have minimal total wirelength. There are five constrains mentioned above. First, all the macros should be placed inside the chip. Second, the fixed macros must not be moved. Third, the orientation is limited to four directions, namely N, FN (for Y-axis flip), S (for X-axis and Y-axis flip), and FS (for X-axis axis flip). Fourth, the minimum distance that must be preserved the channels between two adjacent macros. The last one is that macros comply with "buffer component area reservation restrictions." Namely, the region between the frame of each macro and the boundary expanded a fixed distance should be overlapped with the space where standard cells could be put in.

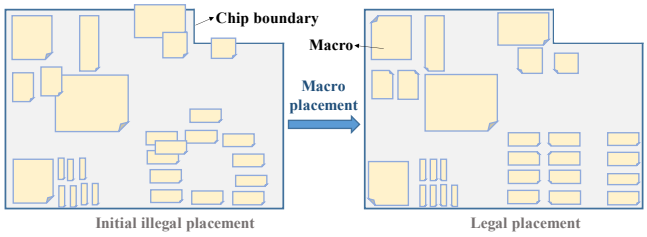

Fig. 3 Macro placement.

Eventually, after macro placement, we would use the NTUplace3 [13] to perform standard cell placement and then estimate total wirelength by half-perimeter wirelength model (HPWL).

4. ALGORITHM

Fig. 4 shows the flow of the entire algorithm. The input data are the initial illegal macro placement. First, deal with the irregular frame and the minimum channel distance limit. When generating the initial legal placement, we would avoid the huge difference between input data and our legal placement which caused to the longer total wirelength. Hence, slice the chip according to the connections between macros. Meanwhile, allocate macros to each domain. Then, decide the position of the macros by our proposed structure, double contours. The final step is to go through our modified SA algorithm in order to optimize the position and the orientation of the macros.

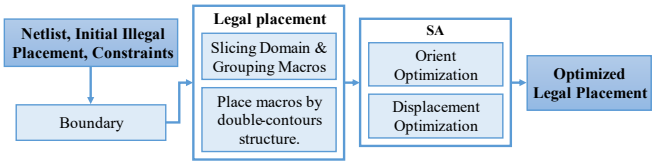

Fig. 4 Flow chart of our algorithm.

4.1. Boundary

A. Deal with the irregular frame and extend the macros

Use the fake fixed macro to fill the irregular frame into a rectangular frame, as shown in Fig. 5(a). In addition, we expand each macro by half of the minimum channel distance, as shown in Fig. 5(b). And the macro must be expanded toward four directions, from, bottom, left and right. Therefore, there is at least a certain distance between components.

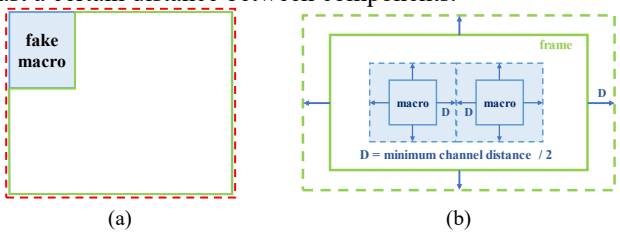

Fig. 5 (a) Deal with the irregular frame. (b) Extend the macros.

B. Integer multiples of the cell height and width

According to the distance between the macro and the four sides of the frames respectively, we will expand toward the direction with a larger distance, as shown in Fig. 6. The value of the expansion is an integer multiple of the least common multiple of the height and width of the standard cells. This purpose is to reserve the valid space to place the standard cells.

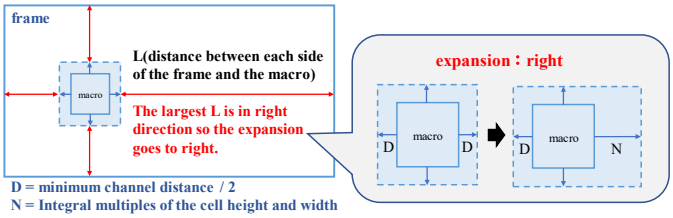

Fig. 6 An example of the macro expansion.

4.2. Slicing Domain and Grouping Macros

In order to minimize the total wirelength, we need to divide the chip into multiple domains at this stage according to the position of the macros on the chip and their connections. And each macro could only put within the block that it belongs to so as to avoid excessive displacement of the macro. Fig. 7 is the flow chart of slicing domain and grouping macros. We will store each domain in array, and then put the macros in the domain into the stack. The exact cut position is based on the net connections between the macros in the stack. Determine the cutline that if the domains on both sides of the cutline can hold macros. The information of the two domains will be added to the array, and then the above actions will be repeated until the domains in the array can no longer be divided. The following will tell more details about how to determine the cutline and how to construct domain information.

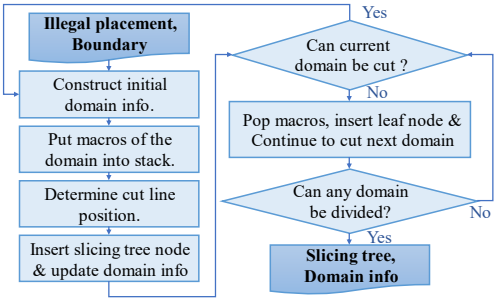

Fig. 7 Flow chart of "Slicing Domain and Grouping Macros."

A. Decide cutline

First, the cutline would be the edge of one of the macros in this domain. Besides, in order to avoid too much difference in the number of macros on both sides after cutting domain, we set the parameter r as the ratio of the number of macros on both sides, as shown in Fig. 8. And limit the cutline to fall in the range of $r >= R_{limit}$, where R_{limit} would decrease. If R_{limit} is closer to 1, indicate that the quantity on both sides is more balanced. Furthermore, if a group of the macros whose net connections between each one is more than others is divided into different domain, it would cause more displacement after placing macros. Therefore, in order to place densely connected macros in the same domain, among the cutlines within the range mentioned above, find the one that the smallest numbers of the nets cross it. In Fig. 8, the number of nets cut is 2 (n4 and n1).

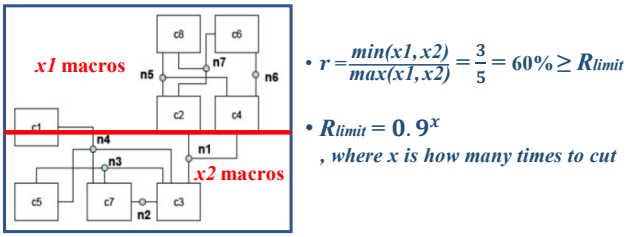

Fig. 8 An example selecting one of the cutline.

B. Construct domain info

Fig. 9 is a schematic diagram of constructing domain info. The upper part is the process of division, and the lower part is to store information according to the domain and macro in the

upper part. First, it will be divided according to the method described in the previous paragraph, and then it will be judged whether to continue to divide from the domain on the left/below of the cutline. Otherwise, it will be divided from the domain on the right/above of the cutline. Domain info is an one-dimensional array which contains the coordinates of the lower left corner of the domain, the length and width of the domain, and the macros in the domain. The macros are recorded in the form of linked-list.

Fig. 9 The process for constructing the domain info.

4.3. *Double contours*

In the previous step, the chip has been divided into multiple domains. In this step, the macros in each domain must be placed legally. Therefore, we determine the position of the macro by the double-contours structure. The advantage is that the macro in the middle will not be moved to the corner of the domain. As the name implies, the double-contours structure has two layers of contours. We assume that the macros could only place on the inner side of the contour, as shown in Fig. 10.

The algorithm we proposed is as shown in Fig. 11. It is mainly divided into two stages. First, try to place all macros. If there are some macros can't find the legal position to put, these macros will be placed in adjacent domains until all macros have a legal location. In the above first stage, each domain will first judge whether to add the second layer of contours. Then, initialize the contours according to this result. Since the fixed macros cannot change their positions, and the placed macros are the opposite, they need to be handled separately. Update the contour according to the location of the fixed macro first, and use the contour to obtain the legal placement of the placed macros afterwards. The following uses a domain as an example to illustrate.

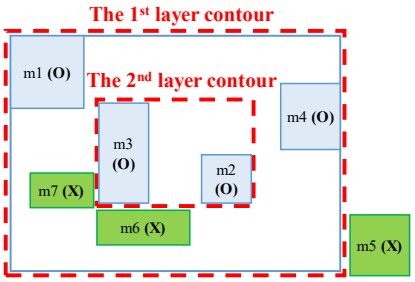

Fig. 10 The proper and the improper position where to place the macros.

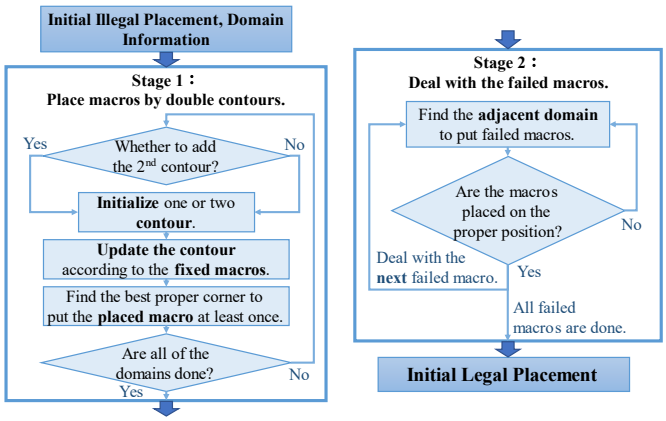

Fig. 11 Flow chart of the double-contours algorithm.

A. *Decide whether to join the second circular contour*

First, we set the second initial contour as a rectangle with the same aspect ratio as the domain block to which it belongs, as shown in Fig. 12. That is, the contour length and width are the domain length and width multiplied by a parameter (*shrink_ratio*) less than 1. If the ratio of the number of macros in the range of the second initial contour to the total number of macros in the domain exceeds *macros_percent* which is a self-defined parameter, the second layer of contour will be added. We set *macros_percent* as 40% in our experiment.

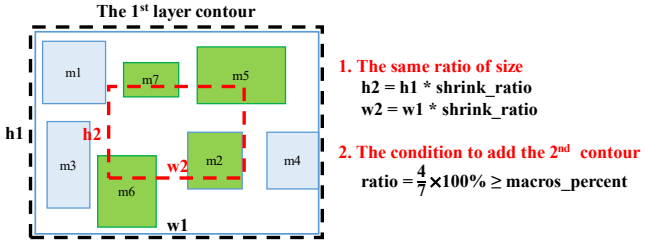

Fig. 12 Confirm whether to add the second layer of the contour.

B. *Deal with fixed macros*

Update the contour according to the location of the fixed macros. There are three possible situations, inside, outside, and on the edge of the domain. In the above three situations, you must first find the side closest to the domain frame, and update the contour so that it bypasses the macro, as shown in Fig. 13.

C. *Deal with placed macros*

The contour has been updated in the previous step. This step will try to place all the macros. First, calculate the distance between each macro and all the proper corners in the contour. Then, try to put the macro on the corner with the smallest distance and confirm whether it would overlap with other macros that have been placed and whether it would exceed the boundary of the domain. If there is a violation, try the next pair of macros and corners with the smallest distance, and so on, as shown in Fig. 14. If none of the macros are successfully placed in the first round, the failed macros will be placed first in the next round until all the macros are successfully placed. In the worst case, the macros cannot be placed successfully, and it would go to the stage 2, as shown in Fig. 11.

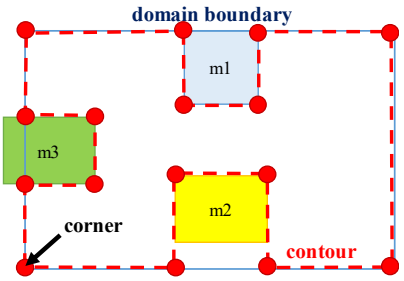

Fig. 13 The relationship between the fixed macro and the domain boundary.

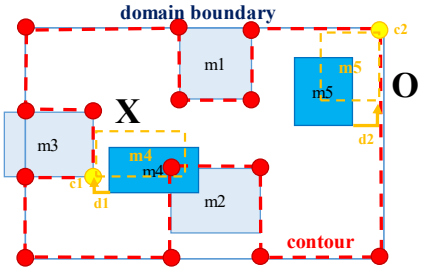

Fig. 14 The picture shows how to handle placed macros. d1 and d2 are the first and second smallest among all the calculated distances between macro and corner. However, when m4 is placed on c1, it will overlap with m2, so this round will choose to place m5 on c2. Eventually, the moving distance is small and the position is legal.

4.4. Modified-SA (simulated annealing)

After the double-contours stage is completed, a legal placement solution will be obtained. In order to optimize the initial placement solution, we adopt the simulated annealing (SA) [10] method in this step and add some additional action. The algorithm flow chart is our modified SA, as shown in Fig. 15.

The disadvantage of SA is that the final output solution may not be optimal due to the possibility that it will update to a poorer solution. Therefore, our modified algorithm is different from the traditional SA. We store the current solution and the better solution accepted previous time in addition in order to avoid the last updated placement solution after SA accepts a poor solution. We will also keep the best solution obtained in the process. Hence, at the end of SA, even if the last updated solution is worse, we still output the best solution. In addition, if SA doesn't accept the poor solution, it would operate the heuristic algorithm [14] trying to improve the current solution.

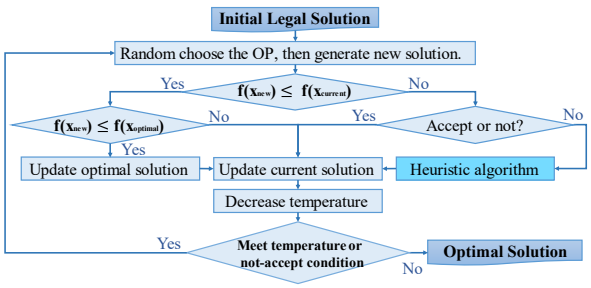

Fig. 15 Flow chart of the SA algorithm.

A. OP introduction

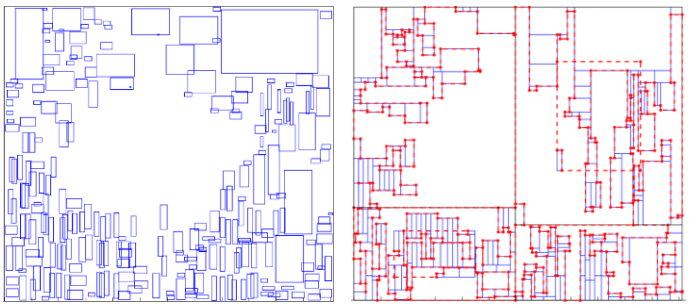
In order to get the optimal solution, how to adjust the direction and position of the macro is very important. The following are some operations (OP) we designed.

- OP1: Move a macro to another domain.
- OP2: Switch two macros in the different domain.
- OP3: Combine two adjacent domains.
- OP4: Slice one domain into two sub-domains.
- OP5: Add one fake macro.
- OP6: Flip one macro.
- OP7: Move a macro in random direction and by random distance.

B. Heuristic algorithm

In order to find the best solution more efficiently and effectively, we also add a Heuristic algorithm into the process. This algorithm will try to move or flip all the macros every time. If each macro is adjusted, it will have its own gain value which is the difference of the total wirelength. Thus, adjust the macro haven't been adjusted with the smallest gain each time. After all the macros are done, a pass is completed. After each pass is completed, it will be compared with the solution of the previous pass. If it improves, continue to the next pass. Otherwise, stop the loop. The advantage of the Heuristic algorithm is that it can efficiently find a better solution, even if there is no guarantee that the solution will be optimal. Therefore, when the OP selected by SA is unable to obtain an acceptable solution, this algorithm will be used to quickly find a better solution.

5. EXPERIMENT



We implemented our macro placement framework in the C++ programming language. All experiments were performed on an Intel Xeon Gold 5320 2.2GHz Linux workstation with 131GB memory. We used the benchmark provided by CAD Contest 2022 [15] for testing. As shown in the second and third column of Table 1, "macro" and "component" represent the number of macros and all components respectively.

For the purpose of analysis, we use Matlab to generate visual images. Fig. 16(a) represents the layouts of initial illegal placement of the input file. Also, Fig. 16(b) represents the legal placement after using our double contour method. The blue rectangle represents the macro. The red dashed lines are contours that may be the first or second layer of the contour. It can be clearly seen that in the initial placement stage, there are many macros that overlap or outside the chip. Moreover, macros are scattered in a messy manner. Through our method to place macros, there are not any macros overlapping or outside the chip. Also, they are placed relatively neatly in the chip.

Here we recall that our framework could be divided into two main stages, "legal placement" and "SA". Therefore, we compare the HPWL result of three different approaches, as shown in Table 1. In Table 1, "single contour" indicates the HPWL estimated by the NTUplace3 [13] after only using the single contour to get the legal placement. The next two columns represent the HPWL after using double contours to get the legal placement and its improvement rate. The last two columns represent the HPWL after using double contours and SA to get the optimized legal placement and its improvement rate.

Table 1 improvement of HPWL of double contours compared to single contour

benchmarks	benchmark info.		single contour	double contour		double contour + SA	
	macro	component		HPWL	improvement	HPWL	improvement
Case 1	175	1,209,716	235,668,699,752	226,441,129,211	3.92%	225,994,886,353	4.10%
Case 2	84	1,876,103	366,912,034,519	363,289,921,227	0.99%	345,702,012,698	5.78%
Case 3	84	1,876,103	401,384,714,466	398,328,082,658	0.76%	353,207,445,548	12.00%

(a) (b)

Fig. 16 (a) Initial placement. (b) Macro placement using double-contours method.

6. CONCLUSIONS

In this paper, we propose a novel double-contours concept for macro placement in mixed-size circuits. By appending a second layer of contour, the macro will not be limited to be placed in the outer frame of the chip, so that there are more possibilities for placement. Moreover, through our improved SA, several operations we design will constantly flip and move macros to get a more optimal placement. The experimental results show that our method in most of the cases can achieve the effect of reducing the wirelength, and in case3 and case5, even improves the HPWL by more than 12%. We believe that after more detailed improvement, such a tool will bring great benefits to mixed-size circuit design.

Hindering Adversarial Attacks with Multiple Encrypted Patch Embeddings

AprilPyone MaungMaung[1], Isao Echizen[1,2], and Hitoshi Kiya[3]
[1]National Institute of Informatics, Tokyo, Japan [2]University of Tokyo, Tokyo, Japan [3]Tokyo Metropolitan University, Tokyo, Japan

***Abstract*—In this paper, we propose a new key-based defense focusing on both efficiency and robustness. Although the previous key-based defense seems effective in defending against adversarial examples, carefully designed adaptive attacks can bypass the previous defense, and it is difficult to train the previous defense on large datasets like ImageNet. We build upon the previous defense with two major improvements: (1) efficient training and (2) optional randomization. The proposed defense utilizes one or more secret patch embeddings and classifier heads with a pre-trained isotropic network. When more than one secret embeddings are used, the proposed defense enables randomization on inference. Experiments were carried out on the ImageNet dataset, and the proposed defense was evaluated against an arsenal of state-of-the-art attacks, including adaptive ones. The results show that the proposed defense achieves a high robust accuracy and a comparable clean accuracy compared to the previous key-based defense.**

I. Introduction

Deep learning has brought major breakthroughs in many applications [1]. Some notable examples are visual recognition [2], natural language processing [3], and speech recognition [4]. Despite the remarkable performance, machine learning (ML) in general, including deep learning, is vulnerable to a wide range of attacks. Particularly, many ML algorithms, including deep neural networks, are sensitive to carefully perturbed data points known as adversarial examples that are imperceptible to humans, but they cause ML models to make erroneous predictions with high confidence [5]–[7]. Not only in the digital domain, adversarial examples can also appear in the physical domain. One work shows that an adversarial example can be photographed with a smartphone, and the taken picture can still fool a neural network [8]. Similarly, another work demonstrated that it is possible to construct 3D adversarial objects [9]. Such physical adversarial attacks may cause serious and dangerous problems by applying paintings or stickers on physical objects [10], [11]. For example, self-driving cars may misclassify a "Stop" sign as a "Speed Limit" [11], and face recognition systems may authenticate unauthorized users as authorized ones [12]–[15].

As adversarial examples are an obvious threat, numerous methods for generating adversarial examples (attack methods) and defenses against them have been proposed in the literature [16]. Adversarial attacks and defenses have entered into an arms race, and attack methods are ahead of defense ones. Once defense mechanisms are known to the attacker, adaptive attacks can be carried out [17], [18]. Most of the defense methods either reduce the classification or are completely broken. Therefore, defending against adversarial examples is still challenging and remains an open problem.

Inspired by cryptography, a new line of research on adversarial defense has focused the use of secret keys so that defenders have some information advantage over attackers [19]–[23]. Key-based defenses follow Kerckhoffs's second cryptographic principle, which states that a system should not require secrecy even if it is exposed to attackers, but the key should be secret [24]. The main idea of the key-based defense is to embed a secret key into the model structure with minimal impact on model performance. Assuming the key stays secret, an attacker will not obtain any useful information on the model, which will render adversarial attacks ineffective. The idea of making adversarial attacks expensive or ideally intractable is further supported on a theoretical basis that adversarially robust machine learning could leverage computational hardness, as in cryptography [25].

However, a recent study shows that applying cryptographic principles alone in algorithm design is insufficient to defend against efficient adversarial attacks [26]. To further harden key-based defenses, researchers have also proposed to use implicit neural representation [26] and ensembles of key-based defenses [27], [28]. Nevertheless, although these defenses seem promising, they have yet to tested on large datasets like ImageNet. Therefore, in this paper, we build upon the idea of key-based defense and propose a novel defense that is not only efficient to hinder adversarial attacks but also scalable to large datasets. The proposed defense utilizes multiple secret patch embeddings and classifier heads that are controlled by secret keys and a pre-trained isotropic network (with the same depth and resolution across different layers in the network) backbone such as a vision transformer (ViT) [29] and ConvMixer [30]. Our contributioins in this paper are as follows.

- We propose a novel defense idea that uses multiple secret patch embeddings.
- We show that the proposed defense is computationally feasible even on ImageNet and report empirical results on the strongest attacks.

In experiments, the proposed defense is confirmed not only to be efficient against attacks, but also to maintain a comparable clean accuracy.

II. Related Work

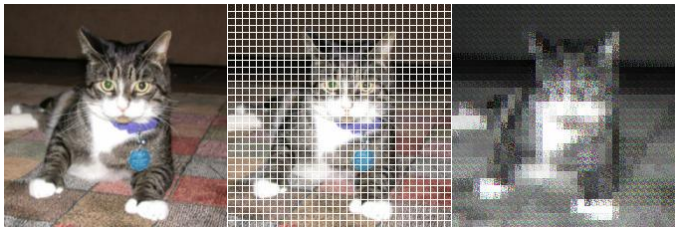
A. Adversarial Robustness

There are two distinct strategies in designing adversarial defenses: (1) classifiers are designed in such a way that they are

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

robust against all adversarial examples in a specific adversarial space either empirically (*i.e.*, adversarial training) or in a certified way (*i.e.*, certified defenses), and (2) input data to classifiers are pre-processed in such a way that adversarial examples are ineffective (*i.e.*, input transformation defenses, key-based defenses).

Adversarial Training. Current empirically robust classifiers utilize adversarial training, which includes adversarial examples in a training set. Madry *et al*. approach adversarial training as a robust optimization problem and utilizes projected gradient descent (PGD) adversary under ℓ_∞-norm to approximate the worst inputs possible (*i.e.*, adversarial examples) [31]. As PGD is iterative, the cost of computing PGD-based adversarial examples is expensive. Much progress has been made to reduce the computation cost of adversarial training as in free adversarial training [32], fast adversarial training [33], and single-step adversarial training [34]. However, adversarially trained models (with ℓ_∞ norm-bounded perturbation) can still be attacked by ℓ_1 norm-bounded adversarial examples [35].



Certified Defenses. Robust classifiers in this direction use formal verification methods in such a way that no adversarial examples exist within some bounds [36]–[39]. Ideally, these defenses are preferred for achieving certain guarantees.. Although certified defenses are attractive, they can be bypassed by generative perturbation [40] or parametric perturbation (outside of pixel norm ball) [41].

Input Transformation. Adversarial defenses in this strategy aim to find a defensive transform to reduce the impact of adversarial noise or make adversarial attacks ineffective (*i.e.*, computing adversarial noise is either expensive or intractable). The works in this direction use various transformation methods, such as thermometer encoding [42], diverse image processing techniques [43], [44], denoising strategies [45], [46], GAN-based transformation [47], and so on. Although these input transformation-based defenses provided high accuracy at first, they can be attacked by adaptive attacks such as [17], [18].

Key-Based Defenses. The defenses with a secret key are similar to the input transformation-based defenses. However, the major difference is that defenders have an information advantage over attackers (*i.e.*, a secret key). The success of adaptive attacks is based on the ability to approximate a defended model's outputs on arbitrary inputs. On this insight, key-based defenses hide a model's decision from attackers by means of training the model with encrypted images. Such key-based defenses include [19], [20]. However, a recent study pointed out that such key-based defenses are still vulnerable to adaptive attacks [26]. Instead, they proposed a new key-based defense by using neural implicit representation [26].

B. Patch Embedding

Inspired by the success of the vision transformer (ViT) [29], a series of works such as [30], [48]–[52] utilizes an isotropic architecture that uses patch embeddings for the first layer. Especially a recent network architecture, ConvMixer [30] showed some evidence that patch embeddings play an important role in achieving high performance accuracy. With hindsight, we fine-tune the patch embedding layer by using block-wise encrypted images to obtain encrypted patch embeddings in this paper.

(a) (b) (c)

Fig. 1. Block-wise image transformation with block size $M = 7$. (a) Plain. (b) Block division. (c) Block-wise shuffling.

C. Block-Wise Image Transformation

The previous key-based defense proposed three block-wise transformation with a secret key for an adversarial defense: pixel shuffling, bit flipping, and FFX-based transformation [20]. In this paper, we adopt block-wise pixel shuffling from [20] for the proposed defense, and the detailed procedure for block-wise pixel shuffling is described as follows.

1) Divide a three-channel (RGB) color image, x with $w \times h$ into non-overlapping blocks each with $M \times M$ such that $\{B_1, \ldots, B_i, \ldots, B_{(\frac{h}{M} \times \frac{w}{M})}\}$.
2) Generate a random permutation vector, v with key K, such that $(v_1, \ldots, v_k, \ldots, v_{k'}, \ldots, v_{3M^2})$, where $v_k \neq v_{k'}$ if $k \neq k'$.
3) For each block B_i,
   flatten three-channel block of pixels into a vector, b_i such that $b_i = (b_i(1), \ldots, b_i(3M^2))$,
   permute pixels in b_i with v such that
   $$b'_i(k) = b_i(v_k), k \in \{1, \ldots, 3M^2\}, \quad (1)$$
   and reshape the permuted vector b'_i back into the three-channel block B'_i.
4) Integrate all permuted blocks, B'_1 to $B'_{(\frac{h}{M} \times \frac{w}{M})}$ to form a three-channel pixel shuffled image, x'.

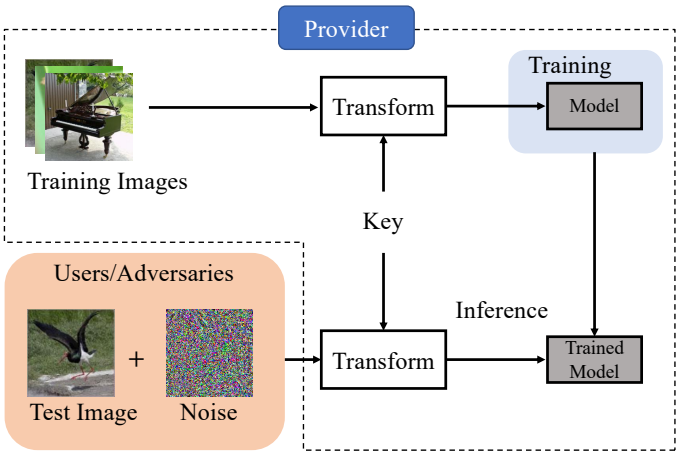
As an example, Fig. 1 shows a plain image with visualization of blok division and block-wise shuffling.

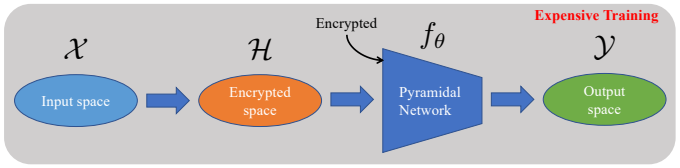
III. Proposed Defense with Encrypted Patch Embeddings

A. Overview

We consider an image classification scenario where a provider deploys a key-based defense and provides application programming interface (API) to users (potentially adversarial) for inference as shown in Fig. 2.

Formally, given a dataset $\mathcal{D}$ with pairs of examples (images and corresponding labels), $\{(x, y) \mid x \in \mathcal{X},\ y \in \mathcal{Y}\}$, a key-based defense in [20] first maps the input space $\mathcal{X}$ to an encrypted space $\mathcal{H}$ by using a blok-wise transformation with





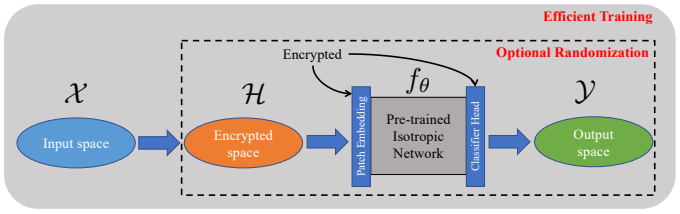


Fig. 2. Overview of image classification scenario with key-based defense.

(a) Previous [20]

(b) Proposed

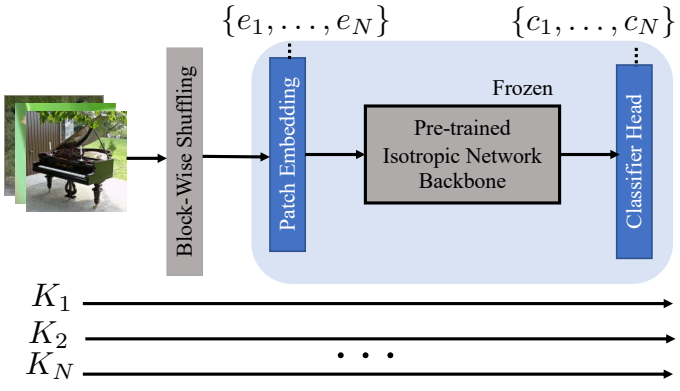

Fig. 3. Difference between previous and proposed key-based defense.

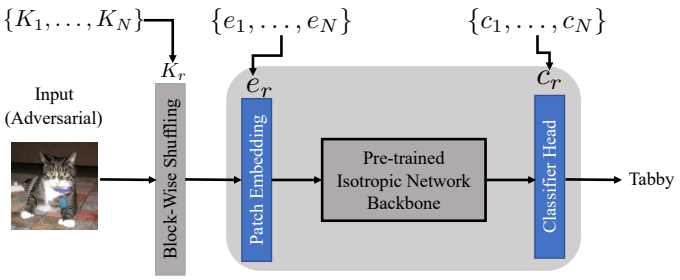
a secret key (*i.e.*, $x \mapsto t(x, K)$). Then, a robust classifier f_θ parameterized by θ ($f_\theta : \mathcal{X} \to \mathcal{Y}$) is trained by using encrypted images $t(x, K) \in \mathcal{H}$.



We build upon the robust classifier f_θ from [20] with two major improvements: (1) efficient training and (2) optional randomization. Figure 3 highlights the difference between the previous key-based defense and the proposed one. The proposed defense leverages pre-trained isotropic networks (such as ViT, ConvMixer, etc.), and fine-tunes only patch embeddings and classifier heads (optionally multiple times with different secret keys). When more than one secret patch embedding is used, the proposed defense becomes a radomized defense. The details of training and inference pipelines for the proposed defense are described in the following subsections.

B. Training

The proposed defense utilizes a patch-based pre-trained isotropic network (such as ViT, ConvMixer, etc.). The training pipeline of the proposed defense is depicted in Fig. 4a. To obtain encrypted patch embeddings, $\{e_1, \ldots, e_N\}$ and encrypted classifier heads, $\{c_1, \ldots, c_N\}$, only the patch embedding layer

(a) Training

(b) Inference

Fig. 4. Training and inference pipelines for proposed defense. During training, pre-trained isotropic network backbone is frozen.

and classifier head in a pre-trained isotropic network is fine-tuned for N times by using encrypted images that are encrypted by a block-wise pixel shuffling t with N secret keys $\{K_1, \ldots, K_N\}$. The detailed procedure of t was previously described in Section II-C.

C. Inference

Figure 4b shows the inference process of the proposed defense. We first sample a random key K_r from a pool of keys, $\{K_1, \ldots, K_N\}$, and select the corresponding patch embedding, $e_r \in \{e_1, \ldots, e_N\}$, and classifier head, $\{c_1, \ldots, c_N\}$. During inference, a test image (potentially adversarial) is transformed with K_r. Then, the corresponding patch embedding e_r and classifier head c_r are selected and attached to the pre-trained isotropic network backbone to carry out the forward pass. Note that when N is greater than 1, the proposed defense provides randomization ability for each inference.

D. Threat Model

We focus on hindering adversarial attacks on a classifier f_θ, which takes block-wise transformed input, $t(x, K)$ with a secret key K. To evaluate the proposed defense, we assume a gray-box threat model, where the attacker has full knowledge of the defense mechanism, pre-trained isotropic network backbone weights, and training data, except a secret key, encrypted patch embeddings weights, and classifier heads. The attacker performs state-of-the-art both targeted and untargeted attacks under ℓ_∞ and ℓ_2 norms.

IV. Experiments and Discussion

A. Setup

We carried out experiments for the proposed defense on ImageNet-1k classification. The ImageNet-1k dataset (with 1000 classes) consists of 1.28 million color images for training and 50,000 color images for validation [53]. To implement the proposed defense, we utilized a publicly available pre-trained isotropic network, ConvMixer-768/32[1] model, which uses a patch size value of 7 on 224×224 images. To inline with the patch size of the patch embedding in the pre-trained model, we also set the same value of 7 for the block size value in the key-based transformation (*i.e.*, $M = 7$). We fine-tuned only the patch embedding layer and classifier head with the same learning rate value of 0.01 as in the original training settings without default augmentation for only one epoch. The fine-tuning process was repeated N times to produce N secret patch embeddings and classifier heads with N secret keys. In our experiments, we used $N = 5$.

For evaluation, we deployed AutoAttack (AA) strategy, which is an ensemble of strong, diverse attacks [54]. We used AA's "standard" version with a perturbation budget value of $4/225$ under ℓ_∞ norm and a value of 0.5 under ℓ_2 norm for all attacks. To account for adaptive attacks, we also utilized a "random" version, which implements Expectation over Transformation (EoT) as described in [17].

B. Results

We performed ImageNet-1k classification of both clean images and adversarial examples on the proposed defended classifier.

Transfer Attacks. We generated adversarial examples for two scenarios.

- **Scenario 1.** Since the proposed defense is built on top of the pre-trained model, it is natural to generate adversarial examples directly on the pre-trained model (which includes pre-trained patch embeddings, isotropic network backbone, and a classifier head).
- **Scenario 2.** We assume the attacker has knowledge of the proposed defense mechanism. The attacker may fine-tune the pre-trained model with a guessed key. Thus, we also simulated this scenario to evaluate the proposed defense.

We carried out attacks on both scenarios, and the results are shown in Table I, where (–) denotes "there is no reported results" or "not applicable". Both clean and robust accuracies were calculated on the validation set of ImageNet (50,000) images. Although the un-defended model (plain) achieved the highest accuracy, it was most vulnerable to all attacks. The results suggest that adversarial examples generated on the pre-trained model were not effective on the proposed defense method with secret patch embeddings and a classifier head. Under attacks, the proposed method achieved comparable accuracy for Scenario 1 and higher accuracy for Scenario 2. However, the proposed method reduced clean accuracy, and we shall improve it in our future work.

Adaptive Attacks. When using $N > 1$, the proposed utilizes random secret patch embeddings and a classifier head from N options. Therefore, the proposed defense produces a randomized prediction on each inference. To counter the proposed randomized defense, we assume that the attacker prepares multiple secret patch embeddings as in the proposed defense. We carried out EoT attacks on the attacker's version of the proposed defense with $N \geq 1$ and evaluated the proposed defense. Table II presents the results of such adaptive attacks. For this experiment, attack success rate (ASR) was calculated for randomly selected 1000 images that were correctly classified by the proposed defense model with $N = 5$. Although the EoT attack was improved when using $N = 5$, the ASR was still low.

C. Discussion

Comparison with state-of-the-art methods. For experiments, we implemented the proposed method in a relatively small isotropic model, ConvMixer-768/32, which contains about 21.1 million parameters (*i.e.*, even smaller than ResNet50). We compare the proposed defense with the previous key-based defense and the top 3 adversarially trained (AT) models [57] in terms of clean and robust accuracy. Note that the key-based defense, including the proposed one, has an information advantage (secret key) over attackers. In contrast, AT models are trained to be robust against all adversarial examples under a specific adversarial space. Overall, the proposed defense improved the robust accuracy but reduced the clean accuracy.

Advantages. The main advantage of the proposed method is its feasibility. Much of the adversarial robustness has been done on low-resolution datasets like CIFAR-10 [58]. In contrast, much less is known for ImageNet due to high computing requirements. The proposed method overcomes this barrier by effectively re-using pre-trained weights and only fine-tuning a patch embedding layer and a classifier head.

Limitations. The proposed method shows the potential of making publicly available pre-trained models to be robust against adversarial examples. However, further evaluation and investigation of the proposed method against adaptive attacks is required. In addition, the proposed method in its current form reduces classification accuracy on clean images, although robust accuracy is improved. We shall address these limitations in our future work.

V. Conclusions

In this paper, we proposed a novel key-based defense by using one or more secret patch embeddings and classifier heads with a pre-trained isotropic network. The proposed method is not only efficient in training even for ImageNet but also effective in hindering strong adversarial attacks. Experiment results showed that the proposed method achieved high robust accuracy against a suit of powerful attacks under different

***Abstract*—LPWA (Low Power Wide Area) is a communication method for the IoT that enables long-distance communication with low power consumption, and PLIM (Packet Level Index Modulation), an extension of LPWA, enables several bits of additional transmission. However, there is a problem of data loss due to packet collision when transmitting simultaneously and on the same frequency channel. The authors have implemented PLIM on a 429 MHz LoRa/FSK and improved the collision rate by randomly creating and assigning mappings in the implementation. In this paper, the authors conducted experiments on a real device using a method of designing optimal mappings using mathematical optimization, showed the effectiveness of the method and how it differs from other mappings, and evaluated the method in a real device environment.**

I. Introduction

In recent years, demand for IoT has been increasing in terms of social issues such as the COVID-19 and population decline, as well as the spread of smartphones and improved convenience of products. One of these is LPWA (Low Power Wide Area), which is a communication method that enables long-distance communication and low-power consumption, and it is attracting attention for the infrastructure of supporting IoT[1]. In LPWA, there is a problem that throughput cannot be increased due to transmission time constraints. PLIM (Packet Level Index Modulation), which switches frequency channels and transmission timing to transmit signals, is expected to be a solution to this problem[2]. PLIM can transmit several bits of data in addition to the existing LPWA, but a problem unique to PLIM is that when multiple sensors transmit data at the same time and on the same frequency channel, packet collisions occur and thus the sent data is lost. To solve this problem, research has been conducted to reduce the collision rate by improving the mapping between the index and the information to be sent[3].

The authors have implemented PLIM on a 429 MHz LoRa/FSK and have shown through experiments that the packet delivery rate (PDR) rate can be improved by using randomly generated mappings for each sensor, as opposed to the conventional method of using one mapping for all sensors. If the optimal mapping constructed by Ref. [3] is applied the implemented PLIM, the additional improvement of PDR is expected but it has not been clarified, yet. In the actual implementation of LPWA, the unsuspicious incidents which is not considered for constructing the mapping table occur, these may cause the degradation of the PDR. Therefore, the performance evaluation of the PLIM with the optimal mapping table in the actual equipment of LPWA is important.

In this paper, we implement the mapping created using a method in the literature[3] that uses mathematical optimization to create optimal mappings on an actual device and measure the PDR over a certain period of time to evaluate whether the improvement is effective in the actual device environment as well.

II. Description of PLIM

PLIM is a communication method in which information to be sent and received corresponds to an index consisting of a frequency channel and a time slot. The fig.1 below shows an image of PLIM. The vertical and horizontal axes are labeled as frequency channel and time slot, respectively. A mapping table is created in advance that maps the indexes to the information to be sent. When sending information, the appropriate index is selected and sent according to this pre-created mapping table. In the fig.1, the sensor sends a packet with the index 1, which corresponds to the information of the number 1, because it wants to send the information of the number 1. In this case, the communication is synchronized between all sensor nodes and the aggregation station, and all sensors transmit at regular intervals.

In PLIM, when multiple sensors send packets with the same index, there is a problem of packet collision and data cannot be demodulated. In particular, if there is spatial correlation in the data, the information sent between nearby sensors will be the same, and if they communicate using the same mapping, collisions are especially likely to occur. In addition, if the data is also spatially correlated and the same mapping is used, collisions are likely to occur between specific sensors, and there is also the problem of not being able to receive data from some sensors. To address this problem, methods to avoid collisions, such as improved mapping, are needed to aggregate data in a stable manner.

There are some frequency bands for using the LPWA standards. The actual device used in this paper uses the 429 MHz band; 429 MHz offers better radio diffraction than the larger frequency band such as 920 MHz and better communication connectivity even in mountains with many obstacles. In addition, the lack of transmission time constraints allows for real-time and flexible mapping changes between each sensor.

III. Description of Optimal Mapping

To avoid collisions that occur in PLIM, this experiment uses the optimal mapping design using mathematical optimization found in Ref.[3]. In the optimal mapping, the mapping with the lowest two-packet collision probability is created using the pre-measured data as training data. The information used for mapping in this experiment is the received signal strength indicator (RSSI) value.

The objective function and constraint equations used in the optimal design should be in accordance with the literature[3], and the experimental parameters should be set appropriately. The following is a list of constraint equations and objective functions for actual machine experiments taken from Ref.[3].

$$\min \sum_{k=1}^{K}\sum_{i_1=1}^{I}\sum_{i_2=i_1+1}^{I}\sum_{j_1=1}^{J}\sum_{j_2=1}^{J} P_{i_1,j_1}P_{i_2,j_2}x_{i_1,j_1,k}x_{i_2,j_2,k} \quad (1)$$

$$\text{subject to} \quad x_{i,j,k} \in \{0,1\} \qquad \forall i \in I, \forall j \in J, \forall k \in K$$

$$\sum_{k=1}^{K} x_{i,j,k} = 1 \qquad \forall i \in I, \forall j \in J \quad (2)$$

$$\sum_{j=1}^{J} x_{i,j,k} \leq 1 \qquad \forall i \in I, \forall k \in K \quad (3)$$

$$1 \leq \sum_{j=1}^{J}\sum_{i=1}^{I} x_{i,j,k} \leq I \qquad \forall k \in K \quad (4)$$

Where the i, j, and k denote the sensor number, RSSI number, and index number, respectively. The $P_{i,j}$ is the establishment of the i-numbered sensor observing the jth RSSI value, and $x_{i,j,k}$ means that the jth RSSI value of the ith sensor is assigned to the kth index when it is 1, and 0 means it is not assigned.The equation (2) indicates that all RSSI values are assigned to one of the indices for all sensors, the equation (3) indicates that at most one RSSI value is assigned to one index for all sensors, and the equation (4) indicates that at least one RSSI value is assigned to one index for all indexes, and at most one RSSI value can be assigned to a maximum number of sensors. In accordance with these constraints, the number of RSSI values should be set to the number of indexes in the actual environment as well.

Equation (1) is the objective function of mathematical optimization, which means minimizing the two-packet collision probability. It minimizes the sum of the collision probabilities between any two sensors, which is different from the original collision probability because some collisions are actually more than three packets. However, since the 2-packet collision probability includes the collision probability of 3 or more packets, reducing the 2-packet collision probability also reduces the probability of 3 or more sensors sending packets at the same time.

In addition, in optimal design, as the number of sensors increases, the number of possible combinations of mapping patterns increases, and the calculation time until the optimal solution is obtained increases. Therefore, in order to measure the environment as close as possible to the prior information in the actual experiment, it is necessary to adjust the number of sensors to minimize the computation time as much as possible and to minimize the number of collisions.

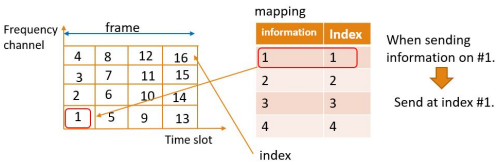

Fig. 1: Image of PLIM

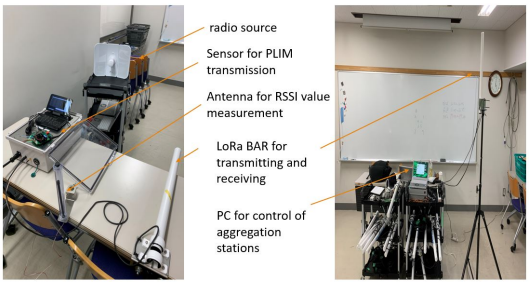

Fig. 2: Construction diagram of sensor (left) and aggregation station (right)

IV. Description of Actual Equipment

This experiment is performed using sensor terminals and aggregation stations implemented with PLIM on 429 MHz LoRa/FSK. The sensor terminals and aggregation stations constructed in Fig.2 are shown.

After receiving a synchronization packet from the aggregation station, the sensor terminal measures the temperature, humidity, and RSSI value, and transmits data at the appropriate timing and frequency channel according to the mapping stored in advance in accordance with the measured data. Since we are dealing with RSSI values, only the antenna for measuring RSSI values is attached to the sensor terminal in Fig.2. Up to 95 mapping patterns can be stored in advance. The information that determines the mapping can be switched by changing a switch on the board of the sensor terminal. The packet contains information such as sensor number, transmission time, index information (selected frequency channel and time slot, mapping number), and measured RSSI value. Up to eight frequency channels and up to 30 time slots can be used, and the mappings to be stored can be changed as needed.

The aggregation station consists of a PC for control, a LoRaBAR(Made by Circuit Design, Inc.) for transmission and reception, and a microcontroller for aggregation and 429 MHz RSSI measurement. The aggregation station can transmit/receive and measure RSSI values using up to eight frequency channels, but since this experiment deals only with transmission/reception using one frequency channel, one LoRaBAR is set up with a tripod. Fig.3 shows a capture of

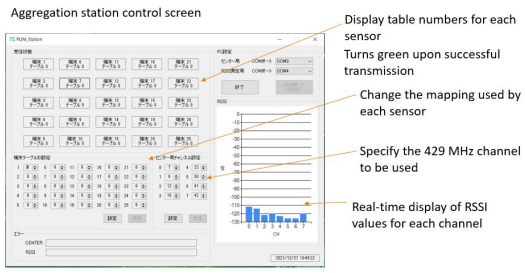

Fig. 3: Control PC screen

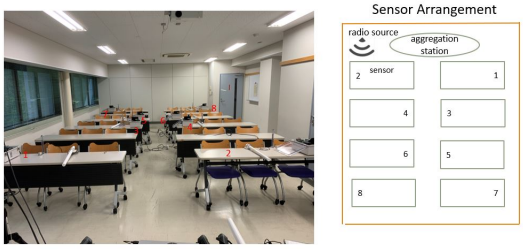

Fig. 4: Sensor arrangement diagram

the screen of the control PC. At the aggregation station, the control PC can change the mapping of each sensor, change the actual frequency channel to be used, and check in real time which sensors have been successfully demodulated and the RSSI values of each channel measured. The aggregated data is saved in a CSV file format on the control PC.

V. Experimental Methods

The experiment was conducted indoors. A diagram of the sensor arrangement is shown in Fig.4. In this experiment, eight sensor terminals are used in a crossed arrangement as shown in the figure. The information to be transmitted by PLIM in this experiment is the RSSI value, which is the received electric field strength of a 5 GHz Wi-Fi radio wave. The location of the radio source is the same for both the preliminary information acquisition and the experimental measurement.The construction of the sensor terminal is shown in the fig.2. Normally, it would be better to treat the antenna for transmission and reception in the upright position, but in this case, it is laid down for convenience and short-distance communication indoors.

The first step is to measure the prior information used for optimal mapping. The locations of the radio sources are shown in the fig.4, and RSSI values are measured at each sensor for 10 minutes to obtain preliminary information. The information obtained here is used to create the optimal mapping. The mapping parameters used to create the mapping are shown in the tableI.When using the optimal design, the number of indices and the number of information to be assigned to be handled for mapping creation must be appropriately determined. In this case, the appropriate quantization width of RSSI values is determined based on the maximum and minimum RSSI values of the prior information obtained; RSSI values are divided into a total of 10 values in 4 dB increments from -97 dBm with a margin between the maximum and minimum measured values. The number of indices is similarly prepared in accordance with the constraint formula, with 10 indices. For the number of indices and RSSI values, the number of indices is set to a small number in consideration of the time required for optimization and the environment in which collisions occur. In addition, since the information to be observed this time is the RSSI values of 5GWi-Fi, the RSSI values to be mapped become large if the quantization width of the RSSI values was small because the observed values are constantly changing. With this in mind, the quantization width of the RSSI value was set to a larger value of 4 dB. For the mappings to be compared, the same parameters as in the optimal design were used, and the RSSI values and indices were randomly assigned to prepare the necessary amount of mappings.

Next, measurements are performed using optimal mappings. For comparison, we also measure random mappings that randomly distribute the information to be sent to the index for each sensor, and fixed mappings that use a common mapping for each sensor. The measurement time is 10 minutes for each, and the number of transmissions is 120 times per sensor for each. For the prepared mappings, the indexes to be assigned are one frequency channel and 10 time slots for a total of 10 indexes this time. This is to ignore the effect of radio wave leakage into other channels when multiple frequency channels are used. As for the radio sources, the power is not turned off until the measurement in all mappings is completed. The position of the radio source is fixed at the one point shown in the fig.4. This is to avoid that when the radio source is moved, the frequency of RSSI values measured by each sensor is scattered, resulting in unbalanced frequency values with few characteristics, and thus reducing the merit of using the optimal design.

TABLE I: Mapping Parameters

Parameters	Value
Range of RSSI	4[dB]
Number of indexes	10
Number of RSSI values	10
Minimum RSSI value	-94[dBm]
Maximum RSSI value	-71[dBm]

TABLE II: experimental results

Mapping	PDR[%]
Optimal Mapping	93.75
Random Mapping	59.58
Fixed mapping	51.98

VI. Experimental Results

The tableII shows the measurement results. The packet delivery rate (PDR) is the percentage of successfully demodulated packets in all transmissions. Comparing the PDR, the optimal mapping improves the PDR by more than 30 percent compared to the random mapping. Random mapping also improves the PDR by several percent compared to fixed mapping, but the optimal mapping results in a much larger improvement. This result indicates that the optimal design rearranged the RSSI values to avoid collisions based on the frequency values of the RSSI values that serve as prior information. In addition, since this experiment is conducted in an indoor environment with a single radio source and a fixed radio source, the possible RSSI values are fixed within a certain range, so it is thought that collisions are more likely to occur with fixed mapping because the RSSI values are similar between sensors that are far from the radio source. When using random mapping, packets from sensors that are far from the radio source can be saved to some extent, but since they are reordered randomly, RSSI values that are frequently transmitted among other sensors are assigned to the same index, which is thought to make it difficult to improve the success rate of transmissions.

Fig.5 shows the indexes selected during transmission when optimal mapping is used, and Fig.6 shows a graph of the indexes selected during transmission when fixed mapping is used. This graph shows which index is selected by each sensor when transmitting. It can be seen that in the fixed case, the indexes used by each sensor for transmission are concentrated on the same index, whereas in the case of using the optimal design, the indexes used by each sensor for transmission are scattered. This also indicates that the optimal design allows each sensor to assign different RSSI values to different indices, which are frequently measured with prior information, resulting in fewer sensors selecting the same index and fewer packet collisions.

The fig.7 shows a graph summarizing the PDR for each sensor when each mapping is used. It can be seen that some sensors have particularly low PDR when using fixed or random mapping, while all sensors have improved PDR when using optimal mapping. As mentioned earlier, since the target of this measurement is the RSSI value of a stationary radio source, it is easy for each sensor to detect a certain RSSI value, and furthermore, since radio waves have spatial correlation, sensors closer to the radio source are more likely to detect a high RSSI value and sensors further away are more likely to detect a low RSSI value, resulting in many sensors detecting the same data. This means that sensors that detect the same data are more likely to be detected. Therefore, in fixed and random mapping, packet collisions frequently occur among certain sensors, resulting in a low PDR for some sensors. In addition, in fixed mapping, sensors 7 and 8, which are far from the radio source, have particularly low PDR, whereas in random mapping, sensors 7 and 8 have improved their PDR and sensor 4 has decreased its PDR. On the other hand, in

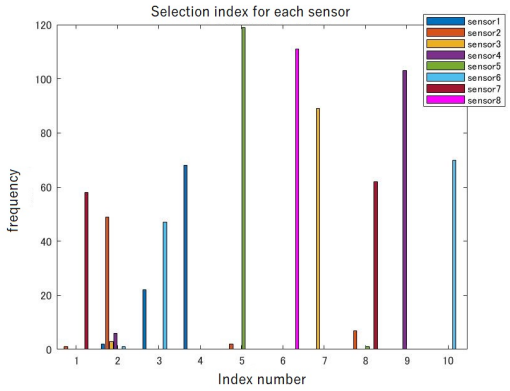

Fig. 5: Selection index per sensor (optimal mapping)

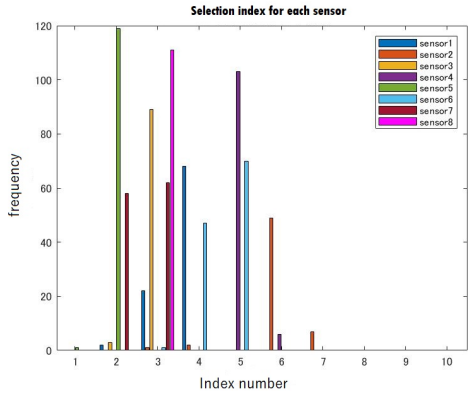

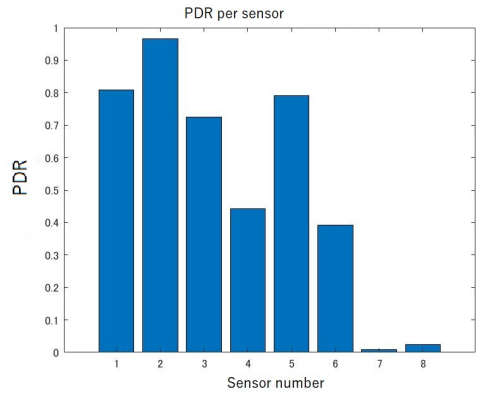

Fig. 6: Selection index per sensor (fixed mapping)

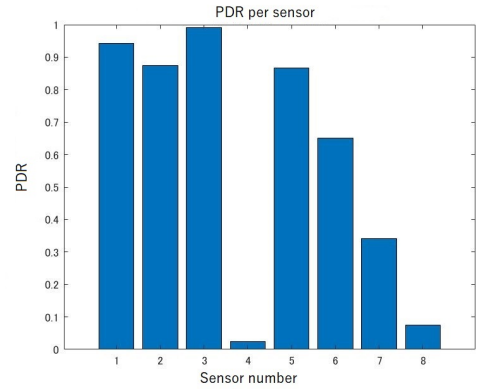
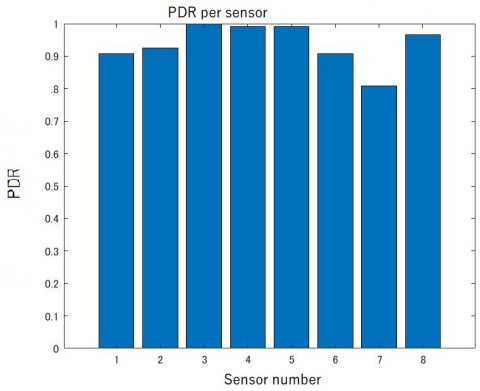
the optimal mapping, the frequently measured RSSI values are assigned to different indices for each sensor, as described earlier, resulting in a lower packet collision rate and a higher PDR for all sensors. This is one significance to the random mapping of the optimal design, indicating that it is possible to collect information at all sensors without discarding any one sensor.



VII. Conclusions

In this paper, we implemented optimal mapping using mathematical optimization on an actual PLIM device and evaluated the comparison between fixed and random mapping in terms of PDR. Significant improvement in PDR was observed when using optimal mapping compared to fixed or random mapping, demonstrating the effectiveness of optimal mapping. This indicated that a lower collision rate also occurs in the actual environment under the same environment as the prior information, because optimal mapping is designed to avoid assigning frequently measured data to the same index based on the trend of data distribution using prior learning. We also showed that the PDR is improved for all sensors, indicating that the optimal design is clearly superior to the method of randomly creating mappings.



In this environment, the number of indexes and sensors was limited in order to ignore the time required for optimization

(a) PDR per sensor (fixed mapping)

(b) PDR per sensor (random mapping)

(c) PDR per sensor (optimal mapping)

Fig. 7: PDR per sensor

and the effects of using multiple frequency channels. Attempts to increase the number of indices and sensors will be the subject of future research.

***Abstract*—Iterative shrinkage thresholding algorithm (ISTA), fast ISTA (FISTA) and alternating direction method of multipliers (ADMM) based algorithm are well known convex optimization algorithms based on proximal splitting for $\ell_1 - \ell_2$ optimization problem in compressed sensing. In our previous study, aiming at the implementation with optical analog devices, we have proposed constant inertial FISTA (CIFISTA) and an approximated ADMM based algorithm, which do not require the operation of division. In this paper, we consider to realize those algorithms with optical analog devices and show concrete configurations of analog circuits using optical devices. We have conducted computer experiments to evaluate the performance of each algorithm, taking into account the effects of the additive noise introduced by optical amplifiers assuming the implementation using optical devices for common optical fiber communications systems. From the numerical results, it has been confirmed that both the proposed CIFISTA and the approximated ADMM based algorithm can achieve faster convergence than ISTA, while the degradation of the steady state mean squared error (MSE) due to the circuit noise is much smaller than that of the conventional ADMM algorithm.**

I. Introduction

In order to achieve high-speed signal processing with low power consumption, the use of analog signal processing technology instead of conventional digital signal processing with electric devices has been attracting much attention [1]. Especially, optical analog device can compute the matrix-vector product by just passing optical signals through the device, and thus the implementation of machine learning techniques, such as deep learning, with the optical analog device has been investigated recently [2], [3], [4].

Compressed sensing is a method of reconstructing unknown sparse vector from underdetermined linear measurement which may include observation noise [5], [6], and various reconstruction algorithms have been proposed so far. One of well-known signal reconstruction approaches is the convex optimization method using proximal splitting [7]. Specifically, fast iterative shrinkage thresholding algorithm (FISTA) [8], which is the fast version of iterative shrinkage thresholding algorithm (ISTA) [9], is one of most famous algorithms of the approach. FISTA has a convergence rate of $O(k^{-2})$, which is known to be optimum for the first order method [10], [11], where k is the number of iterations in the algorithm. It is also known that alternating direction method of multipliers (ADMM) algorithm [12] can achieve comparable convergence rate to FISTA for $\ell_1 - \ell_2$ optimization problem.

In our previous study, we have considered to realize FISTA and the ADMM algorithm with optical analog devices. Since FISTA requires the operation of division by a dynamic value in the update equation of the inertial parameter, while it is difficult to calculate the division with optical analog device, we have proposed constant inertial FISTA (CIFISTA) [13] by simply setting the inertial parameter of FISTA to be a constant value. Moreover, we have developed an approximated ADMM based algorithm [14] by using different formulation from the existing ADMM algorithm for $\ell_1 - \ell_2$ optimization problem. Although both the conventional ADMM and the proposed approximated ADMM do not require any division operation in the update equations, and thus both algorithms could be implemented with optical devices, but the proposed algorithm has an advantage over the conventional ADMM that it is free from matrix inversion. In the previous studies [13], [14], we have numerically confirmed that both proposed algorithms can achieve comparable convergence performance to FISTA and the existing ADMM algorithm. However, the optical analog signal processing specific aspects, such as signal attenuation by optical devices or additive noise introduced by optical amplifiers, have not been taken into consideration.

In this paper, we evaluate the performance of the proposed CIFISTA and the proposed approximated ADMM algorithm to see the applicability of the proposed algorithms to the implementation with optical analog devices. In order to evaluate the power of the additive noise added at the optical amplifier, we present concrete optical circuit configuration of each algorithm and clarify the required amplifier power gain in the optical analog circuit. Since additive noise power at the amplifier depends on the amplifier power gain as well as the signal bandwidth, we can determine the noise power for each algorithm from the derived circuit configuration and the assumption of the signal bandwidth of 10 GHz, which corresponds to common optical fiber communications systems. From the numerical results, it can be observed that the CIFISTA, the approximated ADMM,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

and the conventional ADMM achieve comparable convergence rates, which is much faster than the rate of ISTA, even in the presence of the additive noise at the amplifier (circuit noise). On the other hand, when it comes to the degradation due to the circuit noise, ISTA achieves the lowest steady state mean squared error (MSE). However, the proposed CIFISTA and the proposed approximated ADMM still achieve acceptable steady state MSE, while the conventional ADMM suffers from larger degradation due to the circuit noise. After all, it can be concluded that both the proposed CIFISTA and the proposed approximated ADMM are suited for the implementation with optical analog circuits.

II. $\ell_1 - \ell_2$ Optimization Problem

In this paper, we consider the problem of estimating an unknown sparse vector $\boldsymbol{x} \in \mathbb{C}^N$ from the underdetermined linear measurement $\boldsymbol{y} \in \mathbb{C}^M$ obtained with a known sensing matrix $\boldsymbol{A} \in \mathbb{C}^{M \times N}$ as

$$\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{n} \in \mathbb{C}^M \quad (M < N), \tag{1}$$

where $\boldsymbol{n} \in \mathbb{C}^M$ is a zero mean white observation noise vector. Such a problem is called compressed sensing [15], and in particular, the $\ell_1 - \ell_2$ optimization problem given by

$$\hat{\boldsymbol{x}}_{\ell_1-\ell_2} = \arg \min_{\boldsymbol{x} \in \mathbb{C}^N} \left(\lambda \|\boldsymbol{x}\|_1 + \frac{1}{2} \|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{y}\|_2^2 \right), \tag{2}$$

is often used to reconstruct the sparse signal. Here, $\lambda > 0$ is a regularization parameter that balances between ℓ_1 sparse regularization term of $\|\boldsymbol{x}\|_1$ and data fidelity term of $\frac{1}{2}\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{y}\|_2^2$.

Several algorithms have been proposed for solving the $\ell_1 - \ell_2$ optimization problem, but, in this paper, we focus on the convex optimization based algorithms using proximal splitting because they can achieve good reconstruction performance with low computational complexity in general.

III. Convex Optimization based Algorithms for $\ell_1 - \ell_2$ Optimization Problem

One of the simplest and most popular reconstruction algorithms will be ISTA shown in Algorithm 1. In the algorithm, $S_\delta(\cdot)$ is the proximity operator of ℓ_1 norm called as soft thresholding function and is defined by

$$S_\delta(x) := \begin{cases} (|x| - \delta)\dfrac{x}{|x|} & |x| \geq \delta \\ 0 & \text{otherwise} \end{cases}, \tag{3}$$

for $^\forall x \in \mathbb{C}$, $^\forall \delta > 0$ [16]. When the argument of $S_\delta(\cdot)$ is a vector, $S_\delta(\cdot)$ becomes a vector obtained by applying (3) for each element of the input vector. Since all operations involved in ISTA except for soft thresholding function* can be achieved with optical devices, ISTA could be implemented with optical analog devices, however, it suffers from slow rate of convergence.

*In this paper, we assume soft thresholding function is calculated in electrical domain by using efficient OEO (optical signal - electrical signal - optical signal) converter devices [17].

Algorithm 1 ISTA

Input: $\boldsymbol{x}[0]$, $\gamma > 0$.
Output: Estimate of $\boldsymbol{x}$
  for $k = 0, 1, 2, \ldots$ **do**
    $\boldsymbol{x}[k+1] = S_{\gamma\lambda}(\boldsymbol{x}[k] - \gamma \boldsymbol{A}^{\mathrm{H}}(\boldsymbol{A}\boldsymbol{x}[k] - \boldsymbol{y}))$
  end for
  return $\boldsymbol{x}[k+1]$

Algorithm 2 FISTA

Input: $\boldsymbol{x}[0]$, $\boldsymbol{z}[0]$, $t[0] > 0$, $\gamma > 0$.
Output: Estimate of $\boldsymbol{x}$
  for $k = 0, 1, 2, \ldots$ **do**
    $\boldsymbol{x}[k+1] = S_{\gamma\lambda}(\boldsymbol{z}[k] - \gamma \boldsymbol{A}^{\mathrm{H}}(\boldsymbol{A}\boldsymbol{z}[k] - \boldsymbol{y}))$
    $t[k+1] = \dfrac{1 + \sqrt{4t[k]^2 + 1}}{2}$
    $\boldsymbol{z}[k+1] = \boldsymbol{x}[k+1] + \dfrac{t[k] - 1}{t[k+1]}(\boldsymbol{x}[k+1] - \boldsymbol{x}[k])$
  end for
  return $\boldsymbol{x}[k+1]$

FISTA is a faster version of ISTA, where the acceleration is achieved by the employment of the update equation using not only the estimate in the previous iteration but also the estimate of one more previous iteration. Detailed steps of FISTA are shown in Algorithm 2. It is known that FISTA can achieve the optimum convergence rate among the first order methods [10], [11]. However, it is difficult to implement FISTA with optical analog devices, because it includes the operation of division with a dynamic value in the update equation of $\boldsymbol{z}[k+1]$.

In order to make FISTA realizable with optical analog devices, in our previous study [13], we have proposed CIFISTA given in Algorithm 3, in which $\frac{t[k]-1}{t[k+1]}$ is replaced by a constant inertial parameter c. In our preliminary numerical experiments, we have confirmed that CIFISTA can achieve comparable convergence performance to FISTA with a proper choice of the inertial parameter c.

ADMM is also a popular convex optimization algorithm using proximal splitting, and it is possible to solve the $\ell_1 - \ell_2$ optimization problem with ADMM as shown in Algorithm 4. ADMM could be implemented with optical analog devices because it does not require the division operation. However, one of major drawbacks of the conventional ADMM will be the necessity of the matrix inversion, which may restrict the

Algorithm 3 CIFISTA (proposed)

Input: $\boldsymbol{x}[0]$, $\boldsymbol{z}[0]$, $\gamma > 0$, $0 \leq c \leq 1$.
Output: Estimate of $\boldsymbol{x}$
  for $k = 0, 1, 2, \ldots$ **do**
    $\boldsymbol{x}[k+1] = S_{\gamma\lambda}(\boldsymbol{z}[k] - \gamma \boldsymbol{A}^{\mathrm{H}}(\boldsymbol{A}\boldsymbol{z}[k] - \boldsymbol{y}))$
    $\boldsymbol{z}[k+1] = \boldsymbol{x}[k+1] + c(\boldsymbol{x}[k+1] - \boldsymbol{x}[k])$
  end for
  return $\boldsymbol{x}[k+1]$

Algorithm 4 ADMM

Input: $\boldsymbol{z}[0]$, $\boldsymbol{v}[0]$, $\eta > 0$.
Output: Estimate of $\boldsymbol{x}$
  for $k = 0, 1, 2, \ldots$ **do**
    $\boldsymbol{x}[k+1] = \left(\boldsymbol{A}^{\mathrm{H}}\boldsymbol{A} + \frac{1}{\eta}\boldsymbol{I}\right)^{-1} \cdot \left(\boldsymbol{A}^{\mathrm{H}}\boldsymbol{y} + \frac{1}{\eta}(\boldsymbol{z}[k] - \boldsymbol{v}[k])\right)$
    $\boldsymbol{z}[k+1] = S_{\eta\lambda}(\boldsymbol{x}[k+1] + \boldsymbol{v}[k])$
    $\boldsymbol{v}[k+1] = \boldsymbol{v}[k] + \boldsymbol{x}[k+1] - \boldsymbol{z}[k+1]$
  end for
  return $\boldsymbol{x}[k+1]$

Algorithm 5 Approximated ADMM (proposed)

Input: $\boldsymbol{x}[0]$, $\boldsymbol{z}[0]$, $\boldsymbol{v}[0]$, $\gamma > 0$, $\rho > 0$.
Output: Estimate of $\boldsymbol{x}$
  for $k = 0, 1, 2, \ldots$ **do**
    $\boldsymbol{x}[k+1] = S_{\gamma\lambda/\rho}\Big(\boldsymbol{x}[k] - \gamma\boldsymbol{A}^{\mathrm{H}}\Big(\boldsymbol{A}\boldsymbol{x}[k] - \boldsymbol{z}[k] + \frac{1}{\rho}\boldsymbol{v}[k]\Big)\Big)$
    $\boldsymbol{z}[k+1] = \frac{1}{1+\rho}\left(\boldsymbol{y} + \rho\left(\boldsymbol{A}\boldsymbol{x}[k+1] + \frac{1}{\rho}\boldsymbol{v}[k]\right)\right)$
    $\boldsymbol{v}[k+1] = \boldsymbol{v}[k] + \rho(\boldsymbol{A}\boldsymbol{x}[k+1] - \boldsymbol{z}[k+1])$
  end for
  return $\boldsymbol{x}[k+1]$

application to large-scale problems†.

In our previous study [14], we have derived a novel ADMM based algorithm obtained by using a different formulation from the existing ADMM. Update equations of the proposed algorithm are shown in Algorithm 5. With the new formulation, the $\ell_1-\ell_2$ optimization problem appears in one of update equations of ADMM, therefore, we have approximated the update equation with a single iteration of ISTA in order to avoid the double loop algorithm. This is the reason why the algorithm is called "approximated" ADMM. Note that the proposed approximated ADMM does not include matrix inversion, and also that the approximated ADMM can achieve comparable convergence performance to the conventional ADMM in our preliminary numerical experiments.

IV. Proposed Optical Analog Circuit Configurations of $\ell_1 - \ell_2$ Optimization Algorithms

Since all reconstruction algorithms discussed in the previous section require iterative signal processing, it would be a natural approach to implement each algorithm with optical analog circuit, where one iteration of the algorithm corresponds to the optical signal propagation of one round in the circuit. As for the optical devices to implement the algorithms, we assume following optical devices are available: signal splitter (SS), adder, subtractor, matrix-vector multiplier, attenuator, amplifier, and delay element. Among the devices, we focus on the impact of SS, adder, and subtractor, because they are

†Note that we do not assume that the matrix inversion is calculated with optical analog devices.

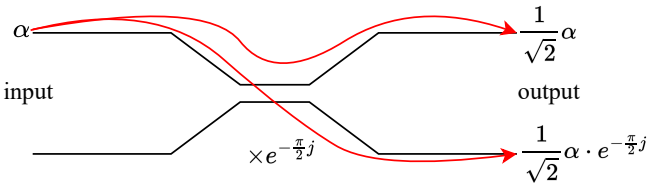

Fig. 1. Beam splitter (BS)

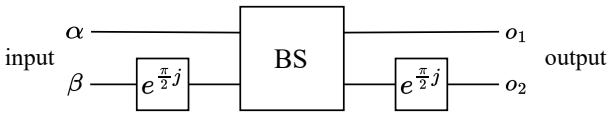

Fig. 2. Optical adder / subtractor

dominant devices in the circuit and are realized with a common optical device, namely the beam splitter (BS), which introduces large signal attenuation.

BS has two input ports and two output ports as depicted in Fig. 1. If we input signal $\alpha \in \mathbb{C}$ from one of the ports, then the output signal from the output port of the same side as the input is $\frac{1}{\sqrt{2}}\alpha$, while the output signal from the other side port is $\frac{1}{\sqrt{2}}\alpha \cdot e^{-\frac{\pi}{2}j}$, where j is an imaginary unit. Thus, if we give the phase shift of $e^{\frac{\pi}{2}j}$ to the lower port in Fig. 1, then BS can be used to realize SS, while the signal power of each output becomes half of the input signal power.

Optical adder and subtractor also can be realized by using BS and phase shifter. Fig. 2 shows the configuration of the adder and subtractor. Based on the property of BS, if we input signals $^{\forall}\alpha, \beta \in \mathbb{C}$ from the two input ports, then output signals from the two output ports will be

$$o_1 = \frac{1}{\sqrt{2}}\alpha + \frac{1}{\sqrt{2}}\beta \cdot e^{\frac{\pi}{2}j} \cdot e^{-\frac{\pi}{2}j} = \frac{1}{\sqrt{2}}(\alpha + \beta), \tag{4}$$

$$o_2 = \frac{1}{\sqrt{2}}\alpha \cdot e^{-\frac{\pi}{2}j} \cdot e^{\frac{\pi}{2}j} + \frac{1}{\sqrt{2}}\beta \cdot e^{\frac{\pi}{2}j} \cdot e^{\frac{\pi}{2}j} = \frac{1}{\sqrt{2}}(\alpha - \beta). \tag{5}$$

Thus, the addition and the subtraction can be realized with the optical analog devices in Fig. 2, while the power of the output signal becomes half of the desired signal as in the case of SS.

Optical analog circuits for the signal reconstruction have several SSs, adders and subtractors, therefore, the optical signal in the circuit suffers from signal attenuation during the propagation. However, at the input of soft thresholding function, which is required in all algorithms considered in this paper, the signal power must be an appropriate value because the soft thresholding function is a nonlinear function. Therefore, we insert optical amplifiers in the circuits before the soft thresholding function in order to compensate the signal attenuation due to BSs. Note that the number of required BSs in the optical circuit depends on the algorithms, and thus the required power gain of the amplifier also depends on the algorithms. Moreover, some optical attenuators must be

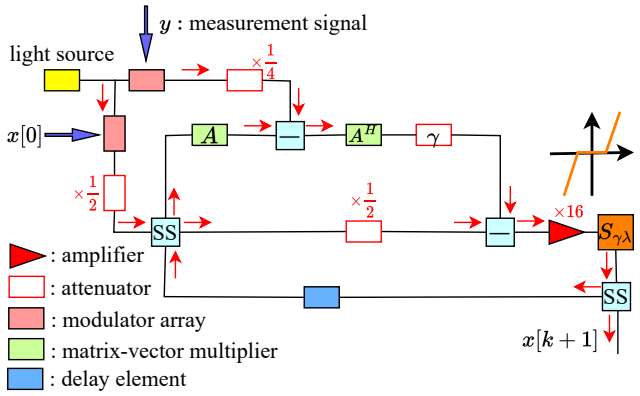

Fig. 3. Optical analog circuit configuration of ISTA

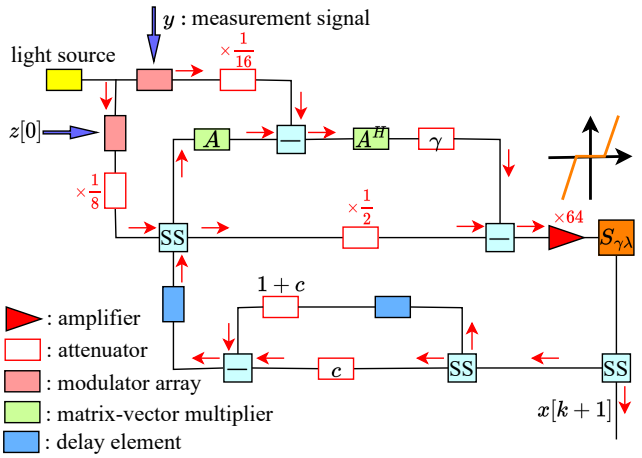

Fig. 4. Optical analog circuit configuration of CIFISTA

inserted at appropriate locations in the circuit to balance the signal power of each term before the addition or subtraction operations. Based on these considerations, we have derived the optical analog circuit configurations of ISTA, CIFISTA, conventional ADMM, and proposed approximated ADMM in Figs. 3 to 6, respectively.

V. Estimate of Additive Noise Power at Optical Amplifier

In the previous section, we have shown that optical amplifiers are necessary in the optical analog circuits of the $\ell_1 - \ell_2$ optimization algorithms. Generally speaking, additive noise is inevitable in the amplification of the signals. Therefore, the additive noise at the amplifier could be one of major performance limiting factors of the proposed approach. In this section, we estimate the power of the additive noise at the amplifier based on the noise model of optical amplifier.

According to [18], the power spectral density of amplified spontaneous emission (ASE) noise for a single erbium doped fiber amplifier (EDFA), which is one of most popular optical amplifiers, is given by

$$G_{\mathrm{ASE}} = F(G-1)h\mu, \tag{6}$$

where F is the amplifier noise figure (NF), G is the amplifier power gain, h is Planck's constant, and μ is the frequency. Thus, the noise power is given by the product of the power spectral density G_{ASE} and the signal bandwidth.

In order to estimate the noise power, we have assumed to use optical devices for common optical fiber communications systems. Specifically, if we assume the wavelength of $1550\,\mathrm{nm}$ corresponding to the standard single-mode fiber, then the frequency will be

$$\mu = \frac{3.0 \times 10^8}{1550 \times 10^{-9}} \approx 1.94 \times 10^{14}. \tag{7}$$

Moreover, by using signal bandwidth of $10\,\mathrm{GHz}$, which is typical for optical fiber communications, the ASE noise power added the optical amplifier with the power gain of G is given by

$$G_{\mathrm{ASE}} \times 10\,\mathrm{GHz} = (G-1) \cdot 2.56 \times 10^{-9}, \tag{8}$$

where the ideal value of $F = 2$ is employed for NF. Some specific values of the additive noise power at the optical amplifier with different power gain G are summarized in Table I.

TABLE I
Estimation of Additive Noise Power for Different Amplifier Power Gain

amplifier power gain (G)	additive noise power
8	1.79×10^{-8}
16	3.84×10^{-8}
32	7.94×10^{-8}
64	1.61×10^{-7}
128	3.25×10^{-7}
256	6.53×10^{-7}

VI. Numerical Results

Here, we evaluate the performance of ISTA, CIFISTA, the conventional ADMM, and the proposed approximated ADMM in the presence of additive noise at the optical amplifier (circuit noise), which is assumed to be white Gaussian noise, via computer experiments.

In the experiments, we set the dimension of unknown sparse vector $\boldsymbol{x}$ to be $N = 500$ and that of linear measurement vector be $M = 200$. We set the number of non-zero elements of $\boldsymbol{x}$ as $K = 25$, and the non-zero elements are randomly generated with independent and identically distributed (i.i.d.) circularly symmetric complex Gaussian (CSCG) distribution with zero-mean and variance $\sigma_{\boldsymbol{x}}^2 = 1$. Note that typical signal power in the optical fiber transmission is around 0.001, thus we have used 1,000 times larger values for the additive noise power at the optical amplifier than the values in Table I. The measurement matrix $\boldsymbol{A} \in \mathbb{C}^{M \times N}$ is generated by randomly choosing M rows of N-point unitary discrete Fourier transform (DFT) matrix. The measurement noise $\boldsymbol{n} \in \mathbb{C}^M$

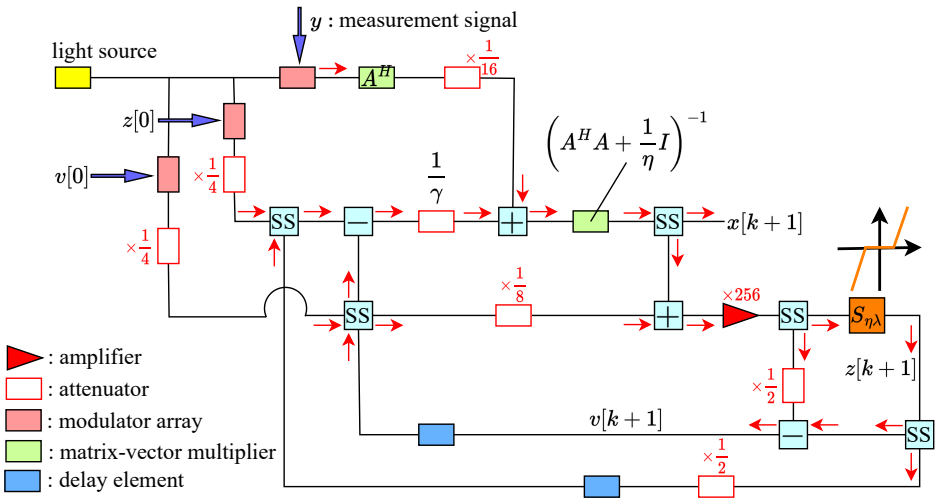

Fig. 5. Optical analog circuit configuration of conventional ADMM

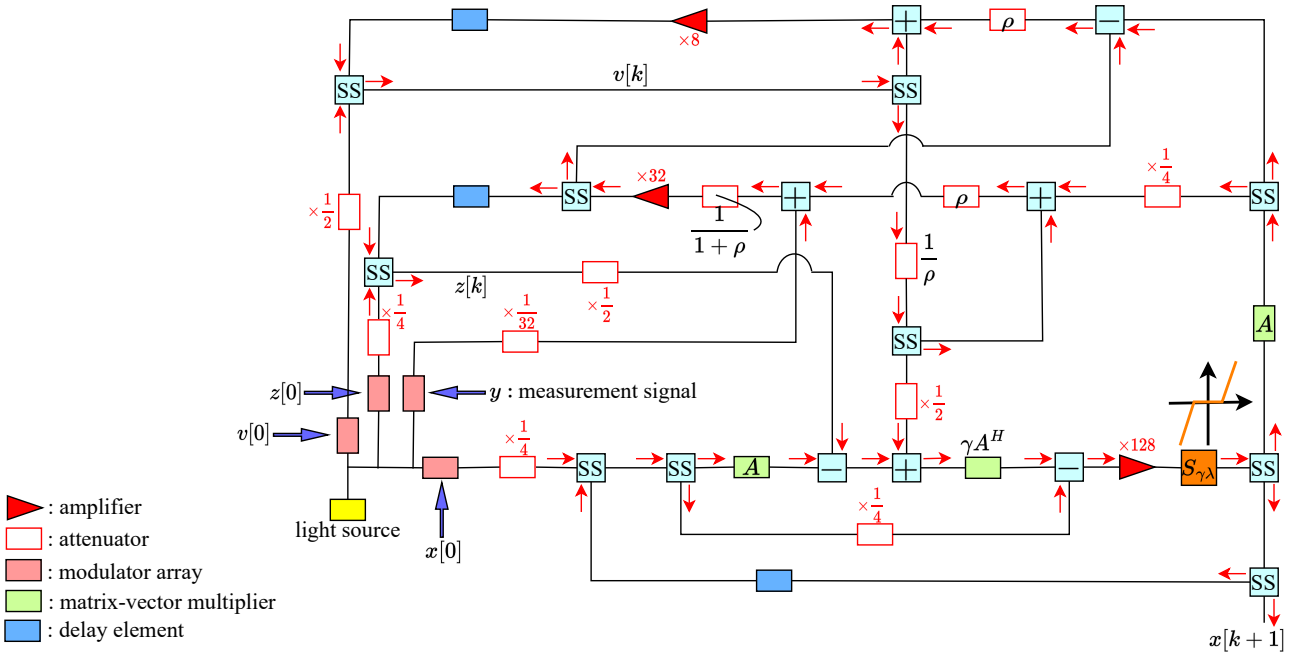

Fig. 6. Optical analog circuit configuration of approximated ADMM

is generated from zero-mean i.i.d. CSCG distribution with the variance corresponding to the measurement signal-to-noise ratio (SNR) of 30dB. We set the regularization parameter for the $\ell_1-\ell_2$ optimization problem to be $\lambda = 0.02$, the constant inertial parameter of CIFISTA $c = 0.65$, and other parameters $\gamma = 0.99$, $\eta = 4.5\times0.99$, and $\rho = 0.20$. The initial values of the vectors in the algorithms are all set to $\boldsymbol{x}[0] = \boldsymbol{z}[0] = \boldsymbol{v}[0] = \boldsymbol{0}$. Under these settings, the MSE performance of each algorithm is evaluated by averaging the results obtained with 100 trials.

Fig. 7 shows the MSE performance of ISTA, CIFISTA, the conventional ADMM, and the proposed approximated ADMM in the absence of the circuit noise. In this case, the performance of FISTA is also shown in the same figure for comparison purpose. From the figure, we can see that all algorithms achieve almost the same steady state MSE, while the convergence rate of ISTA is much slower than other four algorithms. CIFISTA achieves similar convergence rate to FISTA in spite of the simplified algorithm with a constant inertial parameter. Also, the proposed approximated ADMM can achieve comparable convergence rate to the conventional ADMM without using matrix inversion.

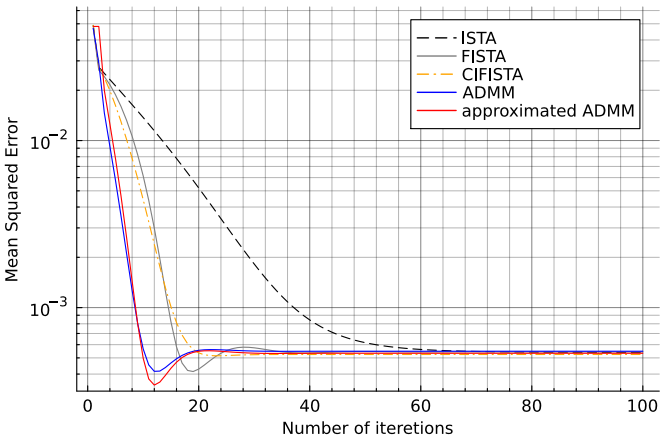

Fig. 7. Comparison of convergence characteristics (no circuit noise)

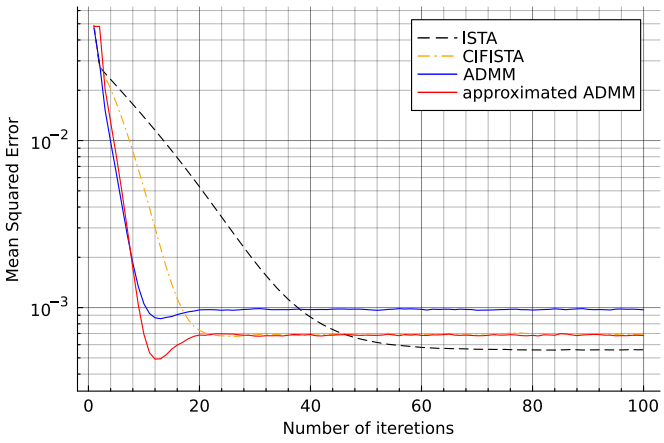

Fig. 8. Comparison of convergence characteristics (with circuit noise)

Fig. 8 shows the MSE performance of ISTA, CIFISTA, the conventional ADMM, and the proposed approximated ADMM in the presence of the circuit noise. As you can see from the figures, the degradation of the steady state MSE of ISTA is almost negligible. On the other hand, a certain degradation of the steady state MSE can be observed for CIFISTA and the approximated ADMM, while the conventional ADMM suffers from larger degradation of the steady state MSE. This could be mainly because the power gain of the optical amplifier is the smallest for the case with ISTA and is the largest for the case with the conventional ADMM. Moreover, the soft thresholding function also could have a certain impact on the steady state MSE performance, since it has a function to eliminate small noises, and only in the case of the conventional ADMM, half of the optical amplifier output with the largest power gain does not pass through the soft thresholding function.

Table II summarizes the comparison results of the convergence performance obtained by numerical experiments and the complexity of the optical analog circuits for the four algorithms. Judging from the balance between the steady state MSE and the convergence rate, both CIFISTA and the proposed approximated ADMM could be good choices for the implementation with optical analog circuits.

VII. Conclusions

In this paper, we have evaluated the performance of convex optimization based algorithms using proximal splitting for the $\ell_1 - \ell_2$ optimization problem assuming the implementation with optical analog devices. We have presented concrete configurations of optical analog circuits to realize ISTA, CIFISTA, the conventional ADMM, and the approximated ADMM. Moreover, we have estimated the additive noise power at the optical amplifier for each optimization algorithm assuming the implementation using optical devices for common optical fiber communications systems. From the numerical results obtained in the presence of the circuit noise, it can be concluded that both the proposed CIFISTA and the proposed approximated ADMM are more suited for the implementation with optical analog circuits than ISTA or the conventional ADMM.

Future work includes the investigation of the attenuation caused by other optical devices, and the implementation of soft thresholding function without using OEO converter.

Abstract — **The waveform of a photoplethysmography (PPG) signal depends on individual physiological conditions. Pulse transition time (PTT), derived from electrocardiogram (ECG) and PPG waveform features, is an important physiological parameter for blood pressure estimation. Filtering can change PPG signal waveform and the timing of PPG feature points. This work aimed to quantitatively investigate the filtering-induced PTT changes at earlobe in healthy subjects of different ages and with different PTT definitions. The ECG and earlobe PPG signals were recorded simultaneously at a sample rate of 2500 Hz for 120 s from 100 healthy adults in 5 age groups (20-29, 30-39, 40-49, 50-59, and over 60 years). The PPG signals were preprocessed using band-pass filtering (pass and stop bands: >0.5 Hz and <0.2 Hz for high-pass filter, <20 Hz and >30 Hz for low-pass filter) and then low-pass filtered (pass and stop bands: <3 Hz and >5 Hz). The PTT difference between the preprocessed and filtered PPG signals was calculated and analyzed. Four pulse feature points were defined and extracted (i.e., maximum peak (MP), valley point (VP), maximal first derivative (M1D), and maximal second derivative (M2D)). The results showed significant effect of PTT definition on filtering-induced PTT relative difference (p<0.001). It was found that the age group (50-59) and the MP definition had the minimum filtering-induce PTT changes. This work suggested that the physiological factors including PTT definition and age should be considered in the PTT-based blood pressure estimation methods.**

I. Introduction

Photoplethysmography (PPG) signal reflects the volumetric changes in microcirculation. PPG signals can be easily measured at different body sites using wearable sensors. Recent years witnessed a rapid development of wearable PPG sensors and relevant applications in daily monitoring of cardiovascular parameters, e.g., heart rate, heart rate variability, blood oxygen saturation, and blood pressure [1, 2]. Pulse transit time (PTT), which is approximated as the interval between the R wave of electrocardiogram (ECG) and a PPG waveform feature (often the end-of-diastolic valley) in the same cardiac cycle [3], is negatively related to blood pressure, providing the possibility of cuffless blood pressure monitoring using wearable PPG sensors [4].

Many physiological factors, including age, body posture, and body site of measurement, can influence the waveform of a PPG signal [5-7]. Compared to those measured from wrist and fingers, the PPG signal from earlobe is less influenced by tissue composition and has less motion artifacts, and using sensors designed specifically for acquisition from ear might bring comparable or even better results than the PPG from fingertip [8]. Aging can influence the biomechanical properties of arteries, veins, and microcirculation, leading to the changes in PPG waveform [3].

In many wearable applications, the original PPG signals are filtered before feature extraction. Filtering can change the waveform of PPG signals and the timing of feature points [9]. Especially, the finite impulse response (FIR) and infinite impulse response (IIR) [10,11] filters are widely applied in PPG signal processing [12]. The nonlinear phase response of the IIR filter may deform the PPG waveform, leading to an inaccuracy of PTT estimation. Currently, the PTT-based blood pressure estimation methods have limited accuracy, where filtering may be a neglected factor. There is a lack of quantitative evaluation of the effect of physiological factors on IIR filtering-induced PTT changes. To address the research gap, in this pilot study, we aimed to quantitatively investigate the effects of age and PTT definition on the IIR filtering-induced PTT.

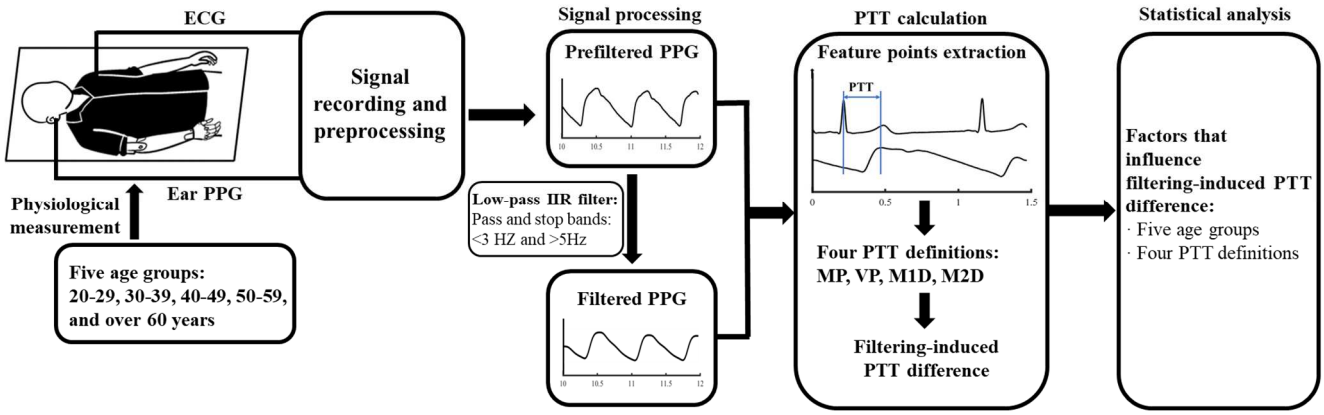

Fig. 1 Flowchart of PPG signal processing and analysis.

II. METHODS

A. Subject and Data Collection

One hundred participants (age: 44±14 (range: 20 to 71) years; 48 males and 52 females) were recruited from staff, students and their relatives in Newcastle Hospitals and Newcastle University with written informed consent. The subjects were equally distributed in five different ranges of age: 20-29, 30-39, 40-49, 50-59, and over 60 years old, i.e., 20 subjects in each age group. No participants suffered cardiovascular disease before. The experimental procedures involving human subjects described in this work complied with the principles in the Declaration of Helsinki, and received ethical permission from the Faculty Research Ethics Panel at Anglia Ruskin University.

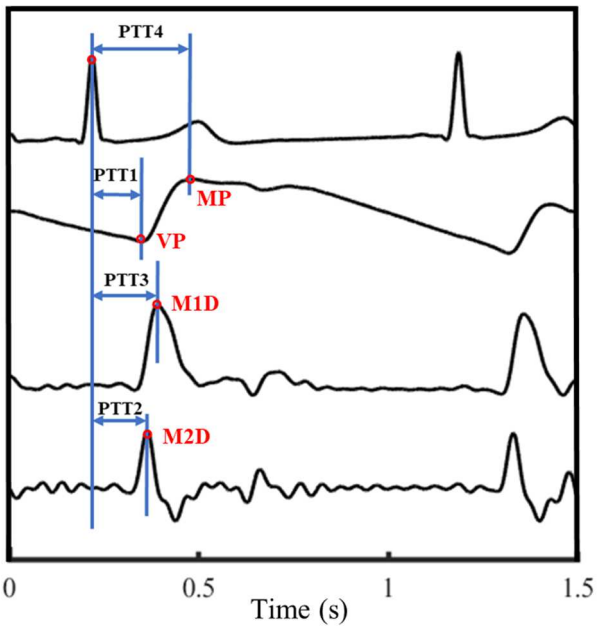

Fig. 2 Four definitions of pulse transit time. From top to bottom, the signals are ECG, PPG, the first derivative of PPG, and the second derivative of PPG.

The experiment began in a thermostatic room maintaining the temperature at 23±1 ℃. In order to stabilize the cardiovascular system, each subject rested in a supine posture on a couch for 5 minutes before signal recording. ECG and PPG signals from the right earlobe were recorded simultaneously for 120 seconds at a sampling rate of 2500 Hz when all signals were clear and stable. During the whole experiment, the subjects kept normal breathing without body movement.

B. Signal Preprocessing and Filtering

The recorded data were imported to MATLAB (R2021b; The MathWorks Inc. Natick, USA) for signal processing. A bandpass filter (0.1-35Hz) was used to preprocess the ECG signal. As shown in Fig. 1, the recorded raw PPG signals were preprocessed with a high-pass IIR filter (1 zero and 10 poles, passband: >0.5 Hz, stopband: <0.2 Hz) to remove the low-frequency and DC components (e.g., 'baseline wander'). A low-pass IIR filter (1 zero and 16 poles, passband: <20 Hz, stopband: >30 Hz) was then used to remove the high-frequency noises including the 50 Hz power line and electrophysiological noises. The preprocessed PPG signals were further filtered with a low-pass IIR filter (1 zero and 13 poles, passband: <3 Hz, stopband: >5 Hz) which was applied in our early study where the details of the filters could be found [11].

C. Definition of PTT

PTT is usually defined as the time interval between the R-peak of the ECG and a reference point on systolic PPG signal segment. The reference point can be derived from different PPG features (e.g., end-of-diastolic valley, systolic peak, etc.), which leads to different PTT values [7]. This work calculated the PTTs defined by four different PPG feature points: end-of-

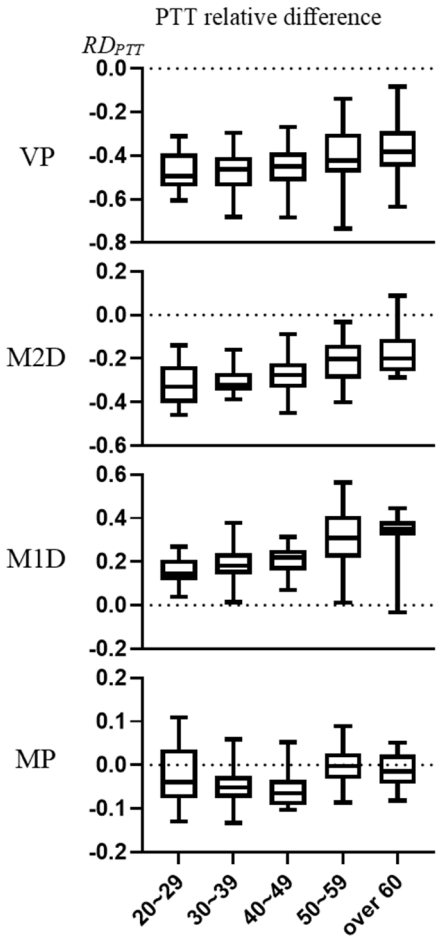

Fig. 3 Box and whisker plots of the PTT relative difference (i.e., RDPTT) of each age group at different PTT definition. The medians are represented by the horizontal lines within the boxes while the first and third quartiles are represented by the box boundaries, whereas the maximum and minimum values are represented by the whiskers.

diastolic valley (VP), systolic peak (MP), the peak of the first derivative of PPG (M1D) and the peak of the second derivative of PPG (M2D), as illustrated with PTT1, PTT4, PTT2 and PTT3, respectively, in Fig. 2.

D. Extraction of Feature Points

On ECG signals, the R wave peak was detected as the maximal value in a cardiac cycle using the Pan Tompkins method [13]. The four PPG feature points (peak, valley, maximal first derivative, maximal second derivative) were extracted from the prefiltered and filtered PPG signals and their derivatives (Fig. 2). The valley and peak detection algorithm were based on the calculation of differentials. Considering the high sampling frequency (2500 Hz), the error caused by the approximation is very limited ($<4 \times 10^{-4}$ s for the timing of any feature point). The details can be found in our published work [11]. Considering the noisy PPG signals in some cardiac cycles, only the valleys within 50-500 ms after the ECG R-peak

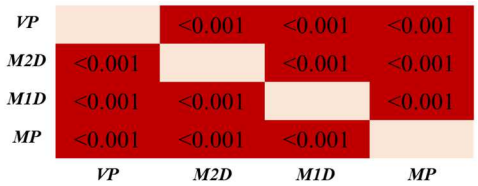

Fig. 4b Results of Dunn's Kruskal–Wallis multiple comparisons between the three types of PTT definition regarding the PTT relative difference. The red color indicates the more significant effect, and the yellow color indicates a less significant effect.

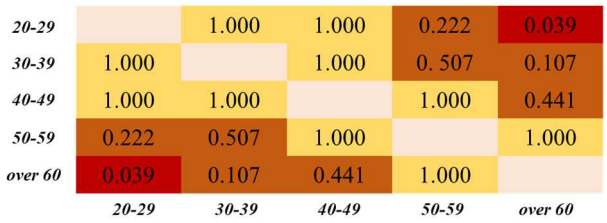

Fig. 4c Results of Dunn's Kruskal–Wallis multiple comparisons between the five age groups regarding the PTT relative difference (except MP). The red color indicates the significant effect, and the yellow color indicates a less significant effect.

(i.e., 50 ms≤ PTT ≤500 ms) were selected for analysis. For each PPG signal, the PTT was calculated as the mean value of PTTs of the selected cardiac cycles.

E. Statistical Analysis

For each subject, the filtering-induced PTT difference was calculated between the PTT values derived from filtered and preprocessed PPG signals. The PTT relative difference was calculated as:

$$RD_{PTT}=(PTT_{filtered}-PTT_{preprocessed})/PTT_{preprocessed} \quad . \qquad (1)$$

Statistical analysis was performed using SPSS (Version 24.0, IBM Corp) and R programming language (R Core Team, 2021). Considering the data size, Shapiro–Wilk test was performed to investigate the normality of data distribution. For normally distributed data (defined as $p>0.05$ in Shapiro–Wilk test). To investigate if there was any significant effect of age, PTT's definition, and their interaction on the filtering-induced PTT relative difference, the analysis of variance (ANOVA) or

Scheirer–Ray–Hare test was performed. ANOVA was performed on normally distributed data where the homogeneity of variance was satisfied (defined as p>0.05 the Levene's test), otherwise the Scheirer–Ray–Hare test was performed as a substitute. To further investigate the difference between age groups, or between PTT's definitions, and to identify the age group and the PTT definition with the highest reliability (i.e., with the least filtering-induced PTT relative difference), the post hoc analysis was performed, i.e., least significant difference and Dunn's Kruskal–Wallis multiple comparisons for ANOVA and the Scheirer–Ray–Hare test, respectively. In the Dunn's Kruskal–Wallis multiple comparisons, the p-value was adjusted via the Benjamini–Hochberg method [14].

III. Results

A. Effect of Age and PTT Definition on the Filtering-induced Differences

Fig. 3 shows the distribution of IIR filtering-induced PTT relative difference (i.e., RD_{PTT}) in five different age groups and four PTT definitions. After the filtering processing, PTTs were shortened except for M1D, with a consecutive trend in different age groups. The relative difference distributions did not satisfy the homogeneity of variance (p=0.16). The relative difference distributions did not satisfy the homogeneity of variance (p<0.05 in Levene's test). Therefore, the Scheirer-Ray-Hare test was performed. There was a significant effect of the PTT definition on the filtering-induced PTT relative difference (p<0.001), whereas the effect of age and their interaction are not significant (p=0.086 and p=0.999, respectively).

B. Comparison between Age Groups and PTT Definitions

The Fig. 4a shows the results of Dunn's Kruskal–Wallis multiple comparisons between the five age groups regarding the PTT relative difference. There are no significant difference between any paired age groups. In Fig. 4b, significant differences are observed between any two PTT definitions (p<0.001 for all). Overall, the age group (50-59) was least influenced by the filtering processing, indicating the highest robustness against filtering-induced PTT difference.

C. Comparison between Age Groups: MP Excluded

It was observed that all type's PTT relative difference showed age dependence except MP (Fig. 3). To investigate the correlation between age and filtering-induced PTT relative difference in the remaining three PTT definitions, the Scheirer-Ray-Hare test was performed without MP results. There was a significant effect of PTT definition on the filtering-induced PTT relative difference (p=0.014). Fig. 4c shows the results of Dunn's Kruskal–Wallis multiple comparisons between the five age groups except MP regarding the PTT relative difference. There is a significant difference between the youngest and oldest age groups (i.e., 20-29 and over 60) in PTT relative difference (p<0.05).

IV. Discussion and Conclusion

The results in this work showed that: 1) filtering processing could considerably change the PTT values. We observed that PTTs were shortened except for M1D after filtering; 2) filtering-induced PTT changes depended on age and the definition of PTT, where the effect of age was consecutive (i.e., higher PTT changes in younger subjects) except MP. Among different PTT definitions, MP showed the minimum filtering-induce PTT changes.

Vascular stiffness increases with age, which has a significant effect on PPG signal waveform. However, no quantitative observation has been disclosed. The results in this work fill this gap and highlight the importance of considering filtering-induced inaccuracy in PTT-based blood pressure estimation, especially when IIR filtering is applied on the earlobe PPG signals where the PTT is shorter compared with that from the fingertip or wrist.

At present, the filter parameters of many commercial wearable PPG sensors are unrevealed. In published works, the filtering parameters are not uniform and narrow frequency bands were widely used (e.g., 0.5-4 Hz [15], 0.5-4 Hz [16], and 0.8-4 Hz [17]). 0.5-10 Hz was suggested for estimation of heart rate from PPG signals [4]. And 0.5-10 Hz with 60 Hz notch filter was used to estimate blood pressure using the PPG signal obtaining from earlobe [18]. Our previous study demonstrated that age and measurement site had significant impacts on the time shift in feature points between prefiltered and filtered fingertip PPG signals [19]. Our results here highlighted the importance of considering the age and PTT definition in PTT measurement, providing the reference for future works on more accurate PTT measurement via a pathway of age- and definition-adjustment towards individualization.

In conclusion, the results in this work showed that the filtering-induced PTT difference was significantly different among different PTT types or among different age groups. The physiological factors including PTT definition and age should be considered in PTT-based blood pressure estimation using wearable sensors.

***Abstract* — With the massive amount of data generated, a data engineering method is needed to process the data to obtain new information, which can later be used for further understanding and business decisions. One of the data processing methods is the k-nearest neighbor (*k*-NN) query. The *k*-NN queries aim to identify *k*-objects with the shortest distance based on object references over the network. However, a critical limitation of the *k*-NN query lies in its inability to process a query when an object has proximity durability to a reference object at a particular time interval. This limitation arises since the *k*-NN query does not consider the durability and time interval variables in its calculation algorithm.**

This article discusses the problem of time interval-based durable *k*-NN queries on time series data by introducing the algorithmic framework and employing dictionary and grid data structure to process these queries. The proposed algorithm, which is a dictionary and grid-based durable *k*-NN queries method, incorporates parallel computing techniques to efficiently search for a collection of *k* objects that exhibit durability in their proximity to a reference object within a predefined time interval. The effectiveness and efficiency of the devised algorithms were assessed through extensive testing using both real-world and synthetic datasets.

Keywords— ***continuous, k-NN queries, multidimensional, time series, grid, data engineering, data banks***

I. INTRODUCTION

One of the data processing methods is the *k*-nearest neighbor (*k*-NN) queries [10][11]. The k-NN query intends to search for a set of *k*-objects that exhibit the shortest distance in relation to the reference objects. However, this method is inadequate when confronted with a scenario wherein an object has proximity durability to a reference object within a specific time interval, as the conventional *k*-NN query is unable to handle such instances.

As an illustration, consider an individual denoted as person A as an asymptomatic carrier and has been infected by a respiratory virus. Person A engaged in conversation with three companions, namely persons B, C, and D. Each of them has a different incoming and leaving time from the meeting room. The three of them were found to be in breach of the health protocols, as they failed to maintain a safe physical distance and did not wear masks. The distance, incoming, and leaving time are shown in Table 1.

TABLE I. INCOMING TIME, LEAVING TIME, AND DISTANCE TO PERSON A

Persons	Incoming Time	Leaving Time	Distances from A
A	2:00 PM	3.00 PM	0 cm
B	1.45 PM	2.45 PM	90 cm
C	2:00 PM	2.55 PM	20 cm
D	2.55 PM	3.15 PM	50 cm

Let us assume the hypothetical scenario where a respiratory virus exhibits a significantly high transmission probability, which is happened when individuals engage in no-health protocol interactions lasting a minimum duration of 15 minutes within a distance of the asymptomatic carrier less than 1 meter. Now suppose a healthcare professional aims to identify individuals who are potentially susceptible to contracting a virus. To pinpoint those most at risk of infection, the healthcare professional intends to search for the two most suspicious infected persons, employing a threshold duration of 15 minutes.

To tackle this problem, we utilize a search strategy based on the *k*-NN query approach, with query point A, $k = 2$, and the durability threshold of 25% (equivalent to 15 minutes from the query point, or A's duration, which is 1 hour). Please note that the search duration is based on the active time of the query point, Person A, from 2 to 3 PM (the incoming and leaving time of A). In addition, to simplify the discussion, it is assumed that the motion of the object remains stationary throughout the duration of this particular example. Later, we use time series geolocation data to illustrate the dynamic situation.

From Table 1, we include B and C as the candidates for the query answers, since they interact with A in 45 and 55 minutes, respectively. Further, we can exclude D since he only interacts from 2.55 to 3.00 PM (5 minutes) and only fulfills 8 % of the search duration to be part of k-*NN* w.r.t. query point person A. Hence, B and C are the answer to the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

durable k-*NN* query with query point A, *k=2*, and durability threshold = 25%.

In this work, we formulate several issues as follows. First, we propose the design and implementation of data structures and algorithms to address the query of durable *k*-NN based on time intervals on time series data. Second, we conduct the performance evaluation of the proposed data structures and algorithms in answering the query of durable-*k*NN query based on time intervals on time-series data. Moreover, in this query, an indexing data structure, namely grid-based indexing, is highly utilized to perform indexing on the data, thereby expediting and facilitating the query process.

We organize our work presentation as follows. Chapter I delves into the introduction and contributions of this work. Chapter II discusses the related works. We address the problem environment of this work in Chapter III. Chapter IV discusses the solutions to the identified issues. Subsequently, Chapter V provides a comprehensive discussion of the performance evaluation results. Finally, Chapter VI concludes the findings and contributions of this study.

II. RELATED WORKS

The work by Ding, Lu, and Liu [5] focuses on developing algorithms for *k*NN queries and *k*NN-Joins in relational databases. Their objective is to design solutions that can be implemented using existing SQL operators without modifying the underlying database engine. Li, Liu, and Wang [6] propose a grid-based index structure suitable for parallel implementations, providing an efficient way to index and search large-scale and high-dimensional data.

In the realm of spatial databases, Chunming, Xiangfeng, and Liqiang [7] introduce the R-Grid algorithm, which enhances the performance of *k*NN retrieval through the utilization of a grid-based spatial index. This approach significantly speeds up the search process in location-based nearest-neighbor queries. Zhang, Yang, and Qin [8] present the GDCF algorithm, which employs bitmap indexing and union-find techniques to support efficient neighbor grid queries. Their approach reduces redundancies and enhances the efficiency of grid-based clustering algorithms.

In the broader context of machine learning, the article by Onel [9] provides an overview of the *kNN* algorithm as a simple and easy-to-implement supervised learning technique for classification and regression tasks.

Several studies have been conducted on the topic of durable queries. In the study by Wang et al. [2], the focus is on identifying objects with sustained quality over time in historical time series databases. The authors propose a framework for processing durable top-k queries, which efficiently retrieves objects that exhibit durable quality over time. Gao et al. [12] also present efficient algorithms for processing durable top-k queries specifically on temporal data.

Another study by Semertzidis [13] introduces a hybrid approach that effectively filters potential matches based on both structure and time in temporal graphs. This approach aims to enhance the identification of durable top-k objects within instant-stamped temporal records. Additionally, Gao et al. [14] further investigate the durable top-k framework and its application to instant-stamped temporal records.

III. PROBLEM BACKGROUND

A. Time Series with Geolocation Data

Time series with geolocation data is a collection of geolocation data (latitude and longitude) acquired through repetitive time measurements. The ubiquity of time series data is undeniable, as time constitutes an inherent facet of all observable phenomena. Table 2 shows time series data pertaining to the positional attributes of the observed object.

TABLE II. THE EXAMPLE OF TIME SERIES GEOLOCATION DATA OF PERSON A

Latitude	Longitude	Timestamp (hh:mm:ss)
-7.53824172425915	112.23824890861432	10:00:01
-7.53824172421915	112.23824890857432	10:00:30
-7.53824172426415	112.23824890861932	10:01:00
-7.53824172425415	112.23824890860932	10:01:30

B. Grid-Based Indexing

The grid index [1] serves as a data structure employed for indexing the data based on their location. Figure 1 presents a visual representation of the two-dimensional grid index.

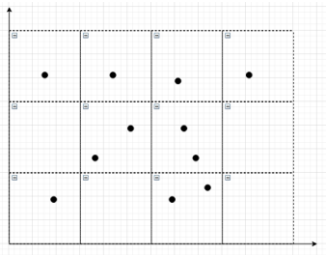

Fig.1 Grid Index

The data is indexed and mapped according to its grid cell. Grid cell *(i,j)* on column *i* and row *j* (started from left bottom corner) contain all objects with a range of coordinate *x* equals [i . θ, (i+1). θ] and coordinate *y* with values [*j. θ*, *(*j+1). *θ*] where *θ* is the length of the grid cell. Moreover, an object with coordinates (*x,y*) is located on grid cell *ci,j* where $i = \lfloor x/\theta \rfloor$ dan $j = \lfloor y/\theta \rfloor$ [1].

C. Durable Query

The concept of a durable query refers to a query that searches for objects with durable quality consistency within a specific time interval in a given dataset, using a time unit [2][12][13][14]. Durable quality can be represented by scores, weights, or other numerical attributes. In a durable query, a threshold is utilized as a boundary value for objects that

exhibit a certain level of resilience in their occurrence (durability) within a time interval.

Drawing from the illustration of the respiratory virus previously, the durable quality is represented by the distance between the individual and the query point (person A).

D. K-NN Query and Continuous Monitoring

The *k*-Nearest Neighbor query is one of the query processing algorithms widely utilized due to its ease of use, effectiveness, and efficiency. This algorithm has been implemented in various fields, including pattern recognition, text categorization, and moving object recognition, among others [3]. The k-NN query aims to find the k-nearest objects based on a reference object.

The search for the *k*-nearest objects can employ various distance functions such as Minkowski Distance, Manhattan Distance, Euclidean Distance, Cosine Distance, Jaccard Distance, and Hamming Distance. In this article, the author utilizes the Euclidean Distance function as it measures the straight-line distance between two points in Euclidean Space.

Moreover, continuous *k*-Nearest Neighbor Monitoring is a method employed to continuously monitor changes in the results of *k*-NN within specific time intervals. If an object identified by the *k*-NN moves away from the *k*-NN region or if there is a new object entering the k-NN region, the *k*-NN computation will be performed to obtain the latest results. Figure 2 provides an illustrative example of Continuous *k*-Nearest Neighbor Monitoring.

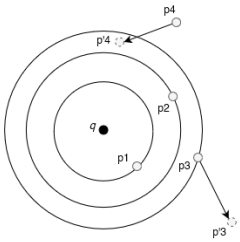

Fig. 2. Example of 3-NN Monitoring

In the illustrative example depicted in Figure 2, the object q has 3-nearest neighbor objects, namely *p1*, *p2*, and *p3*. At a certain point in time, object *p3* moves away from q. Simultaneously, object *p4* approaches *q* and has a closer distance to *q* compared to *p3* before it moves away. Due to these changes, a new search for the 3-nearest neighbors must be performed.

Initially, the system will search for a set of objects that qualify as candidates by comparing the distances between these objects and the reference object with the radius of the reference object [4].

Once the number of candidates meets the value of k, the computation of *k*-NN can be performed. When there are changes in *the k*-NN result objects (objects that exit the *k*-NN result region or new objects entering the *k*-NN result region), a new search will be conducted to identify fresh candidates that satisfy the value of k.

E. Durable k-NN Query on Time-Series Data

The Durable *k*-Nearest Neighbor Query on Time Series Data (DkNNT) is designed to retrieve a set of *k*-nearest objects that exhibit a durable level of proximity (durability) to a reference object within a specific time interval.

The significance of the DkNNT query, when applied to the context of tracing over respiratory virus disease lies in its ability to identify individuals who have the closest distance and a resilient level of proximity to individuals exposed to the virus within a defined time interval. This enables the tracing of individuals who are at risk of exposure and infection by the virus.

The brief example presented in Chapter I explains the concept of basic computations of DkNNT under the assumption of static movement. This example serves to illustrate the fundamental principles involved in the context of the given scenario. Clearly, persons *B* and *C* are the answer to the DkNNT query w.r.t. the query point A, *k*=2, and durability threshold = 25%.

It is important to note that there is a possibility of having more than *k* records that meet the criteria to be included as candidates for answering the Durable K-Nearest Neighbor in Time (DkNNT) query. However, due to the dynamic nature of the environment, we also take into consideration the number of time slices in which a record occurs as a factor in determining the query results on every periodic checking, denoted as *Δs*. The more frequently a record appears in each check, the higher it is regarded as a component of the DkNNT query. By incorporating this parameter, we can ensure obtaining a bounded number of DkNNT query results.

IV. Proposed Method

This section presents the approach employed to address the Durable *k*-Nearest Neighbor query based on time intervals, including the data structures and processing algorithms utilized. The utilization of symbolic notations throughout the article and its descriptions can be referred to in Table III.

TABLE III. List Of Symbols

Symbol	Description
r	Durability thresholds
tb	Start time of query interval
tc	End time of query interval
k	Number of query results
Δmin	Minimum time for the object to be part of the query result
Δs	Number of occurrences for an object to be part of DkNNT query results
sref	Reference object
candidates	DkNNT candidates

future candidates	Possible DkNNT candidate for the next timestamp
knn_list	*k*NN object list
radius	Minimum distances to find the candidates from the reference object
CS	Candidate of query results
RS	Query results

A. Data Structure

There exist three main data structures that are utilized to support the computation of the DkNNT query, they are Dictionary, Grid Index, along with Object Data Timestamp and Grid Position.

1. Dictionary
   The dictionary data structure is employed to construct the Grid Index, store data objects in the Grid Index, store the timestamp and grid position of data objects in the Object Data Timestamp and Grid Position, store the candidate of *k*-NN objects, and store the *k*-NN objects themselves. The key-value structure of each dictionary can be observed in Fig. 4 and Fig. 5.

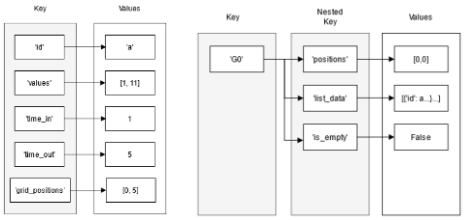

Figure 1. Structure of Dictionary for Data Object and Grid Index

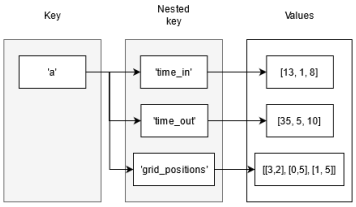

Figure 2. Structure of Dictionary for Object Data Timestamp and Grid Position

2. Grid Index
   The Grid Index is a data structure designed for indexing multidimensional data by grouping data according to their respective grid cells. It serves as an efficient mechanism for organizing and accessing data in a grid-based manner.

3. Object Data Timestamp and Grid Position
   We also utilize the Object Data Timestamp and Grid Position to store the list of arrival and departure times, as well as the list of Grid Cell positions for each object. This information proves valuable in tracking the movement of the reference object (*sref*) within the Grid Index. By maintaining these records, we can effectively monitor the trajectory and changes in the position of the reference object.

B. The Algorithms

As mentioned previously, the proposed algorithm to process DkNNT query consists of two-step processing, they are data precomputing and query processing tasks.

1. Data Precomputing
   Data precomputing is a process that enhances the performance of query processing algorithms by efficiently indexing the dataset using a Grid Index and storing the timestamp and grid position lists of each data object in the Object Data Timestamp and Grid Position structure.
   The process begins with the construction of the Grid Index data structure, followed by populating each cell in the Grid Index with the corresponding data objects. Once the Grid Index has accommodated all the data objects, the Object Data Timestamp and Grid Position are formed to store the lists of arrival and departure times, as well as the grid cell positions for each object. Upon completion, the Grid Index along with Object Data Timestamp and Grid Position are serialized and stored in disk files for future utilization during query processing. The overall workflow of the data precomputing process is implemented in Algorithm 1 and Algorithm 2.

Algorithm 1 Data Precomputing

Input: dataset
Output: Grid Index *GRID*, Object Data Timestamp and Grid Position *ODTGP*

```
list_object_data ← dataset
GRID ← init Grid Index
GRID.getListData(list_object_data)

51:     for index in range(lower_bound, upper_bound) do
52:         iterators ← index
53;     Generate all possible neighbors_direction from iterators
54:     neighbor_candidates ← neighbor_direction
55:     neighbor_candidates ← neighbor_candidates – previous_neighbor
56:     for neighbor ∈ neighbor_candidates do
57:         if isValidNeighbor(neighbor) then
58:             valid_neighbor_list ← neighbor
59:     return valid_neighbor_list
```

2. Query Processing

Query processing is the second stage of the Durable k Nearest Neighbor query algorithm, aimed at processing user input queries using the Grid Index and Object Data Timestamp and Grid Position obtained from the data precomputing phase. The process begins by validating the time interval of the user's reference object. Next, an iteration is performed to search for k-nearest neighbors (k-NN) by identifying candidates and upcoming candidates from the reference object (sref). Once the candidate search process is completed, k-NN objects are obtained as the k-NN objects of *sref*. Subsequently, the monitoring process for changes in the k-NN is conducted until the durable query result objects are obtained, which are then returned and displayed to the user. The overall workflow of the query processing is implemented in Algorithm 3 and 4.

Algorithm 3 *Query Processing*

```
        Input: Reference object sref, number of nearest object k, initial interval
        timestamp tb, final interval timestamp tc, durability threshold r
        Output: list of durable k-NN objects RS
1:      grid ← GRID
2:      odtgp ← ODTGP
3:      data_length ← grid.getAmountData()
4:      isValidTimestamp, valid_sref ← checkObjectValidity(sref, tb, tc)
5:      if k > data_length -1 then
6:          return error
7:      if tb ≥ tc then
8:          return error
9:      if isValidTimestamp then
10:         Δmin ← ⌈r * (tb - tc)⌉
11:         radius ← sqrt( k / π * data_length)
12:         CS ← ∅
13:         RS ← ∅

V. PERFORMANCE EVALUATION

The experiments were conducted to assess the performance in terms of computational time and memory usage for each operation. The experimental environment is outlined in Table 4, providing insights into the specific conditions under which the tests were carried out.

TABLE IV. TESTING ENVIRONMENT

Environment	Specification
Hardware	Prosesor: Intel Core i5 7200U @ 2.50GHz (4 CPU) RAM: 8192 MB
Software	Operating System: Windows 10 Enterprise LTSC 64-bit

A. *Datasets*

There exist three datasets that are utilized to represent the location distribution of the record for the performance testing, they are Independent (IND), anti-correlated (ANT), and real-life data, Forest Cover (FC)

B. *Evaluation Scenario*

By default, we define the value of the performance evaluation setup as follows:

a. number of spatial dimensions: two dimensions
b. the data size: 50,000
c. the number of grids (in a dimension): 10
d. time interval: 100
e. k= 50; and
f. durability threshold: 70%;

Using the above default value, we vary the value of some testing parameters in each scenario of evaluation as follows:

1. effect of the number of spatial dimensions: two- and three-dimensions;
2. effect of the size of data: 10K, 30K, 50K, 100K, 200K, and 300K;
3. effect of the value of k: 25, 50, 75, and 100;
4. effect of the time interval: 10, 50, 100, 500, 1000;
5. effect of the durability threshold: 30%, 50%, and 70%.

C. *Evaluation Results of Query Processing*

1. Effect of the Number of Spatial Dimensions

In the case of independent data (IND), the variation in attribute dimensions in Table V has a highly significant influence on the execution time required by the query processing to handle user input queries. This is attributed to the random distribution of data values in each attribute, leading to a scattered placement of data points on the grid. As a result, the search process for the k-nearest neighbor (k-NN) candidate list and the search process for the k-NN object list become more time-consuming.

On the other hand, in the case of anti-correlated data (ANT) and forest cover data (FC), there is a decrease in execution time as the attribute dimensions increase. This is because in higher dimensions, the characteristics of the anti-correlated (ANT) and forest cover (FC) data cluster together to form an area or

region, reducing the need for extensive candidate verification operations.

TABLE V. EFFECT OF DIMENSIONAL SIZE IN QUERY PROCESSING

Size of Dimension	Running Time (s)		
	IND	ANT	FC
2	0,35	2.1	2,41
3	43.2	0.39	0,59

2. Effect of the Size of The Data

The variation in the amount of data in Fig.6 has a significant impact on the execution time of query processing for all three types of datasets. As the amount of data increases, the number of data points within each grid cell also increases. Consequently, the verification process for the k-nearest neighbor (k-NN) candidate list becomes more time-consuming.

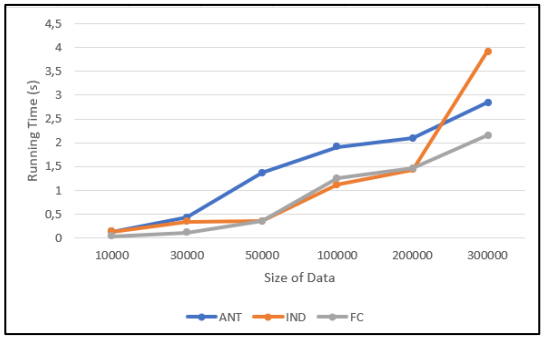

Figure 6. Size of Data vs Running Time

3. Effect of the *k*

Similar to the changes in the data quantity, the alteration of the value of *k* in Fig.7 has a significant impact on the execution time of query processing in all three types of datasets. This is due to the fact that as the value of *k* increases, the algorithm needs to expand the search area, resulting in a larger radius for the reference object (*sref*). Consequently, the process of gathering the list of *k*-NN candidate objects becomes more extensive as it requires visiting grid cells located within the radius region of *sref*.

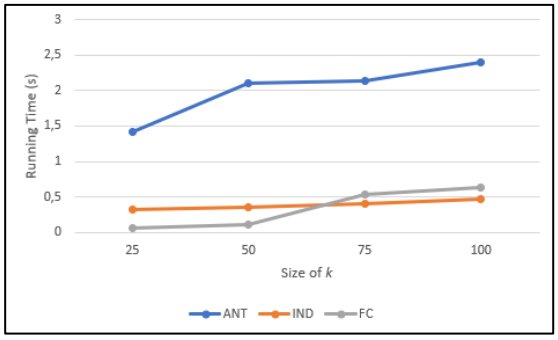

Figure 7. Size of *k* vs Running Time

4. Effect of the Time Interval

The variation in time interval magnitude in Figure 8 has a significant influence on the execution time of query processing in all three types of datasets. In the ANT dataset, the running time starts to increase from the search at a time interval of 100. Conversely, in the IND and FC datasets, the impact of the interval increase becomes significant only at a time interval of 1000. This is due to the fact that as the time interval expands under these conditions, the process of monitoring the list of *k*-NN query result objects becomes more time-consuming. This is because there are more objects that need to be checked for their appearance and departure within the search radius.

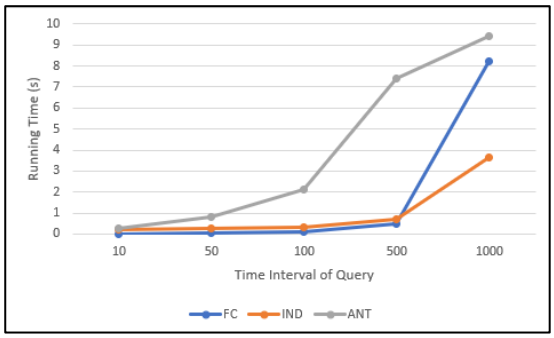

Figure 8. Time Interval vs Running Time

5. Effect of the Durability Threshold

Upon observing the overall graph in Fig.9, the movements of both indicator lines are not significantly pronounced across all three types of datasets. This indicates that the durability threshold does not have a substantial impact on the execution time of query processing, as the durability threshold primarily affects the size of a small search scope among the final candidates, and it is highly dependent on the size of the time interval.

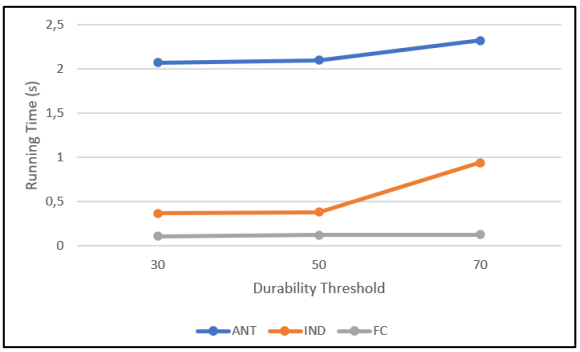

Figure 9. Durability Threshold vs Running Time

VI. CONCLUSIONS

In this study, we discussed the data structure and query algorithm for Durable k-Nearest Neighbor using Grid Indexing, which consists of two processes: data precomputing and query processing. A series of experiments have been conducted, comparing various parameter variations and utilizing both synthetic and real-life datasets, to evaluate the effectiveness of the proposed solution. From the experimental results, it can be concluded that the proposed solution is highly sensitive to the number of dimensions, data size, and time interval.

***Abstract*—Image enhancement in low-light conditions is not solely a matter of adjusting the illumination. Due to the limited capabilities of capturing devices, there are also issues of hidden noise bursts and color distortion in dark environments. The Retinex model, which decouples observed image space into different subspaces for image enhancement, has been extensively validated as effective. Inspired by this model, this paper proposes a low-light image enhancement method based on Retinex model decomposition, guided by deep neural networks.The proposed approach decomposes the image into the illumination map responsible for light adjustment and the reflectance map responsible for removing degradation. A light enhancement network is trained using image pairs captured with different exposures to achieve user-friendly adjustable light intensity enhancement. To alleviate the issue of color distortion, a reflectance restoration network incorporates illumination guidance information. Additionally, a diffusion model is employed as a noise detector to eliminate unnecessary noise and other distortions in the brightened low-light images by fitting the conditional distribution between different images. Experimental results demonstrate that the proposed method outperforms in terms of color preservation in low-light images with varying light intensities. It effectively removes noise while preserving image details.**

I. Introduction

Images captured in low-light environments often have visually displeasing effects for both humans and machines. Simply increasing the ISO of the capturing device or adding additional background lighting often introduces additional challenges. While higher ISO enhances the sensitivity of the image sensor, it also amplifies image noise. Background lighting can partially illuminate the environment, but point light sources can cause uneven lighting and introduce unexpected highlights. Moreover, the high cost of hardware development has made the development of a practical low-light image enhancer a hot research topic.

In accordance with the Retinex theory [1], the Single-scale Retinex (SSR) [2] technique utilizes a Gaussian blurred version of the input as the illumination map. By subtracting this illumination map from the input, the final result is obtained. To improve upon this approach, the Multi-scale Retinex (MSR)[3] extends SSR by combining the results of multiple Gaussian blur functions with different variances. Additionally, LIME [4] proposes a method to refine the initial illumination through the Max-RGB assumption and the structure preserving constraint. However, these methods primarily focus on enhancing the brightness of low-light images and often overlook hidden degradation such as noise and color distortion.

The aforementioned approaches are traditional algorithms for enhancing low-light images. However, in recent years, deep learning methods have dominated the field due to their strong generalization capabilities and high performance. For instance, MSR-Net[5] integrates the MSR mechanism into a neural network and utilizes BM3D[6] for denoising.Although there have been advancements in visual quality, the approach still inherits the limitations from traditional MSR methods. In an effort to overcome these limitations, [8] proposes the integration of a semantic segmentation technique with a Retinex-based model. The objective is to leverage semantic clues for improved illumination adjustment. However, it is important to note that these methods, while yielding satisfactory results, still struggle to effectively tackle issues related to noise and color distortion.The Progressive Retinex method [7] addresses light and noise issues by iteratively estimating illumination maps and noise levels. However, it does not effectively tackle color distortion. On the other hand, [9] decouples images into low-frequency and high-frequency layers to reduce noise and enhance details respectively. TBEFN [10] combines enhanced and denoised results from two branches. However, most of these methods fail to consider the relationship between illumination changes and degradation, leading to issues such as residual noise and over-smoothing. EnlightenGAN [11] leverages larger-scale unpaired training data using the GAN mechanism. While it alleviates the need for paired data, its focus is mainly on addressing lighting issues, leaving other defects insufficiently addressed.

To effectively enhance the brightness of low-light images while preserving color accuracy and minimizing noise, achieving a satisfactory visual experience, our contributions can be summarized as follows:

- Cleverly partitioning the image into different subspaces and applying corresponding operations to address noise and color distortion issues separately.
- Enabling interactive adjustment of the illumination intensity, allowing users to have control over the brightness enhancement according to their preferences.
- Taking into consideration the relationship between color distortion and illumination adjustment, we propose an illumination-guided color restoration network. This network performs well in restoring colors for images with varying levels of brightness.
- By incorporating diffusion models from the image gener-

II. Related Work

A. Adjust Reflection With Illumiation

Retinex theory decomposes an image I into its reflectance map R and illumination map L, represented in the subsequent formulation.

$$I = R \circ L \tag{1}$$

where $\circ$ designates the Hadamard product operator.Actually, the model may encounter challenges due to the limitations of the capturing sensor, leading to images suffering from complex degradation. As a result, according to [14] the expected rela-

tionship between the reflectance component and illumination is modeled as:

$$I = R \circ L + E = \tilde{R} \circ L = (R + \tilde{E}) \circ L \tag{2}$$

where E designates the pollution component, $\tilde{R}$ stands for the polluted reflectance, $\tilde{E}$ is defined as E/L with element-wise division. From this we can know that the degradation caused by R is related to changes in the illumination component.Moreover, when capturing images in low-light conditions, sensors (such as CCD or CMOS) exhibit sensitivity and non-linearity towards insufficient photons across different light spectrums. This sensitivity often leads to color distortion, even when proper measures have been taken to address illumination and noise issues. Consequently, to obtain high-quality results from degraded inputs, an effective algorithm must address the complex interplay of dim light, noise, and color distortion, which are closely intertwined.

B. Diffusion Model

Diffusion Models (DMs) [15] is a type of generative model proposed in 2020. Unlike other generative networks , the diffusion model applies noise progressively to the image during the forward diffusion process, gradually deteriorating the image into pure Gaussian noise. Then, during the reverse sampling process, it learns to reconstruct the real image from the Gaussian noise. This approach allows for connecting a complex data distribution with a simple and analyzable distribution using a Markov chain composed of a finite number of time steps.

To avoid the computationally expensive generative reverse process of DMs for sampling normally-exposed images, we focus on harnessing their capability to capture complex conditional data distributions. Specifically, [17] utilize DMs to capture the relationship between under-exposed and normally-exposed images. Previous research has demonstrated that DMs can also serve as backbone feature extractors, accurately predicting features based on noisy inputs[16].

III. Our Proposed Method

A. General Framework

As shown in Fig. 1,our network framework consists of three main components: the decomposition part, the adjustment part, and the fusion part. The decomposition part is accomplished by the Decom-Net, while the adjustment part includes the Lighten-Net for illumination adjustment, the Restoration-Net for color restoration, and the Denoise-Net for noise removal. Finally, the image fusion is performed using a simple fusion network. In the following sections, we will provide detailed descriptions of each network component.

B. Demon-Net

According to the Retinex theory, the reflectance of an image should remain constant under different lighting conditions. Therefore, in the decomposition network, we refer to [12] and utilize the linear combination of three different losses $\mathcal{L}^{Dn}$ to constrain the paired images during the decomposition process.

$$\mathcal{L}^{Dn} = \mathcal{L}_{re} + \beta_{ir}\mathcal{L}_{ir} + \beta_{is}\mathcal{L}_{is} \tag{3}$$

From (3), β_{ir} and β_{is} are constants. When the image pairs in the dataset are decomposed, the normal-exposed images I_{Normal} are split into $[L_{Normal}, R_{Normal}]$, while the low-light images I_{Low} are decomposed into $[L_{Low}, R_{Low}]$.The three losses correspond to the following (4), (5), (6).

$$\mathcal{L}_{re} = \sum_{i=Low,Normal} \sum_{j=Low,Normal} \lambda_{ij} \| R_i{}^{\circ} I_j - S_j \|_1 \tag{4}$$

$$\mathcal{L}_{is} = \sum_{i=Low,Normal} \| \nabla I_i{}^{\circ} \exp\left(-\beta_x \nabla R_i\right) \|_1 \tag{5}$$

$$\mathcal{L}_{ir} = \| R_{Low} - R_{Normal} \|_1 \tag{6}$$

where λ_{ij} and β_x are both constant coefficients. The symbol ∇ represents the gradient, which includes both the horizontal component and the vertical component.

The Decom-Net consists of five convolutional layers, with a ReLU activation applied between the first two convolutional layers. The remaining three convolutional layers do not have a ReLU activation function. The specific structure is shown in Fig. 1.

C. Restoration-Net

The reflectance maps extracted from low-light images, as depicted in Fig. 2. As the light becomes dimmer, the images are accompanied by increasingly severe color distortion. In order to find an appropriate restoration function, the objective can be simplified as follows[14]:

$$\begin{aligned} \mathcal{L}^{Rn} = & \left\| \widehat{R} - R_{Normal} \right\|_2^2 + \left\| \nabla \widehat{R} - \nabla R_{Normal} \right\|_2^2 \\ & - \mathrm{SSIM}\left(\widehat{R}, R_{_{Normal}} \right) \end{aligned} \tag{7}$$

where $SSIM(,)$ is the structural similarity measurement.The term $\widehat{R}$ refers to the restored reflectance map. In other words, it represents the estimate or reconstructed version of the reflectance map in the image. The loss focuses on capturing and preserving the texture details of the images during the restoration process. The specific configuration of the reflectance map restoration network can be found in Fig. 1, which provides a detailed breakdown of the network architecture, including the number of layers, types of layers. This information serves as a reference for understanding the internal structure and design choices of the network used for reflectance map restoration.

D. Lighten-Net

There is no standard for the intensity of light enhancement. To be able to adjust the intensity of light enhancement flexibly and meet different requirements, we will utilize existing pairs of$[L_{Normal}, L_{Low}]$ images. By calculating the intensity ratio between the two, we obtain the illumination adjustment

(a) Input (b) BIMEF [8] (c) EnlightGAN [9] (d) LIME [10] (e) RetinexNet [11] (f) Zero_DCE [1] (g) Ours (h) Ground Truth

Fig. 3. Visualized images of different low-light image enhancement algorithms on the LOL test dataset.

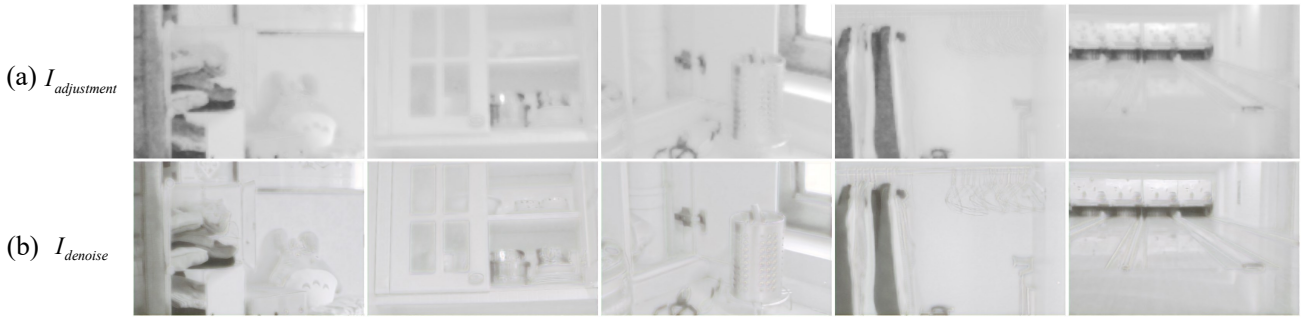

Fig. 4. Comparison images of the illumination component before and after denoising with the diffusion model.

coefficient. This coefficient is then expanded to a feature map and combined with the low-light illumination map as input for training and learning in the network. The following losses are used as constraints:

$$\mathcal{L}^{Ln} = \left\| \widehat{L} - L_t \right\|_2^2 + \left\| |\nabla \widehat{L}| - |\nabla L_t| \right\|_2^2 \tag{8}$$

The network architecture is designed to be lightweight, consisting of three convolutional layers. Specifically, it includes two convolutional layers followed by a ReLU activation function, and one additional convolutional layer. The output of the network is then passed through a Sigmoid activation function. This streamlined architecture aims to achieve computational efficiency while still delivering effective results.

E. Denoise-Net

Each network designed to address specific problems may introduce different forms of defects in its resulting outputs. Inspired by [17], we use the diffusion model as noise detector to alleviate this problem. We aim to capture the underlying data distribution between the under-exposed images b and the corresponding normally-exposed images I_0.

During the forward diffusion process, Gaussian noise is incrementally added to the data according to a predefined schedule of variances $\alpha_1, \ldots, \alpha_t$, Gaussian noise is defined as $z_1, z_2, z_3 \ldots \sim N(0, I)$. Mathematically, this can be represented as shown in (9).

$$I_t = \sqrt{\bar{\alpha}_t} I_0 + \sqrt{1 - \bar{\alpha}_t} z_t \tag{9}$$

TABLE I

RESULTS ON THE LOL TEST SET FOR DIFFERENT METHOD

Methods	SSIM	PSNR	MAE	LPIPS
LIME[4]	0.484	17.181	0.124	0.372
BIMEF[20]	0.595	13.875	0.206	0.326
RetinexNet[12]	0.425	16.774	**0.126**	0.474
EnlightenGAN[11]	0.652	17.483	0.135	0.322
ZeroDCE[21]	0.562	14.861	0.185	0.335
Ours	**0.761**	**17.656**	**0.126**	**0.233**

I_t represent the image after adding t steps of noise, $\bar{\alpha}_t{=}\alpha_t\alpha_{t-1}\alpha_{t-2}\cdots\alpha_1$ is a cumulative multiplication operation. The conditional diffusion model aims to maximize the likelihood of $p(\,I_0|\,b)$ The reverse diffusion process is characterized by parameterized Gaussian transitions[17]. It guides the diffusion model to predict the potential noise involved in the sampled I_t. Given I_t and the noise prediction from the diffusion model, we can compute an estimation of I_0:

$$I_0 \approx \widehat{I}_0 = \frac{1}{\sqrt{\bar{\alpha}_t}} I_t - \left(\sqrt{\frac{1}{\bar{\alpha}_t} - 1}\right) Z_\theta\left(I_t, t, b\right). \tag{10}$$

where Z_θ presents diffusion model. It utilizes an improved U-Net model for modeling, incorporating channel and time step embeddings through residual blocks. The structure of the residual block is illustrated in the bottom left corner of Fig. 1.

IV. Experimental Analysis

A. Implementation Details

To accommodate the diverse and sensor-specific forms of image degradation, we opted to train our model using a dataset called LOL. This dataset comprises 485 pairs of real-exposure images. The original images are in a portable network image format with a size of 400x600 pixels. For the Decom-Net, we set the batch size to 16 and the patch size to 48x48 pixels. For the Restoration-Net and Lighten-Net, the batch size is set to 4 and the patch size is set to 384x384 pixels. Regarding the diffusion model used for denoising, we fix the diffusion steps (T) to be 1000. We employ the AdamW [18] technique for optimization, with a learning rate of $1{\times}10^{-6}$.

B. Performance Evaluation

We visualize our algorithm and some state-of-the-art low-light image enhancement method on the LOL test set, as shown in Fig.4.Our method outperforms the competing method on the LOL test set. The results obtained by our method exhibit significantly better performance, with effectively reduced noise and fewer artifacts. In contrast, the outputs generated by the other competitors suffer from issues such as irregular illumination, residual noise, and texture/color distortions. Especially, comparing the images in the third and fourth rows, it is evident that our method successfully corrects the greenish hue, resulting in a more realistic tone in the enhanced images.

In this study, we utilize several full-reference metrics to evaluate the performance of the proposed method. These metrics include the structural similarity index measure (SSIM), peak signal-to-noise ratio (PSNR), mean absolute error (MAE), and learned perceptual image patch similarity (LPIPS) [19]. By employing these metrics, we can assess various aspects of image quality, such as structural similarity, noise levels, pixel-wise differences, and perceptual similarity.A higher value for PSNR and SSIM indicates superior image or video quality. On the other hand, for metrics like MAE and LPIPS , a lower value is desirable as it signifies better quality. As shown in Table 1, it is evident that our method consistently outperforms the other methods.

C. Ablation

To validate the effectiveness of different subnetworks, we selected images with varying lighting conditions from the LOL test dataset for testing. Firstly, we utilized the trained decomposition network to obtain the reflectance map and illumination map of the low-light images.By comparing the original reflectance map obtained from the decomposition with the reconstructed reflectance map obtained after passing through the Restoration-Net in Fig.2, we can clearly observe that the green noise artifacts have been effectively removed, resulting in an overall improvement in image quality. Additionally, considering the denoising operation applied to the reflectance map during the network refinement stage, we compared the popular BM3D algorithm with the diffusion-based denoising method used in this study. We found that while traditional denoising methods like BM3D offer some benefits for smoothing images, they are unable to handle large areas of colored noise effectively. This finding further validates the effectiveness of our proposed Restoration-Net in recovering the color information in the reflectance map.

In Fig. 4, we selected the illumination component maps adjusted by the Lighten-Net and applied a diffusion denoising model(Denoise-Net). By comparing the first and second rows of the image, we can observe that the diffusion model not only helps in noise removal but also effectively restores image details. The illumination component map, which contains more lighting details, enables the recovery of additional detailed features in the enhanced images.

V. Conclusion

This paper reveals the challenges of noise and color shift (green tint) in low-light image enhancement. To address these specific issues, the approach involves decomposing the image into different subspaces. The Restoration-Net is proposed to tackle color distortion in the reflectance map, while the Lighten-Net addresses the problem of illumination adjustment and enhancement. The Denoise-Net is employed to remove noise while preserving image details. These three networks work on individual image components and, in the end, the improved outcomes are created by merging the altered components. Experimental results demonstrate our method demonstrates superior performance by effectively suppressing noise, reducing artifacts, addressing illumination irregularities, and rectifying color distortions, ultimately producing visually

pleasing and realistic results on the low-light images of the LOL test set.

***Abstract*—Face anti-spoofing technique is a critical preset security measure for face recognition system. However, most existing detection techniques can only detect face spoofing and cannot provide fine-grained information on the type of spoofing attack. Additionally, DNN-based detection models lack the ability to extract diverse attack features distributed across different network depths and have a high number of parameters, making them challenging to train. To address these issues, we propose a face anti-spoofing method based on recursive self-attention and multi-scale fusion. Firstly, we introduce the design of recursive neural networks into self-attention mechanisms, combining multiple shared-weight self-attention blocks in a recursive form to extract features in the deep layer of the model while reducing the number of parameters. Furthermore, we combine atrous convolution with self-attention mechanisms, using atrous convolution with different atrous rates to provide multi-scale fusion capabilities for self-attention mechanisms. Extensive experiments on benchmark datasets demonstrate that our proposed method achieves superior performance while remarkably reducing the number of model parameters.**

I. Introduction

As facial recognition is increasingly used in various scenarios, malicious attackers are attempting to disrupt facial recognition systems by using techniques such as synthesizing realistic faces [1]–[4] or face spoofing [5]–[9]. According to research, there are currently five main types of face spoofing attacks, including print attacks [10], replay attacks [11], partial and full mask [12]–[16], and even make-up attacks [17]. We classify mainstream anti-spoofing systems into two categories: one based on external physical auxiliary equipment or user actions, such as using near-infrared cameras for auxiliary shooting judgment, or requiring user assistance for head shaking, mouth opening, and other actions. The other type is based on DNN (Deep Neural Networks) to develop automatic face anti-spoofing systems [18], such as [17], [19]–[26]. The former obviously increases the deployment cost of facial recognition systems and reduces their usability. As Fig. 1 shows, the latter is limited to binary classification, i.e., it can only detect whether a face is real or spoofed, and cannot distinguish specific types of facial spoofing attacks, which is disadvantageous for some demanding evidence collection scenarios.

Therefore, to provide stronger support for evidence collection work, [27] proposes a novel fine-grained classification detector that explores the potential of the Transformer structure

Fig. 1. The vanilla face anti-spoofing systems can only accomplish a binary classification task (left), while our proposed method can further distinguish among different types of spoofing attacks (right).

in face anti-spoofing forensics. They combine the task characteristics of face anti-spoofing forensics to introduce convolutional operations into self-attention mechanisms, achieving good results. Inspired by [27], we also consider that different types of facial spoofing attacks have different features, which are distributed in convolutional neural networks at different depths and are difficult to extract uniformly through a single CNN (Convolutional Neural Network) structure. Therefore, before making classification judgments, combining these features distributed at different convolutional depths plays a very important role in fine-grained classification. However, [27] fully explores the artifacts hidden in the shallow layers of DNNs in facial spoofing attacks, but there is still an issue with insufficient feature extraction in the abstract features of deeper networks. These abstract features play a crucial role in detecting more challenging attacks such as silicone masks. Therefore, different from [27], we attempt to deepen the network structure while maintaining the overall parameter reduction, thereby further improving the model's detection performance and training speed. Then the contributions of this paper are as follows:

- The design of RNN (Recurrent Neural Networks) is introduced into self-attention mechanisms, remarkably increasing the model's depth while maintaining a basic parameter number. This further enhances the model's ability to extract deep abstract features.
- An atrous self-attention mechanism with multi-scale feature fusion capability is achieved through the introduction of atrous convolution in the recurrent self-attention mechanism.
- Experimental results demonstrate that this method

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

achieves high accuracy and fine-grained classification ability on large-scale datasets.

II. Method

A. Preliminary

The detection model structure proposed in this paper is shown in the Fig. 2. The stride convolution self-attention module is derived from [27]. This module provides two advantages: Firstly, it reduces the overall computational cost as the feature map resolution decreases. Secondly, by varying the feature map resolution, it enables each stage of convolution to have a different receptive field, thereby improving the utilization of the convolutional spatial pyramid property and facilitating feature extraction at multiple levels. Then, new feature maps are obtained through stride self-convolution. To further explore the evidential clues, we use three recurrent self-attention modules with consistent structures to extract image features. Finally, we introduce a self-attention mechanism in the classifier and increase its depth.

B. Recursive Self-Attention

The depth of neural networks significantly affects the accuracy of model description, including Transformer-style models [28]. However, the self-attention mechanism requires an increase in weight matrices for each additional layer, resulting in a substantial increase in the overall number of model parameters. Therefore, most self-attention-based models use a limited number of layers. This issue also exists in the previous methods, where increasing model depth leads to a significant increase in parameters and computational power required for training. To address this, We propose to concatenate multiple self-attention modules with shared parameters into a whole recursive self-attention module.

In Fig. 2, we present a detailed construction of the first recursive self-attention module, each recursive self-attention module undergoes three rounds of multi-scale fusion self-attention processing, and the three multi-scale fusion self-attentions inside the module share the same parameters. The design of parameter sharing ensures that the total number of parameters in each recursive self-attention module is the same as that by using the multi-scale fusion self-attention mechanism only once, which controls the overall parameter amount while significantly improving the feature extraction ability of the model. Specifically, the output of each multi-scale fusion self-attention is processed by a layer of SiLU (Sigmoid Linear Unit) [29] activation function, which is shown below:

$$SiLU(x) = x \cdot Sigmoid(x), \tag{1}$$

where x represents the input feature map, and $Sigmoid(\cdot)$ represents the Sigmoid function, which is used to limit the feature values to the range [0, 1]. The reason for using this activation function is twofold: on the one hand, it plays a role similar to the gate controller in LSTM (Long Short-Term Memory) [30], filtering the data during the process of stacking residuals; on the other hand, it has been proven in the work of [29], that the self-calibration property of the SiLU activation function can help the model fit the data more accurately during the training phase. In addition, the recursive self-attention module uses residual operations similar to ResNet, which adds the input to the final output. This approach has the advantage of enhancing the flow of neural network gradients and mitigating the degradation of neural network gradients.

Furthermore, [31] shows that if a model is entirely composed of self-attention mechanisms, the model's weight matrix rank will quickly degrade to 1 due to the rapid convergence speed. Therefore, to mitigate the model's degradation, we add a MLP (Multilayer Perceptron) consisting of two linear mappings at the end of each recursive self-attention module. Finally, the output feature map y is normalized using LN (Layer Normalization) [32]:

$$y = \frac{x - \mathrm{E}[x]}{\sqrt{\mathrm{Var}[x] + \epsilon}} * \gamma + \beta \tag{2}$$

where x represents the input feature vector, $\mathrm{Var}[\cdot]$ represents the standard deviation, $\mathrm{E}[\cdot]$ represents the mean, ϵ is an infinitesimal quantity to solve the problem of division by zero, and γ and β are two trainable affine transformation parameters. Compared with the commonly used BN (Batch Normalization) [33] in computer vision, which normalizes across different channels of the feature map, LN normalizes each sample, [34] and [35] have conducted extensive comparisons and analyses of the two normalization methods. In short, LN can make the model converge more easily without introducing additional normalization, as there is no normalization operation in the feedforward network of the Transformer-style structure. Additionally, when the model settings cannot use a large batch size due to memory limitations, LN has better performance.

C. Multi-scale Fusion Optimization Based on Atrous Self-Attention

In order to further enrich the semantic features contained in the features, we introduce three atrous convolutions after linear mapping. As Fig. 3 illustrates, these three atrous convolutions share the same weights, with the only difference being their atrous rate. Since the convolutional stride in this part is 1, the resolution of the output feature map remains consistent with that of the input feature map. The final query value Q can be obtained by simply adding the outputs of the three atrous convolutions at corresponding positions. Additionally, since the three atrous convolutions share the same weights, they do not relevantly increase the number of model parameters. By using atrous convolutions with different atrous rate, our method achieves multi-scale feature fusion.

Our method combines features from multiple scales to reduce the risk of model misjudgment in face anti-spoofing. For instance, employing a single-scale feature extraction method with a small receptive field for extracting the specular reflection features of the pupil region exhibits certain similarities with the specular reflection features present in partial replay attacks and mask attacks. However, utilizing a multi-scale feature fusion approach, where the receptive field for feature

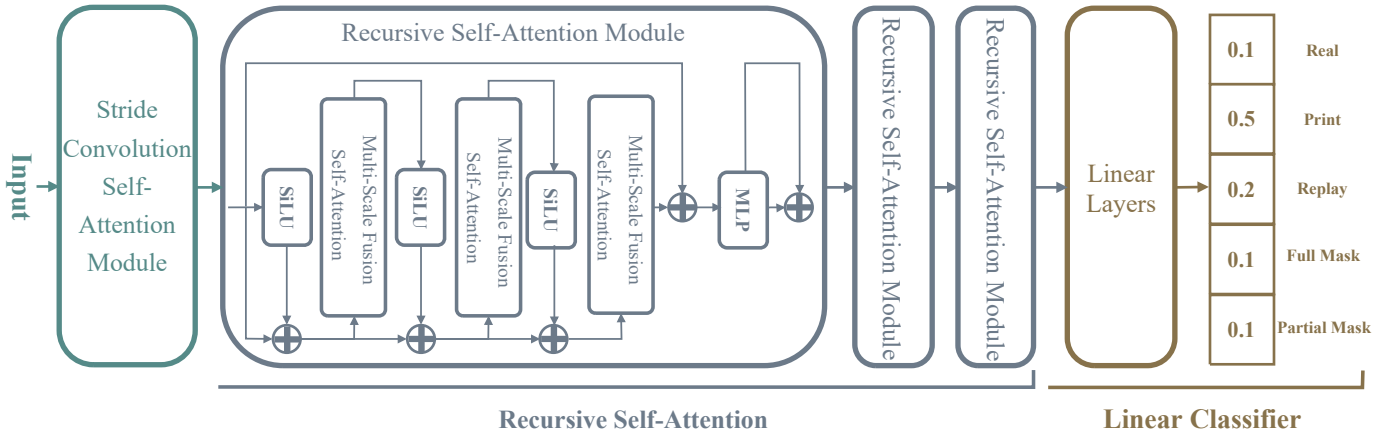

Fig. 2. Overview of our proposed fine-grained detection network.

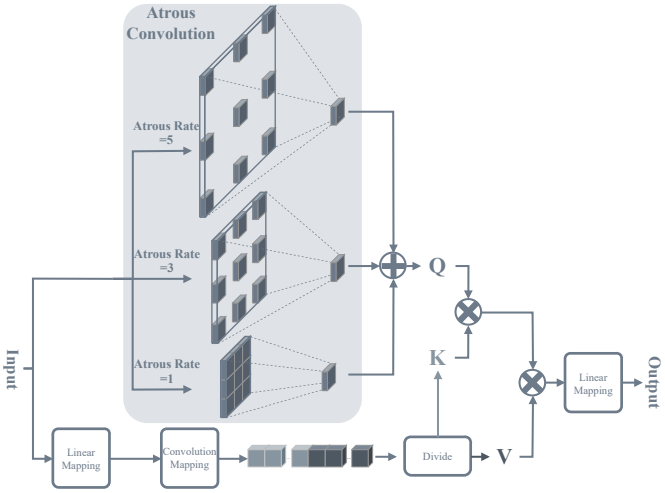

Fig. 3. Multi-scale self-attention structure.

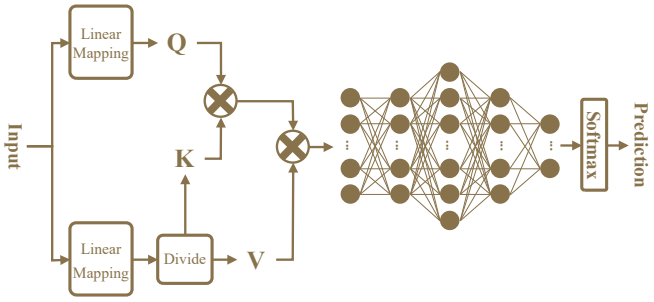

Fig. 4. Linear classifier structure.

extraction encompasses the entire eye reflection region, results in distinct differences between the extracted specular reflection features and the specular artifacts present in other types of attacks, thereby facilitating fine-grained classification. Therefore, we use multi-scale fusion to obtain Q, which reflects the correlation between feature points in the self-attention mechanism. This optimizes the weight matrix based on the judgment of the correlation weights between each feature point and other feature points at different scales.

In the process of computing K and V, since the key vector K and the value vector V respectively represent the key semantics of the feature point and the feature itself, they are semantically close in the self-attention mechanism. Therefore, the processing of K and V is combined here. First, a linear mapping layer is used to map the input feature matrix to another high-dimensional space by doubling the last dimension of the input matrix. Then, convolutional mapping is introduced to reduce the resolution of the output feature map. After rearranging the obtained feature map y_{output}, the front and back parts respectively represent K and V. The calculation method between Q, K, and V is as follows:

$$y_{output} = V \cdot (F_{dropout}(F_{softmax}(Q \cdot K))), \tag{3}$$

where $F_{softmax}(\cdot)$ represents the softmax operation, and $F_{dropout}(\cdot)$ represents the dropout operation.

D. Linear Classifier

As shown in Fig. 4, we add a self-attention module and slightly increas the number of linear layers in the classifier. The vanilla self-attention mechanism is directly used in the classifier. Since the linear classifier is at the final stage of the entire model, the resolution of the feature map at this point has become relatively low. That can effectively avoid the problem of parameter explosion when the input image is too large. At the same time, since it is located in the deep layer of the neural network, the deep model pays more attention to the abstract features in the feature map that are directly related to face anti-spoofing classification. Therefore, we directly use the linear mapping-based self-attention in the linear classifier. Additionally, since the self-attention mechanism itself is nonlinear, no additional activation function is added here. Subsequently, the features processed through the linear mapping-based self-attention are fed into the classification network, which consists of an input layer, three hidden layers composed of fully

connected layers, and an output layer with the same number of nodes as the fine-grained classification categories. Finally, we use cross-entropy with label smoothing as the loss function, and the overall loss function ℓ_{cls} is formulated as:

$$\ell_{cls}(x, y) = \sum_{i}^{n_{cls}} -y_i \times LogSoftmax(x_i), \tag{4}$$

$$LogSoftmax(x_i) = log\left(\frac{\exp(x_i)}{\sum_j \exp(x_j)}\right), \tag{5}$$

where x represents the predicted value, y represents the true sample label, and n_{cls} represents the number of categories in the fine-grained classification. Overall, this loss function is similar to the standard cross-entropy, but the difference is that when calculating the loss function, the cross-entropy with label smoothing first smooths the predicted value based on Eq. (5), thereby improving the model's generalization and accuracy.

III. Experiments

A. Datasets and Experiment Setup

In this section, we conduct extensive experiments to verify the effectiveness of our proposed model. We suggests classifying face spoofing attacks into four types, namely replay, print, partial mask, and full mask. To validate our approach, the model is tested on multiple datasets, including CeFA [36], WMCA [37], which encompass all attack modes, and HifiMask [38], which is currently the largest 3D mask attack dataset.

For all images in the dataset, facial detection is performed using 3DDFA-V2 [39], and the resulting facial images are cropped and resized to a uniform size of 128×128. Any image in the dataset that is not in the RGB format, such as near-infrared images, are discarded. The experimental results presented in this paper are obtained using only RGB images. The model is trained with the following parameters: an initial learning rate of 0.0002, a batch size of 64, a decay rate of 0.001, and optimization using the AdamW [40].

Experiments are primarily conducted using the standards specified in ISO/IEC 30107-3 [41]. Spoofing images are defined as positive samples, while genuine images are defined as negative samples. TP (True Positive) represents the number of spoofing attacks that are correctly identified, FP (False Positive) represents the number of spoofing attacks that are incorrectly identified as genuine faces, TN (True Negative) represents the number of genuine faces that are correctly identified, and FN (False Negative) represents the number of genuine faces that are incorrectly identified as spoofing attacks. The following sections will provide detailed explanations of these evaluation metric.

APCER (Attack Presentation Classification Error Rate) represents the probability of incorrectly identifying a spoofing attack as a genuine face. The calculation for APCER is as follows:

$$APCER = \frac{FP}{FP + TN}, \tag{6}$$

BPCER (Bona Fide Presentation Classification Error Rate) represents the probability of incorrectly identifying a genuine face as a spoofing attack. The calculation for BPCER is as follows:

$$BPCER = \frac{FN}{TP + FN}, \tag{7}$$

ACER (Average Classification Error Rate) represents the overall classification error probability. The calculation for ACER is as follows:

$$ACER = \frac{APCER + BPCER}{2}, \tag{8}$$

In addition, we use ACC (Accuracy) as an evaluation metric, measuring the ratio of correctly classified samples to the total number of samples across all categories.

B. Results on the Homogenous Datasets

The experiments in this section are conducted on CeFA [36], HifiMask [38] and WMCA [37] datasets, respectively. Specifically, CeFA provides four evaluation protocols, one of which is primarily used to measure the generalization ability of models in the face of multi-modal scenarios, while our method only focuses on RGB images as a single modality. Therefore, in the experiment, we use three of CeFA's evaluation protocols. Protocol 1 comprehensively evaluates the impact of different skin colors and races on face anti-spoofing model; Protocol 2 evaluates the model's generalization ability when facing unknown attack methods; Protocol 3 comprehensively considers the above two situations. HifiMask provides two evaluation protocols. Protocol 1 comprehensively evaluates the impact of different subjects on the model and is used to test the model's generalization ability when facing unknown faces. Protocol 2 evaluates the impact of different mask materials on the model, including transparent plastic, gypsum, and resin. As the WMCA dataset does not provide relevant protocol standards, we simply divide the training, validation, and testing sets in a 6:2:2 ratio.

Firstly, we conduct experiments on the benchmark dataset WMCA [37] to validate the performance of our proposed method against various types of face spoofing attacks. As shown in Table I, our proposed method outperforms the other methods on the WMCA [37] dataset. The multi-scale fusion feature extraction ability proposed in this paper enables effective detection of almost all attack types. However, full-face masks might be misjudged due to their similarity to real faces. Furthermore, due to the fact that the full-face masks attack does not compromise the digital integrity of the image but rather replaces the identity information at a physical level, it becomes challenging to learn the forgery characteristics of this type at the image level. As a result, the detection performance is degraded.

Next, we continue our experiments on the benchmark dataset CeFA [36]. As shown in Table II, the proposed method outperforms the baseline method remarkably in some scenarios of the CeFA [36] dataset. In Protocol 1 and Protocol 2, the performance of the proposed method is slightly lower than FGDNet, but the overall gap is not remarkable. This is because our proposed method incorporates certain design aspects from

TABLE I
PERFORMANCE COMPARISON ON THE WMCA DATASET.

Evaluation Metric(%)	Method	Partial Mask		Full Mask			Print	Replay	Avg.
		Glasses	Hard Mask	Fake Head	Silicone Mask	Paper Mask			
APCER	ResNet [42]	95.9	29.4	4.9	66.2	34.7	7.1	31.7	38.6
	MA-Net [43]	73.4	19.7	4.4	50.7	1.7	0.6	6.3	22.4
	FGDNet [27]	0	0	25.0	14.3	12.3	10.5	11.1	10.4

	Ours	0	0	4.5	3.1	2.6	1.1	1.3	1.8

FGDNet, specifically in terms of fine-grained feature learning, which enables the method to retain the ability to learn subtle discriminative features. In Protocol 3, which is the most challenging, due to the incorporation of the recursive self-attention mechanism, we are able to highly correlate the long distance within the hidden layers, thereby facilitating the exploration of finer discrimitative features, the proposed method outperforms [27] remarkably, demonstrating the robustness of the proposed method.

TABLE II
PERFORMANCE COMPARISON ON THE CEFA DATASET.

Protocol	Method	APCER(%)	BPCER(%)	ACER(%)
CeFA_Protocol 1	ResNet [42]	28.1	6.4	17.3
	PSMM-Net [36]	17.4	13.8	15.6
	MA-Net [43]	16.7	12.4	14.6
	FGDNet [27]	0.4	0.3	0.4
	Ours	2.4	0	1.2
CeFA_Protocol 2	ResNet [42]	40.7	0.6	20.7
	PSMM-Net [36]	25.3	2.2	13.8
	MA-Net [43]	20.9	1.2	11.1

	Ours	0.1	17.9	9.0
CeFA_Protocol 3	ResNet [42]	49.4	5.3	27.4
	PSMM-Net [36]	33.1	17.2	25.2
	MA-Net [43]	30.4	18.1	24.3
	FGDNet [27]	1.1	19.3	16.2
	Ours	1.4	1.2	1.3

To further verify the model's ability to detect 3D mask attacks with a richer datadset, we conduct experiments on the HifiMask [38] dataset. As shown in Table III, our proposed method exhibits strong performance in detecting 3D mask attacks. Compared to prior detection methods, our proposed method, during the training stage, mitigates the excessive reliance on the dataset and to some extent prevents model overfitting by introducing the operation of stride convolution mapping. Therefore, the proposed method remarkably outperforms the baseline methods on the more challenging Protocol II, demonstrating the generalization ability of our approach.

TABLE III
PERFORMANCE COMPARISON ON THE HIFIMASK DATASET.

Protocol	Method	APCER(%)	BPCER(%)	ACER(%)
HifiMask_Protocol 1	ResNet [42]	3.7	5.7	4.7
	Auxiliary [19]	4.9	1.8	3.4
	CDCN [44]	3.3	3.9	3.6
	Ours	4.1	2.4	3.2
HifiMask_Protocol 2	ResNet [42]	22.4	14.6	18.5
	Auxiliary [19]	12.1	11.2	11.4
	CDCN [44]	12.6	16.8	14.7
	Ours	8.4	4.0	6.2

Finally, to demonstrate the performance of our proposed method in fine-grained classification, we compare it with another method FGDNet [27] for fine-grained face anti-spoofing. This part of the experiment is conducted on three datasets, CeFA, WMCA, and HifiMask, as shown in Table IV. The detection performance of our proposed method is superior

to FGDNet. This attributes to our improvement in the self-attention module, which enables more efficient extraction of long-distance features. Meanwhile, due to preserving the local features of the image, we have deepened the structure of the feature extraction network, resulting in a more robust feature extraction performance.

TABLE IV
PERFORMANCE COMPARISON OF FINE-GRAINED FACE ANTI-SPOOFING METHODS.

Method	CeFA	WMCA	HifiMask
FGDNet [27]	91.2	89.6	90.1
Ours	94.3	96.1	92.7

C. Ablation Study

In this section, we conduct a set of ablation experiments on the HifiMask dataset to demonstrate the effectiveness of the components in our proposed model.

TABLE V
RESULTS OF ABLATION EXPERIMENTS ON MULTI-SCALE SELF-ATTENTION.

Method	APCER	BPCER	ACER	ACC
Without Multi-Scale Self-Attention	15.2	7.8	11.5	77.9
With Multi-Scale Self-Attention	11.5	3.0	7.2	90.2

Firstly, let us validate the importance of the multi-scale feature fusion improvement. In the ablation experiment, we compare the three dilated convolutions carrying different dilation rates (with multi-scale self-attention), with three dilated convolutions carrying the same dilation rate of 1 (without multi-scale self-attention). As shown in Table V, the experimental results show that multi-scale feature fusion remarkably improves the performance of the model.

TABLE VI
RESULTS OF ABLATION EXPERIMENTS ON THE SELECTION OF ACTIVATION FUNCTION.

Activation Function	APCER	BPCER	ACER	ACC
RELU	15.7	6.1	10.9	77.5
GELU	10.7	4.0	7.4	86.0
SiLU	11.5	3.0	7.2	90.2

Secondly, in order to illustrate the impact of different activation functions on the performance of the detection model, we conduct ablation experiments on the selection of activation function. We replace the SiLU function in the recursive self-attention module with the commonly used ReLU function in computer vision and the Gaussian Error Linear Units (GELU) function. Table VI results show that the SiLU function remarkably enhances the performance of the model.

TABLE VII
RESULTS OF ABLATION EXPERIMENTS ON THE RECURSIVE SELF-ATTENTION.

Method	OULU	SiW	WMCA	CeFA
Without Recursive Self-attention	13.5	9.5	11.5	80.2
With Recursive Self-attention	11.5	3.0	7.2	90.2

Thirdly, in order to demonstrate the significant role played by recursive self-attention in model, we conduct ablation experiments on the recursive self-attention module. As shown in Table VII, "Without Recursive Self-attention" refers to the self-attention mechanism with only one multi-scale feature fusion operation, while "With Recursive Self-attention" refers to a recursive structure formed by using three multi-scale feature fusion operations in the self-attention mechanism, which is the structure employed in our proposed method. By observation, it can be seen that the use of recursive self-attention mechanism effectively improving the model's detection performance. By employing a recursive operation combined with three-level feature fusion, the depth of the feature extraction network is increased, thereby enhancing the model's capability to extract abstract features at deeper levels. Consequently, this leads to an improvement in the model's detection performance.

D. Analysis of computational complexity

TABLE VIII
COMPARISON OF POWER CONSUMPTION.

Method	Parameter Volume ($\times 10^6$)	FLOPs ($\times 10^9$)
STDN [17]	1.3	79.8
ViT-FAS [45]	85.8	33.7
FGDNet [27]	20.1	6.8
Ours	10.1	6.2

Finally, we validate the computational parameter and power consumption of the proposed model through comparative experiments. As shown in Table VIII, it can be seen that compared to the STDN model based on GAN [46] network and the ViT model based on the original Transformer network, the proposed method has significant advantages in computational complexity. Moreover, due to the design of shared weights in the recursive self-attention with atrous convolution kernel, the parameter volume of our proposed method is significantly lower than that of FGDNet, and the power consumption is slightly lower than that of FGDNet.

IV. CONCLUSIONS

In this work, we propose a novel face anti-spoofing method that leverages recursive self-attention and multi-scale feature fusion. To increase model depth without significantly increasing parameter volume, we introduce RNN into the self-attention mechanism. To extract local features, we employ a

self-attention module based on stride convolution and a recursive self-attention module with three consecutive parameter-sharing mechanisms and residual connections. Additionally, we introduce multiple weight-sharing dilated convolutions to extract features at different scales and improve the loss and activation functions. Our proposed method basically better than the state-of-the-art performance on the benchmark CeFA, WMCA, and Hifimask datasets, and the ablation experiments demonstrate the importance of key components.

***Abstract* — In modern social networks, existing style transfer methods suffer from a serious content leakage issue, which hampers the ability to achieve serial and reversible stylization, thereby hindering the further propagation of stylized images in social networks. To address this problem, we propose a leak-free style transfer method based on feature steganography. Our method consists of two main components: a style transfer method that accomplishes artistic stylization on the original image and an image steganography method that embeds content feature secrets on the stylized image. The main contributions of our work are as follows: 1) We identify and explain the phenomenon of content leakage and its underlying causes, which arise from content inconsistencies between the original image and its subsequent stylized image. 2) We design a neural flow model for achieving loss-free and biased-free style transfer. 3) We introduce steganography to hide content feature information on the stylized image and control the subsequent usage rights. 4) We conduct comprehensive experimental validation using publicly available datasets MS-COCO and Wikiart. The results demonstrate that StyleStegan successfully mitigates the content leakage issue in serial and reversible style transfer tasks. The SSIM performance metrics for these tasks are 14.98% and 7.28% higher, respectively, compared to a suboptimal baseline model.**

I. INTRODUCTION

With the rapid development of Internet social networks and AI image generation technology, multimedia communication through the use of digital images has become a prevalent method for information exchange. Style transfer techniques [1] have gained significant popularity in image processing software, allowing users to transform ordinary digital images into captivating artistic styles. However, these existing style transfer methods inadvertently introduce modifications to the subtle textures and content information within the images. Consequently, when performing serial style transfers with a stylized image, severe corruption and artifacts occur within the content features, giving rise to the content leakage phenomenon [2], as illustrated in Figure 1.

The phenomenon of content leakage pertains to the profound transformation undergone by a stylized image, rendering it virtually indiscernible to the unaided human vision when refer to its original content, subsequent to a series of stylistic transmutations, whether proceeding sequentially or reversely. Furthermore, current de-styling methods face challenges in accurately extracting the original content information directly from the stylized image, often resulting in circular inconsistencies during the image reconstruction process [3].

The presence of content leakage hinders the achievement of high-quality serial style transfer and reverse style transfer, thereby impeding the widespread dissemination of stylized images on social networks. Furthermore, the increasing attention from social users to privacy security and copyright protection issues arising from the dissemination of stylized images in social networks highlights the need for an effective

Fig. 1 Content leakage phenomenon in style transfer.

solution to control subsequent stylized permissions. This study aims to address two key problems:

1) How to achieve leak-free style transfer in social networks?

2) How to control the subsequent usage of original content?

To address the first problem, we have designed a reversible neural flow network as a fundamental solution for achieving leak-free style transfer. This network eliminates content reconstruction loss during the encoding-decoding process and mitigates feature offset errors in the style transformation process. To tackle the second problem, we have introduced image steganography as a means to embed content features into stylized images. This approach enables precise control over subsequent stylized content usage rights. Only social users with specific extraction methods can extract the embedded content features, allowing them to perform high-quality stylization while preserving the original content. By integrating the aforementioned methods, we have successfully resolved the issues of content leakage and subsequent control of stylized images in existing social networks. This achievement not only allows for the more seamless and controlled dissemination of stylized images within social networks, ensuring the preservation of their artistic effects and maximizing their impact during dissemination, but also hold significant practical implications for the diverse transmission of world art.

II. Related Work

The successful application of deep learning in computer vision tasks has opened up new possibilities for image style transfer, as initially proposed by [4] using the concept of image iteration. This approach utilized pre-trained convolutional neural networks to extract content and style features and encode them into semantic representations. Building upon this foundation, [1] further advanced the previous method [4] by incorporating additional control over spatial location, color information, and cross-space scales, resulting in significant improvements in the quality of stylized images. However, it is important to note that image iterative methods suffer from slow stylization due to the iterative pixel-by-pixel optimization required for matching style features between the output and input images.

To accelerate the style transfer process, [5] introduced a feedforward model approach aimed at achieving real-time style transfer by training feedforward networks to approximate the iterative optimization process. However, this approach prioritized transfer speed at the expense of image quality degradation. In order to address the trade-off between transfer speed and image quality, [6] made significant improvements to the network proposed in [5] by replacing the batch normalization layer with an instance normalization layer. Additionally, [7] introduced conditional instance normalization to enable real-time style transfer across multiple styles learned during training. Despite these advancements, both image iteration-based and feedforward model-based style transfer methods faced a common challenge in practical applications: they were limited to specific styles and struggled to generalize to arbitrary stylizations. To overcome these limitations, the Adaptive Instance Normalization (AdaIN) method [8] was developed. [8] investigated the impact of statistical properties of stylized image features on the stylization process and proposed an affine transformation based on the mean and standard deviation of stylized images. AdaIN had a significant influence on subsequent research in style transfer, leading to the proposal of various style transfer methods [9-16]. As a result, style transfer entered the era of arbitrary style transfer.

In practical applications on social networks, stylized images have the potential to alter the original content information. This leads to a significant issue of content leakage when social users perform serial and reverse stylization on these stylized images. While [17] focused on de-styling, their work only addressed face de-styling. To tackle this problem, [18] introduced STNet, a steganographic network based on style transfer, which embeds secret information within the style features of the stylized image. Building upon this, [19] proposed PSTNet, which enhances embedding capacity and steganalysis resistance during the stylization process. Motivated by advancements in steganography, [20] attempted to embed content image features on stylized images, while [21] explored hiding content image features among layered stylized features. However, the content features still experience changes in texture details and spatial locations. Existing image steganography-based style transfer methods only address the loss of content from the stylized images generated after transfer, failing to provide a fundamental solution to the content leakage problem that occurs during the transfer process.

Fig. 2 Test results of iterative inference with the AdaIN

III. PRE-ANALYSIS

A. Reasons

To address the content leakage problem, we first investigate and summarize the causes, which can be categorized as follows:

1. Lossy image reconstruction

The model architecture commonly adopted by existing methods for style transfer consists of encoder-decoder pairs. This architecture is based on the intuitive explanation that the decoders of existing style transfer methods cannot achieve lossless image reconstruction of the input content images. To illustrate this point, three methods [22-24] use VGG19 as an encoder and train a decoder to invert the features of VGG19 into the image space. However, despite using image reconstruction loss or content loss functions to train the decoder, it was found in [23] that the feature inversion is imperfect due to the loss of spatial information during the pooling operation in the encoder. Consequently, the accumulated errors in image reconstruction can gradually interfere with the content details and result in content leakage.

2. Biased decoding training

In addition to the image reconstruction loss, which can explain part of the content leakage phenomenon, the biased decoder training scheme is another major contributing factor. In this case, we will use the training scheme of AdaIN as an example to explain how its loss function is configured in a way that leads to content leakage. Specifically, AdaIN trains the decoder using a weighted combination of content loss and style loss, where

$$L_{content} = \left\| E(D(t)) - t \right\|_2 \tag{1}$$

$$L_{style} = \sum_{i=1}^{L} \left\| \mu(\varphi_i(D(t))) - \mu(\varphi_i(s)) \right\|_2 + \sum_{i=1}^{L} \left\| \sigma(\varphi_i(D(t))) - \sigma(\varphi_i(s)) \right\|_2 \tag{2}$$

In Eqs. (1) and (2), t denotes the output of AdaIN, E, D represent the encoder and decoder respectively, φ_i denotes the layer used to compute the style loss in VGG19, μ, σ represents the mean and standard deviation of the feature map.

Figure 2 illustrates the process of style transfer using the AdaIN self-encoder. Without any style image for transfer guidance, a content image is given as input. Each round involves using the output of the previous round's decoder as the input for the next round's encoder. As the number of inference rounds increases, the generated results start exhibiting strange artistic patterns. This phenomenon suggests that during training, AdaIN's encoder is biased towards style rendering.

3. Biased transfer module

In addition to the image reconstruction loss and decoding training bias, the transfer principle of some style transfer modules itself introduces a bias for the content features. Let's take the style decorator module in Avatar-Net as an example. The style decorator, inspired by deep image analogy [25], consists of two main steps. In the first step, the algorithm identifies a corresponding feature block in based on the content similarity between two feature blocks from . Then, in the second step, it finds a corresponding feature block in by replacing the corresponding feature block in . This replacement operation creates a feature block that cannot be recovered from , resulting in a bias towards stylistic features and content leakage.

B. Remedies

Based on the above analysis, realizing loss-free and bias-free style transfer is a necessary prerequisite to solve the content leakage problem. To achieve loss-free feature extraction, we propose a feature extraction network based on the neural flow model. This network maps the content features and style features of an image into the latent space in a loss-free manner, which is then inputted to the style transfer module. The specific details of the network will be introduced in Section IV. In addition, to achieve bias-free style transfer, we introduce the AdaIN-based style transfer module. This module ensures separable and bias-free image content and style features. The reasons for introducing this module will be described below.

The mechanism of the popular generic style transfer methods at this stage can be seen as a natural evolution of the bilinear model [26]. The model separates image features into content factors and style factors, and then performs style transfer by replacing the style factors in the content image with the style factors in the target image.

Definition 1 *Suppose there is a bilinear style transfer module* $f_{cs} = C(f_c)S(f_s)$*, where* C, S *denotes the content factor and style factor in the bilinear model, respectively. If* $C(f_{cs}) = C(f_c)$ *and* $S(f_{cs}) = S(f_s)$*, then* f_{cs} *is an unbiased style transfer module.*

Theorem 1 *The adaptive instance normalization in AdaIN is an unbiased style transfer module.*

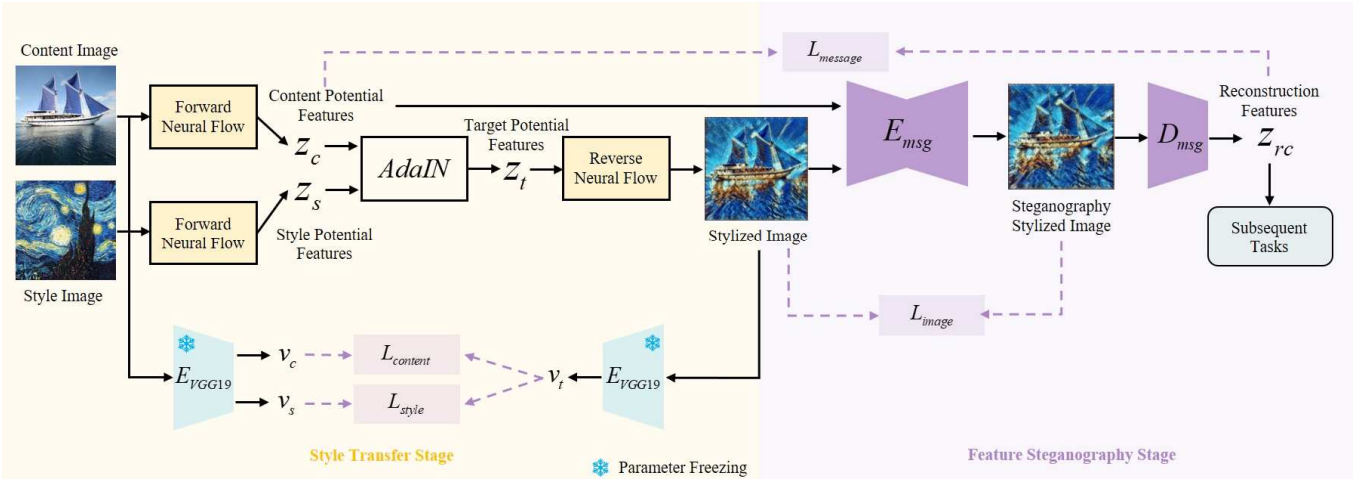

Fig. 3 The overview of proposed StyleStegan

Proof 1 *Assuming that both* f_c *and* f_s *satisfy the generality of the data distribution, it follows that:*

$$f_{cs} = C(f_c)S(f_s) = \frac{f_c}{\sigma(f_c)}\sigma(f_s) \tag{3}$$

where,

$$C(f) = \frac{f}{\sigma(f)}, \quad S(f) = \sigma(f) \tag{4}$$

since,

$$\sigma(f_{cs}) = \sigma\left(\frac{f_c}{\sigma(f_c)}\right)\sigma(f_s) = 1 \times \sigma(f_s) = \sigma(f_s) \tag{5}$$

we have,

$$C(f_{cs}) = \frac{f_{cs}}{\sigma(f_{cs})} = \frac{f_c}{\sigma(f_c)} = C(f_c) \tag{6}$$

$$S(f_{cs}) = \sigma(f_{cs}) = \sigma(f_s) = S(f_s) \tag{7}$$

Therefore, the adaptive instance normalization in AdaIN is an unbiased style transfer module.

IV. Proposed Method

A. Overview of StyleStegan

To address the two issues mentioned, namely achieving leak-free style transfer in social networks and controlling the subsequent usage of stylized original content, we propose a feature steganography-based approach. Our method involves a two-stage model that combines style transfer and feature steganography, as depicted in Fig. 3.

During the style transfer phase, we employ a reversible neural stream-based feature network to map the features of the style image I_s and the content image I_c to the latent space without loss, resulting in z_s and z_c. We then utilize the AdaIN-based unbiased style transfer module to perform stylization on the latent features. Finally, we project the target latent features back into the image using the reversible neural stream, yielding the stylized image I_t.

In the feature steganography phase, the steganographic network is trained to learn a feature steganography encoder. This encoder hides the content features in the latent space into the stylized image completed in the previous phase, resulting in a steganographic stylized image. Additionally, a feature extraction decoder is learned in conjunction with the feature steganography encoder. The purpose of this decoder is to extract content feature information from the steganography stylized image. The steganography stylized image is pre-embedded by the social user who owns the content copyright. Within this stage, the method offers flexibility in parameter *–stage* settings. It can be configured as a two-stage end-to-end model to complete the subsequent stylization of the social user's original content usage rights. The choice depends on the social user's preferences.

B. Style Transfer Stage

In the style transfer stage, we borrowed the idea of the Glow model [27] to construct a reversible neural flow-based feature network. This network serves as both a deep feature extractor and an image synthesizer within the overall framework. Figure

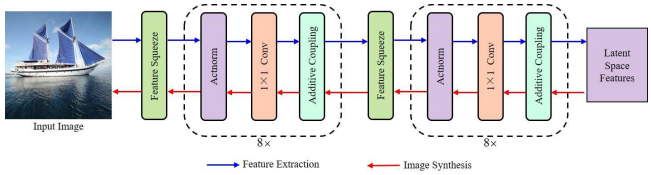

Fig. 4 Reversible neural flow based feature network

4 illustrates the network, which comprises three reversible transformations with learning parameters: additive coupling, reversible 1 × 1 convolution, and activation normalization. It is worth noting that all components of this network are reversible, ensuring loss-free information propagation during both forward and backward propagation. The specific description of the network is provided in the following section.

1. Additive coupling layer

[28,29] proposed an expressive and reversible layer called affine coupling. This network, however, utilizes a specific variant of affine coupling known as additive coupling. In the additive coupling layer, the parameters undergo positive calculations, as demonstrated in Equations (8) to (10):

$$x_a,\ x_b = split(x) \tag{8}$$

$$y_b = NN(x_a) + x_b \tag{9}$$

$$y = concat(x_a,\ y_b) \tag{10}$$

where function $split()$ divides a tensor x precisely along the channel dimension, while $NN()$ being an inherently symmetrical neural network boasting inputs and outputs of identical dimensions. Function $concat()$ adeptly interlaces two tensors along the channel dimension.

2. Reversible 1×1 convolutional layer

To ensure that all dimensions of the feature maps are equally affected, the channel dimensions of the feature maps in additive coupling processes should be swapped. For this purpose, a learnable reversible 1 × 1 convolutional layer is employed in the second transformation of this network, allowing for flexible channel permutation. The forward calculation of this layer is shown in Equation (11):

$$y_{i,j} = \mathrm{M}x_{i,j} \tag{11}$$

where M represents a weight matrix of dimensions $c \times c$, wherein c denotes the channel dimension of tensors x and y. The function responsible for the inverse computation of this weight matrix is denoted as $x_{i,j} = \mathrm{M}^{-1} y_{i,j}$.

3. Activating Normalization layer

The final transformation in this network replaces the conventional batch normalization method with activation normalization. Activation normalization involves applying an affine transformation to each channel of the tensor, as shown in Equation (12):

$$y_{i,j} = w \square\ x_{i,j} + b \tag{12}$$

where i, j symbolize the spatial coordinates within the tensor, w, b represent the erudite weights and bias parameters governing affine transformation. The inverse computational function is elegantly denoted as $x_{i,j} = (y_{i,j} - b) / w$

In this stage, the above three layers of reversible transforms combine to form a stream, and every eight streams create a block. Alongside the three transformations mentioned earlier, the compression operation divides the features into smaller feature blocks based on the spatial dimension, and then merges these blocks along the channel dimension. This compression operation is inserted between the input and block-to-block of the network, aiming to decrease the spatial size of the two-dimensional feature map. The loss function in this stage is determined by weighting the content loss and style features, which are calculated using the same equations as Equation (1) and (2), and will not be elaborated here.

C. Feature Steganography Stage

In the feature steganography stage, the network contains a steganography encoder and a corresponding steganographic decoder. The steganography encoder hides the content features z_c into the stylized image I_t and produces the encoded image I_e, which is the output of the two-stage model. And the steganography decoder tries to decode z_c from I_e.

As a steganographic scheme, the encoded image I_e and the stylized image I_t should exhibit a visually imperceptible difference. To achieve this, the steganography encoder is trained to minimize the disparity between the two images. This optimization is carried out using a loss function defined as:

$$L_{image} = \left\| I_e - I_t \right\|_2 \tag{13}$$

The Steganography encoder consists of 1 input layer, 3 convolutional layers, and 1 output layer. It takes the stylized image as input and performs splicing embedding of steganographic features in the channel dimension. The encoder continuously optimizes the embedding of secret information and image visual quality throughout the remaining convolutional layers. Finally, it produces the steganographic stylized image as output.

The steganographic decoder is trained to optimize the extraction of content features from the steganographic stylized image. This is achieved by minimizing the loss function, as defined in Equation (14):

$$L_{message} = \left\| D_{msg}(I_e) - z_c \right\|_2 \tag{14}$$

The steganography decoder is composed of 1 input layer, 6 convolutional layers, and 1 output layer. It takes the steganographic stylized image as input and continuously optimizes the extraction accuracy of steganographic features in the 6 convolutional layers.

Finally, it outputs the extracted steganographic features. The objectives of the feature steganography phase can be summarized as Equation (15):

$$L_{steganography} = \lambda_{img} L_{image} + \lambda_{msg} L_{message} \tag{15}$$

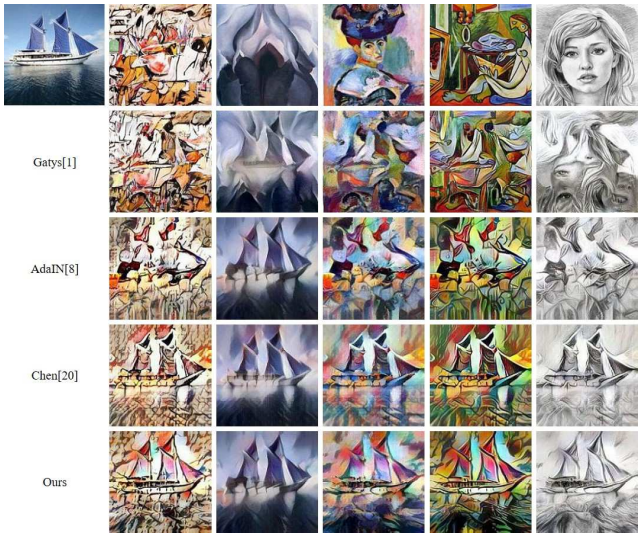

Fig. 5 Comparison of the effectiveness in serial style transfer tasks

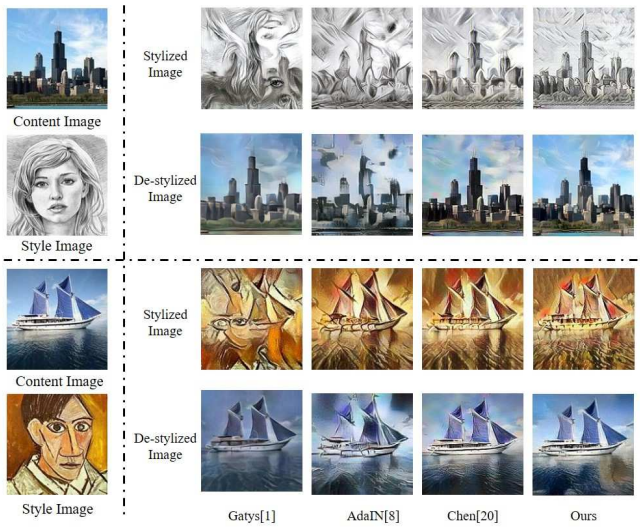

Fig. 6 Comparison of the effectiveness in reverse style transfer tasks

V. EXPERIMENTS

A. Dataset and Environment

This paper follows a similar dataset setup as described in [8] to build the training set for the model. The training dataset is constructed by randomly selecting 20,000 content images from the training set of MS-COCO [30] and 20,000 style images from the training set of WikiArt [31]. To ensure consistency, the selected images were first resized to a minimum size of 512 while maintaining the aspect ratio. Subsequently, random cropping was applied to obtain images of size 256 × 256. For the test dataset, 1000 content images and 1000 style images were randomly chosen from the test sets of MS-COCO and WikiArt respectively, without any crossover with the training dataset. During stylization, each content image was paired with one of the 10 randomly selected style images from the test set. Importantly, the test images used for experimentation were never included in the training process to prevent bias during learning and inference.

For the experimental environment setup, the Google online computing platform Colaboratory was used for training and inference with a Tesla T4 GPU with a video memory size of 15 GB, a system RAM size of 16 GB, a disk memory size of 128 GB, a CUDA version number of 12.0, a Python version number of 3.8, and the deep learning framework used was Pytorch, whose version is 2.0.0+cu118.

B. Visual Comparison

In the experimental design, we compare the proposed model in this paper with the baseline model of [1], the adaptive instance normalized baseline model of [8], and the end-to-end model of [30]. These comparisons are made to validate the qualitative results through serial and reverse style transfer tasks.

1. Serial style transfer

Serial style transfer aims to apply a new style to a stylized image while minimizing the impact of previous stylizations. The desired outcome of serial style transfer is to achieve an artistic rendering effect similar to directly and separately stylizing the original content with the new style. In the experiments conducted for this task, we compare the results of our method with existing methods, as depicted in Figure 7.

The obtained results demonstrate that our method effectively reduces the corruption of content features caused by intermediate style transfers. This is achieved by selectively and discreetly embedding content features into each stylized image, catering to the specific requirements of users for subsequent style transfers. By doing so, the original content features can be extracted and utilized in each style transfer operation.

2. Reverse style transfer

The goal of reverse style transfer is to de-stylize a stylized image while preserving its original content as much as possible. Ideally, the outcome of reverse style transfer should closely resemble the input content image. However, the baseline model of Gatys et al [1] and AdaIN [8] do not provide a direct approach for reverse style transfer using the original content image as the reference for the target style and applying the stylization to the given stylized image. This method requires access to the original content image. In contrast, the model developed by Chen et al [20] and the present method can extract the hidden features necessary for de-styling using only the given stylized image. To evaluate the effectiveness of the

Tab. 1 Quantitative experimental Results of serial and reverse style transfer

		Gatys[1]	AdaIN[8]	Chen[20]	Ours
Serial	L2↓	7.5239	0.0213	0.0148	**0.0104**
	SSIM↑	0.0473	0.5471	0.7143	**0.8213**
	LPIPS↓	0.4316	0.4614	0.2437	**0.1483**
Reverse	L2↓	4.4331	0.0368	**0.0187**	0.0193
	SSIM↑	0.2041	0.3826	0.4796	**0.5145**
	LPIPS↓	0.3694	0.4628	**0.3323**	0.3802

present method in reverse style transfer, it is compared with existing methods, and the experimental results are presented in Figure 6. The results demonstrate that the proposed method achieves better content image reconstruction in the reverse style transfer task.

C. Quantitative Comparison

Quantitative experiments entail the application of different models for conducting serial style transfer and reverse style transfer tasks. These models generate output images, which are subsequently compared to their respective desired images. The aim of this comparison is to assess the performance of the models in both serial style transfer and reverse style transfer. The findings from these quantitative experiments are presented in Table 1.

VI. CONCLUSIONS

We address the issue of content leakage that commonly arises in serial and reverse style transfer and propose a corresponding solution. Our experimental results demonstrate the superiority of our method in both serial and reverse style transfer tasks. Specifically, our method achieves a 14.98% and 7.28% higher SSIM compared to the suboptimal performing baseline model for the two tasks, respectively. The specific contributions of our work are as follows:

1. We analyze the phenomenon of content leakage in typical style transfer methods and identify image reconstruction loss, decoding training bias, and transfer module bias as potential causes.

2. To ensure content integrity and style consistency in stylized images, we design loss-free and bias-free reversible neural flow networks. These networks eliminate content reconstruction loss during encoding and decoding, as well as feature bias error during style transfer.

3. We develop a model for content feature steganography and extraction, which allows the embedding of content features into stylized images. This enables subsequent high-quality stylization while ensuring that only authorized users with specific extraction methods can retrieve the original content, providing control over the stylized images.

4. We conduct experimental validation on the MSCOCO and Wikiart public datasets to showcase the visual effectiveness and outstanding performance of our method in generating stylized images. Our results provide solid evidence for the effectiveness of our approach in addressing the content leakage problem in serial and reverse style transfer tasks.

***Abstract*—The topic of robust watermarking has long been a subject of interest in the field of information hiding, and in these days, the robustness against cross-media attacks, such as screen-capture and printer-capture attacks, have become an increasingly pressing concern. Previous work in the field, such as StegaStamp, one of the most popular open-source screen-shoot resilient watermark scheme, has achieved promising results in terms of decoding accuracy. However, the visual quality of some watermarked images by this scheme is still not inadequate for practical purposes. In this paper, we propose an optimization that could significantly enhances the visual quality of watermarked images. We use a graph-based method to build graph from image blocks, compute a loss designed with inspiration from GLR, and add it to the existing loss function of the neural network during training. As demonstrated by the experiment results, we have achieved substantial improvements in the quality of watermarked images, in both visual quality and metrics, while still maintaining strong robustness and decoding capability.**

I. Introduction

In the era of big data, there is an increased demand from individuals and organizations for the privacy, security, and authenticity of their information. Watermarking technology has emerged as an important solution to meet these needs. By embedding a unique identifier within sensitive documents or images, the authenticity of these files can be confirmed. Additionally, it can be used to trace the source of sensitive information leaks in the confidential departments of companies. To ensure that the watermark remains intact and recognizable during multiple transmissions, the robustness of the watermark is a crucial factor to consider.

Previous studies on robust image watermarking[1], [2] have focused on resisting attacks on the digital channel, such as noise, rotation, and JPEG compression, among others. These types of attacks are common in digital transmissions. However, with the proliferation of multimedia devices such as projectors, cameras, printers, and scanners, the way information is transmitted has changed dramatically. Smartphone performance enhancements allow eavesdroppers to more stealthily capture high-fidelity and less traceable documents, which has resulted in substantial business losses. Therefore, cross-media distortions must also be taken into account in the robustness of the watermark. For instance, in tracking the origin of sensitive information leaks from a screen-captured image by a mobile phone, or verifying the authenticity of a photo on the passport, new attacks such as Moiré patterns and perspective warps (as shown in Figure 1) can significantly affect the accuracy of watermark recognition. Compared to distortions on the digital channel, which has been studied for a long time and can be accurately simulated, the cross-media distortion is more complex and random in nature, making quantitative analysis challenging. This type of attack imposes higher demands on the robustness of watermarks.

Fig. 1. The serious distortion imported by screen-capture

Several methods have been proposed to address these challenges, such as the intensity-based SIFT algorithm and DCT-based method proposed by Han et al.[3]. While this work provides important new insights, its accuracy in terms of keypoint location and message decoding is not adequate. Another method, StegaStamp[4], which has almost became the most popular open source robust watermark scheme since its publication, uses a learned steganographic algorithm to achieve high bit accuracy in a variety of scenarios and seems to perform well in terms of watermarked image quality, also referred to as perceptual invisibility of watermark. However, the paper only shows the performance of watermarking on images with complex textures. Through our attempts, we found that it performs poorly on images with relatively simple textures. Let's take the most famous Lenna image as an example(shown in Figure 2). After applying StegaStamp watermarking, many areas in the face and shoulders of the image appear to be blurry or *dirty*.

To improve the perceptual invisibility of robust watermark, we consider graph-based methods, which have been successfully used in fields such as image denoising, image deblurring, and 3D point cloud denoising[5]–[7]. All of these tasks seem to be related to our task of reducing *dirty* watermarks from images. Among these methods, we found that GLR (Graph Laplacian Regularizer) is often used to establish similarity

Fig. 2. Result of original StegaStamp and our optimized version.

relationships among image pixels and enhance the model's understanding of the spatial structure of the image. This improves the performance of image processing tasks, and gives us a new insight to improve the quality of watermarked images. In this paper, inspired by the GLR, we present an optimization for improving the image quality of deep learning-based watermarking schemes. Our algorithm builds graph from the images and add a new loss function in the training process to reduce the *dirty* appearance of *flat* areas in watermarked images. The algorithm maintains high decoding accuracy against many real-world attacks in the experiment, while significantly improving the perceptual invisibility of watermark. To sum up, the contributions of this paper can be listed as follows:

- We present a novel optimization graph-based method to improve the visual quality of robust watermarked images.
- To demonstrate the effectiveness of our approach, we deployed this optimization on one of the previously most popular robust watermarking schemes, StegaStamp, and showed how our method can make watermarked images more practical and usable in the real world.
- A comprehensive set of experiments were conducted to show the performance of our optimization. In the experimental results, we demonstrated a visible improvement both in visual quality that can be perceived by the human eyes, and in metrics including PSNR and SSIM, and equivalent decoding accuracy compared to the original method under various real-world attacks. Our optimization enables the new scheme to produce better image quality even when embedding a message of three times the length.

II. Related Work

In this section, we overview previous works on robust watermark and graph-based digital image processing.

A. Robust Watermark

The field of robust watermarking has been the subject of extensive research, with many mature methods developed over time. Most of these methods embed watermarks in transformed domains, such as the DFT (Discrete Fourier Transform) or DWT (Discrete Wavelet Transform), to avoid spatial feature degradation that can occur as a result of image processing attacks like noise and compression. For instance, Lagzian et al. [2] presented a robust watermarking scheme that combined DWT and SVD, which demonstrated improved performance against common attacks compared to previous methods. Khedr [1] also proposed a robust watermarking scheme for multiple images that utilized both DWT and DCT for embedding.

However, the emergence of new real-world cross-media attacks has prompted researchers to develop new robust watermarking schemes. Han Fang et al. [3] presented a screen-shooting resilient watermarking scheme that aimed to address distortion in the screen-shooting process. The method used an intensity-based SIFT (scale-invariant feature transform) algorithm for keypoint detection, and proposed an embedding algorithm based on modification of DCT coefficients. However, after some production, we found that locating keypoints accurately in real-world complex environments was still challenging. Additionally, the method was prone to incorrect keypoint detection in simple images and also resulted in noticeable texturing in the plain areas of images, affecting image quality.

In addition to traditional methods, deep learning and neural network algorithms have also been applied in the field of robust watermarking. JiRen[8] proposed the first end-to-end method of watermark with neural network. Kangli [9] proposed a GAN-based robust watermarking scheme, where the generator and decoder played against a discriminator in an encoder-decoder setup. Huynh-The [10] presented a scheme using a convolutional encoder-decoder neural network that was resistant to multiple attacks.

For screen-shoot resilient watermarking using deep learning, the key issue to consider is how to address the non-differentiablility of the cross-media distortion. LFM[11] try to solve this problem by training an additional CDTF(camera display transfer function) function seperately to model the display-camera process, with a dataset of screen-captured images. This function is located between the embed layers and the recover layers, and is trained before the whole end-to-end system. Although it performs not bad, collecting such a dataset is very time-consuming and labor-intensive.

Not long after that, StegaStamp[4] is proposed and outperformed LFM significantly. It choose to use a UNet-based encoder-decoder network to embed the watermark. The key novelty of the strong robustness of this work is that, it analyze and model the distortion process manually, and apply a set of differentiable image perturbations to simulate the screen-camera distortion. This work performs well in terms of bit accuracy and was highly resistant to screen-camera and print-camera attacks compared to LFM. However, when used to embed watermarks in relatively simple images, the watermarked images often appeared *dirty*, particularly in important areas such as human faces and plain areas such as backgrounds. This significant drawback limits its application in critical use cases where images are not always as complex as those presented in the paper.

B. Graph-based Image Processing

Graph-based methods[12] have been widely employed in the domain of image processing for various tasks such as denoising, deblurring, and super-resolution. Normally, GSP(Graph

Signal Processing) is applied in data that can be represented by graph structure naturally, like social network, to deal with relationship among nodes in the network. Although image are typically represented in 2D form, the desire of representing the relationships between pixels in an image has led us also to apply graph signal processing here. The fundamental idea behind these methods is to represent pixels in an image as nodes in a graph and model their relationships as edges with assigned weights. In this way, notions like transform and smoothness can also be derived.

In [13], Pang et al. utilized graph Laplacian regularization for the purpose of image denoising, formulating the problem as an optimization problem. They derive the optimal edge weights for local graph-based filtering using gradient estimates, and analyze the effect of the gradient estimates both theoratically and experimentally. Bai et al. [6] also proposed a graph-based approach for blind image deblurring. They first proved that there is a skeleton image can be used to estimate the blur kernel, converting the blind blurring into non-blind blurring; and then they design a RGTV(reweighted graph total variation) prior for this problem. However, since the original RGTV is an non-convex non-differentiable optimization problem, they leverage the new graph spectral interpretation for RGTV and design a new algorithm that solves for the blur kernel. These studies demonstrate the effectiveness of graph-based methods in preserving the structure and visual content of images.

III. Methodology

In this section, we first review some basic concepts of graph and graph signal processing, and then propose our optimization loss.

A. Preliminary

Graph is a common data structure used to represent relationship among entities. An undirected edge-weighted graph can be represented by $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$ where $\mathcal{V}$ denotes the node set and $\mathcal{E}$ denote the edge set.

To deal with information on the graph, we need to introduce graph signal processing. Graph signal denotes a function $f : \mathcal{V} \Rightarrow R^n$, which means some n-dimentional signal on each node. A key component in graph signal processing is the graph Laplacian matrix L, which represents the relationships between nodes in the graph and encodes prior knowledge about the graph structure. The graph Laplacian matrix is defined as:

$$\mathbf{L} = \mathbf{D} - \mathbf{A} \tag{1}$$

where $\mathbf{D}$ is the degree matrix and $\mathbf{A}$ is the adjacant matrix of the graph. This matrix works as the operator to compute divergence of the gradient at each node.

B. Loss Design

To first build graph from images, we split a image into 16*16 blocks with step length 8. Each node in the graph denotes a pixel in the block, and the edge weight is defined as

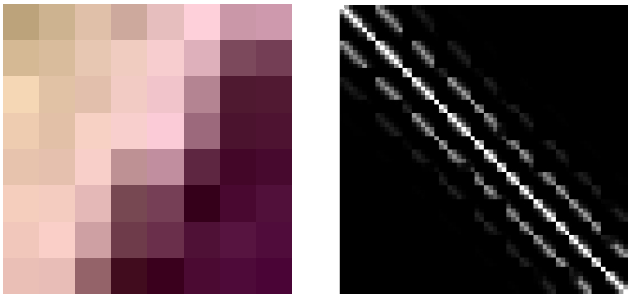

Fig. 3. The image block(left) and the graph built from it(shown in adjacant matrix, black means high edge weight).

$$w_{i,j} = exp(-\delta_{i,j}) \tag{2}$$

where

$$\delta_{i,j} = \frac{(x_i - x_j)^2}{\sigma_x^2} + \frac{(l_i - l_j)^2}{\sigma_y^2} \tag{3}$$

denotes the estimated feature distance between pixel i and j[14], which follows the design of bilateral filtering, taking into account both the pixel intensity and the location. In the equation above, x_i represents the pixel value, l_i represents the location of node i, and σ_x, σ_y denote the corresponding coefficient of these two factors respectively.

The graph constructed from a image using above formula has the property that, edges between close pixels with similar values have large weights, while edges between pixels with large distance or dissimilar values have small weights. In this way, the *flat* area of the image has large edge weights in the graph. A visualization of this graph construction process is shown in Figure 3. For a 8*8 block example shown in the figure, the graph has 64 nodes where each node denotes a pixel. The relationship between adjacent pixels in the original image is represented in the adjacency matrix by contiguous cells, while adjacent pixels in columns are depicted as parallel lines. The lighter-colored cells in the adjacency matrix correspond to flat regions in the image, while the breakpoints in the white slashes indicate the edges.

As we now have the ability to represent *flat* areas in the image, the next step is to design a loss function that ensures the corresponding areas in the watermarked image remain *flat*. Consider the definition of Graph Laplacian Regularizer(GLR)[15] which is commonly used in works with similar purpose:

$$S_{\mathcal{G}}(\mathbf{u}) = \mathbf{u^T L u} = \sum w_{i,j}(\mathbf{u}_i - \mathbf{u}_j)^2 \tag{4}$$

The GLR represents the smoothness of a graph signal $\mathbf{u}$ with respect to graph G. For our purpose, we want the graph signal of watermarked image is smooth with respect to the graph of the original image. Therefore he formula of our loss is similar to the one above that

$$Loss_{GLR} = \sum_{blocks} \mathbf{u_B}^{\mathbf{T}} \mathbf{L_A u_B} = \sum w_{\mathbf{A}i,j}(\mathbf{u_B}_i - \mathbf{u_B}_j)^2 \tag{5}$$

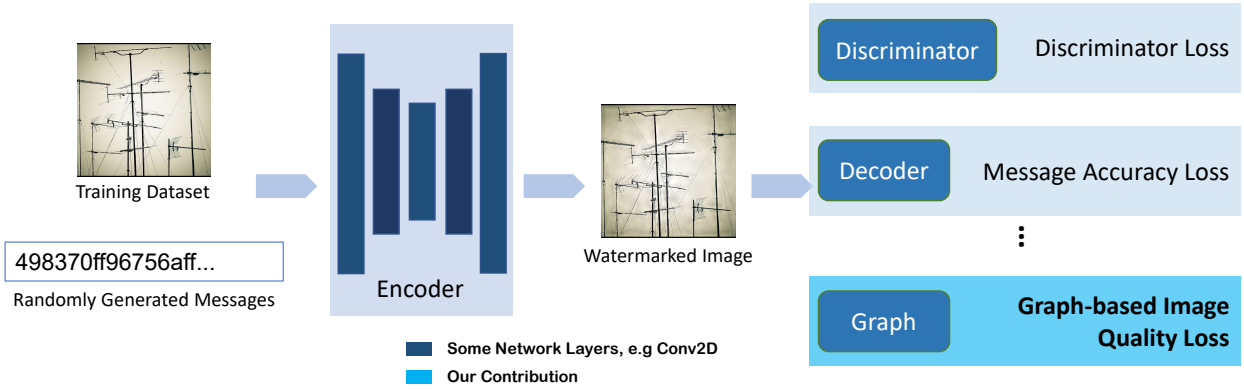

Fig. 4. Sturcture of deep learning based watermarking scheme.

where the variables with subscript **A** denote the original image and the ones with subscript **B** denote the watermarked image.

With this loss function, we want to learn the structure-adaptive watermarked images that's as similar as possible to the original one in *flat* areas. For the watermark generated during training process, if it's still *dirty* in flat areas as in Figure 2, this loss function will punish the intermediate results and let the watermark be more concentrated on areas with complex textures where the variation is less likely to be recognized by the human eye. By minimizing this loss, we can enforce the watermarked image to have graph signal smooth with respect to the original graph.

IV. Experiment

Since our optimization method is general for all deep learning based watermark schemes, we need to utilize it in a specific frame work for experiment. We choose the popular StegaStamp[4] here. In the following subsections, we outline the typical architecture of deep learning-based watermarking and explain how our approach fits into it. Then, we provide a brief overview of the experimental setup. Finally, we present the results of image quality and watermark invisibility improvement through both quantitative metrics and visual examples, and analyze the robustness against various common attacks after our optimization.

A. System Overview

Our method can be applied to most deep learning-based robust watermarking schemes. The typical structure of these schemes is illustrated in Figure 4. In this architecture, images and messages are fed into an encoder-decoder neural network for training. The normal loss during training typically includes the message cross-entropy loss, the discriminator loss of the original image and the watermarked image, and so on. Our main contribution, the GLR loss, is added to this structure to explicitly enhance the visual quality of the watermarked images.

Let's take StegaStamp, the one we choose to embed our method for experiments, as an example.The structure of StegaStamp end-to-end system can be summarized as *Encoder-Perturbation-Decoder*. The *encoder* is a U-Net style architecture that receives a four channel 400 × 400 pixel input (input image RGB channels plus one for the message) and outputs a three channel RGB residual image. The *perturbation* is a combination of distortion simulation functions that are derivable. The *decoder* is a spatial transform network that accepts a transformed image and outputs the decoded message with the same length of original input. The system is trained end-to-end and the loss follows the formula below:

$$L = \lambda_R L_R + \lambda_P L_P + \lambda_C L_C + \lambda_M L_M \tag{6}$$

where L_R, L_P, L_C, L_M denote the L_2 regularization loss, LPIPS[16] loss, critic loss and the cross entropy loss of the message respectively, and the λs denotes the coefficients. Our loss can be directly added here as:

$$L_{new} = L + \lambda_G Loss_{GLR} \tag{7}$$

where $Loss_{GLR}$ is described in Formula 5.

B. Experiment Setup

We choose the same training and testing dataset as the original paper. The training dataset is mirflickr dataset[17]. The testing dataset used for visualization and robustness experiment consists of 100 images randomly sampled from ImageNet[18]. For robustness tests, the messages is encoded with the same BCH error-correcting code as in the original paper, with 56 bits valid information and 100 bits total length, which is sufficient for general purpose. For the screen-capture and print-capture experiments, we use the HUAWEI Mate40 Pro cellphone to take photos. The display is SANC N50 Plus and the printer is Canon LBP9100C color.

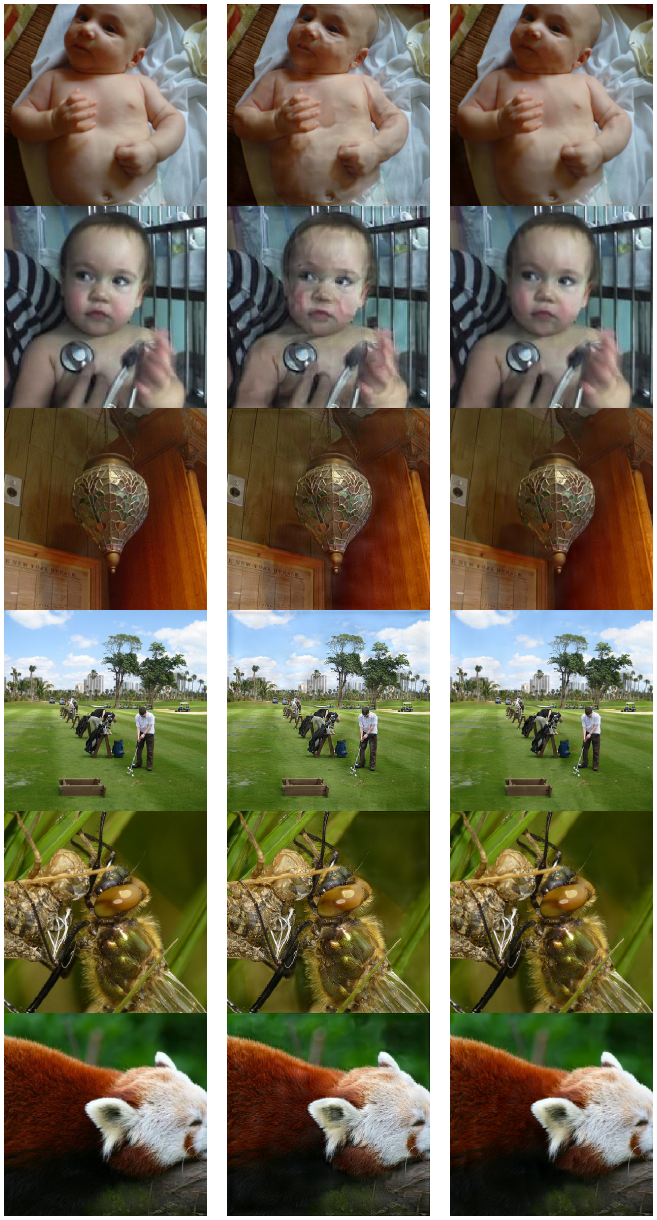
C. Results

First we show our image quality improvement by both metrics and visual examples. Table I showcases the significant improvements we achieved in terms of visual quality-related metrics. PSNR and SSIM data of original StegaStamp are obtained from their paper. When the length of the embedded message was the same, our PSNR and SSIM were considerably

TABLE I
IMAGE QUALITY METRICS COMPARISON. FOR BOTH PSNR AND SSIM, HIGHER IS BETTER.

	PSNR↑		SSIM↑	
Message Length	StegaStamp	Optimized	StegaStamp	Optimized
50 bits	29.88	35.18	0.930	0.988
100 bits	28.50	35.42	0.905	0.987
150 bits	26.47	32.67	0.876	0.983

higher than those of the original method. Even when embedding messages with three times the length (150 bits compared with 50 bits), the model with our optimization performs still better than the original one. Some image quality comparison examples of watermarked images are shown in Figure 5. For the images containing faces and skin(the first two baby images and the Lenna example in Figure 2), our method significantly improves the quality; for images with relatively flat/simple backgrounds(the chandelier and the golf course), our optimized images show a slight improvement; for images with complex textures(the insect amd the animal), although there is also some improvement on the blurred background areas, the improvement in these areas is not easily observable by the naked eye, meaning the visual difference is not significant for these images.



Improving visual quality alone is not sufficient for real-world applications, as we still need to keep sufficient robustness to resist various attacks. Therefore, we also conducted a series of experiments in various scenarios to prove the robustness of our method. Table II and III shows the robustness against screen-caption attacks, from varying horizontal angles and distances between the camera and the screen. Besides, we also show our strong robustness against JPEG compression attacks in Table IV.

TABLE II
COMPARISON OF BIT ACCURACY UNDER SCREEN-CAPTURE ATTACKS FROM DIFFERENT HORIZONTAL ANGLES.

		Bit Accuracy		Decoding success rate	
		StegaStamp	Optimized	StegaStamp	Optimized
left	10°	98.28%	98.74%	94%	97%
	20°	98.64%	98.82%	96%	97%
	30°	98.46%	98.64%	96%	97%

20 cm	97.72%	97.93%	86%	91%
30 cm	98.68%	98.24%	98%	93%

(a) Original image (b) StegaStamp (c) Ours

Fig. 5. Watermarked Image Quality Comparison.

Inevitably, improving the visual quality of watermarked images will almost certainly lead to a decrease in robustness. Although it performs well or even better in most of the scenarios mentioned above, we found that there is a slight loss of robustness when suffering severe distorion and when the images are too simple to embed something at the same time. As shown in Table V, optimization seems to result in some decrease in decoding success rate under print-capture and print-scanner attacks, although the bit accuracy does not decrease significantly.

After careful study and comparison, we found that the images that are difficult to recognize after optimization are almost all images of simple objects placed on a white back-

TABLE IV
COMPARISON OF BIT ACCURACY UNDER JPEG COMPRESSION ATTACKS WITH DIFFERENT QUALITY.

JPEG Quality	Bit accuracy		Decode success rate	
	StegaStamp	Optimized	StegaStamp	Optimized
75	99.79%	99.92%	100%	100%
60	99.72%	99.84%	100%	100%
45	99.78%	99.55%	100%	100%
30	99.66%	98.72%	100%	95%

ground(some of them are shown in Figure 6), which are already very difficult to embed a 100-bit watermark into, and are common in the ImageNet dataset that's normally used for object detection and image classification. The original StegaStamp actually embed the watermark at the boundary of these images, and the shape was similar. Such a watermark is not only easily recognizable by the naked eye, but also meaningless. After excluding these images, our optimized method also achieve similar accuracy in print-related attacks. Since these images are rarely or cannot be used to embed watermarks in the real world, and our optimization method can still successfully decode these images under screen-capture and JPEG compression attacks, we believe that the differences in the decoding success rates shown in Table 6 is acceptable, and our optimization does improve the image quality in a way that is applicable to real-world scenarios.

TABLE V
COMPARISON OF BIT ACCURACY UNDER PRINT-CAPTURE AND PRINT-SCANNER ATTACKS.

	Bit accuracy		Decode success rate	
	StegaStamp	Optimized	StegaStamp	Optimized
print-capture	98.41%	96.73%	98%	85%
print-scanner	97.21%	95.62%	90%	80%

V. CONCLUSION

In this paper, we present a novel graph-based optimization for improving the quality of watermarked images of deep learning-based watermarking systems. The optimization is demonstrated through its deployment on the StegaStamp framework. The experimental results indicate that our method maintains similar robustness under various types of attack and noticeably improves the image quality as evidenced by both objective metrics and subjective observation.

***Abstract*—Currently, print-scan-resilient watermarking algorithms remain a challenging research direction. In the industrial field, there is a huge demand for copyright protection of trademark images, which are particularly vulnerable to attacks such as printing and scanning for counterfeiting purposes. Therefore, this paper proposes a print-scan-resilient watermarking scheme based on the human eye's insensitivity to changes in image brightness, using circular masks and linear interpolation to modify the brightness component and achieve local gradients in colour images for embedding copyright information. Then the information is extracted by comparing the mean brightness values of the modified local region and its concentric outer ring. Because the watermark information is distributed across various local regions of the image and integrated with local brightness gradients, it is less susceptible to damage or forgery even after printing and scanning, ensuring the robustness of the algorithm. Experimental results demonstrate that this method shows excellent robustness when the embedding strength surpasses 5 and the modified area radius is well-suited.**

I. Introduction

Digital watermarking is commonly employed in various domains such as digital copyright management, information security, and privacy preservation [1][2][3][4]. It aims to embed specific identification information into digital media such as images, audio, and video without compromising quality. This allows for effective identification of media ownership and tracking of its usage while maintaining the integrity and quality of the media itself. In practical scenarios, digital watermarks often encounter various attacks and threats, including image processing attacks, cropping attacks, and print-scan attacks, with the latter being the most common and challenging attack method [5][6]. Adversaries print materials with digital watermarks and then scan or photograph them again, attempting to remove the digital watermark or forge a new watermark to deceive detection systems. This attack is not only easy to implement, and cost-effective, but also has the potential to spread digital content to uncontrolled environments, posing a significant threat to copyright protection [7][8][9]. Correspondingly, there is an enormous economic demand for utilizing digital watermarking technology that is resistant to print-scan attacks to safeguard the copyright of trademark images.

Most existing anti-print scan algorithms typically convert the original image into the frequency or wavelet domain for processing. For instance, K. Solanki et al. proposed an algorithm called 'Selective Embedding in Low Frequencies' (SELF), which can effectively resist print-scan attacks [10]. R. Riad and colleagues utilized the improved spread spectrum technique to embed the watermark within a middle frequency band of an image's discrete Fourier transform [11] . Ruanaidh et al. present a watermarking method based on the log polar map of DFT magnitudes [12]. The method suggested in [13] also utilizes DFT magnitudes, but the watermark is designed with circular symmetry to avoid the need for log-polar coordinate transformation. Tang and Huang inserted a set of peaks into selected DFT coefficients to achieve watermark embedding [14]. In addition, others also embed watermarks by modifying the polarity of discrete cosine transform (DCT) coefficients [15] or by efficiently integrating the three components, red, green and blue [16]. Some composite watermarking schemes have also been proposed, such as using the discrete wavelet transform-discrete cosine transform [17]. However, these algorithms involve complex processes, are limited by certain assumptions, and are better suited for carrier images with complex texture information, making them less applicable to copyright protection for trademark images in practical scenarios.

Considering the aforementioned circumstances, this paper presents a print-scan-resilient watermarking scheme designed specifically for trademark images. The scheme achieves watermark embedding by modifying brightness values in a dispersed manner within the spatial domain, creating a localized colour gradient in the image. Experiments demonstrate that the proposed method effectively withstands print-scan attacks while ensuring the concealment of the watermark.

II. Proposed scheme

This scheme utilizes the brightness gradient between monochromatic smooth regions in trademark images to embed and extract watermarks in local areas. Specifically, the watermark information is embedded in an image by adjusting the brightness values and utilizing error diffusion techniques for seamless integration into neighbouring pixels. During the extraction process, circular masks are employed to sample and compare local areas of the image, improving the scheme's resistance against attacks such as printing and scanning. In addition, robustness has been enhanced through the implementation of BCH error correction coding techniques.

A. Embedding Process

This method modifies the brightness component and achieves local gradients in colour images to embed watermarks. The process of modifying the brightness involves several steps, as illustrated in Fig.1. First, locations that meet the brightness modification condition are selected as centre coordinates. Next, the original RGB image is converted to the YCbCr format and the Y component is separated from the Cb and Cr channels. Then, based on the copyright information bits encoded by BCH, the brightness value gradually varies from the centre to the outside of the circular area determined by each centre, forming a transition effect from dark to light or from light to dark, i.e., a radiation-like brightness gradient. The modified Y component is ultimately combined with the Cb and Cr channels and transformed back into a colour image, resulting in the watermarked trademark image.

To illustrate the key steps of implementing the local gradient effect, i.e., the specific operations within the loop in Fig.1, more clearly, this paper takes a certain central coordinate as an example to describe how to modify the brightness component in the circular regions determined at that position to achieve the embedding operation. This process consists of two parts: mask operation and linear interpolation.

1) Mask operation: A grid of the same size as the original trademark image is constructed to enable pixel-level operations on the separated Y component. First, the Euclidean distance of each pixel point to the centre is calculated, and those with distances less than or equal to the radius of the modifiable region are marked as 1 while the rest are marked as 0. Here, the radius denoted as r_1 is an adjustable parameter used to control the size of the circular region that can be modified. The result of the above operation is a two-dimensional distance mask matrix, referred to as DK_{r_1}, which is shown in Fig.2. Subsequently, a binary matrix is obtained to mark the circular region where brightness pixel values can be modified. Specifically, for each nonzero element in the DK_{r_1} matrix, the minimum distance is subtracted and then divided by the distance difference, obtaining distance parameters within the range of [0, 1], which are stored in the distances map denoted as DM_{r_1}.

2) Linear interpolation: According to the BCH-encoded binary number corresponding to the circle's centre, a new pixel average value μ_2 is calculated based on the original pixel average value μ_1 and embedding strength dif within a modifiable circular region, as shown in Eq. (1). Subsequently, an evenly spaced sequence of length r_1 is constructed from μ_2 to μ_1, referred to as the gradient vector. Finally, the distance parameter DM_{r_1} is mapped into the range of the gradient vector gradient using linear interpolation, and the resulting values are assigned to the corresponding pixels inside the circular region to achieve a gradient effect.

$$\begin{cases} \mu_2 = \mu_1 + dif & binary\ number = 0 \\ \mu_2 = \mu_1 - dif & otherwise \end{cases} \tag{1}$$

Specifically, the principle of linear interpolation is to estimate the function value y_q at an unknown position x_q, given a set of n known data points (x_i, y_i), where $X = \{x_i\}$ represents the positions of the data points on a one-dimensional coordinate axis and $Y = \{y_i\}$ represents their corresponding function values. On a one-dimensional coordinate axis, the set of known data points $\{(x_i, y_i)\}$ can be viewed as a series of ordered line segments connecting each point. When estimating the function value y_q at position x_q, we first find the two nearest data points (x_k, y_k) and (x_{k+1}, y_{k+1}) to x_q in terms of their positions along the axis. Assuming $x_k < x_{k+1}$, then x_q lies between x_k and x_{k+1}. We can use these two data points to calculate the interpolated function value y_q for x_q using the linear interpolation formula:

$$y_q = y_k + (x_q - x_k)\frac{y_{k+1} - y_k}{x_{k+1} - x_k} \tag{2}$$

Here, the factor $\frac{y_{k+1}-y_k}{x_{k+1}-x_k}$ represents the slope of the line segment between (x_k, y_k) and (x_{k+1}, y_{k+1}), and $(x_q - x_k)$ represents the distance between x_q and x_k.

Once the principle of interpolation is known, the mapping process described above becomes clearer. Specifically, the gradient is represented as the function values corresponding to the end points of an interval, which indicates the range of the gradient effect. This effect involves a transition in pixel values from μ_2 to μ_1 within a circular region. Using DM_{r_1}, the distance between each pixel point in the circular region and the centre can be calculated to determine the modified pixel value based on distance. The resulting values are assigned to the corresponding pixel points within the circular region, causing the brightness values within the region to gradually change from the centre outwards, ultimately forming a radiation-like gradient effect.

B. Extraction Process

The flowchart for watermark extraction is shown in Fig. 3. Prior to this step, it may be necessary to correct for any perspective distortion in the obtained colour image with watermark using specialized image processing software. This technology is well-established and will not be the focus of this discussion. Corresponding to the embedding process, it is necessary to convert the original image and the watermarked image to the YCbCr colour space to obtain the Y component.

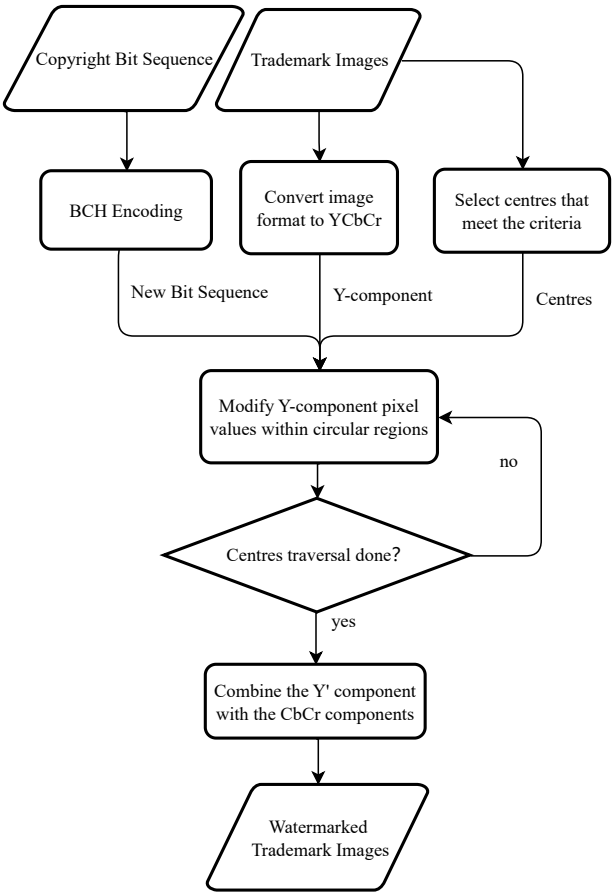

Fig. 1. Watermark embedding processes

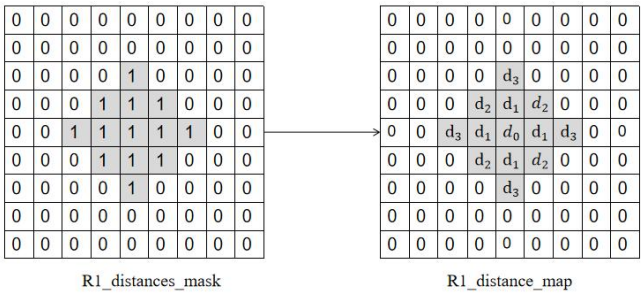

Fig. 2. The DK_{r_1} and DM_{r_1} of a circular region

Then, a mask is applied to extract the annular region for each known centre coordinate, and the average difference between the pixel values within the annular region and the average pixel value within the inner circular region with the same centre is calculated. After iterating through all predefined centre coordinates and performing the aforementioned operations, the extraction results from each local region are concatenated to form a binary code sequence. Subsequently, these sequences are used as input to the BCH decoder for error correction and decoding, finally yielding the corrected watermark information.

To provide a clearer description of the process for masking

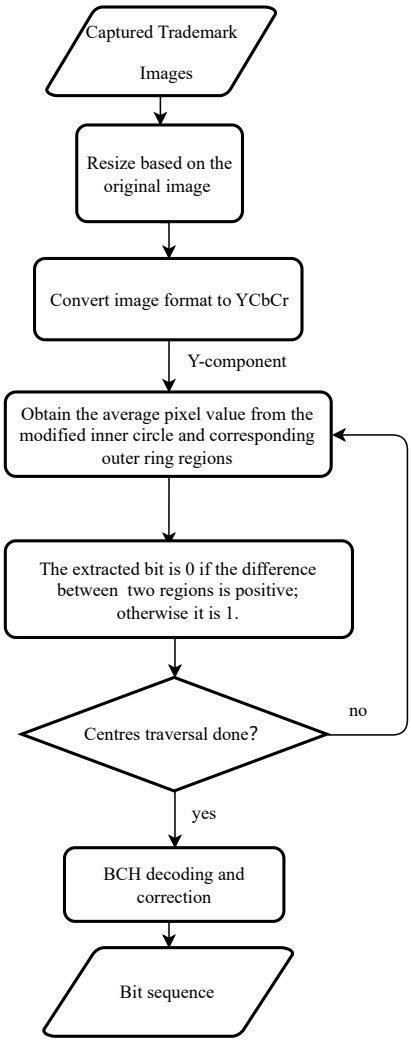

Fig. 3. Watermark extraction process

operation and calculate the difference, for the same center coordinate in the embedding method, the specific extracting process is as follows:

After constructing the grid, perform a masking operation on the Y component of the watermarked image. This mask matrix is referred to as DK_{r_2}, which extracts information from the grey annular region marked as 1 shown in Fig. 4. The limited rule for the area range states that the distance between a pixel and the centre of a circle should be greater than the modifiable circle radius r_1 and less than the user-defined radius r_2. r_2 is also manually specified, and it is required that the pixel values within the circular area formed by the centre and r_2 must be similar.

Next, the areas marked as 1 in theDK_{r_2} and DK_{r_1} matrices are calculated, i.e., the pixel mean of the blue area and grey area in Fig .4, and their difference is used to extract information. If the difference value is greater than 0, the extraction result is considered as 0, otherwise, it is considered as 1.

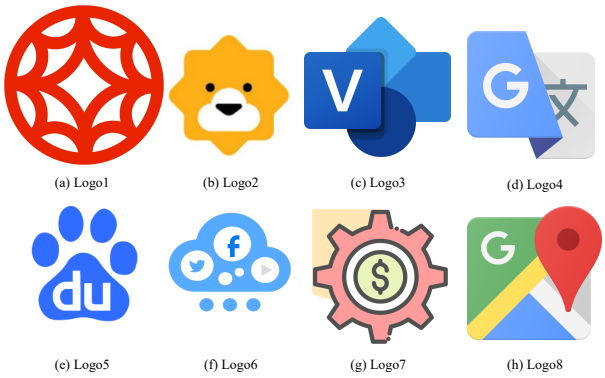

Fig. 5. Trademark images

III. Experimental Results

To demonstrate the effectiveness of the proposed method, as shown in Fig. 5 ,eight different trademark images are selected as experimental samples, and the optimal size of the modifiable circular area radius is determined for each one. The original watermark (15 bits, including 11 information bits) is then embedded into these eight images with embedding strengths of $dif = 5$, $dif = 10$, $dif = 15$, and $dif = 20$, respectively. Refer to Fig. 6 for the embedding effect of logo1. Fig. 7 displays the effect of logo1 after being printed and scanned, as well as the result after correction, with a partial enlargement of the image to better showcase the gradient effect. Extraction experiments are conducted for each embedding strength, and the bit correctness rate is used as the evaluation metric. The bit correctness rate (BCR) is defined as the ratio of the number of correctly extracted bits to the total number of extracted bits. This metric provides a measure of the accuracy of the watermark extraction process.

To increase the accuracy and credibility of the results, each combination is repeated at least 20 times during the experiments. Additionally, other factors that may affect the experimental results, such as image clarity and noise, are carefully controlled during the experiment.

According to the TABLE 1, when the embedding strength

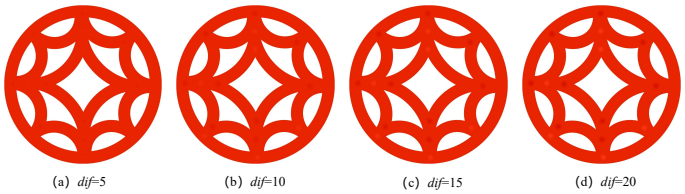

Fig. 6. Results of Logo1 with different embedding strengths.

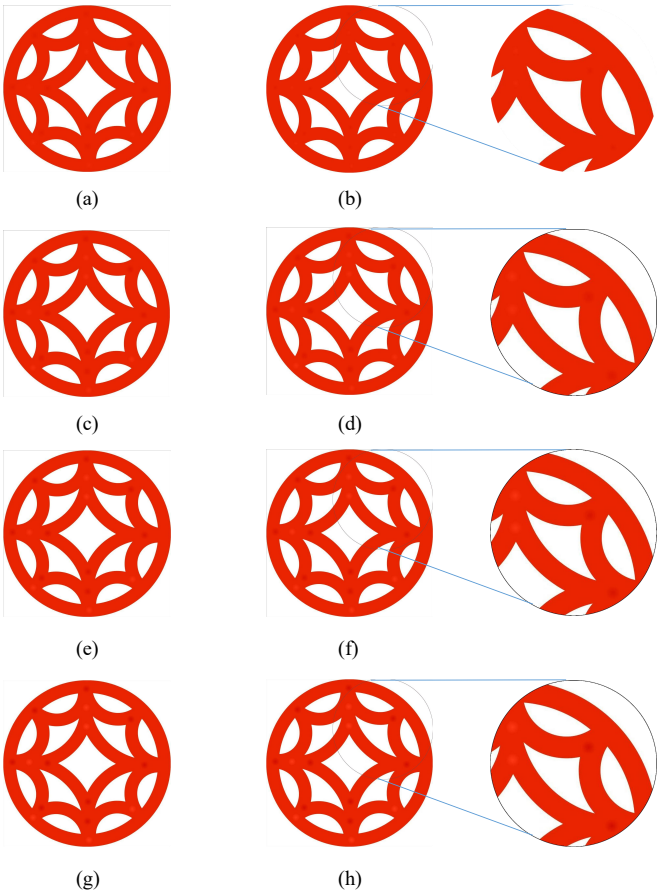

Fig. 7. (a), (c), (e), and (g) represent logos that have been printed and scanned with dif values of 5, 10, 15, and 20, respectively. (b), (d), (f), and (h) are the corrected logos corresponding to (a), (c), (e), and (g), respectively, and have been selectively enlarged.

is greater than 5 and the inner circle radius is appropriate, the probability of successful extraction is higher, which demonstrates excellent robustness.

IV. Conclusions

In this paper, we fully consider the graphic characteristics of trademark images and propose a new print-scan-resilient watermarking scheme that adopts a watermark embedding method based on the local circular region gradient while ensuring the robustness and invisibility of the watermark. This method can effectively avoid interference from the quality of printing ink and includes steps for correcting perspective distortion and using BCH encoding for error correction to enhance the water-

TABLE I
BIT CORRECTNESS RATE OF 8 TRADEMARK IMAGES

mark's resistance to attacks. The performance of this method is verified through experiments. However, there is still room for further improvement in the performance of this method. In future work, we will not be limited to simple trademark images and will continue to explore the application of this print-scan-resilient watermarking scheme in other scenarios.

AI-Generated Image Detection using a Cross-Attention Enhanced Dual-Stream Network

Ziyi Xi, Wenmin Huang, Kangkang Wei, Weiqi Luo and Peijia Zheng
GuangDong Province Key Laboratory of Information Security Technology, Sun Yat-sen University, GuangZhou, China
E-mail: luoweiqi@mail.sysu.edu.cn xiziyi@mail2.sysu.edu.cn

***Abstract*—With the rapid evolution of AI Generated Content (AIGC), forged images produced through this technology are inherently more deceptive and require less human intervention compared to traditional Computer-generated Graphics (CG). However, owing to the disparities between CG and AIGC, conventional CG detection methods tend to be inadequate in identifying AIGC-produced images. To address this issue, our research concentrates on the text-to-image generation process in AIGC. Initially, we first assemble two text-to-image databases utilizing two distinct AI systems, DALL·E2 and DreamStudio. Aiming to holistically capture the inherent anomalies produced by AIGC, we develope a robust dual-stream network comprised of a residual stream and a content stream. The former employs the Spatial Rich Model (SRM) to meticulously extract various texture information from images, while the latter seeks to capture additional forged traces in low frequency, thereby extracting complementary information that the residual stream may overlook. To enhance the information exchange between these two streams, we incorporate a cross multi-head attention mechanism. Numerous comparative experiments are performed on both databases, and the results show that our detection method consistently outperforms traditional CG detection techniques across a range of image resolutions. Moreover, our method exhibits superior performance through a series of robustness tests and cross-database experiments. When applied to widely recognized traditional CG benchmarks such as SPL2018 and DsTok, our approach significantly exceeds the capabilities of other existing methods in the field of CG detection.**

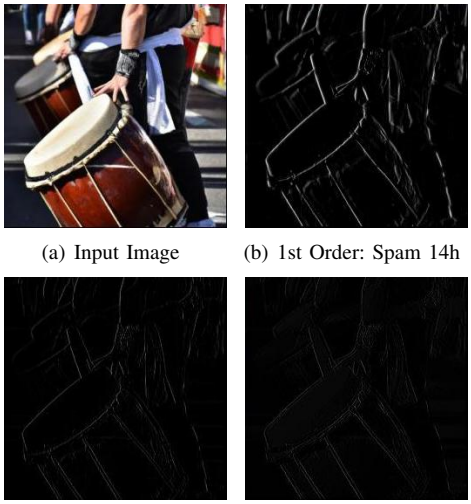
The prompt for the second row is: "The charming old-fashioned streetcars that trundled along the tracks added a touch of nostalgia to the scene."

I. Introduction

AI-generated content (AIGC), which pertains to the production or creation of content through artificial intelligence systems, has exerted a significant influence across various application scenarios, particularly with the emergence of large-scale models. The content produced by generative AI models comprises text, image, audio, video and cross-modal transformations like text-to-image, text-to-audio and more [1]. Among these, text-to-image has garnered enormous attention in social media platforms, primarily owing to its potential to supplant human visual design. In this field, several representative models have emerged, one such model is DALL·E, which is trained using Variational Autoencoders, another important model is VQGAN-CLIP based on Generative Adversarial Networks (GANs). Nowadays the diffusion model has become the core approach in text-to-image generation, with popular models like Stable Diffusion, Disco Diffusion, MidJourney, and DALL·E2 etc [2]. By typing the prompt containing expected image concepts, attributes and styles, users can cultivate an realistic or artistic image which is significantly correlative with the prompt. Some image examples are shown in Fig.1. Compared to conventional Computer-generated Graphics (CG) technology, more ease of operation, low capitalized cost and high-quality image feedback have propelled text-to-image generation into the forefront of internet. Therefore how to distinguish text-to-image graphics (denoted as T2I for short) from Photographs (PG) generated by a digital camera has emerged as a pressing issue that requires resolution.



To our knowledge, only a limited number of works have focused on distinguishing between T2I and PG. Certain methods capable of distinguishing between these two image types capitalize on familiar classification techniques prevalent in computer vision, such as ResNet [3], [4] and EfficientNet [5]. However, these methods often fall short in providing a comprehensive analysis of inherent artifacts in T2I images and usually necessitate pre-training. As an alternative, we could harness contemporary methods established for distinguishing between CG and PG, given that these methods are adept at detecting variations in lighting, color, texture, and other

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

attributes present in PG. To date, several conventional methods have been proposed for CG and PG detection. For instance, Quan et al. [6] employed a 7×7 convolutional kernel in the initial layer to adaptively extract noise information. Yao et al. [7] designed three fixed high-pass filtering kernels to capture high-frequency information from images. Zhang et al. [8] developed a module comprising plain convolutional structures to extract correlations between adjacent pixels in RGB color space. He et al. [9] applied a Gaussian filter as a preprocessing step on the input image to achieve a robust network. Quan et al. [10] leveraged the SRM [11] to extract residual information from different channels. Other prevalent solutions include strategies based on transfer learning [12]–[15], the integration of Convolutional Neural Network (CNN) and Recurrent Neural Networks (RNN) [16], and those based on self-supervised learning [17], among others.

While the methods mentioned above prove effective for CG and PG detection, directly applying these techniques to T2I and PG detection might not yield optimal results. This limitation is due to the unique generative mechanisms present in T2I and CG. Inspired by successful approaches in CG detection, such as those presented in [9], [10], we propose a novel cross-attention enhanced dual-stream network specifically designed for T2I and PG detection. Our method incorporates two streams: a residual stream and a content stream. The residual stream employs a SRM [11] residual extraction module, which meticulously extracts texture information from the images. Conversely, the content stream focuses on the low-frequency aspects of the images, utilizing a dedicated network structure. The information extracted from both streams is downscaled using CNN modules, and then fused via a cross multi-head attention mechanism situated in the network's middle layer. After independent learning, the features from both streams are combined through channel concatenation, and a classifier is subsequently utilized to discern whether the image is T2I or PG. To ascertain the efficacy of our proposed method, we generate two T2I databases. Comprehensive comparative and ablation experiments have affirmed the superiority of our method. In summary, our contributions in this paper include:

- We propose a novel dual-stream framework that combines a residual stream and a content stream to comprehensively explore the generation traces of T2I. Moreover, we introduce a cross multi-head attention mechanism to enhance information exchange between the two streams.
- To assess the performance of our approach, we construct two T2I databases using two AI systems: DALL·E2 and DreamStudio. Each database consists of 20,000 generated images covering various scenarios.
- Our method excels in detection performance on our custom databases (DALL·E2 and DreamStudio) and outperforms comparable methods on established CG detection datasets, specifically DsTok and SPL2018. Moreover, we have conducted several ablation experiments to validate the effectiveness of our model design.

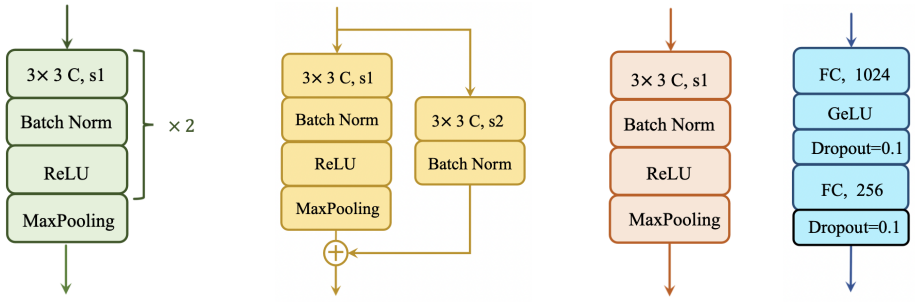
II. Proposed Method

The network architecture of the proposed model is visualized in Fig. 3. In the following subsections, we will provide a detailed description of the residual stream, content stream, cross-attention module, feature fusion and classifier utilized in the proposed model, respectively. Additionally, we will demonstrate the loss function employed in our model.



A. Residual Stream

Previous studies in CG detection [7], [10] and image steganalysis [18], [19] have shown that forgery artifacts are often present in the high-frequency components of images. To better detect these artifacts, several studies have employed multiple high-frequency filters from the SRM during image preprocessing to generate corresponding residual images. In our proposed model, we adopt a similar approach inspired by the methodologies presented in papers [10], [19]. As shown in the Fig. 3, the dimension of the input image is $3 \times s \times s$, where 3 means the color channels and $s \times s$ represents the resolution of input image. We begin by applying 30 SRM kernels individually to each of the RGB color channels in the input images. In this way, the input image is transformed into the residual domain for further feature analysis. Fig. 2 illustrates an example of the resulting residual images after filtering with three typical SRM kernels. This approach generates a total of 90 different residual images, aiming to capture a comprehensive representation of the multi-channel residual information. To facilitate further learning, we downscale 90 residual images using a custom-designed stacked CNN modules, which consist of one Module a and two Module b1. Module a and Module b1 are defined as follows:

- Module a: As shown in Fig. 3-(b), it comprises two consecutive groups of 3×3 convolutional layer, batch normalization (BN), ReLU, finally followed by a maximum pooling layer of size 3×3 with a stride of 2.

(a) The network architecture of the proposed model

(b) Module a (c) Module b1 (d) Module b2 (e) MLP

Fig. 3. The network architecture of the proposed model, and four modules used in the proposed model. The variable h corresponds to the number of headers. FC means fully connected layer. C represents the number of output channels, s1 means the stride of convolution kernel is 1.The symbol $\bigoplus$ denotes element-wise summation, and $\ominus$ means element-wise subtraction, ⓒ means channel-wise concatenation.

- Module b1: As shown in Fig. 3-(c), it includes two parts: convolutional downsampling and pooling downsampling. The pooling downsampling involves a sequence of 3×3 convolutional layer, BN, and a ReLU, followed by a maximum pooling layer of size 3×3 with a stride of 2. In parallel, the input feature maps are downscaled in another branch using a 3×3 convolutional layer with a stride of 2. The downscaled feature maps from both branches are fused together through element-wise addition, then activated by ReLU function.

After 90 residual feature maps through one Module a and two Module b1 in sequence, we can obtain $\chi^{l-1} \in R^{256 \times \frac{s}{8} \times \frac{s}{8}}$, as labeled in Fig. 3.

B. Content Stream

As mentioned earlier, the residual stream primarily focuses on image texture while disregarding the underlying content information. Unlike traditional steganography, where the modifications are usually minimal and do not disrupt the mid-to-low frequency information of the original image, images generated by T2I or CG often exhibit significant statistical differences

Fig. 4. The visualization of $\tilde{\ell}$ with 6 channels.

compared to images captured by a camera. Therefore, to address the limitations of relying solely on the residual stream, we propose a content stream that specifically targets forgery traces in the mid-to-low frequency range.

In the proposed content stream, we first utilize a 1×1 convolution to generate three composite images which integrate the R, G, and B channels. This step is performed to enhance

the breadth of channel information. Next, we concatenate the above three channels and the RGB image to obtain feature maps with 6 channels(denoted as ℓ). Then, pass the ℓ through a 3×3 convolution, and $conv_{3\times3}(\ell)$ is subtracted from ℓ to obtain the feature maps $\tilde{\ell}$, as Eq. (1). Subsequently, apply 3×3 convolution to $\tilde{\ell}$ for further learning, and then concatenate the $\tilde{\ell}$ and $Conv_{3\times3}(\tilde{\ell})$ along the channel dimension to obtain ℓ_{out} with 12 channels, as Eq. (2). Fig. 4 visualizes $\tilde{\ell}$, where it can be observed that four out of the six channels exhibit distinct content variations in the image, while the remaining two channels primarily capture edge information.

$$\tilde{\ell} = \ell - conv_{3\times3}(\ell) \tag{1}$$

$$\ell_{out} = Concat(\tilde{\ell}, conv_{3\times3}(\tilde{\ell})) \tag{2}$$

Following that, ℓ_{out} are downscaled through the stacked CNN modules which involve one Module a and two Module b2. Finally get the feature map $\phi^{l-1} \in R^{256\times\frac{s}{8}\times\frac{s}{8}}$. As shown in Fig. 3-(d), the Module b2 consists of 3×3 convolutional layer, BN layer, ReLU layer, and Maximum pooling layer of size 3×3 and a stride of 2.

C. Cross-Attention Module

To facilitate the interactive fusion of dual-stream, we propose a cross-attention module to exchange information between dual-stream. The details are as follows:

First, flattening the output of two streams χ^{l-1} and ϕ^{l-1} respectively, and exchange the last two dimensions to obtain $\chi^{l-1}, \phi^{l-1} \in R^{\frac{s^2}{64}\times256}$, followed by a layer normalization. Then, send them to the subsequent cross multi-head attention module (CMA), as shown in Fig. 5. Its principle and implementation details are as follows:

The ViT [20] is a Transformer-based model for image classification. It treats the input image as a sequence of patches and maps each patch to a single vector using linear mapping. Self-attention (SA) mechanism, the core of transformer, utilizes three variables: Q (Query), K (Key), and V (Value). In essence, it computes the attention weights between Query token and Key token, and multiplies them with the corresponding Value token associated with each Key. The formula for SA can be expressed as follows, d_k means the dimension of token:

$$SA = softmax(\frac{QK^T}{\sqrt{d_k}})V \tag{3}$$

Denotes the number of heads is h. We split χ^{l-1}, ϕ^{l-1} into h parts, attaining $\chi_i^{l-1}, \phi_i^{l-1} \in R^{\frac{s^2}{64}\times\frac{256}{h}}$, where $i \in \{1, 2, ..., h\}$. Different from SA, CMA calculates the degree of correlation between different vectors at each space position. In each head i, We can obtain the Query $Q_{\chi_i^{l-1}} \in R^{\frac{s^2}{64}\times\frac{256}{h}}$ and Key $K_{\phi_i^{l-1}} \in R^{\frac{s^2}{64}\times\frac{256}{h}}$ by linear projection respectively. Following that, ϕ_i' is obtained by multiplying the attention matrix with ϕ_i^{l-1}. d_k is $\frac{256}{h}$ here.

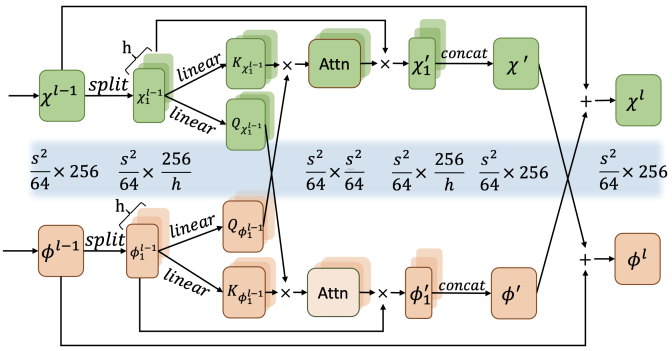


Fig. 5. The specific calculation process of the proposed CMA mechanism.

$$\phi_i' = softmax(\frac{Q_{\chi_i^{l-1}} \times K^T_{\phi_i^{l-1}}}{\sqrt{d_k}})\phi_i^{l-1} \tag{4}$$

Subsequently, the ϕ_i' obtained from each head are concatenated together to obtain the ϕ' relevant to χ^{l-1}, and add it to the χ^{l-1} to get the output χ^l. Similarly, we can obtain ϕ^l. After that, a layer normalization and an MLP module are applied, as Fig. 3. The cross-attention module utilizes transformer encoder structure in general as paper [20] and repeats it for twice. After through the cross-attention module, we can obtain the outputs $\in R^{\frac{s^2}{64}\times256}$.

$$\chi^l = \chi^{l-1} + Concat(\phi_1', \phi_2', ..., \phi_h') \tag{5}$$

D. Feature Fusion and Classifier

After through the cross-attention module, we need to convert the output from cross-attention module back to the feature maps with its original dimensions, swap the last two dimensions before reshaping and obtain the $\phi^l, \chi^l \in R^{C\times\frac{s}{8}\times\frac{s}{8}}$. The downsampling process further progresses as the feature maps are passed through a series of stacked CNN modules which involve two Module b1/b2. Afterwards, the feature maps are concatenated together by channel. Finally, classification is performed utilizing global average pooling and fully connected layer.

E. Loss Function

The loss function used in the proposed model is the cross entropy loss, which is defined as follows.

$$\text{Loss} = -\frac{1}{N}\sum_{i=1}^{N}\left[y_i \cdot \log p\left(y_i\right) + \left(1 - y_i\right) \cdot \log\left(1 - p\left(y_i\right)\right)\right] \tag{6}$$

Here, N stands for the number of samples in a batch. The symbol y_i denotes the true label of the i-th sample, where $y_i \in \{0, 1\}$. On the other hand, $p(y_i)$ indicates the predicted probability associated with the true label y_i.

III. Experiments Result

In this section, we begin by providing a detailed explanation of the process for creating two T2I databases, along with the implementation details of our model. Subsequently, we conduct comparative experiments on T2I databases, comparing our approach with seven contemporary CG detection methods and ResNet18[4]. Additionally, we assess the robustness of our model against various post-processing operations and employ it for CG detection. Finally, we design ablation experiments to illustrate the validity of the proposed model.

A. Constructing Databases and Experimental Setup

Firstly, we randomly select 20,000 uncompressed PG images of size 256×256 from the ALASKA database[1], which is widely used in image steganalysis and forensics. To construct the T2I dataset, we start by extracting specific spots or tangible objects from the selected PG images, such as sports fields, lakes, the sun, indoor scenes, Gothic architecture, and more. We then utilize ChatGPT to expand these keywords into 5,000 prompts. For each prompt, we use the APIs of two modern AI systems, namely DALL·E2[2] and DreamStudio[3], to generate four different images. Finally, we create two databases, referred to as DALL·E2 and DreamStudio, each containing 20,000 PG images and their corresponding T2I images with similar scenes. Some image examples are shown in Fig. 6.

It is important to note that the original sizes of the DALL·E2 and DreamStudio images are 256×256 and 512×512, respectively. To ensure uniformity, we resize all PG and T2I images to three different resolutions: 256×256, 128×128, and 64×64. Following the resizing, we apply JPEG compression to the images using a randomly selected quality factor ranging from 75 to 95. Consequently, we have a total of six distinct databases generated by the two AI systems, each incorporating the three resolutions. For each database, we partition the 20,000 PG-T2I image pairs into three mutually exclusive sets: 12,000 pairs for training, 3,000 pairs for validation, and the remaining 5,000 pairs for testing purposes.

We employ an Adam optimizer with an initial learning rate of 2×10^{-4} and a batch size of 64. The learning rate is reduced by a factor of 0.1 every 30 epochs, and the total number of training epochs is set to 120. The number of heads (i.e. h) is set as 8. For training, we utilize 4 NVIDIA TITAN Xp GPUs. During evaluation, we consider the True Positive Rate (TPR) and the True Negative Rate (TNR) as our performance indicators. Once this manuscript is accepted, we will provide the source code of our model online [4], allowing readers to replicate our experimental results.

B. Comparative Experiments

To highlight the efficacy of our model, we conduct comparative studies against eight relevant techniques, including ResNet18 [4] and seven other contemporary methods for CG detection. These experiments are carried out on DALL·E2 and DreamStudio across three distinct resolutions. The results are presented in Table I. A review of these findings indicates that, in most instances, our proposed model outperforms the alternatives. T2I poses a significant challenge when it comes to visual discernment. Despite this, our model, along with several CG detection algorithms such as CGNet[15], has demonstrated the ability to detect T2I with considerable effectiveness, especially when the image resolution is high. For instance, at the resolution of 256×256, the accuracies of several methodologies exceed 98.5%. Remarkably, even when the resolution drops to 64×64, our model maintains an impressive performance, achieving 93.1% and 97.8% accuracy for the two T2I databases, respectively. It's worth noting that,

although ResNet18 was advocated for T2I detection in the research [4], our empirical results suggest that its detection performance falls short when compared to certain classic CG detection methods.

C. Robustness against Post-processing

In this section, we assess the robustness of our proposed model in the face of seven post-processing techniques, encompassing adjustments to chromaticity, brightness, contrast, sharpness, rotation, and the application of Gaussian blur and mean blur. Chromaticity, brightness, contrast, and sharpness modifications are facilitated by the ImageEnhance function from the Pillow library, while the remaining alterations are executed using the OpenCV library. To create a more realistic simulation of complex real-world scenarios, we've incorporated randomness into the parameters controlling the image alterations. For instance, the factors governing the degree of image manipulation (chromaticity, brightness, contrast) are randomly selected from a range of 0.5 to 2.5 for each image in the test dataset. Similarly, the factor controlling image sharpness is an arbitrary integer within the range of 0 to 4. Rotation degrees range from 0 to 360, and the kernel size for both Gaussian and mean filters is 5×5. In our experimental procedures, we utilize the models obtained from the previous subsection III-B to evaluate the post-processed test images directly. To keep the process simple, we restrict the detection accuracy display to image sizes of 256×256. The results of these experiments are illustrated in Table II and Table III for DALL·E2 and DreamStudio, respectively.

Observations from these tables reveal that our proposed model exhibits superior performance in terms of average accuracy when compared to current methods. Additionally, we find that among all post-processing operations, current methods demonstrate comparatively lower robustness against rotation

D. CG Detection

In this section, we assess the performance of our model on two widely used datasets in the field of CG detection, namely SPL2018 [16] and DsTok [21]. The SPL2018 dataset consists of a comprehensive collection of 13,600 images. It includes both CG images obtained from over 50 game rendering software and professionally captured photorealistic PG images using various camera models under diverse environmental conditions. To create training, validation, and testing sets, we partitioned the dataset following a ratio of 10:3:4, respectively. The DsTok dataset comprises a total of 9,700 images sourced from the internet. We partition them into training, validation, and testing sets using a ratio of 3:1:1. All test images are processed using center cropping with dimensions of 224×224, 112×112, and 56×56.

We conduct comparative experiments on both datasets at different resolutions, as presented in Table IV. The results demonstrate that our method consistently achieves the highest accuracy for both DsTok and SPL2018 at varying image resolutions. The improvement is particularly significant for DsTok. For example, our proposed method achieves accuracy improvements of 3.6%, 3.1%, and 4.2% compared to the sub-optimal method QuanNet for the three resolutions. In the case of SPL2018, our accuracy outperforms CGNet by 0.8%, 0.4%, and 0.8%, respectively.

E. Ablation study

The proposed model, as depicted in Fig. 3, incorporates two streams, namely the residual stream and the content stream, along with the cross-attention module to enhance information exchange between the two streams. In this section, we conduct an ablation study to investigate the impact of the residual stream, content stream, and cross-attention module in our proposed model for both the T2I and CG detection tasks. Among them, the residual stream and content stream are followed by the corresponding parts of feature fusion and classifier to achieve the task goal of binary classification. The image resolutions used in our experiments are 256×256 and 224×224 for the respective tasks. The results of the ablation study are presented in Table V. From the results presented in Table V, we observe that employing all three components (i.e., both streams and the cross-attention module) in the proposed model consistently achieves the highest detection accuracy across all cases. When any of the components is removed, the performance of the corresponding model experiences varying degrees of decline in most cases. These results strongly demonstrate the rationale behind the proposed model and reinforce its effectiveness for both the T2I and CG detection tasks.

IV. CONCLUSION

In this study, we have directed our attention towards the Test-to-Image (T2I) generation process inherent in AIGC, adopting an innovative, cross-attention enhanced dual-stream network for T2I and PG detection. In an endeavor to appraise the effectiveness of our proposed method, we generate two distinct T2I graphics databases, leveraging the capabilities of DALL·E2 and DreamStudio systems. Through exhaustive comparative and ablation experiments, our method affirms its superiority in detection performance, repeatedly surpassing traditional CG detection techniques across a diverse range of image resolutions. Importantly, our method demonstrate exceptional performance not just on our novel databases, but also excelled when applied to mainstream CG detection

datasets, specifically DsTok and SPL2018.

This research heralds a substantial advancement in the field of AI-generated image forgery detection. Our innovative, cross-attention enhanced dual-stream network offers a promising solution to the escalating challenges introduced by AIGC. The effectiveness of our approach lays a compelling groundwork for further exploration and enhancement in this domain, with the potential to evolve into more sophisticated and dependable techniques for image forgery detection amid the dynamic environment of AI-generated content. Looking towards the future, we plan to further fine-tune this dual-stream network approach and broaden our investigations to its applicability in detecting other types of AI-generated forgeries, thus bolstering our comprehensive response to the expanding realm of artificial intelligence in content creation.

Abstract—Identifying camera models used in digital images is an essential component of image forensics, which plays a vital role in preventing image-related crimes. While deep learning techniques, especially Convolutional Neural Networks (CNNs), are currently the most commonly used approach for Camera Model Identification (CMI) due to their high efficiency and accuracy, the performance of the CNN-based method will be adversely affected by the image content due to its structure.

In this study, we introduce a novel approach to CMI, which utilizes the Residual Neural Network (ResNet), Adaptive Preprocessing Module (APM), and Weight Fusion of Global Information (WFGI) to overcome this issue. The results of the experiment indicate that our proposed method has achieved an accuracy exceeding 97.5% when tested on a large-scale dataset that consists of 45 different camera models based on the Vision and Dresden database. Furthermore, our approach exhibits robustness under different attack scenarios, thereby highlighting its potential for practical use in image forensics applications.

I. Introduction

Images have been an essential medium for conveying information in human society since their inception due to their efficient and vivid characteristics. Smart devices such as smartphones, tablets, digital cameras, and smart wearables generate vast images daily and distribute them worldwide, making images increasingly crucial as information carriers. However, technological advances have also led to security risks, as image editing software has made it easy to modify image information which brings up the issue of credibility [1]. False images disseminated widely through the internet may cause a series of social security problems, making it vital to confirm the source of images to prevent harm to society. Camera Model Identification (CMI) studies can provide ideas to solve this problem.

A. Existing Methods

Fig. 1 illustrates the primary pipeline of the digital image imaging process. Almost every step in the imaging process leaves corresponding features and traces, and many successful works have taken advantage of these features to solve the problem of CMI. Generally, existing approaches to CMI can be categorized into three categories: those based on differences in camera hardware, those based on differences in software, and those based on deep learning.

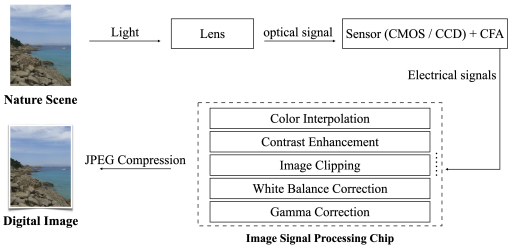

Fig. 1. The pipeline of image acquisition.

1) Hardware-based approaches involve utilizing differences in camera hardware, such as camera component attributes and differences in manufacturing processes. For instance, some researchers have used dust particles in front of the camera lens [2], lens distortion [3], and Photo Response Non-Uniformity (PRNU) [4] [5] [6] [7] to identify individual cameras.
2) Software-based approaches, on the other hand, determine the device through the differences in software, the unique features left by the imaging process of an image can be traced back to the corresponding camera model. Such as through the CFA interpolation [8], Automatic White Balance(AWB) [9] and compression statistics [10].
3) Deep learning-based approaches represented by convolutional neural networks (CNNs) has significantly improved the accuracy and scalability compared to traditional methods. With advanced neural networks such as GoogleNet [11], ResNet [12], and DenseNet [13], researchers have started applying these high-performance networks to CMI [14] [15] and furtherly demonstrating their superior performance compared to traditional CNNs.

B. Research Contributions

Although CNN-based solutions have become mainstream in CMI due to their excellent performance, they extract deep-level information related to devices, not content information. However, due to structural characteristics, image content still affects CNN-based approaches' performance. Therefore, scholars have proposed techniques to suppress content interference, such as preprocessing with denoising filters or algorithms and patch selection strategies. However, both techniques have areas for improvement. Preprocessing images with denoising filters or algorithms can enhance noise information and improve identification performance, but it can also cause the loss of partial original image information and retain "fingerprints" [16] that may help in identification. The patch selection strategy increases training data, improving training efficiency and accuracy. Still, since the resolution of selected patches is smaller than the complete image, original image information is insufficient, making it difficult to obtain good robustness [17]. This paper proposes a new method that performs well in large-scale datasets and maintains robustness in different manipulation scenarios by combining both techniques.

This paper is organized as follows: Section 2 presents related work briefly. Section 3 describes the method based on ResNet, APM, and WFGI. Section 4 introduces experimental settings, datasets, and experimental results analysis. Additionally, the method's robustness is verified by considering different attack scenarios. Finally, the paper concludes with a summary and brief introduction to future work.

II. Related Work

A. Patch Selection Strategy

Patch selection strategy is regarded as an effective and straightforward method that can improve the accuracy of the CNN-based method in CMI, and it is often used with the majority voting rule. In [18], Bondi et al. first proposed using the patch selection strategy to solve the problem of CMI and achieved 93% identification accuracy in the data set containing 18 camera models.

By extracting patches from the image, the interference of CNN by the image's content can be avoided to a certain extent because the smaller resolution will force the CNN to extract the deep-level information instead of content information. However, this also brings another problem: how to confirm the number of patches and extract the patches. In [19], the authors proposed selecting patches using a fixed-size window to slide over the completed images. In contrast, the authors randomly selected patches from the original images in [20]. In [17], Yunxia et al. proposed to select representative patches based on multiple criteria after enhancing the training data and conducted experiments on the Dresden database [21], including 6 camera brands, 18 camera models, and 74 camera instances, achieving an average performance of 98.14%, 92.62%, and 41.54% respectively.

B. Model Fusion

Model fusion usually refers to combining the logits of two or more different models differently. Among many methods of model fusion, the representative ones are voting, averaging, bagging, and boosting.

In [22], Aniket et al. proposed a method based on AdaBoost and achieved 99.1% average identification accuracy in the experiment of 10,507 images collected by ten cameras in the Dresden database. In [23], Anselmo et al. proposed a data-driven ensemble approach consisting of two models and reported 92.51% identification accuracy in the data set consisting of 2740 JPEG images from 10 camera models.

You et al. in [24] proposed Multiscale Content-Independent Feature Fusion Network (MCIFFN). MCIFFN is composed of three parallel networks. The experimental results show that MCIFFN achieves 98.51% accuracy in the data set containing 23 camera models from the Dresden database.

C. Preprocessing image by filter or algorithm

To maximize the extraction ability of the convolutional neural network, many scholars try to use different techniques to preprocess the image before feeding the original images into CNN.

In [4], Lukas et al. mentioned that each camera's sensor has a unique pattern noise. They use a wavelet-based denoising filter to extract the pattern noise from the image and then use the noise to determine the different cameras. Amel et al. in [25] respectively applied a High pass filter [26] and wavelet-based denoising filter [27] to preprocess images and compared the influence of these two different filters on identification accuracy.

III. Proposed Method

Figure 2 shows the pipeline of our method, which includes two stages: the training and testing stages.

During the training stage, two steps are executed in order. Firstly, the APM divides the training set into two blocks: the first is the Median Filter Residual (MFR) obtained by applying a median filter on the original image, and the second consists of patches obtained using the Elastic Patch Selection (EPS) algorithm. Secondly, we use two independent base models to process the MFR and patches obtained in the first step separately. Finally, we obtain one model trained on MFR, which we call the MFR model, and one model trained on patches, which we call the patch model.

During the testing stage, three steps are executed in order. Firstly, the APM divides the test set into MFR and patches. Secondly, we use the MFR and patch models for processing the MFR and patches separately, resulting in two independent logits, as shown in the lower part of the

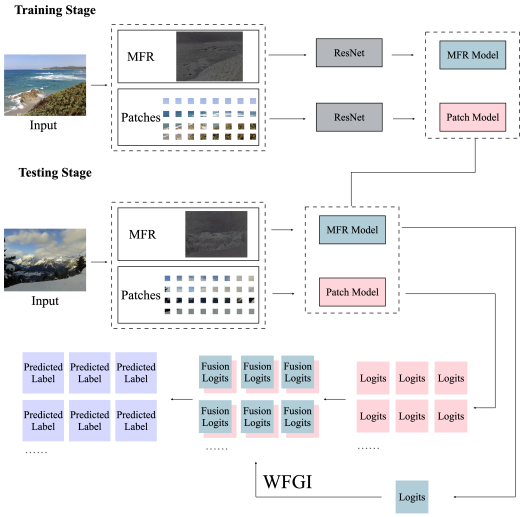

Fig. 2. The structure of our proposed method.

Fig. 2. Thirdly, the two independent logits are fused using the WFGI.

In this paper, we would use the ResNet with eighteen layers structure which was first proposed by Kaiming et al. in [12] as the base model due to its excellent performance under the deep structure situation compared with traditional neural networks.

A. Adaptive Processing Module

The first step of the proposed method in both the training and testing stages is to preprocess the dataset using APM, which consists of MFR extraction and patch extraction by EPS algorithm.

- MFR Extraction: The extraction process is as follows: assuming that the size of the median filter kernel is $k \times k$, and the original image is $O(i,j)$, then the output processed image by the median filter is $P(i,j)$. The MFR is

$$\begin{aligned} MFR &= MedianFilter_{k\times k}(O(i,j)) - O(i,j) \\ &= P(i,j) - O(i,j) \end{aligned} \tag{1}$$

  The median filter size will be determined by experiment in section 4.
- Patch Extraction: The patches are selected from the original images using the EPS algorithm, as shown in Figure3. The patch selection strategy has been demonstrated in many studies to be effective in improving accuracy. However, the methods of patch selection, size, and the number of patches significantly affect the model's performance.
  We propose an EPS algorithm to maximize the efficiency of model training and preserve the image's global information. EPS algorithm automatically calculates the step size of the horizontal and vertical movement of the crop window based on the patch selection number, crop window size, and original image size. This processing ensures that non-overlapping patches cover the whole image to the maximum extent possible. However, getting overlapping patches is unavoidable for images with small resolutions since the total area of patches may already exceed its pixel sum, as shown in Fig. 3.

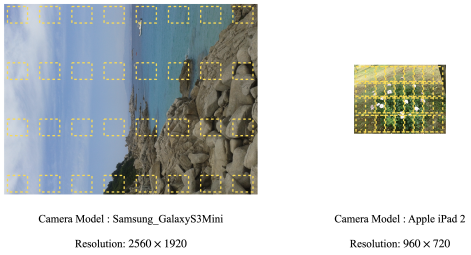

Fig. 3. The operation of EPS algorithm.

B. Weight Fusion of Global Information

The WFGI, the core of our proposed method, is a model fusion. Generally speaking, the conventional model fusion can only fuse different logits obtained by different models for processing the input with the same quantitative dimension, which is a one-to-one fusion approach. Our proposed WFGI is a one-to-many approach, which can fuse the logits obtained by the MFR model processing the MFR extracted from the image and multiple logits obtained by the patch model processing the patches of the image.

In Fig. 2, the MFR model outputs logits of one image while the patch model outputs N logits since we have divided a complete image into N patches by the EPS algorithm. Due to the number of logits output by the two models being different in dimension, it cannot be operated like the conventional model fusion. Therefore, we will weigh and fuse the logits output by the MFR model with the logits of each patch in a one-to-one way. Finally, each patch will get new fusion logits after WFGI. The process of WFGI is shown in the following formula:

$$L_F^{N_i} = L_M \times W_M + L_P^{N_i} \times W_P \tag{2}$$

where W_M and W_P represent the weights of MFR model and patch model respectively. L_M denotes the logits output by the MFR model and $L_P^{N_i}$ is the ith logits of the N patch of patches output by patch model. In this way, each patch can obtain complete image information through fusion with the output of the MFR model, which can effectively enhance its confidence. We will evaluate the identification performance of WFGI in experiment 2 in section 4. In this paper, we set both W_M and W_P to 0.5.

C. Performance Evaluation

In the early stages of CMI development, as with other classification tasks in the field of computer vision, the evaluation of accuracy was based on the following formula:

$$Accuracy = \frac{No.\ of\ correctly\ classified\ images}{No.\ of\ total\ images\ for\ testing} \times 100\% \quad (3)$$

However, the image-level accuracy can not well evaluate the classification ability of the model due to the majority voting operation has good fault tolerance to the prediction results of patches. Therefore, some researchers have proposed a more stringent evaluation protocol [28] [17], directly using the prediction results of patches to calculate the accuracy, which is called patch-level accuracy and the formula is as follows:

$$Accuracy = \frac{No.\ of\ correctly\ classified\ patches}{No.\ of\ total\ patches\ for\ testing} \times 100\% \quad (4)$$

In this paper, we would use patch-level accuracy to evaluate the performance of the proposed method unless otherwise specified.

IV. Experiments

For experiments in this research, we would use two databases: the Vision database [29] and the Dresden database.

For the Vision database, we will use all camera models inside the database, selecting the model instance with the most significant number of natural images for those models with more than one instance. We will consider Galaxy S III Mini GT-I8190N and Galaxy S III Mini GT-I8190 as the same camera model, as suggested in [20]. Therefore, the Vision database provides a total of 29 camera models. For the Dresden database, we will merge Nikon D70s and Nikon D70 into Nikon D70, as suggested in [17] [30], and randomly choose 16 camera models. Lastly, obtaining a large-scale data set containing 45 camera models. Detailed information is shown in Table I.

For our paper's experiment, we randomly chose 140 images from each camera model as the database, achieving a total of 6300 images. Thirty images from each camera model are used for the test set. At the same time, the remaining part is the development set (train set and validation set), and the ratio between the train set and validation set is set to 9:1. Unless otherwise specified, the following experiments were performed on the database constructed above.

All experiments were conducted on the PyTorch [31] and using the SGD optimization algorithm with initialization value as 0.001 and momentum as 0.9. The step size and gamma value of the learning rate decay are set to 50 and 0.1, respectively, while the maximum epoch setting is 100.

A. Experiment 1: Determined the parameter settings

In this experiment, we use ResNet to carry out experiments on the first 18 camera models in Table I to determine the parameter settings of the APM, including the size of the median filter kernel and the number of patches in the EPS algorithm introduced in section 3.

To determine the size of the median filter kernel, we firstly use median filters (implemented with the "cv2.medianblur" built-in function of the OpenCV library [32]) with different sizes ranging from 3 to 9 as shown in Table II to extract the MFR from the images, then fed MFR into ResNet and observe the impact of different sizes of median filters on the identification accuracy.

As the experiment result shows in Table II, using the median filter to preprocess the input image can effectively improve the identification accuracy. Taking everything into consideration, the size of the kernel will be set as 3.

Next, we would determine the number of patches selected by the EPS algorithm. We set the number of patches

TABLE II
Comparison of identification accuracy in different sizes of the median filter kernel.

Median Kernel Size	Original	3	5	7	9
Training Time (min)	11.81min	11.19min	12.73min	13.62min	13.71min
Accuracy (100%)	69.81%	92.96%	91.11%	90.74%	87.59%

ranging from 8 to 64 as shown in Table III.

The experiment results in Table III illustrate that the identification accuracy increases with the increase of the number of patches. However, it should be noted that the training time of the neural network will become longer at the same time, and the computational cost will also increase. Considering the balance between training efficiency and identification accuracy, the number of patches of our proposed EPS algorithm will be set to 32.

B. Experiment 2: Validation the performance of WFGI

This experiment aims to validate the performance of WFGI, which is the core of our proposed method. In this experiment, we would use the first 18 camera models from Table I as the experiment data set.

For ID1 in Table IV, we would only evaluate the performance of the patch model since we are now assessing the identification performance of the proposed method without WFGI. For ID2 in table IV, we would fuse the MFR model with the patch model by WFGI to obtain the identification accuracy after fusion.

The result in Table IV reveals that the fusion of the MFR model and patch model through WFGI can effectively improve identification performance with a slight increase in computational cost. Although ResNet can achieve 96.06% accuracy in 18 camera models, after WFGI, it can still achieve more than 2.5% improvement to 98.92% high accuracy, which demonstrates the potential of WFGI.

C. Experiment 3: Results on Vision database

In this experiment, we would use all the camera models from the Vision database, which is the first 29 camera models in Table I. We would compare our accuracy with Marra's method [20], which is currently the method with the most significant number of camera models and the highest identification accuracy on the Vision database to our best knowledge.

All the camera model we use in this experiment are precisely the same as [20], except we used the same numbers of test images while using fewer train and validation images, so this is a stricter setting technically. Therefore, it is reasonable to directly reuse the experimental results reported in [20]. In addition, [20] provides both patch-level and after majority voting image-level identification accuracy, so for comparison, we will also provide image-level accuracy in this experiment.

We report the identification accuracy of our proposed method in Table V. In [20], Marra et al. used DenseNet-40, DenseNet-121 and XceptionNet[33] with patch selection strategy to implement CMI respectively, where XceptionNet-based method obtained 95.15% patch-level accuracy and 99.31% image-level accuracy respectively. Compared with them, the experiment result demonstrates that our method achieved 98.41% patch-level accuracy and 99.54% image-level accuracy, respectively, which is highest in Table V.

D. Experiment 4: Results in large-scale data set

This experiment is performed on all camera models shown in Table I to evaluate the performance of our proposed method on a large-scale data set containing 45 camera models.

As the experiment result shows in Table VI, our proposed method shows good identification performance on a large scale of different camera models, achieving 97.54% accuracy across 45 camera models.

At the same time, we compare our proposed method with the situation using GoogleNet or AlexNet [34] as the base model. The result in Table VI reveals that whether using ResNet, GoogleNet, or AlexNet, WFGI can significantly improve the accuracy of identification, which demonstrates the generality of the WFGI.

E. Experiment 5: Result in manipulated data sets

In the actual application of CMI, the images we need to identify may have been variously processed or contaminated and do not have the original ideal quality.

Therefore, whether the proposed method has good robustness is very important for practical application. In this experiment, we selected 5 camera models from the Vision database. Each camera model provides 200 images, of which 80 are used as the test set, and the remaining 120 are divided into the train set and validation set in a ratio of 9 to 1, i.e. 108 and 12. The total number of the train set, validation set, and test set is 540, 60, and 400, respectively. Details of the data set is shown in Table VII. To test our proposed method's robustness, we propose four different simulation scenarios:

- JPEG Compression: JPEG compression by using the "cv2.imwirte" built-in function of the OpenCV library with two quality factors 70%, and 90%.
- Gaussian noise: Adding Gaussian noise by using the "imnoise" built-in function of the Matlab [35] with two variances settings, 0.1 and 0.01.
- Salt and Pepper noise: Adding salt and pepper noise by using the "imnoise" built-in function of the Matlab with two density settings: 0.1 and 0.01.
- Resize Operation: Resize the data set by using the "resize" built-in function of the Pytorch by two rescale factors, 0.9 and 1.1.

TABLE III
Comparison of identification accuracy in different numbers of patches selected by EPS

No. of Patches	8	16	32	64
Training Time (min)	29.50min	49.49min	93.75min	170.49min
Accuracy (100%)	93.91%	95.08%	96.06%	96.63%

TABLE IV
Comparison of identification accuracy with/without the WFGI.

ID	Method	Accuracy (100%)	Training Time (min)
1	ResNet	96.06%	93.75min
2	ResNet-WFGI	98.92%	104.94min

TABLE V
Comparison of identification accuracy in Vision data base including 29 camera models.

Method	Patch-Size	Pacth-Level Accuracy	Image-Level Accuracy
		%	
DenseNet-40-Based Method [20]	32 × 32 × 3	87.96	97.80
DenseNet-121-Based Method [20]	224 × 224 × 3	93.88	99.10
XceptionNet-Based Method [20]	299 × 299 × 3	95.15	99.31
Proposed Method	224 × 224 × 3	98.41	99.54

TABLE VI
Identification accuracy in the data set containing 45 camera models.

Method	Accuracy (100%)	Training Time (min)
AlexNet [34]	85.62	103.81
AlexNet-WFGI	94.28	114.26
GoogleNet [11]	95.07	292.49
GoogleNet-WFGI	97.44	310.33
ResNet	95.15	212.24
ResNet-WFGI	97.54	227.48

TABLE VII
Camera models used in testing robustness experiments.

ID	Camera Model	Brand	Resolution
1	P70A	Lenovo	1280 × 720
2	Xperia Z1 Compact	Sony	1920 × 1080
3	iPhone6 Plus	Apple	1920 × 1080
4	P8 GRA-L09	Huawei	1920 × 1080
5	Galaxy S4 Mini GT-19195	Samsung	1920 × 1080

Based on the above, we now have eight different data sets obtained from different manipulation of the original data set. In the training stage, the train set and validation set of both the original data set and manipulated data set are combined to generate a new data set called integrated data set. In this way, it increases the volume of the train set and validation set by 9 folds to 4860 and 540, respectively.

In the testing stage, the test set of the original data set and the test set of each manipulated test set will be counted for accuracy separately, as shown in Fig. 4.

In scenario one, we first test the performance of our proposed method under JPEG compression with different quality factors. In addition to the above-mentioned quality factors of 70% and 90%, we use the JPEG compression function with quality factors of 50%, and 80% to manipulate the test set of the original data set, as we did above, and then count and compare the accuracy.

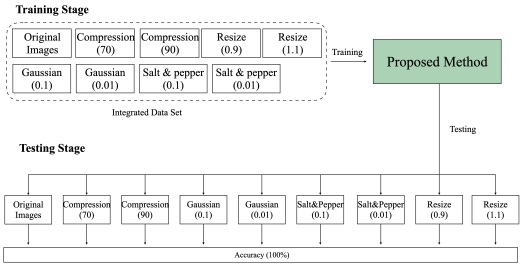

Fig. 4. The experiment setting of robustness validation.

TABLE VIII
Experiment results of our method under the scenario of JPEG compression.

Camera Models	Quality Factors				
	Original	50%	70%	80%	90%
	%				
P70A	99.88	99.10	98.95	99.22	99.69
Xperia Z1.	99.92	93.44	99.80	99.88	99.92
iPhone6 Plus	99.69	91.45	99.45	99.61	99.88
P8 GRA-L09	98.91	97.19	98.52	98.36	98.67
Galaxy S4.	99.77	96.33	98.67	99.06	99.41
Average	99.63	95.5	99.08	99.23	99.52

As seen in Table VIII, compared with original images, images after JPEG compression are slightly lower but still maintain a high identification accuracy. It is worth noting that the images with quality factors of 50% and 80% have not appeared in the train set and validation set. However, our proposed method can still achieve good accuracy, indicating that our method is generalized for JPEG compression and does not biased to the specific quality factor.

In scenario two, we evaluate the performance of the proposed method under the scenario contaminated by Gaussian noise. To further study the influence of Gaussian

noise on identification accuracy, we manipulate the test set with variances of 0.02, 0.03, 0.04, 0.05, 0.06, 0.07, 0.08, and 0.09 to validate whether our method can maintain good robustness under the noise of different variance which does not appear in the train set and validation set, and observe the trend that the identification accuracy with the gradual increase of noise variances.

As seen in Table IX, the accuracy of different variances shows certain dependence. The closer the variance of the test image is to 0.1 or 0.01, both of these settings appear in the train set and validation set, the higher the identification accuracy will be. Based on the analysis, we can conclude that the proposed method has a good generalization for Gaussian noise with different variances, even for the variance settings that do not appear in the train set and validation set.

In scenario three, we investigate the robustness of the proposed method under the scenario contaminated by adding salt and pepper noise.

As we did in scenario 2, we also manipulated the test set with densities of 0.02 to 0.09 to validate whether our method can maintain good robustness under the noise of different densities which does not appear in the train set and validation set. Table X presents the results. On the whole, our method can maintain good robustness. When the density is 0.03, it has the most significant influence on the accuracy, which is more than 7% lower than the original test set but still more than 90%.

In scenario four, we examine the performance of our proposed method in resisting resize operation. Table XI illustrates that our proposed method is robust to the resize operation of different re-scale factors. Although the factor of 0.7 has the greatest impact on the accuracy, it still maintains accuracy of 92.73%.

V. Conclusion

In this paper, we propose a camera model identification method based on ResNet, APM, and WFGI to improve the identification performance of the CNN-based method on CMI. Compared to other CNN-based methods, our proposed method fuses logits of different dimensions output from two models using WFGI. This approach saves global information using the patch selection strategy, allowing our method to maintain robustness while ensuring high accuracy. The experimental results show that the proposed method achieves more than 98% identification accuracy using a data set containing 29 camera models based on the Vision database.

In addition, we proposed four simulation scenarios to ensure that our method is robust under different adversarial conditions. These are JPEG compression, adding Gaussian noise, adding salt and pepper noise, and resizing operation. The experimental results show that our method can perform well in different scenarios. In future work, we aim to explore a particular fusion structure that can combine the patch selection strategy and global information of complete images without using model fusion.

***Abstract*—Screen content video (SCV) has been applied to various scenes, e.g. online meeting, remote desktop, cloud game, AR/VR and so on, generating massive screen content data and bringing huge pressure on transmission bandwidth. Rate control is an effective technique for improving bandwidth utilization, but existing rate control methods of SCV has not exploited characteristics of human visual system (HVS) fully, leaving space to improve coding efficiency. Therefore, this paper studies the characteristics of HVS and proposed a subjective rate control method for screen content coding (SCC). Concretely, first, a novel coding tree unit (CTU) level subjective rate-distortion (R-D) model is built by utilizing structural feature. Then, on this basis, a global optimization scheme of CTU-level bit allocation is derived. Finally, experimental results show that compared to the default rate control method in HM-16.20+SCM-8.8, the proposed method could averagely save 2.64% bit cost under similar subjective quality.**

I. Introduction

Screen content video has been applied to various scenes, e.g. online meeting, remote desktop, cloud game, AR/VR and so on, generating massive screen content data and bringing huge pressure on transmission bandwidth. To relieve the pressure of efficient transmission and storage of screen content, HEVC (high efficiency video coding)-SCC was formulated to improve compression efficiency of screen content coding (SCC) [1], plenty of new techniques (intra block copy, palette etc.) were designed by considering the features of screen content. At the same time, rate control (RC) as a crucial technique in enhancing the efficiency of compression, with its primary goal being to reduce distortion as much as possible within the constraints of bitrate limitations. General RC methods (e.g. HM-SCM) use objective quality metrics to measure image distortion, e.g. PSNR (Peak Signal to Noise Ratio), MSE (Mean Squared Error), ignoring the subjective perceptual characteristics of human visual system (HVS), leaving visual redundancy.

Hence, in recent years, there has been a tendency among researchers to utilize the perceptual attributes of the HVS to optimize RC and numerous Subjective Bit Allocation methods at the Coding Tree Unit (CTU) level have been introduced. Li et al. [2] found a linear relationship between SSIM and MSE by testing and proposed an CTU-level DSSIM -DMSE model to guide SSIM-based bit allocation. Zhou et al. modeled the pixel-level JND factor as distortion weights to optimize distortion at the frame level and CTU level [3]. Xiang et al. [4] proposed a fresh CTU-level perceptual distortion model using the JND factor to represent masking effects and then optimized the λ for each CTU. However, the above subjective bit allocation methods are designed for natural content video. Contrasting natural content video, screen content video possesses distinct features, for example, screen content image is usually mixed with graphics and text, containing plenty of sharp edges. Therefore, directly applying the rate control method of natural content video to screen content video will degrade encoding efficiency seriously.

Nowadays, researchers proposed many CTV-level rate control methods for screen content video. Yang et al. adopted three independent parameter updating methods for three different types of CTUs according to their respective rate-distortion (R-D) relationships [5]. Sanchez et al. [6] utilized the rate distortion information from coded CTUs to predict the current coding unit, due to the presence of numerous recurring words and patterns in the same screen content image. Chen et al [7] estimated the complexity of the remaining CTUs by a specially designed pre-analysis to allocate bitrate to each CTU. Esmaeeli et al. [8] proposed a content-based HEVC-SCC R-D model for different modes and sizes of CTUs. In conclusion, these RC techniques leveraged the unique attributes of screen content, thereby enhancing the efficiency of the coding process.

To the best of our understanding, there presently isn't a CTU-level subjective RC method specifically for screen content coding. This paper investigates the attributes of the HVS and puts forth a subjective rate control method designed for screen content coding. Experimental findings demonstrate that the suggested method could improve visual quality of screen content coding under similar bit consumption compared with the state-of-the-art method.

The remainder of this paper is organized as follows. Section II introduces the proposed subjective RC method. Section III describes the experimental design and results. Lastly, Section IV provides the conclusion for this paper.

II. Proposed Subjective Rate Control Method

A. Subjective R-D Modeling

The efficiency of bit allocation depends on the correctness of its R-D model. To choose a proper distortion model for screen content coding, A number of models for image quality (PSNR, SSIM, GMSD [9], GFM [10], ESIM [11], GSIM [12] and VSI [13]) were tested for HEVC-SCC distortion. The model

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

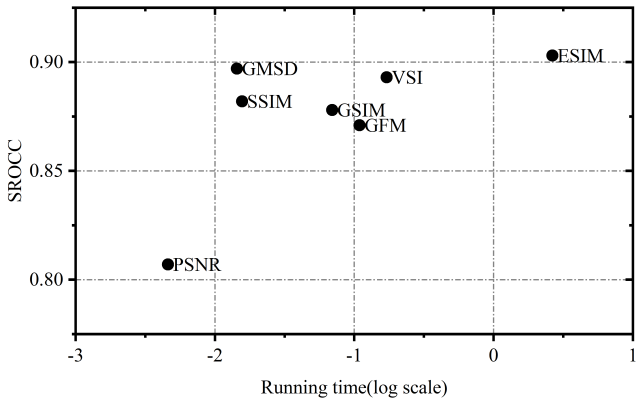

Fig. 1. Accuracy and complexity of the quality evaluation model.

accuracy and complexity of all models are shown in Fig.1. The accuracy of the quality models is assessed using the Spearman Rank-Order Correlation Coefficient (SROCC). Running time is used to evaluate computational complexity.

As evident from Fig. 1, GMSD is characterized by its precision and low computational complexity. In other words, GMSD achieves good compromise between model accuracy and computational complexity. Therefore, GMSD is applied to assess the subjective quality in this paper.

As mentioned above, screen content image is usually mixed with graphics and text, containing plenty of sharp edges. Thus structural information is very sensitive for HVS. To assure structural quality, gradient information is used to build the R-D model. The paradigm of the proposed R-D model is inspired by [14], to verify the performance of our model, we conducted an experiment, where a screen content sequence (*SlideEditing*) was randomly selected and encoded using the reference software HM-SCM, configured with low delay encoding mode and the encoded QP is 22. The bit cost and GMSD of each CTU are extracted and the R-D relationship are shown in Fig. 2, the fitting accuracy is over 96.04%. Thus the R-D model is built as

$$\frac{RG}{\mathrm{GMSD}} = \kappa R + \eta, \tag{1}$$

where κ and η represented factors associated with the screen contentt, R is the actual coded bitrate, G refers to the gradient magnitude and GMSD denotes the distortion.

B. Bit Allocation Optimization

From the R-D model expressed in (1), the value of λ can be deduced as follows:

$$\lambda = -\frac{\partial D}{\partial R} = -\frac{\eta G}{(\kappa R + \eta)^2}. \tag{2}$$

R can be written as

$$R = \frac{\sqrt{-\eta G/\lambda} - \eta}{\kappa}. \tag{3}$$

The distortion D can be calculated as follows:

$$D = \frac{G(\sqrt{-\eta G/\lambda} - \eta)}{\kappa\sqrt{-\eta G/\lambda}}. \tag{4}$$

Given target bitrate, the Lagrange multiplier optimized target is formulated as

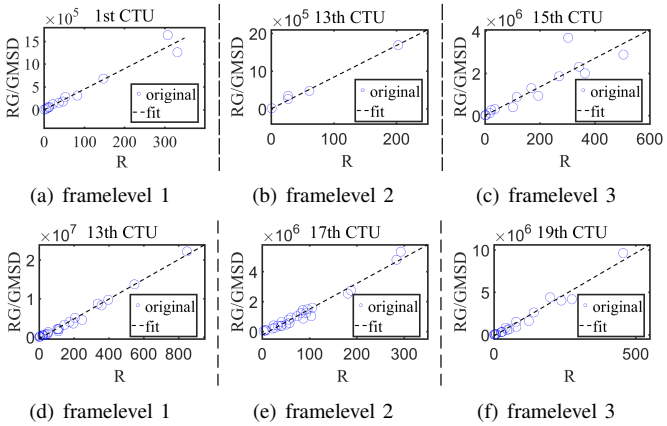
$$\begin{aligned} \{\lambda_1^*, \lambda_2^*, \ldots, \lambda_M^*\} &= \arg\min \textstyle\sum_{i=1}^{M} D(\lambda_i) \\ &\text{s.t. } \textstyle\sum_{i=1}^{M} R(\lambda_i) \le R_c, \end{aligned} \tag{5}$$

where λ_i^* denotes the optimal value of the ith CTU, M represents the count of CTU in a single fram, while R_c denotes the target bits of one frame.

According to Karush-Kuhn-Tucker (KKT) condition, (5) could be transformed into unconstrained optimization problems as

$$\begin{aligned} L = \sum_{i=1}^{M}\left(\frac{G_i}{\kappa_i} - \frac{\eta_i G_i\sqrt{-\lambda_i/\eta_i G_i}}{\kappa_i}\right) \\ + \mu\left(\sum_{i=1}^{M}\frac{\sqrt{-\eta_i G_i/\lambda_i} - \eta_i}{\kappa_i} - R_c\right), \end{aligned} \tag{6}$$

where the variables satisfy



$$\begin{cases} \kappa_i > 0, i = 1, \ldots, M \\ \eta_i < 0, i = 1, \ldots, M \\ \lambda_i > 0, i = 1, \ldots, M \\ \dfrac{\partial L}{\partial \lambda_i} = -\dfrac{\eta_i G_i}{\kappa_i}\cdot\sqrt{-\dfrac{1}{\eta_i G_i}}\cdot\frac{1}{2}\lambda_i^{-\frac{1}{2}} - \mu\cdot\dfrac{\sqrt{-\eta_i G_i}}{\kappa_i}\cdot\frac{1}{2}\lambda_i^{-\frac{3}{2}} \\ \mu\left(\sum_{i=1}^{M}\dfrac{\sqrt{-\eta_i G_i/\lambda_i} - \eta_i}{\kappa_i} - R_c\right) = 0. \end{cases} \tag{7}$$

The optimized Lagrange multiplier can be derived as

$$\lambda_i^* = \left(\frac{\sum_{i=1}^{M}(\sqrt{-G_i\eta_i}/\kappa_i)}{R_c + \sum_{i=1}^{M}(\eta_i/\kappa_i)}\right)^2. \tag{8}$$

The optimized bit allocation at CTU-level can be written as

$$R_i = \frac{\sqrt{-\eta_i G_i/\lambda_i^*} - \eta_i}{\kappa_i}, \tag{9}$$

(a) framelevel 1 (b) framelevel 2 (c) framelevel 3

(d) framelevel 1 (e) framelevel 2 (f) framelevel 3

Fig. 2. The fitted R-D model for (a)-(c):*SlideEditing* and (d)-(f):*Desktop*.

where R_i denotes the bits allocated to the ith CTU, κ_i and η_i are model parameters associated with screen content, G_i is the gradient magnitude of the ith CTU.

C. Model Parameter Update

Parameter Initialization: In the proposed R-D model, κ and η are two parameters pertaining to the screen content. Parameters of the first CTU at every frame level are initialized according to the average model parameter fitting results. In our experiment, κ and η are set to 7410 and -1000, respectively.

Parameter update: Model parameters will be updated after encoding one CTU, the updated parameters will be used for the next co-located CTU at the same frame level. Referring to method in [15], κ_{new} and η_{new} are updated as in (10) and (11)

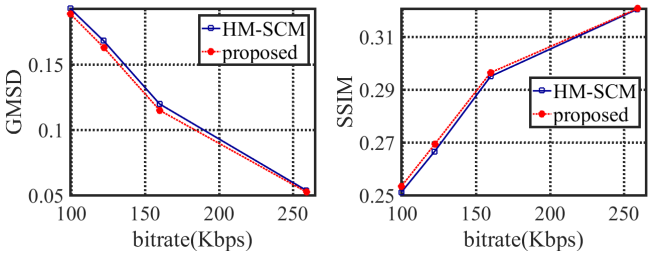
$$\kappa_{new} = \frac{\lambda_{old} R_{real} G_{old} + D_{real} G_{old}}{D_{real}^2}, \tag{10}$$

$$\eta_{new} = -\frac{\lambda_{old} R_{real}^2 G_{old}}{D_{real}^2}, \tag{11}$$

where λ_{old} and G_{old} are the parameter of the encoded CTU, R_{real} and D_{real} are the actual consumption bitrate and actual distortion of the encoded CTU, respectively.

D. Summary

The method we proposed could be outlined as follows:



1) Initialize R-D model parameters;
2) Calculate gradient magnitude of the current CTU;
3) Allocate bits to the current CTU according to (8) and (9);
4) Finish encoding the current CTU;
5) Update model parameters according to (10) and (11);
6) Return to 3) until finishing encoding of the current frame.

III. Experimental Result

In this section, we initially present the design of the experiment, followed by a comparison of the R-D performance, and finally, we present the subjective quality comparison.

A. Experimental Design

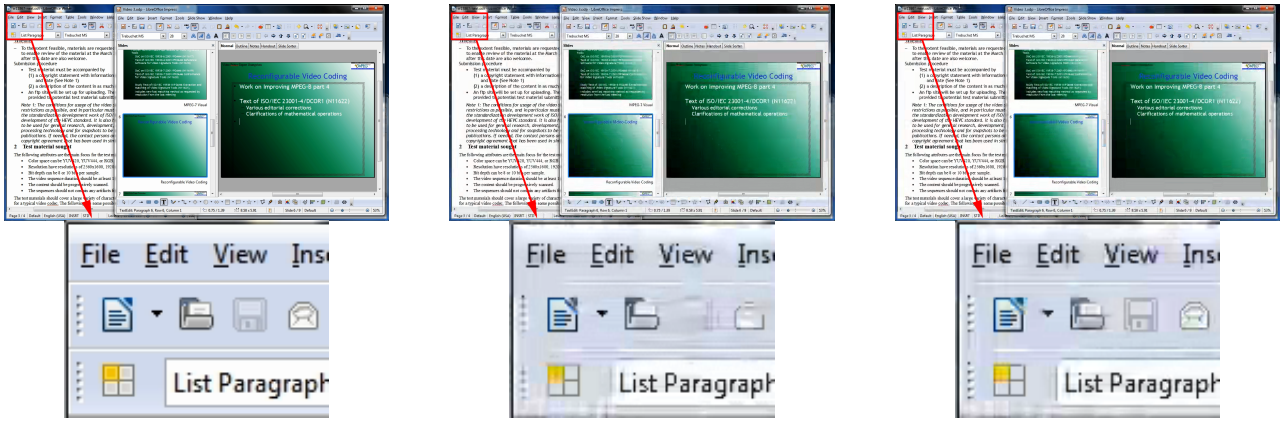
In order to confirm the effectiveness of our method, we implement it in HM-SCM which refers to HM-16.20+SCM-8.8 [16] in this paper and the default RC method in HM-SCM is compared with our method. Test screen content sequences are randomly selected from the Common Test Conditions proposal [17], containing TGM (Text and graphics with motion) type sequences (*ChineseDocumentEditing*, *CircuitLayoutPresentation*, *ClearTypeSpreadSheet*, *Desktop*, *EnglishDocumentEditing*, *SlideEditing*, *WordEditing*), M (mixed content) type sequences (*BasketballScreen*, *KristenAndSaraScreen*, *video_conferening_doc_sharing*) and A (animation) type sequences (*BigBuck*, *ChinaSpeed*). These sequences are all encoded with low delay B (LDB) configuration. The sequences are encoded utilizing four distinct QPs (22, 27, 32, 37) to generate the target bitrate of RC methods. The testing platform is a computer with hardware device Intel (R) Core (TM) i3-10100 @ 3.60 GHz.

(a) in terms of GMSD (b) in terms of SSIM

Fig. 3. R-D curve comparison for *ClearTypeSpreadsheet*.

TABLE I
Rate Distortion Performance Compared with HM-SCM

Type	Sequence	BD-rate(%)		
		GMSD	PSNR	SSIM
TGM	*ChineseDocumentEditing*	-3.53	-2.03	-3.00
	CircuitLayoutPresentation	-2.47	-0.99	-2.36
	ClearTypeSpreadsheet	-2.57	-1.84	-2.02
	Desktop	-4.40	-4.45	-5.94
	EnglishDocumentEditing	-4.55	-1.01	0.74
	SlideEditing	-1.33	-2.18	-6.36
	WordEditing	-3.69	-4.29	-3.40
M	*BasketballScreen*	-3.02	-7.03	-4.24
	KristenAndSaraScreen	-0.35	-2.79	-1.18
	video_conferencing_doc_sharing	-4.85	-8.46	-2.68
A	*BigBuck*	-2.85	-5.45	-3.09
	ChinaSpeed	-1.02	-2.42	-2.06
	Average	**-2.64**	**-3.58**	**-2.97**



B. R-D Performance Comparison

The encoding efficiency is evaluated using the BD-rate (Bjøntegaard delta bit rate), which represents the bitrate saving under the same quality. Table I displays the BD-rate results (using three quality metrics) of the method we proposed in comparison to HM-SCM. As evident from Table I, firstly, compared with HM-SCM, the proposed method could averagely achieve BD-rates of 2.64%, 3.58% and 2.97% in terms of GMSD (the smaller GMSD is, the higher the quality is), PSNR and SSIM respectively. Secondly, the method we proposed could realize a performance gain for all the sequences. Thirdly, the method proposed could attain performance benefits for all three type sequences (TGM, M, A).

Moreover, Fig. 3 provides a comparison of the R-D curves for *ClearTypeSpreadsheet* using GMSD, PSNR, and SSIM as evaluation metrics. It can be observed that the method proposed delivers the highest quality at all the bitrate consumption.

C. Subjective Quality Comparison

Fig. 4 shows a comparison of subjective quality for *SlideEditing*, contrasting the proposed method with HM-SCM. We can see that under similar bit consumption, the proposed method could preserve more structural information than HM-SCM for

(a) Original

(b) HM-SCM (bit: 232, GMSD: 0.078, PSNR: 29.065, SSIM: 0.314)

(c) Propose (bit: 224, GMSD: 0.071, PSNR: 29.637, SSIM: 0.317)

Fig. 4. Subjective quality comparison for 186th frame of *SlideEditing* encoded with LDB configuration and QP 37.

the graphics content, thereby has better visual quality than HM-SCM. The key factor is that the proposed method allocate more bits for CTUs with more sharp edges.

D. Encoding Complexity

$$\Delta T_{all} = \frac{T_P - T_C}{T_C} \times 100\%, \tag{12}$$

$$\Delta T_G = \frac{T_G}{T_C} \times 100\%, \tag{13}$$

Table II presents the increase in encoding complexity when comparing the proposed method with HM_SCM, where ΔT_{all} represents the total encoding complexity increase and is defined as in (12), ΔT_G represents the encoding complexity increase caused by gradient calculation and is defined as in (13), T_P represents the the encoding time of the proposed method, T_C denotes the encoding time of HM_SCM, T_G is the time cost of gradient calculation. We can see that firstly, the proposed method averagely increases encoding time by 9.06% compared with HM_SCM. Then, the encoding complexity increase is mainly caused by gradient calculation. And the computational time of gradient calculation could be further reduced through code optimization (such as parallelism). Finally, for sequences of TGM type, ΔT_G is larger than ΔT_{all}, because the proposed bit allocation scheme allocates more bits for key frames, which could reduce quality refinement and encoding time [18].

TABLE II
ENCODING COMPLEXITY INCREASE

Type	ΔT_{all}	ΔT_G
TGM	11.23%	11.36%
M	11.06%	10.89%
A	4.89%	4.31%
Average	9.06%	8.85%

E. Conclusion

In this paper, we propose an optimization scheme for subjective bit allocation at the CTU-level, aimed at boosting the compression efficiency of screen content coding. First, a novel R-D model is constructed grounded on the perceptual characteristic of HVS, measured by the gradient magnitude similarity deviation value. Then, the CTU-level subjective bit allocation for screen content coding is derived, using the subjective R-D model as a foundation. Finally, experimental results indicate that, the proposed method could obviously improve the subjective quality under similar bit consumption compared to existing methods.

Multimodal Emotion Recognition based on 2D Kernel Density Estimation for Multiple Labels Fusion

Zhaojie Luo* and Kazunori Komatani *
* SANKEN, Osaka University, Japan
E-mail: luo@sanken.osaka-u.ac.jp; komatani@sanken.osaka-u.ac.jp

***Abstract*—Psychological emotion can be typically categorized into discrete emotion states, such as anger, happiness, and neutrality labels, as well as estimated as degrees of a 2D continuous valence-arousal (VA) space. Previous studies on multimodal emotion recognition have employed fusion mechanisms for multiple modalities but treated emotion labels and VA degrees as separate recognition tasks. By modeling the relationship between these different labels, it becomes possible to leverage training datasets with different types of labels for improving multimodal emotion recognition. In this study, we explore the utilization of multiple labels by employing a 2D Kernel Density Estimation (2D-KDE) method to mathematically model their relations. Subsequently, we propose a label fusion layer (LFL) based on these relations to adjust the predicted probabilities of emotion states obtained from existing baselines of multimodal emotion recognition networks. Through extensive experiments, we demonstrate the effectiveness of our proposed model in improving emotion recognition performance and achieving superior results on the IEMOCAP and OMG-Emotion datasets.**

I. Introduction

The recognition of emotions in human-to-human communication is greatly influenced by the underlying emotional aspects embedded in our language. The emerging field of automatic emotion recognition (AER) aims to identify emotions from various input signals, such as audio, text, or facial image signals. Previous studies have shown that humans rely on multiple modalities to comprehend emotions, rather than relying solely on a single modality [1]. For example, research highlighted in [2] indicates that voice calls convey more information than text messages, suggesting that the effective prosody of audio can provide additional cues for emotion recognition. Similarly, studies have indicated that face-to-face communication is more effective in conveying emotions compared to voice calls alone [3], suggesting that visual cues play a significant role in emotion classification.

Given the importance of multiple modalities in emotion recognition, fusion methods that combine different modalities have gained substantial popularity in the field. These fusion methods can be broadly categorized as early fusion [4], late fusion [5], [6], or hybrid fusion approaches [7], [8].

On the other way, in the realm of emotions, previous research has put forth two primary perspectives on their classification. The first perspective posits that emotions are distinct and fundamentally different constructs [9]. According to this view, emotions are discrete categories that are not directly comparable to one another. The second perspective suggests that emotions can be characterized in terms of dimensional groupings [10]. This perspective proposes that emotions can be represented along continuous dimensions, specifically valence (measuring positivity or negativity) and arousal (quantifying the intensity or strength of the emotional response). In light of these perspectives, psychological labels for emotions can typically be divided into two categories. The first category encompasses discrete emotion states such as anger, happiness, and neutrality, which represent specific emotions. The second category involves a continuous two-dimensional (2D) space that encompasses degrees of valence and arousal, providing a more nuanced representation of emotions.

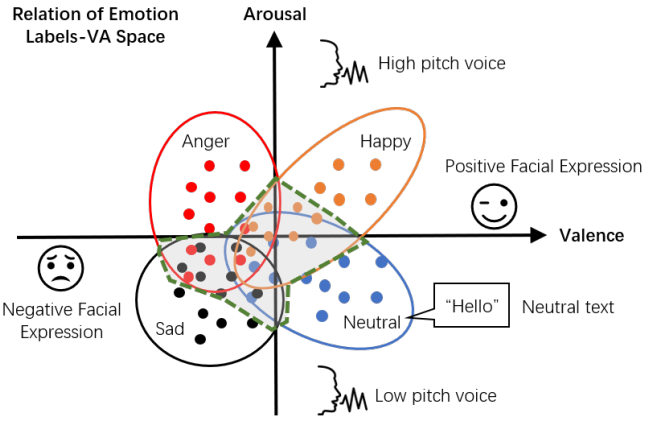

Fig. 1. Relations between emotion states and Valence-Arousal space.

However, previous studies have predominantly treated emotion state labels and valence-arousal degrees as separate entities, utilized for distinct tasks such as emotion classification and valence-arousal degree estimation, respectively. Limited efforts have been made to integrate these different label types into a unified task. Recent studies have proposed that employing the valence-arousal (VA) space to represent both emotion dimensions and emotion states is a more efficient and effective approach for solving multimodal-related problems than relying solely on discrete emotion states [11].

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

To illustrate this integration, Figure 1 exemplifies how different modalities can be associated with the VA space. The pitch feature of audio, recognized as one of the most reliable emotion features [12], can be easily annotated with arousal degrees. Visual features, on the other hand, are well-suited for recognizing valence degrees. The text modality provides a crucial basis for recognizing emotion states. By utilizing the VA space, a more comprehensive and holistic representation of emotional information can be achieved. This, in turn, leads to improved performance in multimodal emotion recognition tasks.

In this study, we aim to improve the accuracy of emotion recognition by leveraging the relationships between emotion states and the valence-arousal (VA) space. To achieve this, we propose a network architecture that integrates VA-degree estimation networks (VA-networks) with emotion state recognition networks (ER-networks) into a single task. The objective is to enhance the overall emotion recognition accuracy by considering both emotion states and VA degrees simultaneously.

Figure 1 illustrates that emotion states and VA degrees exhibit overlapping and non-overlapping areas in the VA space. This indicates that they are neither entirely independent nor completely dependent on each other. To address this relationship, we utilize a 2D kernel density estimation (KDE) technique to calculate the probability area in the VA space for each emotion state. This KDE-based estimation allows us to quantify the association between emotion states and their corresponding VA regions. We refer to these KDE probability estimates as Label Fusion Layers (LFL). The LFL acts as a mechanism to adjust the predicted results for the basic emotion state recognition task by considering the probability distribution of VA degrees associated with each emotion state. By incorporating this information, we aim to refine and improve the accuracy of the emotion state predictions.

To evaluate the effectiveness of our proposed LFL approach, we compare its performance against several baseline models. These baselines include the BC-LSTM model, which is based on Long Short-Term Memory (LSTM) networks [5], the MMAN model, which is based on Transformer networks [8], and the HFGCN model, which utilizes Graph Convolutional Networks (GCN) [13]. We experiment with different kernel sizes in the 2D KDE to examine their impact on the performance of the emotion recognition task.

To conduct our evaluation, we utilize publicly available datasets, namely the IEMOCAP dataset [14] and the OMG-Emotion dataset [15]. These datasets provide a diverse range of multimodal data, including audio, visual, and textual modalities, along with annotations for emotion states and VA degrees. By employing these datasets, we can assess the performance of our proposed LFL approach in comparison to the baseline models and gain insights into its effectiveness in enhancing emotion recognition accuracy.

The rest of the paper is organized as follows. Section II presents the details of the related works. Section III introduces the proposed labels fusion based network. Section IV describes the experimental setup. Section V reports the results and analysis. Finally, conclusions are drawn in Section VI.

II. Related Work

A. Valence Arousal Space and Discrete Emotion States

In the field of emotion research, the Valence-Arousal space is a commonly used two-dimensional representation that captures the emotional dimensions of valence and arousal. Valence represents the positivity or negativity of an emotion. It ranges from negative or unpleasant emotions (e.g., sadness, anger) to positive or pleasant emotions (e.g., happiness, joy). The valence dimension is typically represented on a continuum, with negative emotions on one end and positive emotions on the other. Arousal, on the other hand, represents the level of physiological and psychological activation associated with an emotion. It ranges from low arousal (e.g., calmness, relaxation) to high arousal (e.g., excitement, fear). The arousal dimension is also represented on a continuum, with low arousal at one end and high arousal at the other.

By combining the valence and arousal dimensions, the Valence-Arousal space allows for a comprehensive representation of emotions. Different emotions can be positioned within this space based on their valence and arousal values. For example, emotions with high positive valence and high arousal, such as excitement, would be located in the upper-right quadrant of the Valence-Arousal space. Discrete emotion states, on the other hand, refer to specific emotions that are categorized and labeled separately. Examples of discrete emotion states include happiness, sadness, anger, fear, surprise, disgust, and neutral. These discrete emotions are distinct and have their own unique characteristics and patterns of valence and arousal within the Valence-Arousal space. In research and analysis, the Valence-Arousal space and discrete emotion states are often used to understand and classify emotions, study emotional responses, and develop models and algorithms for emotion recognition and analysis

B. 2D Kernel Density Estimation

Two-Dimensional Kernel Density Estimation (2D KDE) is a statistical technique used to estimate the probability density function (PDF) of a two-dimensional random variable based on observed data points. It extends the concept of Kernel Density Estimation (KDE), which is primarily used for univariate data, to handle data in two dimensions. The kernel function determines the shape and width of the smoothing window around each data point. It is typically a symmetric, positive-valued function, such as the Gaussian kernel. The bandwidth parameter, denoted by h, controls the width of the kernel and influences the smoothness of the estimated density. A larger bandwidth results in a smoother estimate but may oversmooth the data, while a smaller bandwidth captures more local details but may introduce more noise.

To estimate the 2D PDF, the kernel function is placed at each data point, denoted by (x_i, y_i), and the contributions from all kernels are summed up. The result is a density estimate, denoted by $\hat{f}(x, y)$, that assigns higher density values

to regions with a higher concentration of data points and lower density values to sparser regions. Mathematically, the 2D KDE can be represented as:

$$\hat{f}(x,y) = \frac{1}{n}\sum_{i=1}^{n} K\left(\frac{x-x_i}{h}, \frac{y-y_i}{h}\right)$$

where n is the number of observed data points, and $K(u,v)$ is the kernel function, typically symmetric and positive-valued. The choice of kernel function, $K(u,v)$, and bandwidth, h, are crucial in 2D KDE. Different kernel functions, such as the Gaussian kernel [16], Epanechnikov [17], biweight [18], or triangular kernels [19], can be used depending on the desired properties of the estimate. Bandwidth selection methods, such as rule-of-thumb bandwidth estimator (RT) [20], automatic bandwidth selectors (Unbiased Cross Validation [21], Biased Cross Validation [22], or Complete Cross-Validation [23]), help determine an optimal bandwidth that balances the trade-off between bias and variance.

In this study, to capture the relationships between emotion states and the VA space, we employ a 2D kernel density estimation (KDE) technique. The KDE estimates the probability density function for each emotion state in the VA space, considering both overlapping and non-overlapping areas. The KDE provides a comprehensive representation of the association between emotion states and their corresponding VA regions.

III. Method

A. Framework

Our proposed architecture, depicted in Figure 2, utilizes emotion recognition networks (ER-networks) and Valence Arousal degree estimation networks (VA-networks) with integrated label fusion layers. Both the ER-networks and VA-networks share identical architectures, which are built upon baseline models such as LSTM, Transformer, and GCN. The detailed explanation of these baseline models can be found in Section IV-C. To enhance emotion recognition using valence arousal degrees, we employ a label fusion layer, as described in Section III-B, which transforms valence arousal degrees into the probability density of emotional states denoted as $\hat{f}_h^{\mathbf{e}}(v,a)$. This transformation is accomplished through the use of 2D kernel density estimation (2D-KDE), a technique explained in Section II-B. The predicted probability distribution ($\mathcal{P}^e(X)$) of emotion labels obtained from the ER-networks is combined with the transferred probability distribution ($\hat{f}_h^{\mathbf{e}}(v,a)$) of emotion labels derived from the VA-networks(consist of valence degrees network and arousal degrees network). This fusion process yields the final probability distribution ($\mathcal{G}^e(X)$) of emotions. For the task of emotion recognition, we output the emotional state with the highest probability.

B. Labels Fusion Layer

To perform the multi-label fusion, we applied 2D kernel density estimation (2D-KDE) to determine the "centered" area of each emotion states $\mathbf{e} \in \{happy, sad, neutral, angry\}$, based on their corresponding valence and arousal degrees

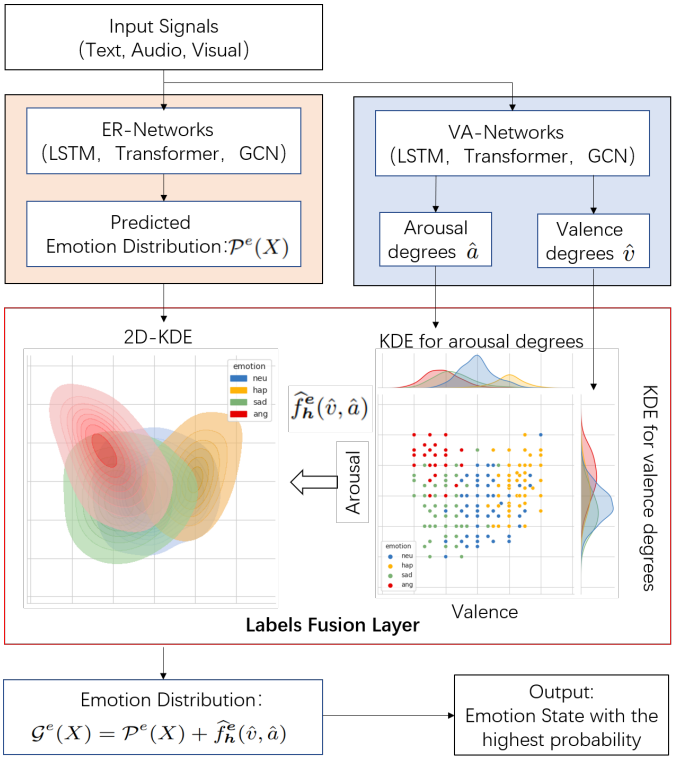

Fig. 2. Architecture for models

$(V^{\mathbf{e}}, A^{\mathbf{e}})$. The 2D kernel density estimation is then applied as follows:

$$\hat{f}_h^{\mathbf{e}}(v,a) = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{h_v^{\mathbf{e}}}\frac{1}{h_a^{\mathbf{e}}}K(\frac{v^{\mathbf{e}}-V_i^{\mathbf{e}}}{h_v^{\mathbf{e}}})K(\frac{a^{\mathbf{e}}-A_i^{\mathbf{e}}}{h_a^{\mathbf{e}}}) \quad (1)$$

Each of the n observations is of the form $(V_i^{\mathbf{e}}, A_i^{\mathbf{e}})$, where the $V_i^{\mathbf{e}}$ indicates the value that the random variable valence degrees $V^{\mathbf{e}}$ takes on at the i th observation, and the $A_i^{\mathbf{e}}$ represents the same for $A^{\mathbf{e}}$. ($h_v^{\mathbf{e}}$, $h_a^{\mathbf{e}}$) are the bandwidths employed in the 2D-KDE for valence degrees and arousal degrees. K is the kernel function, which are described in the 2D-KDE of the related work (Section II-B). Among the Kernels, the Gaussian kernel [16] and the Epanechnikov kernel [17] are often used in previous media data density estimation works. As proved in [24], the Gaussian kernel is quick and easier to compute, thus we choose Gaussian Kernel $K(x) = \frac{1}{\sqrt{2\pi}}exp\left(\frac{1}{2}(-x^2)\right)$ as Kernel function. Then the Density function $\hat{f}_h^{\mathbf{e}}(x)$ can be calculated as

$$\begin{aligned}\hat{f}_h^{\mathbf{e}}(v,a) &= \hat{f}_{h_v^{\mathbf{e}},h_a^{\mathbf{e}}}(v^{\mathbf{e}},a^{\mathbf{e}}) \\ &= \frac{1}{n}\sum_{i=1}^{n}\frac{1}{h_v^{\mathbf{e}}}\frac{1}{h_a^{\mathbf{e}}}\cdot\frac{1}{\sqrt{2\pi}}exp\left\{\frac{1}{2}\left(-(\frac{v^{\mathbf{e}}-V_i^{\mathbf{e}}}{h_v^{\mathbf{e}}})^2\right)\right\} \\ &\quad\cdot\frac{1}{\sqrt{2\pi}}exp\left\{\frac{1}{2}\left(-(\frac{a^{\mathbf{e}}-A_i^{\mathbf{e}}}{h_a^{\mathbf{e}}})^2\right)\right\}\end{aligned} \quad (2)$$

For the bandwidth ($h_v^{\mathbf{e}}$, $h_a^{\mathbf{e}}$), as described in Related work (Section II-B), the previous works tried objective rule-of-thumb bandwidth estimator (RT) [20] and automatic bandwidth

selectors (Unbiased Cross Validation [21], Biased Cross Validation [22], and Complete Cross-Validation [23]) to minimize the estimation error of the target density $\hat{f}_h^{\mathbf{e}}()$. Among them, the RT ($h_{RT} = (\frac{4\hat{\sigma}^5}{3n})^{\frac{1}{5}} \approx 1.06\hat{\sigma}n^{-1/5}$) is a quick, simple, and inexpensive selector for the optimal choice for normal-like data. As shown in Fig. 2, the Valence and Arousal degrees trend to be normal-like data, the bandwidth in $\hat{f}_h^{\mathbf{e}}()$ can be calculated as

$$h_a^{\mathbf{e}} = (\frac{4\hat{\sigma_a^{\mathbf{e}}}^5}{3n})^{\frac{1}{5}} \approx 1.06\hat{\sigma_a^{\mathbf{e}}}n^{-1/5}; \\ h_v^{\mathbf{e}} = (\frac{4\hat{\sigma_v^{\mathbf{e}}}^5}{3n})^{\frac{1}{5}} \approx 1.06\hat{\sigma_a^{\mathbf{e}}}n^{-1/5} \tag{3}$$

where, $\hat{\sigma_a^{\mathbf{e}}}$ and $\hat{\sigma_v^{\mathbf{e}}}$ are the standards of valence degrees and arousal degrees for emotion $\mathbf{e} \in \{neutral, happy, angry, happy\}$.

Note that the kernel weights correspond to equal bandwidth in each direction, i.e. $\boldsymbol{h} = (h_a^{\mathbf{e}}, h_a^{\mathbf{e}})^\top = (1,1)^\top$. When we use different bandwidths, the observations around (v, a) in the density estimate $\widehat{f}_{\boldsymbol{h}}^{\boldsymbol{e}}(v, a)$ will be used with different weights in both dimensions.

C. Classification

For the classification stage, the multimodal emotion features X are fed into three fully connected networks: an emotion classifier, a valence classifier, and an arousal classifier. Each of these networks includes a fully connected layer with a softmax function to produce the probability distributions of the emotion labels $\mathcal{P}^e(X)$, arousal degrees $\mathcal{P}^a(X)$, and valence degrees $\mathcal{P}^v(X)$. To incorporate the valence and arousal degrees into the emotion probability, we extract the maximum outputs of the arousal degrees $\hat{a} = argmax(\mathcal{P}^a(X))$ and valence degrees $\hat{v} = argmax(\mathcal{P}^v(X))$. These values are then transferred to the emotion probability distribution $\widehat{f}_{\boldsymbol{h}}^{\boldsymbol{e}}(\hat{v}, \hat{a})$ using the Label fusion Layer described in Section III-B. Finally, the distribution $\mathcal{G}^e(X)$ of the emotion labels can be adjusted as follows:

$$\mathcal{G}^e(X) = \mathcal{P}^e(X) + \widehat{f}_{\boldsymbol{h}}^{\boldsymbol{e}}(\hat{v}, \hat{a}) \tag{4}$$

D. Training Steps

According to the VA model [25]–[27] based on psychology, emotions can be categorized or described using a two-dimensional VA subspace. In light of this, we have designed a special loss function $L_{e,v,a}$ to jointly predict emotion labels and VA degrees. This loss function employs categorical cross-entropy $\mathcal{L}$ for both emotion classification and VA classification. The formulation is as follows:

$$L_{e,v,a} = W_1\mathcal{L}(\mathcal{P}_i^e, y_i^e) + W_2\mathcal{L}(\mathcal{P}_i^v, y_i^v) + W_3\mathcal{L}(\mathcal{P}_i^a, y_i^a), \\ \mathcal{L}(\mathcal{P}_i, y_i) = -\sum_{i=1}^{C} y_i \log(\mathcal{P}_i) \tag{5}$$

In this equation, C represents the number of input data, and $\mathcal{P}_i^e, \mathcal{P}_i^v, \mathcal{P}_i^a$ are the model's output probability distributions for the emotion labels, valence degrees, and arousal degrees, respectively, for the i-th data sample. The expected labels for emotion, valence, and arousal are denoted as y_i^e, y_i^v, y_i^a, respectively. The weights W_1, W_2, W_3 are hyperparameters that determine the importance of each loss term and can be set manually or optimized using methods such as the Tree-structured Parzen Estimator (TPE) [28], which is an automatic hyperparameter tuning method. In our experiments, we found that setting $W_1 = 0.6$, $W_2 = 0.2$, and $W_3 = 0.2$ yielded the best results for the weights.

As the VA degrees are discrete but ordinal, we experimented with different types of loss functions in our multitask loss formulation, including both regression-type and classification-type losses. However, the cross-entropy loss was found to be significantly better than other types of losses.

TABLE I
DISTRIBUTION OF TRAINING AND TEST SETS.

Dataset	Split	Utterance
IEMOCAP	Train/Test	5810/1623
OMG-Emotion	Train/Test	2441/2229

IV. EXPERIMENTAL SETUP

A. Dataset

In this work, we utilizes the relation between emotion states and the Valence-Arousal space, which requires datasets (such as IEMOCAP and OMG-Emotion) that include both valence and arousal labels, as commonly used in multimodal emotion recognition.

The **IEMOCAP** [14] dataset comprises 10,000 videos consisting of 5-minute dyadic conversations, specifically collected for human emotion analysis. Each conversation involves two speakers, and the dialogues are further segmented into individual spoken utterances. Each utterance within every dialogue is annotated with an emotion label. To align with previous works, we consider the emotion classes of angry, happy (excited), sad (frustrated), and neutral. Moreover, in addition to emotion labels, each utterance was assessed by two evaluators for its valence and arousal degrees, which range from one to five. The final valence and arousal (VA) degrees were obtained by averaging the scores from the two evaluators.

The **OMG-Emotion** [15] dataset were collected from YouTube with no environmental constraints. The dataset is annotated with seven discrete emotion states: *disgust, fear, happiness, surprise, sadness, anger,* and *neutral*. Additionally, it includes two continuous emotion labels: *arousal* in the range [0,1] and *valence* in the range [-1,1]. This study specifically focuses on four emotion classes: *anger, happiness (including surprise), sadness (including disgust and fear)*, and *neutral*, aligning with previous research in the field.

Speakers in the training and test sets were kept disjoint from each other for both datasets under the assumption of being unknown at inference time. We used 10% of the training dialogues as the validation set and followed the previous work [8], [15] to set distribution of training and test sets shown in Table I

B. Features Extraction

We followed *Poria et al.* [5] for the extraction of low-level features. To extract these features, we initially separate the input video of an utterance into its corresponding text, video frames, and speech modalities. Then, individual pre-trained networks, transferred from other tasks, are employed for the extraction process. For each modality, the feature of each utterance is extracted as a fixed-length vector."

Speech: We utilized the OpenSMILE toolkit [29] in combination with the IS13-ComParE feature set [30] to extract various features from the speech waveform, including pitch and voice intensity. The extraction process involved a frame-rate of 30 Hz and a sliding window of 100 ms. Prior to feature extraction, the raw waveform underwent normalization using Z-standardization, and a voice intensity threshold was applied to identify segments with vocal expressions. The extracted features encompassed Mel Frequency Cepstral Coefficients (MFCC), spectral centroid, spectral flux, beat histogram, beat sum, voice intensity, pitch, mean, root quadratic mean, among others [31].

Text: Word2Vec [32] has been widely adopted as a pre-trained word vector representation for text due to its effectiveness in sentiment classification. In our approach, each word in an utterance transcript is initially embedded into a 300-dimensional Word2Vec vector. These embedded word vectors are then concatenated, padded if necessary, and further standardized into a 1-dimensional vector by passing through a CNN [33].

Visual frames: To extract the body language of the speaker, we employ a pre-trained 3D-CNN [34] originally designed for human action recognition. The 3D-CNN is applied to the consecutive visual frames capturing the speaker's upper body. By analyzing the relevant features within each frame and the changes across a given number of consecutive frames, known as motion cues, the 3D-CNN effectively captures the body language information.

C. Baseline Systems

We evaluated the proposed labels fusion layers using the following multimodal emotion recognition baseline models over 5-folds cross-validation: BC-LSTM [5], MMAN [8], and HFGCN [13]. BC-LSTM and MMAN are baseline and state-of-the-art (SOTA) methods in multimodal emotion recognition, respectively, and they were trained using only emotion state labels. HFGCN, on the other hand, was trained using both emotion state labels and valence arousal degrees, employing cross-entropy as the multitask loss. In cases where the baseline models did not report certain results on the datasets, we re-implemented the models to ensure a comprehensive evaluation. In the context of 2D Kernel Density Estimation, the bandwidth plays a crucial role. Therefore, we experimented with different bandwidth sizes: normal size (h), half size ($h/2$), and double size ($2h$). The choice of bandwidth size is essential for achieving accurate 2D Kernel Density Estimation results.

BC-LSTM : BC-LSTM (Bidirectional Convolutional LSTM) is the LSTM baseline method, in which context-aware utterance representations are generated by capturing the contextual content from the surrounding utterances using a Bi-directional LSTM network. It is commonly used for sequential data analysis, such as natural language processing and time series prediction tasks.

MMAN: MMAN represents a recent advancement in multimodal AER, leveraging the power of the Transformer architecture, hybrid fusion LSTM network, and multimodal attention mechanisms. By effectively integrating multimodal information and capturing long-range dependencies, MMAN aims to improve the accuracy and performance of multimodal emotion recognition tasks with cross attention for multi modalities.

HFGCN : This is a recent state-of-the-art GCN-based multimodal AER method that uses GCN to fuse multimodal information with the intermodality interactions. In HFGCN, the multimodal information is represented as a graph, where each modality is considered as a node. The GCN layers capture intermodality interactions by propagating information through the graph. This allows the model to leverage the relationships and dependencies between different modalities to enhance the fusion process.

LFL variants: This is our proposed method that applies labels fusion layers based on 2D kernel density estimation with different bandwidth (h, $h/2$, and $2h$) in baseline models as (LFL_h), ($LFL_{h/2}$) and (LFL_{2h}).

TABLE III
RESULTS OF HFGCN AND PROPOSED MODEL HFGCN (LFL_h) EVALUATING WITH DIFFERENT MODALITIES (TEXT (T), AUDIO (A), AND VISUAL (V)) IN IEMOCAP DATASET (AVG. F1 %) OVER 5-FOLDS CROSS-VALIDATION.

Modalites	T	A	V	T+A	T+V	A+V	T+A+V

V. RESULTS AND ANALYSIS

A. Comparison with baselines

Table II presents the results, which demonstrate that the application of the label fusion layers (LFL) to the baseline models leads to improved average F1 scores. This improvement indicates that the 2D Kernel Density Estimation (2D-KDE) technique for label fusion is effective in enhancing emotion recognition performance. It is worth noting that the F1 scores for angry and happy emotions showed larger improvements compared to sad and neutral emotions. This observation aligns with the fact that the overlap areas of the former emotions were smaller, as illustrated in Figure 3. However, it is important to note that for some baseline models, there was a slight decrease in F1 scores specifically for sad and neutral emotions. This suggests that the efficacy of the 2D-KDE approach depends on the relationship between the annotated VA degrees and the emotion labels. The relationship between the two factors can influence the performance of the label fusion process.

B. Comparison with different bandwidth

In our evaluation, we considered different bandwidth values ($h/2$, h, and $2h$) for the density estimation in the proposed label fusion layers (LFL). Comparing the results, we found that the Gaussian Kernel with a normal size (h) generally produced the best outcomes for most emotions. Figure 3 visually illustrates that using a normal size h allows for appropriate positioning of density centers for each emotion, resulting in more effective minimization of overlap areas compared to other bandwidth sizes. Smaller overlap areas generally correspond to better results, as demonstrated in this study. Based on these findings, we conclude that the Gaussian Kernel is an effective option for emotion label density estimation in the LFL. The bandwidth can be set using the rule-of-thumb bandwidth estimator, which provides a reliable estimation for achieving optimal performance.

C. Comparison with different datasets

The results presented in Table II and Figure 3 reveal that when comparing the performance of LFL with the same bandwidth across different datasets, there were greater improvements observed in the IEMOCAP dataset compared to The OMG-Emotion dataset. This difference in performance can be attributed to the nature of the data in each dataset. The OMG-Emotion dataset consists of wild data collected from YouTube videos, where the valence degrees are annotated on

a scale from -1 to 1 and arousal is annotated on a scale from 0 to 1. In contrast, the IEMOCAP dataset is an acted emotion database where valence arousal degrees are annotated on a scale from 1 to 5 levels. The less separated valence and arousal annotations in The OMG-Emotion dataset compared to the clearer distinctions in the IEMOCAP dataset can explain the difference in LFL performance. The LFL approach tends to be more efficient when there is a clear distinction between emotional data in the datasets. Therefore, the LFL approach is particularly effective in datasets where the emotional categories are well-separated and distinct.

D. Comparison with different modalites

As mentioned in the introduction, different modalities can provide complementary information due to variations in labeling styles. Therefore, we extended our comparison by applying the label fusion layers (LFL) to the HFGCN model, which demonstrated the best results among different modalities in Table II. Table III presents the results, indicating that utilizing all modalities together leads to improved performance. Furthermore, when comparing the uni-modality results obtained with and without LFL, we observed that the visual and speech modalities showed greater improvements compared to the text modality. These findings suggest that individuals express their valence and arousal more prominently through speech and visual cues rather than text. The richer and more expressive nature of speech and visual modalities allows for capturing and conveying emotional information more effectively. Incorporating these modalities in multimodal emotion recognition models, particularly with the aid of LFL, contributes to better performance.

VI. Conclusion

In this work, we have proposed a label fusion layer (LFL) that utilizes a 2D Gaussian Kernel Density Estimation to adjust predicted probabilities of emotion states using valence-arousal (VA) degrees. The main objective was to enhance emotion state recognition by exploiting the correlation between emotion states and VA degrees. Through experiments, we have demonstrated the effectiveness of our proposed method across different baseline models, including LSTMs, Transformer, and GCN. We have also observed that the efficiency of the method can be influenced by the choice of dataset, such as IEMOCAP and OMG-emotion, as well as the modality involved, including text, audio, and visual. Overall, our work showcases the potential of employing multiple label fusion techniques for improving the accuracy of emotion recognition systems. By incorporating VA degrees and leveraging the correlation between VA degrees and emotion states, we have achieved promising results in enhancing emotion recognition performance.

RobustL2S: Speaker-Specific Lip-to-Speech Synthesis exploiting Self-Supervised Representations

Neha Sahipjohn*, Neil Shah*†, Vishal Tambrahalli*, Vineet Gandhi*
* CVIT, Kohli Centre for Intelligent Systems, IIIT Hyderabad, India
† TCS Research, Pune, India

***Abstract*—Significant progress has been made in speaker-dependent Lip-to-Speech synthesis, which aims to generate speech from silent videos of talking faces. Current state-of-the-art approaches primarily employ non-autoregressive sequence-to-sequence architectures to directly predict mel-spectrograms or audio waveforms from lip representations. We hypothesize that the direct mel-prediction hampers training/model efficiency due to the entanglement of speech content with ambient information and speaker characteristics. To this end, we propose RobustL2S, a modularized framework for Lip-to-Speech synthesis. First, a non-autoregressive sequence-to-sequence model maps self-supervised visual features to a representation of disentangled speech content. A vocoder then converts the speech features into raw waveforms. Extensive evaluations confirm the effectiveness of our setup, achieving state-of-the-art performance on the unconstrained Lip2Wav dataset and the constrained GRID and TCD-TIMIT datasets. Speech samples from RobustL2S can be found at https://neha-sherin.github.io/RobustL2S/**

I. Introduction

Understanding lip movements offers a distinct advantage in situations where auditory cues are unavailable. It proves particularly valuable for individuals with hearing impairments, and speech disorders and aids in speech rehabilitation by providing visual feedback [1]. The synthesis of accurate speech from lip movements can assist in tasks such as movie dubbing [2], language learning, forensic investigations [3], video conferencing in noisy conditions, voice inpainting [4] or giving artificial voice to people who cannot produce intelligible sound.

The problem of Lip-to-Speech synthesis is inherently ill-posed because a sequence of lip movements can correspond to multiple possible speech utterances [5]. Additional challenges arise from factors such as head pose movements, non-verbal facial expressions, variations in capture quality, and ambient noise, which further complicate the problem. Reliance on contextual information, such as environment, place, topic, etc., can help alleviate the Lipreading challenges [6], [7]; however, such information may not always be available.

Most existing approaches constitute an encoder-decoder architecture; the encoder maps the lip sequence to intermediate representations, which are then directly decoded into mel-spectrograms. The major drawback of this approach is that apart from speech content, the decoder is also forced to predict the time-varying speaker and ambient noise characteristics present in the ground truth Mel. We hypothesize that this dependence hurts the model's performance in terms of speech intelligibility, reducing its usability for various downstream applications [8]. Our work addresses these limitations by taking a modularized approach, exploiting the advances in Self-supervised learning (SSL) in audio and audio-visual scenarios.

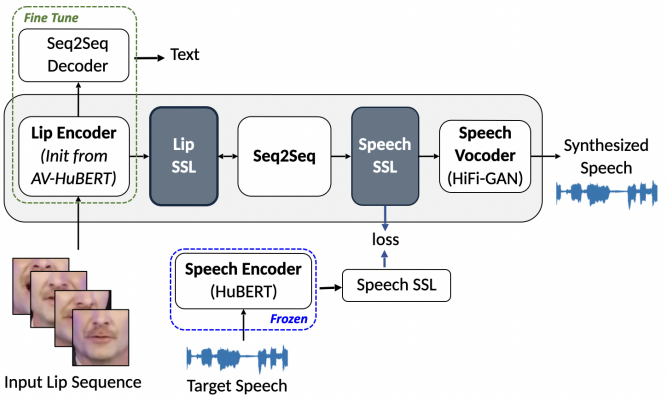

Fig. 1. The proposed RobustL2S model utilizes lip encoder and speech encoder to extract SSL representations from lip sequences and their corresponding speech. A Seq2Seq model maps the lip representations to speech representations, which are then decoded to synthesize speech.

Fig. 1 illustrates the proposed RobustL2S framework. In contrast to direct mel prediction from lip features, we take a two-staged approach. The first step extracts SSL representations of lip sequences and maps them to corresponding speech SSL representations using a sequence-to-sequence (Seq2Seq) model. The key idea is to use speech embeddings that disentangle the content from the speaker and ambient information. The second stage maps the content-rich speech embeddings to raw speech using a speaker-conditioned vocoder. The proposed RobustL2S framework simplifies training and brings robustness to variations in head-pose, ambient noise, and time-varying speaker characteristics, leading to significant gains in speech intelligibility. To validate the efficacy of our approach, we perform comprehensive experiments on GRID [9], TCD-TIMIT [10] and Lip2Wav [5] datasets. The quantitative measures and MOS scores show that the synthesized speech generated by our method accurately represents the intended content and improves on the intelligibility/naturalness compared to current state-of-the-art methods [11], [12] on all three datasets.

More formally, our work makes the following contributions: (1) We propose a novel modularized framework for Lip-to-Speech synthesis exploiting self-supervised embeddings for

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

both lip and speech sequences (2) A Seq2Seq network for cross-modal knowledge transfer to map lip SSL representations to speech SSL representations; and (3) Thorough experimental results demonstrating that RobustL2S is capable of synthesizing high-quality speech, achieving state-of-the-art results in objective and subjective evaluation without requiring additional data augmentation [11].

II. Related Work

A. Lip-to-Speech synthesis

1) Constrained Lip-to-Speech synthesis: Constrained lip-to-speech synthesis tackles speech generation from videos with limited vocabulary and minimal head movement [9], [10]. Ephrat *et al.*[13] introduced a CNN-based approach to predict Linear Predictive Coding features from silent talking videos. They later enhanced their model to a two-tower CNN-based encoder-decoder architecture [14], encoding raw frames and optical flows separately. [15] propose a combination of an autoencoder for extracting bottleneck features from audio spectrograms and a lipreading network comprising CNN, LSTM, and fully connected layers, for visual feature extraction. On the other hand, [16] utilizes a stochastic modeling approach employing a variational autoencoder. Other methods [17]–[20] employ GANs to synthesize speech from video frames. [21] train an attention-based encoder-decoder model to reconstruct speech from silent facial movement sequences without human annotations. [22] performs multi-modal supervision, using text and audio, to complement the insufficient word representations to reconstruct speech with correct contents from the input lip movements. [23] achieves zero-shot Lip-to-Speech synthesis using variational autoencoder to disentangle speaker and content information and a face identity encoder for unseen speakers.

2) Unconstrained Lip-to-Speech synthesis: Unconstrained lip-to-speech synthesis focuses on generating speech from real-world videos of individuals talking. This approach considers videos with an extensive vocabulary and significant head movements. Seminal work by Prajwal *et al.* [5] introduced a 3D-convolution plus autoregressive Seq2Seq model, adapted from Tacotron2 [24] for single speaker Lip-to-Speech synthesis. Their model generates mel-spectrograms based on the input video frames. In contrast, [25] employed a non-autoregressive architecture to expedite the inference process. It uses 3D-convolution blocks, a transformer condition module, and a Glow decoder module [26] for refining the mel-spectrograms. [27] expanded on [5] by training a transformer model to learn a joint latent distribution for speech generation. The VV-Memory architecture [28] combines audio and visual information using a key-value memory structure to enable video-to-speech reconstruction and speaker-independent speech retrieval. A recent work [11] proposed an end-to-end non-autoregressive transformer for synthesizing speech directly from unconstrained talking videos. Their approach involves a visual encoder, an acoustic decoder, a linear layer, and a GAN-based vocoder operating on Mel-spectrograms. LipSound2 [21] investigates cross-modal self-supervised pre-training of an encoder-decoder architecture with a location-aware attention mechanism to map face image sequences to mel-scale spectrograms. In contrast, our proposed RobustL2S differs by using content-rich SSL representations [29] and learning target speech representations from lip sequences.

B. Self-supervised representation for Lip-to-Speech synthesis

Traditional works on Lip-to-Speech synthesis encode lip or face sequences to hidden states, followed by a decoder to generate Mel-spectrograms. An independently trained vocoder transforms them into time-domain waves. However, these Mel frames are highly correlated along both time and frequency axes which may degrade the performance of entire Lip-to-Speech synthesis [30]. Moreover, these Mel-spectrograms have higher variance than that of quantized speech SSL representations increasing the complexity of training a Seq2Seq model. Due to its recent emergence, the utilization of SSL representation in Lip-to-Speech synthesis remains limited.

In VCVTS [12], vector quantized contrastive predictive coding (VQCPC) units are extracted from lip movements, and a speaker encoder, pitch predictor, and decoder are used to infer Mel frames. A separate voice conversion model and vocoder are employed for speaker representation learning and speech synthesis.

Revise [31] employs a combined audio-visual speech recognition module (P-AVSR - initialized with AV-HuBERT - an audio-visual SSL model) and a modified text-to-speech synthesis module (P-TTS) for generalized speech enhancement tasks. P-AVSR predicts discrete units derived from a self-supervised speech model, and P-TTS converts these units into speech using a modified HiFi-GAN [29] trained on the LJSpeech [32] dataset. Our work closely relates with [31] utilizing SSL representations for Lip-to-Speech synthesis. However, we utilize disentangled AV-HuBERT and HuBERT [33] features and a decoupled training procedure to train a Seq2Seq model. Additionally, the existing works have not yet fully capitalized on SSL representations for speaker-specific Lip-to-Speech generation, and our efforts aim to address this gap.

III. Method

A. Preliminaries

RobustL2S consists of four modules: two encoders - an encoder that extracts lip representation from video sequences and a pre-trained HuBERT model that generates speech features for corresponding speech sequences, a Seq2Seq model that maps lip representations to speech representations, and a modified HiFi-GAN vocoder that synthesize speech using the speech representations. We introduce four functions as follows:

- $f_{\mathrm{l}} : L^{T \times W \times H} \mapsto L_{\mathrm{ssl}}$, which maps the input lip sequence to its corresponding SSL representation. Here, T represents the number of time steps (frames), and H and W correspond to the spatial dimensions of the frames.
- $f_{\mathrm{s}} : X \mapsto S_{\mathrm{ssl}}$, which maps the ground-truth raw speech to its corresponding SSL representation.

- $f_{\text{s2s}} : L_{\text{ssl}} \mapsto S_{\text{ssl}}$, which maps the lip representation to its corresponding speech representation.
- $f_{\text{voc}} : S_{\text{ssl}} \mapsto \widehat{X}$, which maps the speech representation to the synthesized speech $\widehat{X}$.

B. Encoder

We use HuBERT [33] for f_{s}, to extract speech representation of target speech signals. HuBERT representation is content rich [29] and agnostic to other variations. Although our framework is compatible with various off-the-shelf SSL models, we specifically utilize AV-HuBERT [34] for f_{l}, our video encoder to extract lip representations. This choice is based on the similarity in training methods between AV-HuBERT and HuBERT, ensuring content-rich representations for improved intelligibility, which aligns with our goals. The HuBERT and AV-HuBERT models are trained using a masked-prediction loss to predict cluster IDs, which are learned using k-means clustering. The labels for the first iteration are derived by clustering MFCC features derived from acoustic frames. For subsequent iterations, more complex features derived from an audio or audio-visual encoder, depending on the specific model being used, are clustered. AV-HuBERT incorporates a modified ResNet [35], [36] as its frontend, coupled with a transformer encoder. We also finetune the pretrained AV-HuBERT using an attention-based Seq2Seq cross-entropy loss as in [34].

C. Seq2Seq model

In recent years, Seq2Seq models have gained significant attention in the field of cross-domain generation. The core concept of our approach is to align representations from two different domains - visual and audio, that share a common generating process. By recovering correspondences between these domains, we facilitate the transfer of knowledge from one domain to the other.

Our Seq2Seq model, denoted as f_{s2s}, adopts a non-autoregressive-based encoder-decoder architecture to map lip representations to their corresponding speech representations. The encoder and decoder consist of feed-forward transformer blocks with self-attention [37], along with 1-dimensional convolutions inspired by Fastspeech2 [38]. A transposed convolution layer is used at the encoder to match the rate of video and audio representations. The encoder takes the lip representation L_{ssl} and encodes it into a sequence of fixed-dimensional vectors. The decoder generates predictions for all representations of S_{ssl} simultaneously. We train three versions of the Seq2Seq model:

- $f_{\text{s2s-units}}$: This encoder-decoder architecture utilizes Cross-Entropy (CE) loss to train the model on the decoded speech units. The input to the architecture consists of cluster IDs from the video encoder, and the decoder predicts the corresponding HuBERT cluster IDs for the audio. The objective can be written as:

$$\mathcal{L}_{\text{CE}} = -\sum_{i=1}^{N} S_{\text{ssl_units_i}} \log(\hat{S}_{\text{ssl_units_i}}), \tag{1}$$

  where $S_{\text{ssl_units}}$ are the ground-truth speech units, $\hat{S}_{\text{ssl_units}}$ are the decoded speech units, and N are the number of HuBERT units.
- $f_{\text{s2s-features}}$: Here the model learns mapping from audio-visual feature to corresponding speech feature vectors. This model utilizes L1 loss, quantifying the difference between the decoded features and ground-truth speech features. The objective can be written as:

$$\mathcal{L}_{\text{L1}} = \frac{1}{T}\sum_{i=1}^{T} |S_{\text{ssl_features_i}} - \hat{S}_{\text{ssl_features_i}}|, \tag{2}$$

  where $S_{\text{ssl_features}}$ are the ground-truth speech features, $\hat{S}_{\text{ssl_features}}$ are the decoded speech features, and T is the time-steps.
- $f_{\text{s2s-features-ctc}}$: This architecture follows the same structure as $f_{\text{s2s-features}}$, but also includes an additional fully connected linear head to predict CTC tokens after the encoder layer. For given input lip representation $L_{\text{ssl}} \in \mathbb{R}^{TxD}$ of length T and dimension D, let Enc_{ssl} be the output of the encoder. The goal is to minimize the negative log-likelihood by using $P_{CTC}(S_{\text{ssl}}|Enc_{\text{ssl}})$ to train the model effectively using the CTC approach and is defined as:

$$\mathcal{L}_{CTC} := -\log P_{CTC}(S_{\text{ssl}}|Enc_{\text{ssl}}). \tag{3}$$

  By weighted summing the L1 and CTC loss functions, the objective function can be formulated as:

$$\mathcal{L}_{\text{Tot}} = \alpha_{CTC} * \mathcal{L}_{\text{CTC}} + \alpha_{L1} * \mathcal{L}_{\text{L1}}, \tag{4}$$

  where $\alpha_{\text{CTC}} \in \mathbb{R}$ and $\alpha_{\text{L1}} \in \mathbb{R}$ are the hyperparameter that balances the influence between two loss.

D. Speech Vocoder

We use a modified version of HiFiGAN-v2 [39] to synthesize speech. It has a generator G and a discriminator D. G runs S_{ssl} through transposed convolutions for upsampling to recover the original sampling rate followed by residual block with dilations to increase the receptive field to synthesize the signal, $\widehat{X} := G(S_{\text{ssl}})$.

The discriminator in our model has the task of distinguishing the synthesized signal $\widehat{X}$ from the original signal X. It is evaluated using two sets of discriminator networks. The multi-period discriminators operate on equally spaced samples of the signals, focusing on capturing temporal patterns and characteristics. On the other hand, the multi-scale discriminators analyze the input signal at different scales, enabling the model to capture both fine-grained details and global structure. The primary objective of the model is to minimize the discrepancy, measured by $D(X, \widehat{X})$, between the original signal and the synthesized signal. This optimization process applies to all the parameters of the speech decoder, improving its overall performance and fidelity.

IV. Experiments

A. Datasets

1) Lip2Wav: The Lip2Wav dataset [5] is a large, person-specific, unconstrained dataset, commonly used for learning Lip-to-Speech synthesis for individual speakers. It consists of real-world lecture videos featuring 5 different speakers. Each speaker has approximately 20 hours of video data, and the vocabulary size exceeds 5000 words for each speaker. We do experiments on all five speakers: Chess Analysis (chess), Chemistry Lectures (chem), Hardware Security (hs), Deep Learning (dl), and Ethical Hacking (eh).

2) GRID-4S: The GRID-4S is a subset of the GRID audio-visual dataset [9] specifically designed for constrained Lip-to-Speech synthesis. This subset includes two male speakers ($s1$, $s2$) and two female speakers ($s4$, $s29$), which are frequently used in the literature [5], [19]. The videos in the dataset were captured in an artificial environment. The vocabulary used in GRID-4S is limited to only 51 words. The sentences in the dataset follow a restricted grammar, with each sentence containing 6 to 10 words.

3) TCD-TIMIT-3S: The TCD-TIMIT-3S is a subset of the TCD-TIMIT dataset, which comprises recordings of 62 speakers captured under studio conditions. Among these speakers, three are trained lip-speakers. The primary objective of selecting this subset was to enable comparison with previous studies [5], [19]. Our focus was solely on the audio-visual data generated by these three lip-speakers. Each lip-speaker delivers 375 distinct sentences that exhibit phonetic diversity. Additionally, two sentences are spoken by all three lip-speakers.

B. Implementation details

1) Data preparation: For the GRID-4S and TCD-TIMIT-3S datasets, we adhere to the convention of randomly selecting 90% data for training, 5% for validation, and 5% for testing, as established in previous works [5], [11], [17], [40]. For Lip2Wav, we adopt the official data split [5]. For consistency, in line with previous works, we evaluated RobustL2S on the Lip2Wav dataset using a speaker-dependent setting [5], [14], [28]. This involved training the network separately with individual speakers. However, for the GRID-4S and TCD-TIMIT-3S datasets, we evaluated RobustL2S in a constrained (seen) speaker setting [5], [17], [40]. The video sequences are resampled to a frame rate of 25 frames per second (fps), while the raw audio is sampled at 16 kHz. We utilize the SFD [41] face detector to detect 68 key points, allowing us to crop a mouth-centered region-of-interest measuring 96×96 pixels. In order to solely assess the advantages of using SSL representation in our proposed setup, we opt not to employ any data augmentation techniques to enhance the quality of synthesized speech. The Lip2Wav dataset does not provide transcripts, so we rely on the Whisper *small* model [42] to extract transcripts. These transcripts are then used for finetuning the AV-HuBERT model.

2) SSL representation: We utilize the official fairseq repository implementation of the BASE models AV-HuBERT [34] and HuBERT [33] for our experiments. We fine-tune the AV-HuBERT pre-trained model with an attention-based STS cross-entropy loss for visual speech recognition [34]. To achieve this, a transformer decoder is added to the pre-trained model, which autoregressively decodes the AV-HuBERT features to target character probabilities. The fine-tuned AV-HuBERT model extracts SSL representations for lip sequences, while HuBERT is employed to extract representations from speech signals. Both models provide 768-dimensional features. For $f_{\text{s2s-units}}$ model, following the approach in [33], [34], the lip features are clustered into 2000 AV-HuBERT units, while the speech features are clustered into 100 HuBERT units, using k-means clustering. For $f_{\text{s2s-features}}$ model, the output features from HuBERT and AV-HuBERT models are used directly.

3) Seq2Seq model: Our model comprises a 6-layer transformer encoder and decoder with a hidden dimension of 512 and 2 attention heads. we set the batch size to 32 and the maximum number of steps to $20,000$. We employ the Adam optimizer with an initial learning rate of 4.4 x 10^{-2}, along with an annealing rate of 0.3 and annealing steps at $[3000, 4000, 5000]$. The HuBERT model encodes speech into features at a frame rate of 50 Hz, while the SSL unit from AV-HuBERT is encoded at 25 Hz. To match these rates, we incorporate a lightweight transposed convolution layer with a kernel size of $[4, 3]$ and a stride length of $[2, 1]$. We set α_{CTC} and α_{L1} mentioned in (4) to 0.001 and 1, respectively.

4) Speech Vocoder: We train modified HiFiGAN-v2[1] to generate audio from speech SSL representations, for all speakers. This model employs encoding of raw audio into a sequence of discrete tokens from a set of 100 possible HuBERT tokens, with a code hop size of 160 raw audio samples. We set the batch size to 16, the learning rate to $2\text{x}10^{-4}$, the number of embeddings to 100, the embedding dimension to 128, and the model input dimension to 256. We train the model up to $300k$ steps. Following the approach in [43], F0 is not used as a feature in our training process. The aforementioned vocoder configuration is effective for speech units. However, for our investigated feature-based models, $f_{\text{s2s-features}}$ and $f_{\text{s2s-features-ctc}}$, we apply a pre-trained k-means[2] clustering model trained on HuBERT features. During the inference phase, the generated features undergo k-means clustering to obtain discrete speech units, which are then passed through the speech vocoder. We train the vocoders for the three datasets separately.

C. Evaluation metric

During our evaluation, we employ several metrics to assess the quality of the synthesized speech. These include: Word Error Rate (WER), Short-Time Objective Intelligibility (STOI) [44], and Extended Short-Time Objective Intelligibility (ESTOI) [45]. Additionally, we conduct subjective evaluations using Mean Opinion Score (MOS), where human evaluators rate

TABLE I
PERFORMANCE COMPARISON: SEQ2SEQ MODEL VS. EVALUATED VARIATIONS VS. NO SEQ2SEQ MODEL EMPLOYED ON CHEMISTRY SPEAKER OF LIP2WAV DATASET.

Baseline (Ours)	**STOI ↑**	**ESTOI ↑**
f_l(pre-trained) + f_{voc}	0.447	0.22
f_l(finetuned) + f_{voc}	0.50	0.27
f_l(finetuned) + $f_{\text{s2s-units}}$ + f_{voc}	0.18	0.013
f_l(**finetuned**) + $f_{\textbf{s2s-features}}$ + f_{voc}	**0.583**	**0.397**
f_l(finetuned) + $f_{\text{s2s-features-ctc}}$ + f_{voc}	0.557	0.368

the quality, intelligibility, and naturalness of the synthesized speech based on their subjective perception.

V. RESULTS

A. Need for Seq2Seq model

We tested our hypothesis of using a Seq2Seq model on the Lip2Wav dataset, specifically for a chemistry speaker, and report our findings in Table I. Fine-tuning the AV-HuBERT model using transcripts consistently improved objective metrics by approximately 0.05 units on both the metrics compared to the pre-trained version. Deploying the Seq2Seq model on the finetuned AV-HuBERT features (f_l(finetuned) + $f_{\text{s2s-features}}$ + f_{voc}) resulted in an increase of approximately 0.08 and 0.12 units in STOI and ESTOI metrics, respectively, compared to not using the Seq2Seq model (f_l(finetuned) + f_{voc}). These results highlight the effectiveness of our Seq2Seq approach using SSL representations for Lip-to-Speech synthesis. The significant performance gap (approximately 0.39 units on both metrics) between the Seq2Seq model using SSL features and the model using SSL units on both evaluated metrics approximates the amount of information lost in speech reconstruction when audio-visual sequences are represented as SSL units instead of SSL features. From now on, we will refer to f_l(finetuned) + $f_{\text{s2s-features}}$ + f_{voc} as RobustL2S. The inclusion of CTC loss in our f_l(finetuned) + $f_{\text{s2s-features-ctc}}$ model resulted in a statistically insignificant decrease of approximately 0.02 units in STOI compared to the model without CTC loss, f_l(finetuned) + $f_{\text{s2s-features}}$. The decrease may be due to the lack of ground-truth transcripts in the Lip2Wav dataset. However, when evaluating our model using CTC loss on datasets (GRID-4S and TCD-TIMIT-3S) with ground-truth transcripts, we observed a slight increase of 0.02 units. Nevertheless, our focus is on working with datasets in the wild that generally lack ground-truth transcripts, so we proceed with experiments excluding the CTC loss.

B. RobustL2S in Constrained settings

Table II and III summarizes the performance of our RobustL2S in the context of Lip-to-Speech synthesis using constrained datasets: GRID-4S and TCD-TIMIT-3S. We compare our results with existing Lip-to-Speech synthesis works, including state-of-the-art approaches. We report the mean test scores on all four speakers of the GRID-4S dataset and all three speakers of the TCD-TIMIT-3S dataset, as documented in previous works. Remarkably, our RobustL2S approach demonstrates significant improvements in terms of STOI and WER

metrics when compared to other approaches. This improvement is particularly noticeable on the TCD-TIMIT-3S dataset, which contains a larger number of novel words that were unseen during training. This observation highlights the ability of our RobustL2S to accurately pronounce new words and effectively capture semantic information from lip movements, resulting in the generation of more intelligible speech.

C. RobustL2S in Unconstrained settings

Table IV provides a synopsis of RobustL2S's performance on the Lip2Wav dataset. This dataset includes a significant amount of silences between words, and RobustL2S shows a notable improvement across all metrics. Despite Lip2Wav's data asynchrony issues, which may affect the quality of the generated speech, RobustL2S demonstrates substantial performance gains in objective metrics, highlighting its overall superiority in producing intelligible speech. However, it is worth noting that RobustL2S performs similarly or slightly worse than [28] on the *hs* and *eh* ESTOI metric. This could potentially be attributed to the poor resolution ($480p$ and $360p$) of the original videos, making it challenging to accurately recognize lip regions.

D. Subjective evaluation

Fig. 2 and Fig. 3 shows the MOS scores on intelligibility (MOS(I)), quality (MOS(Q)), and naturalness (MOS(N)) of synthesized speech from evaluated methods on Grid-4S and Lip2Wav datasets. We requested ten English-proficient subjects to score five randomly selected samples from different methods on the Lip2Wav and GRID-4S datasets. It can be observed that our model outperforms the evaluated methods, exhibiting higher Mean Opinion Score (MOS) values. This demonstrates that the proposed approach inherits the advantages of disentangled SSL features and the mapping of lip sequences to content-specific information. As a result, our model not only inherently improves the intelligibility aspect of synthesized speech but also generates speech that is highly natural and of high quality.

VI. Conclusions

We propose a novel framework for Lip-to-Speech system, called RobustL2S, which accurately synthesizes spoken content from silent videos. This is accomplished by utilizing a non-autoregressive based sequence-to-sequence model to establish an inter-modality mapping, allowing us to learn a suitable decoding space from the lips' self-supervised (SSL) representations. We further demonstrate the effectiveness of mapping SSL features rather than SSL units for synthesizing intelligible speech. Both quantitative and qualitative results showcase state-of-the-art performance in constrained settings (such as GRID and TCD-TIMIT) and unconstrained settings (like Lip2Wav). In our future work, we aim to introduce emotive effects in the synthesized speech, considering that HuBERT embeddings are known to lack prosody information. Additionally, we plan to explore diffusion-based speech vocoders and their application in a multi-lingual setup.

***Abstract* —Nipple in Profile (NIP) is one of the positioned criteria for mammography quality evaluation. The current evaluation work relies on manual reviewing, which is subjective and time-consuming. This paper introduces a novel NIP recognition based on a convolutional neural network (CNN) without referring to prior information, which outputs an objective recognition result in real-time. Amazingly, the added value associated with the proposed method is nipple detection which analyzes the extracted gradient-weighted class activation mapping (Grad-CAM) based on three-category classification. In this work, the defined categories are Nipple in Profile, Nipple not in Profile, and non-nipple. For the NIP recognition, we only exploit the comparison between the Grad-CAMs of Nipple in Profile and Nipple not in Profile. Our method is more creative than the typical classification approaches to realize multiple tasks with a single classification. The experiment results demonstrate that the three-category classification with Densenet-121 achieves better performance in both NIP recognition and nipple detection.**

I. INTRODUCTION

Mammography uses a low-dose X-ray to generate projected images and is a common way of screening breast lesions. Then, approved radiologists screen mammograms for detecting suspicious findings, e.g., mass, calcifications, architecture distortion, and asymmetry. When radiologists have difficulty screening inadequate-quality mammograms, hospitals recall patients to retake mammograms. However, it's been a while since the last shot. Furthermore, the retaking task becomes costly and time-consuming for patients living in remote areas. To solve such problems, radiographers need a skill in quality evaluation, and they decide whether retake mammograms depending on their domain knowledge and experiences. Up to now, mammography quality evaluation still relies on manual reviewing. In [1, 2], the documents list evaluation criteria defined over four quality levels: Perfect, Good, Moderate, and Inadequate. For example, one of the positioned criteria addressed in [3-10], the difference of posterior nipple lines (PNL) on Craniocaudal (CC)-view and Mediolateral-Oblique (MLO)-view mammograms at the same laterality should be less than 1 cm.

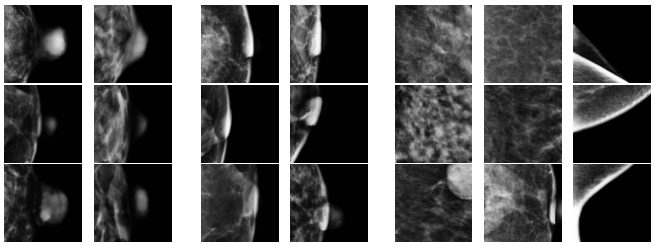
Recently, researchers developed deep learning techniques for assessments of the mammogram positioned quality. In [11], Watanabe et al. proposed positioned quality classifications for inframammary fold and nipple profile based on the deep convolutional neural network (DCNN). In the previous works, we presented convolutional neural network (CNN)-based mammography quality evaluation methods for skinfolds [12] and inframammary fold [13]. Those two methods aimed at the criteria of absence of skin folds and well-demonstrated inframammary fold addressed in [1, 2, 9]. Brahim et al. [14] analyzed the nipple position, pectoralis muscle angle and level using the self-designed CNN models. To highlight the relevance of the model prediction, they extracted gradient-weighed class activation mapping (Grad-CAM) for nipple position detection and then determined whether the nipple was in profile. However, their method downscaled mammograms resulting in small nipple vanishing and misdetermined the nipple was not in profile.

This paper presents a CNN-based method to recognize Nipple in Profile (NIP). The NIP is one of the positioned criteria for mammography quality evaluation, which associates with retro-areolar tissue well-separated. Our method performs NIP recognition without prior information, such as nipple position. Amazingly, the added value associated with the proposed method is a nipple detector, which analyzes the extracted Grad-CAM based on a three-category classification. In this work, the three categories represent Nipple in Profile, Nipple not in Profile, and non-nipple. The samples extracted from the breast area and background belong to the non-nipple.

The training dataset consists of 224×224 samples annotated with one of three labels in advance. During the training process, we train three-category classifiers by seven CNN models, including, Squeezenet, Densenet-121, Resnet-18,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Resnet-101, Alexnet, Vgg-16, and Vgg-19. During the inference process, the trained model applies to entire mammograms. For nipple detection, our method analyzes the Grad-CAMs of all categories. For NIP recognition, we only exploit the comparison between the Grad-CAMs of Nipple in Profile and Nipple not in Profile. Therefore, the proposed method realizes NIP recognition and nipple detection using a single classification model. The main contributions of our work can be summarized as follows:



- We construct a CNN-based three-category classification for NIP recognition that performs without referring to prior information.
- We implement nipple detection based on the constructed classification by analyzing the Grad-CAMs.
- Extensive experiments verify the effectiveness and efficiency of the constructed classifications, and Densenet-121 is the better choice by summarizing the performance of NIP recognition, nipple detection, and computation complexity.

The rest of this paper is organized as follows: the related work and the proposed method are introduced in Sections II and III, respectively. The experiment results are revealed in Section IV, and the conclusion is drawn in Section V.

II. The Related Work

A. Nipple Detection

There were plenty of nipple detection approaches investigated for various applications, such as mammography quality evaluation [13-19]. However, those approaches were workable under the condition of a visible nipple which presents a unique shape. For example, Lin et al. [15] used Digital Database for Screening Mammography (DDSM), and nipples were in the profile of the attained mammograms. Another researcher developed techniques to estimate invisible nipples. In [16], Jas et al. estimated the farthest pixel from the base to the breast boundary and then found the position of an invisible nipple. In [17], Chae et al.'s method analyzed the fibroglandular tissue. In [13, 18], the previous work computed the curvature values of pixels on the breast boundary, and the pixel with the highest curvature value determined the position of a visible nipple. Moreover, we assumed that an invisible nipple overlapped breast tissue as a superposed area, and this area presented brighter intensity than the surrounding pixels on mammograms. Therefore, in [18], the previous work employed U-Net to detect a bright-intensity region and treated the detection result as a superposed area.

(a) C_0 (b) C_1 (c) C_2

Fig.1. Samples of (a) Nipple in Profile, (b) Nipple not in Profile, and (c) non-nipple.

B. Nipple in Profile

Breast nipple is a significant reference for mammography quality evaluation. For example, for an adequately positioned breast [1, 2, 19], the difference between PNLs on CC-view and MLO-view mammograms should be within 1cm. The PNL is a line started at the posterior nipple perpendicularly towards a pectoral muscle. Furthermore, the Nipple in Profile is the positioned criterion associated with retro-areolar tissue well-separated. Fig.1(a) and Fig.1(b) illustrate the samples with NIP and Nipple not in Profile (NnIP), respectively.

In [10], Bassett et al. found a large proportion of mammograms with NIP in their experiments. They claimed NIP is a secondary consideration for positioning a breast in mammography. However, while nipples were unseen in both CC-view and MLO-view mammograms, a third-view mammogram was required in screening mammography. Similarly, in [7], Huppe et al. presented a report about mammography against various positioning criteria for full-field digital mammography and digital breast tomosynthesis. They showed results that nipples were visible in the profiles of most mammograms. In [20], Holen et al. concluded that no evidence supports the correlation between NIP and odds of screen-detected breast cancer and recall. However, they did not confirm whether screening mammography encounters a negative effect while the criterion of NIP is removed or relaxed.

In summary, there is no direct evidence of whether removing the criterion of NIP negatively influences mammogram screening. However, occurring unseen nipples in both CC-view and MLO-view mammograms can be costly in mammogram screening. Consequently, NIP analysis is essential for mammography quality evaluation.

III. The Proposed Method

A. Problem Statement

NIP recognition determines whether a nipple is in profile or not in a mammogram. An intuitional way is to analyze a

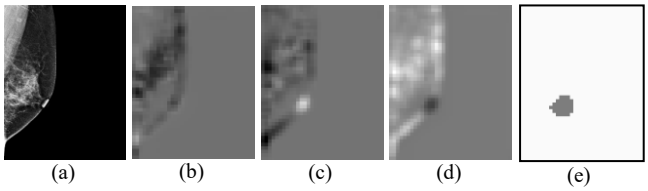
detected nipple sample by a two-category classification. However, an inevitable issue is that the efficiency of nipple detection affects the performance of NIP recognition. As we mentioned in Section II, most nipple detection approaches were available for visible nipples and had difficulty detecting invisible/inverted nipples. There is a potential risk in nipple detectors. For risk avoidance, the proposed method recognizes NIP based on an entire mammogram rather than a nipple sample.

B. Three-category Classification

The proposed method implements a three-category classification rather than a two-category one. The three categories represent Nipple in Profile (denoted as C_0), Nipple not in Profile (denoted as C_1), and non-nipple (denoted as C_2). Fig.1 shows the training samples of those categories. The non-nipple consists of samples extracted from the breast area and background, including fibroglandular tissue, fatty tissue, pectoralis muscle, and breast boundary.

During the training process, we train three-category classifiers by seven CNN models, including, Squeezenet, Densenet-121, Resnet-18, Resnet-101, Alexnet, Vgg-16, and Vgg-19. The training dataset consists of 224×224 samples in three categories. During the inference process, the trained model applies to an entire mammogram. Subsequently, the method extracts Grad-CAMs over categories and estimates an index image. Let $s_i(x,y)$ be the score of the Grad-CAM at the coordinate (x,y) in C_i, where $i=\{0, 1, 2\}$. The index $d(x,y)$ denotes the category corresponding to the maximum score at (x,y) estimated by,

$$d(x,y) = \arg\max_{i=\{0,1,\ldots,N\}} s_i(x,y) \tag{1}$$



For instance, Fig. 2 shows a mammogram and its Grad-CAMs. The bright-tonal pixel represents a high score in the Grad-CAMs of Figs.2(b)-(d). Fig.2(e) is the index image constructed by (1) with N=3, and the black, gray, and white pixels in the index image represent C_0, C_1, and C_2, respectively.

C. Nipple Detection and NIP Recognition

Analyzing the Grad-CAM in C_2, we identify the pixels with higher scores in C_2 than those in C_0 and C_1 as a portion of non-nipple. Therefore, excluding the pixels corresponding to C_2 in the index image, the rest constitutes candidates of nipple areas. The proposed method determines the detected nipple area (denoted as A) according to,

$$\begin{aligned} \mathrm{A} &= \Omega_{j^*}, \\ j^* &= \arg\max_{j=\{0,1,\ldots,N_C\}} \left\{ \arg\max_{i=\{0,1\}} \left(s_i(x,y) \middle| (x,y) \in \Omega_j \right) \right\}, \end{aligned} \tag{2}$$

where Ω_j represents the jth candidate, and N_c is the total number of candidates. In Fig.2(e), the gray pattern is the detection result. In the case of Fig.2, the mammogram is NnIP by manual reviewing. Analyzing the Grad-CAMs in C0 and C_1, the nipple area in C_1 (as shown in Fig.2(c)) expresses brighter tones than that in C_0 (as shown in Fig.2(b)). It signifies that our method determines that the nipple is not in profile in the mammogram.

Fig.2. Three-category classification: (a) a testing mammogram with Nipple not in Profile, the Grad-CAMs in (b) C_0, (c) C_1, (d) C_2, and (e) the index image

D. Performance Evaluation

This work utilizes ten measures to evaluate the performance of the proposed method and the compared ones. Those measures correspond to three aspects: the accuracy of NIP recognition, the efficiency of nipple detection, and the computational complexity of a classification model. In NIP recognition, we compute sensitivity (SEN), specificity (SPC), accuracy (ACC), and Cohen's kappa coefficient [21] based on a confusion matrix. Landis and Koch characterized the kappa coefficient into six magnitudes guidelines [22]. The negative coefficient represents no agreement, and the kappa coefficient ranging from 0.8 to 1 is an almost perfect agreement for the model. In nipple detection, two measures, Intersection over Union (IoU) and Dice coefficient (Dice), compute the similarity of nipple area between the ground truth and the detection result.

The parameter size of a classification model and the processing time of an inference process are two bases. Then, we compute the size-reducing rate (SRR) and time-reducing rate (TRR) based on those two bases for evaluating computational complexity, which is formulated as,

$$SRR_k = \frac{(\max_i V_i) - V_k}{(\max_i V_i)}, \tag{3}$$

$$TRR_k = \frac{(\max_i T_i) - T_k}{(\max_i T_i)}, \tag{4}$$

where Vk and Tk denote as the parameter size and the processing time, respectively. The subscript k represents a CNN model, that is k={Squeezenet, Densenet-121, Resnet-18, Resnet-101, Alexnet, Vgg-16, Vgg-19}.

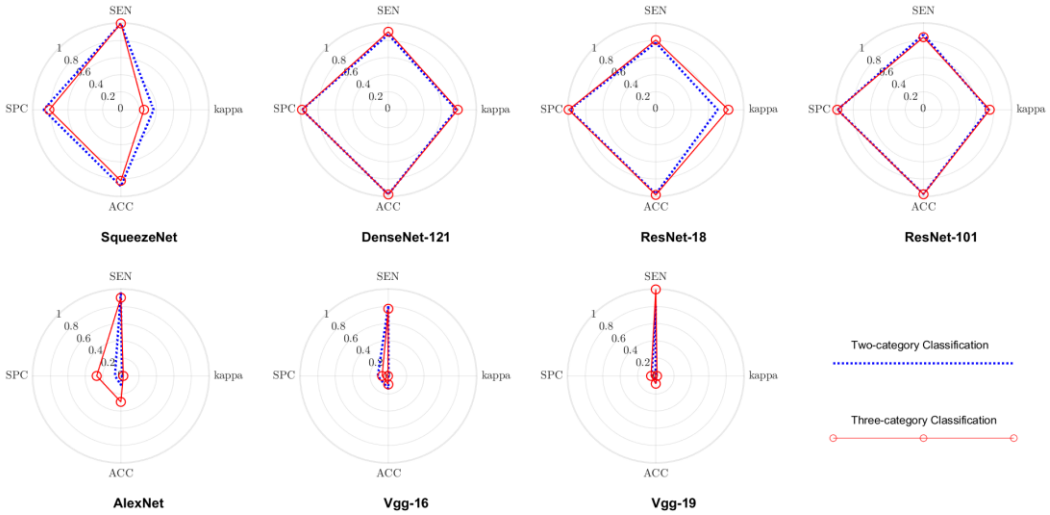

Fig.3. Radar charts against four measures for two-category and three category classifications with seven CNN models for NIP recognition

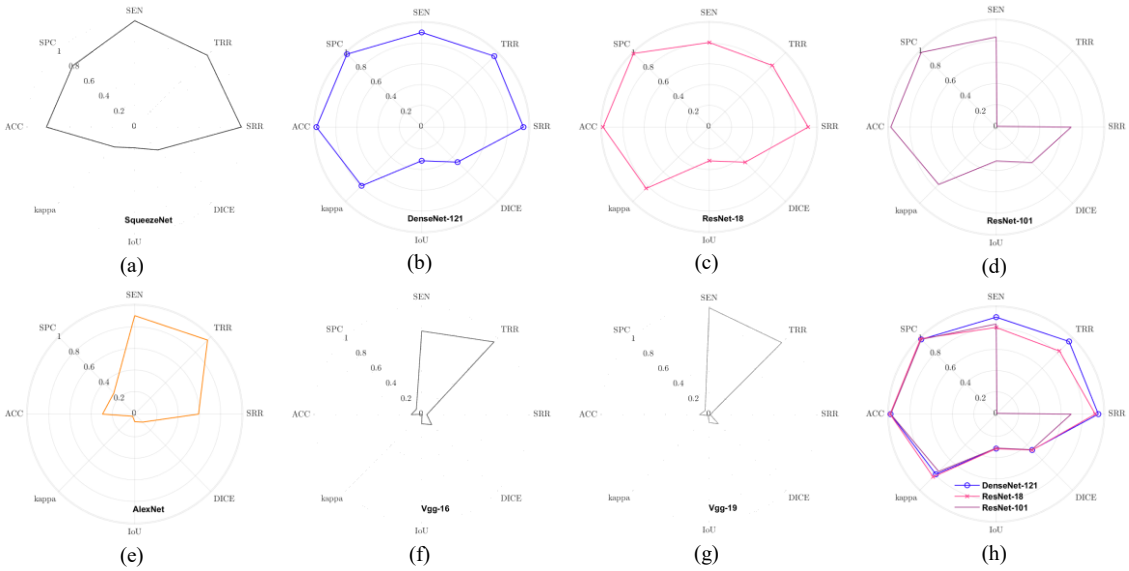
Additionally, a radar chart is an approach to visualize the performance against eight measures for the seven CNN models. The selected eight measures include SEN, SPC, ACC, kappa, IoU, Dice, SRR, and TRR. The radar chart assists us to choose the best combination according to the aspects.

IV. The Experiment Results



In the experiments, we emphasized two tasks: NIP recognition and nipple detection. The proposed method implemented multi-category classifications with various CNN models for finding the proper combination. The training dataset consisted of 224×224 samples extracted from 1004 CC-view and 1006 MLO-view mammograms. The testing dataset consisted of 392 CC-view and 394 MLO-view mammograms. All programs run on a personal computer with NVIDIA GeForce GTX 1660 and RAM 32 GB.

A. NIP Recognition

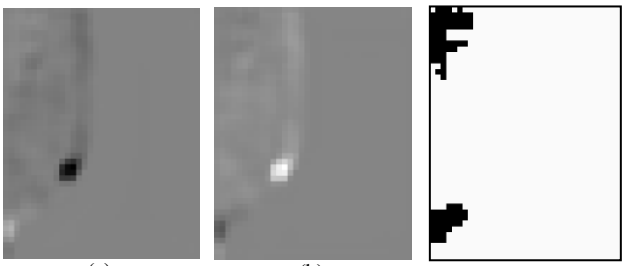
In the first experiment, two-category and three-category classifications with seven CNN models were implemented, including Squeezenet, Densenet-121, Resnet-18, Resnet-101, Alexnet, Vgg-16, and Vgg-19. This work defined three categories: Nipple in Profile (C_0), Nipple not in Profile (C_1), and non-nipple (C_2). The CC-view training dataset consisted of 1896, 1873, and 3042 samples in C_0, C_1, and C_2. Similarly, the MLO-view training dataset consisted of 2889, 2958, and 7098 samples in C_0, C_1, and C_2. During the model training process, two-category classification only utilized the datasets of C_0 and C_1. During the recognition process, we extracted the Grad-CAMs in C_0 and C_1 and then determined the category of NIP. Summarizing the recognition results of CC-view and MLO-view mammograms, Fig.3 illustrates radar charts against four measures for the two-category and three-category classifications with CNN models, and those measures are sensitivity (SEN), specificity (SPC), accuracy (ACC), and Cohen's kappa coefficient (kappa). Compared two classifications with the same model, the performance were similar in Densenet-121 and Resnet-101. Furthermore, three-category classifications achieved better performance than two-category ones with CNN models, except for Squeezenet and Vgg-16. The Densenet-121, Resnet-18, and Resnet-101 were more outstanding than the others performed in three-category classification, and the kappa coefficients were 0.791, 0.827, and 0.754, respectively. According to [21], the three-category classification with Resnet-18 was almost perfect, and the classifications with Densenet-121 and Resnet-101 were substantial.

B. Nipple Detection

Two-category classification got worse detection results in C1 due to misrecognition. The texture of non-nipple is similar to the samples in C_1 but different from the ones in C_0. Therefore, the two-category classifier recognized the non-nipple around a nipple as C_1 rather than C_0. It resulted in inaccurate detection results. For example, applying a two-category classification to Fig.2(a), the extracted Grad-CAMs in C_0 and C_1 were respectively in Figs.4(a) and 4(b), and the index image was in Fig.4(c). The black and white pixels in the index image represent C_0 and C_1, respectively. Therefore, Fig.4(c) expresses the misrecognition results in non-nipple in two-category classification and shows none of the nipple areas. We computed IoU and Dice between the ground truth and the detected nipple area. TABLE I lists the measures of nipple area detection using three-category

(a) (b) (c) (d) (e) (f) (g) (h)

Fig.5. Radar charts against eight measures for (a) Squeezenet, (b) Densenet-121, (c) Resnet-18, (d) Resnet-101, (e) Alexnet, (f) Vgg-16, (g) Vgg-19, and (h) the superposition of (b), (c), and (d).



classifications with CNN models. Resnet-18, Densenet-121, and Resnet-101 had the similar performance.

C. Computation Complexity

We further considered the computation complexity of three-category classifications by calculating two self-defined measures: SRR and TRR. Vgg-19 required the largest parameter size among all models, and Resnet-101 took much time in the inference process. Therefore, the SRR of Vgg-19 and the TRR of Resnet-101 were zeros. TABLE II lists the SSR and TRR of CNN models.

D. Combination Selection

Figs.5(a)-(g) illustrate the radar charts against eight measures for seven CNN models, and those measures are SEN, SPC, ACC, kappa, IoU, Dice, SRR, and TRR. Summarized the experiment results among NIP recognition, nipple detection, and computation complexity, the top 3 models were Densenet-121, Resnet-18, and Resnet-101 in order. Fig.5(h) shows a superposition of the radar charts of those models. Densenet-101 and Resnet models were neck and neck in NIP recognition and nipple detection. Densenet-101 needed less computation complexity in the inference process, especially processing time. Consequently, a three-category classification with Densenet-121 is the best choice for this work. In NIP recognition, this combination achieved an accuracy of 0.982 and a kappa coefficient of 0.791. In nipple detection, the Dice coefficient and IoU were 0.468 and 0.315, respectively. The average time in mammogram inference was 2.75 sec.

V. CONCLUSION

This paper presents the CNN-based 'Nipple in Profile' recognition method using a three-category classification. The proposed method is implemented without prior nipple information. By contrast, the added value associated with our method is nipple detection by analyzing the extracted Grad-CAMs. We experimented with multi-category classifiers

integrated with seven CNN models, and Densenet-121 was the best choice. The experiment results demonstrated that the proposed method was superior to the other models. It achieved an accuracy of 0.982 and a kappa coefficient of 0.791 in NIP recognition; the Dice coefficient and IoU were respectively 0.468 and 0.315 in nipple detection. Our method is more creative than the typical classification approaches to realize multiple tasks with a single classification.

***Abstract*—Visual storytelling is a learned ability that humans have developed through the course of their evolution. In contrast to written records and descriptions, people are now sharing glimpses of their lives through short videos. Human conversations largely rely on visual and auditory inputs, followed by corresponding feedbacks. For machines, the conversion of images to texts serves as a bridge between visual and linguistic information, enabling machine-human interactions more naturally. Video captioning—involving automatically generating textual descriptions from videos—is one of the core technologies that enable such applications. In this work, we present CLIP-CAP, an automatic method for transforming visual contents to concise textual descriptions. We investigate the CLIP pretraining model as well as its potential in this task. Through experiments on the ActivityNet Captions dataset, we show that the proposed CLIP-CAP model outperforms existing video captioning methods in terms of several different metrics.**

I. Introduction

With the rapid development of information technology, robots have become an integral part of our lives, enhancing productivity and convenience. Powered by Artificial Intelligence (AI), robots have the potential to capture the surrounding environment through cameras and provide descriptive text. Video captioning—which automatically translates video clips into natural language sentences—enables natural communication between humans and machines. This technology can be leveraged to enhance human-robot interaction, as well as enable applications such as improved accessibility for visually or hearing impaired individuals, automated video indexing, content search on social media, and quick multimedia information retrieval (see Fig. 1).

As reported in [1], traditional supervised learning methods require a large amount of labeled data, which can be costly and may suffer from issues such as label inconsistency and bias. Label inconsistency refers to the variation in labels assigned to the same sample by different annotators, which can lead to inconsistent model performance during training and testing. On the other hand, bias refers to the potential influence of subjective factors on labelers, resulting in inaccurate or unfair labeling of certain categories. These challenges and limitations in data annotation pose difficulties for traditional supervised learning approaches.

In recent years, a significant breakthrough has been witnessed in the field of natural language processing (NLP) with the emergence of foundation models. Foundation models are large-scale neural network architectures that are pre-trained on vast amounts of text data, enabling them to learn rich and diverse language representations. Additionally, the advent of multimodal foundation models, such as the Contrastive Language-Image Pre-training (CLIP) model [2], has further expanded the capabilities of foundation models. CLIP integrates visual and textual information, allowing the model to understand and generate coherent descriptions for images and videos. The success of foundation models, including CLIP, can be attributed to their ability to capture complex language patterns and visual representations, thereby enabling them to tackle challenging tasks. Furthermore, their pre-training and fine-tuning framework allows for efficient transfer learning, enabling adaptation to specific downstream tasks with relatively small amounts of task-specific data.

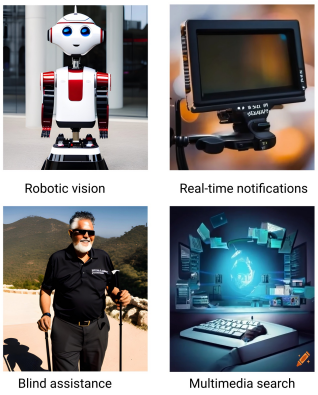

Fig. 1. Converting visual into textual information for human-machine interaction. Examples include robots using this technology to enhance visual perception and interact with users, real-time notification based on surveillance footage, assisting blind individuals in understanding their surroundings, and conducting diverse video searches.

Traditional video captioning approaches often struggle to capture the nuanced and complex relationships between visual and textual modalities, limiting their descriptive capabilities. By leveraging the power of CLIP, which has demonstrated exceptional performance in multimodal tasks, in this study we seek to enhance the accuracy and contextual relevance of video captions using CLIP. The motivation is based on two observations. First, CLIP's pre-training on massive amounts of image and text data enables it to learn joint representations

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

that effectively bridge the gap between visual and textual information. Second, CLIP's contrastive learning framework encourages the model to understand the underlying semantic relationships between images and their corresponding captions. The potential of CLIP for video captioning lies in its ability to leverage this learned multimodal understanding to generate captions that not only describe visual content accurately but also capture the context and intention behind the scenes.

In this paper, we develop an effective video captioning system based on the CLIP model [2] and an encoder-decoder framework named VLCap [3]. The experimental results on the ActivityNet Captions dataset [4] demonstrate the effectiveness of the proposed system in improving video captioning performance. By leveraging CLIP's description capabilities and the novel loss functions from [3], our system offers promising advancements in video-to-text translation tasks. This study contributes to the field of video captioning and opens up avenues for further exploration and improvement in this domain.

II. Related Work

Image analysis and natural language processing are among the core techniques in vision-language tasks. With the emergence of deep neural networks, most video captioning methods employ Recurrent Neural Networks (RNN) [5] to perform sequence modeling and utilize one or more Convolutional Neural Networks (CNN) [5] to analyze visual content. For instance, CNN is used as the encoder and the Long Short-Term Memory (LSTM) model is used as the decoder in [6]. Specifically, this approach employs three modules to process the video: (i) LOCATE for object detection in the video, (ii) RELATE for action detection in the video, and (iii) FUNC for natural language processing. However, in the RNN-based text generation models trained using the Teacher-Forcing method, there is a problem known as exposure bias. During training, the model uses previously generated words to predict the next word, leading to accumulated errors.

To address such issues, the Self-Critical Sequence Training (SCST) approach is proposed [5], utilizing reinforcement learning. SCST combines a sequence training model with Actor-Critic [7] to overcome the aforementioned problem and improve computational efficiency. In recent years, a novel architecture named Transformer has been introduced, which incorporates self-attention mechanisms to explore overall context in a sequence. Unlike the network architectures of RNN or CNN, Transformer performs better in training long sentences or videos. However, the use of attention mechanisms also increases its computational cost. Recent studies use Transformer as a foundational framework and optimize it with various methods [8]–[12]. For example, a new cross-model module is proposed in [13] to address the issues of poor computational efficiency and information asymmetry. Additionally, the skip-connected network is incorporated to further enhance the performance.

The proposed CLIP-CAP network is developed based on [3], which has two notable aspects. First, the fundamental Transformers heavily rely on self-attention mechanisms, which enable machines to learn the important relationships between words, similar to how humans understand words in a sentence. However, many existing video captioning methods use CNN as the encoder, which lacks self-attention. Therefore, an Adaptive Attention Mechanism (AAM) [14] is used in the encoding module, incorporating self-attention into the neural network. Second, most existing methods rely on Maximum Likelihood Estimation (MLE) for loss computation. However, MLE only considers the loss for the entire video and does not evaluate the learning progress of the model. To address this issue, a novel loss function, named the VL loss, is introduced in [3]. This method divides the video into multiple events and computes the VL Loss for each event, resulting in a more accurate error assessment.

III. Method

As displayed in Fig. 2, the model architecture consists of two main modules: the Encoder and the Decoder. The Encoder is responsible for processing the input video and generating visual features. On the other hand, the Decoder contains an attention mechanism and creates sentences based on the visual features. In this work, we rely on one of the powerful foundation models, CLIP [2], to compute effective visual features for this task. We now describe the background of CLIP, as well as the technical details of our video captioning system.

A. CLIP Pre-training

The core concept of CLIP [2] is to map text and images into the same space. Two encoders are involved in the training of CLIP—text encoder and image encoder. The text encoder is used to map a piece of text to a specific point in the space. The image encoder is used to map an image to a specific point in the same space.

Fig. 3 illustrates the training process of CLIP. It takes one batch at a time with n pairs of texts and images. A batch of texts involving n segments is fed into the text encoder to obtain text features $\{T_1, T_2, T_3, \ldots, T_n\}$. Similarly, the batch of n images is fed into the image encoder to obtain image features $\{I_1, I_2, I_3, \ldots, I_n\}$.

The CLIP model is optimized by using the loss: for the i-th pair of features (T_i, I_i) describing the same instance, the features should be as similar as possible, with a larger dot product between them indicating better similarity. This refers to the light blue area in Fig. 3. For the non-corresponding pairs in the batch, we want them to be as dissimilar as possible, ideally resulting in a dot product of zero. By using this contrastive loss, paired images and texts are mapped to surrounding points in the space, while non-matching images and texts will be mapped to different points that are far away from each other.

B. Encoder

We apply the encoder-decoder framework described in [3]. The video is first segmented into multiple small clips, referred

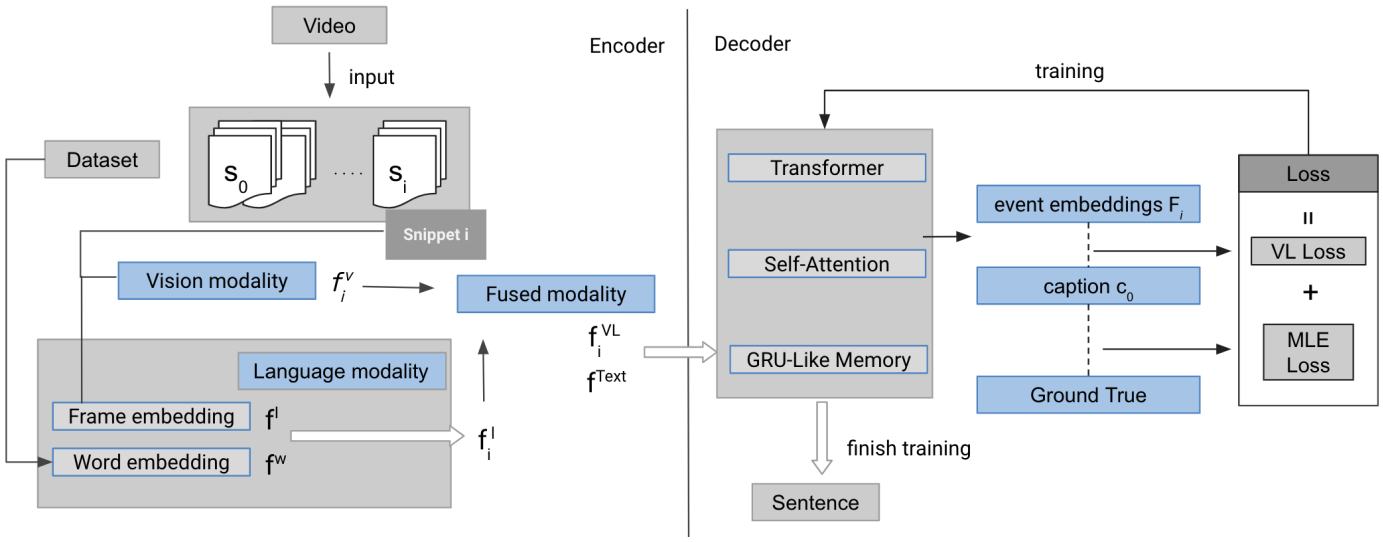

Fig. 2. Overall architecture of the proposed video captioning model. It consists of two modules: (i) CLIP-CAP Encoder takes a snippet S as input and returns VL feature as output (left). (ii) CLIP-CAP Decoder takes a list of VL features and returns a predicted caption (right).

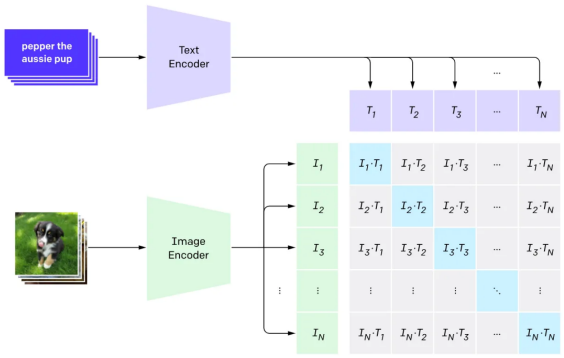

Fig. 3. Illustration of CLIP. The model trains an image encoder and a text encoder to predict image-text pairings. (Source: OpenAI - https://openai.com/research/clip)

to as events V_e. Each event is assigned a start time e_i^s and an end time e_i^e, i.e., $V_e = \{V_i | e_i^s < i < e_i^e\}$. The events are then fed into the Encoder as individual units. We then divide each input event V_e into L snippets, i.e., $V_e = \{S_i\}_{i=1}^{L}$. As depicted in Fig. 2 (left), the encoder employs three modalities to extract features from each snippet. The workflow of these modalities is illustrated in Fig. 4.

1) Vision Modality: The vision modality module is responsible for processing visual features. In this work, we apply CLIP [2] to compute visual features f_i^v for each snippet.

2) Language Modality: The language modality module is responsible for handling language features and consists of two stages: frame embedding and word embedding. In the frame embedding stage, the input snippet is transformed into visual features f^l using Vision Transformer [15]. In the word embedding stage, the language vocabulary is transformed into word features f^w. Both features (f^l and f^w) are then normalized using the pre-trained matrix [16] W from CLIP. Finally, the Adaptive Attention Mechanism (AAM) [14] is applied to filter out the language features f_i^l that are most relevant to the visual features.

3) Fused Modality: The fuse modality module combines the features generated by the two modules, namely the visual feature f_i^v and the language feature f_i^l, using self-attention mechanisms. This module generates the overall feature vector f_i^{VL} for the given snippet. Finally, L snippet feature vectors are combined to form the event feature vector f_i^{VL} and are sent to the Decoder.

C. Decoder

The input of the Decoder consists of the features F_i^{VL} generated by the Encoder for each event and the sentence obtained from the previous training session. The Transformer technique is used to construct the relationships between words in the sentence (intra-event coherence), while the GRU-Like Memory (historical information) handles the temporal aspects between sentences. At the end of each training session, a predicted caption c_i is generated, and then the Maximum Likelihood Estimation (MLE) is used to calculate the error, resulting in L_{MLE}. As mentioned earlier, using MLE alone cannot evaluate the current learning progress of the model. Therefore, the VL loss proposed in [3] is used in this work. This loss function involves using the event embeddings F_i generated by the Decoder and the sentences c_i obtained during each training iteration. These are processed through the Text Transformer to obtain the features f^T. The loss L_{vl} is computed as follows:

$$L_{vl} = -\sum_{i,j=1}^{N} 1_{i=j} \log e^p(f_i \cdot f_j^T) + 1_{i \neq j}(1 - \log e^p(f_i \cdot f_j^T)). \quad (1)$$

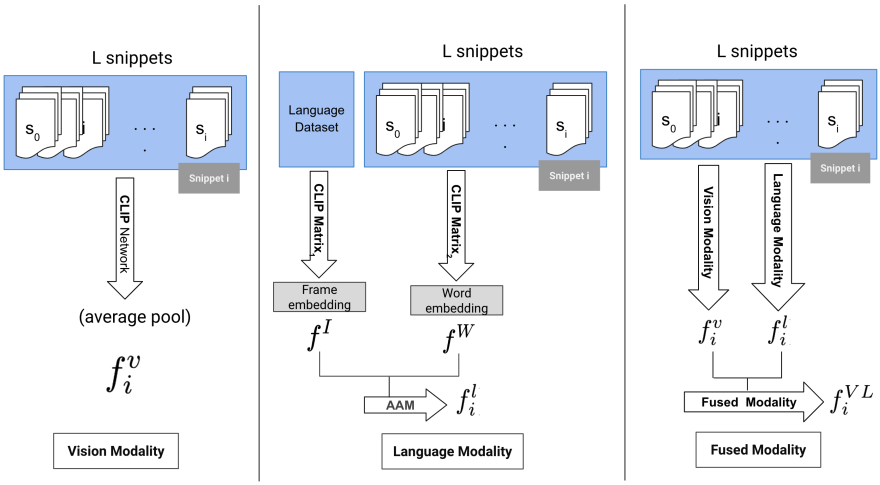

Fig. 4. Workflow of the vision modality (left), language modality (middle), and fused modality (right) in the encoder.

Finally, the training loss is a combination of L_{MLE} and L_{vl}:

$$L_{VL} = L_{MLE} + L_{vl}. \quad (2)$$

The Encoder and the Decoder are trained in an end-to-end manner.

IV. Experiments

The proposed CLIP-CAP model was trained and evaluated using the ActivityNet Captions dataset [4]. We used the pre-trained CLIP [17] model to compute visual features and did not fine-tune the model. The training samples were used to train the Encoder and the Decoder.

We evaluated the proposed CLIP-CAP model using three standard accuracy metrics, including BLEU@4 [18], METEOR [19], CIDEr [20], and one diversity metric, R@4 [21]. It is worth noting that we had fewer training samples to train CLIP-CAP due to the unavailability of approximately 3,000 videos in this dataset. Table I shows the comparison results with the state-of-the-art methods. Bold indicates the best result and underlined indicates the second best result. Although we used fewer training samples to train CLIP-CAP, it has the best performance in all metrics in comparison with other methods. Fig. 5 showcases a few results by comparing the descriptions generated by our model with the ground truth. The descriptions generated by our model are accurate and reasonable.

Next, we investigated the effectiveness of the CLIP features. In this experiment, we replaced the CLIP features with the C3D features, as shown to be a powerful representation for video captioning in [3]. As these features have different dimensions, we reduced the 100x2048 C3D features to 100x512 by using an autoencoder for a fair comparison. We used a smaller dataset comprising 16,580 samples in this experiment. The first two rows in Table II show the result. The CLIP features surpass the reduced C3D features in all metrics.

Finally, we reported the performance of the model using the original C3D features (2048-d) and that of using the concatenation of the C3D and the CLIP features (2560-d). The results are shown in the last two rows in Table II. These features are not complementary. Using the combined features achieved a comparable performance with C3D in BLEU and METOR, and slightly improved C3D in CIDEr and R@4.

Fig. 5. Descriptions generated by our method. (Left) A man is mowing the lawn on his lawn; the ground truth is "A man is seen pushing a lawn mower across a lawn to cut the grass." (Right) He starts mowing the lawn on the lawn; the ground truth is "The man continues moving the machine all along the yard while the camera captures his movements."

V. Conclusions

In this work, we have developed CLIP-CAP, a system for automated video description generation. The CLIP-CAP approach takes advantage of the powerful foundation model, CLIP. The pre-trained CLIP [17] model brings several advantages to a video captioning system, including semantic consistency and generality. It significantly simplifies the training pipeline, improves model performance, and enhances efficiency. Experiments on the ActivityNet Captions dataset demonstrate the effectiveness of CLIP-CAP, which outperforms state-of-the-art methods in four metrics.

Currently, our model focuses on processing visual content alone. In the future, we aim to integrate additional modalities such as audio information to further optimize our model's capabilities. Additionally, we aspire to implement dense video captioning as part of our ongoing advancements.

***Abstract* —Collecting or transmitting point cloud data is often subject to noise, which can potentially affect the accuracy of geometry and color representation in different spatial domains. This study addresses the denoising problem specifically for 3D point cloud color data and proposes two dedicated denoising algorithms based on the characteristics of noise in different spatial domains. In the denoising process, the RGB color space is first transformed into the YUV color space for further denoising operations. Surface smoothing is achieved by employing either a median filter or a bilateral filter based on the impact of noise on spatial information. These algorithms, built upon 2D image processing techniques, offer two key contributions: 1) color correction on spatial points to enhance denoising performance, and 2) the use of low-complexity filters while maintaining comparable filtering effectiveness, resulting in nearly a twofold reduction in processing time.**

Keywords – Median Filter, Bilateral Filter, Point Cloud.

I. INTRODUCTION

Point cloud is an unordered collection of points in 3D space. Information such as color, normals, transparency, position, or light intensity can be obtained through various acquisition methods such as scanning or capturing reconstruction. Point clouds have been increasingly applied in various fields, including medical modeling, heritage reconstruction, autonomous vehicle navigation, urban planning, and more. Compared to traditional 2D images that can only present a single perspective, point cloud data avoids issues such as occlusion and viewpoint transformation. However, during the acquisition process, point cloud data may suffer from geometric and color noise due to sensor errors, environmental interference, improper operation during acquisition, or noise introduced during transmission and compression, resulting in a degradation of its original quality.

Denoising has always been one of the significant challenges in point cloud technology. Unlike one-dimensional signals or two-dimensional images, point clouds do not possess explicit structural data. Therefore, the problem is primarily defined using Graph Signal Processing (GSP) [1] techniques. In previous literature, numerous denoising algorithms have been proposed [2]-[3], but most of them focus on addressing noise affecting the 3D positions. However, the color attributes of point clouds often come with noise, and even the noise in the positional attributes can indirectly impact the color information.

This paper focuses on the color denoising problem in point cloud space. Assuming the geometric space is either noise-free or has been corrected by previous denoising algorithms in the position space, the objective is to reduce noise in the color attributes without decreasing the number of points or altering the position properties of the point set. By adopting the concept of graph signal processing, each point in the point cloud is treated as a node in an undirected graph. Building upon well-established filtering algorithms developed for two-dimensional

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

images, the proposed denoising algorithm aims to remove noise from the color attributes without affecting the spatial positions.

II. PROPOSED ALGORITHM

After observing point cloud data affected by noise interference, this paper proposes different algorithms for processing color data based on specific circumstances, as illustrated in Fig. 1. Initially, a K Nearest Neighbors (KNN) search is performed to achieve a smoothing effect using the color information of neighboring points. Followed by the data preprocessing, the denoising process is applied using the proposed algorithms.

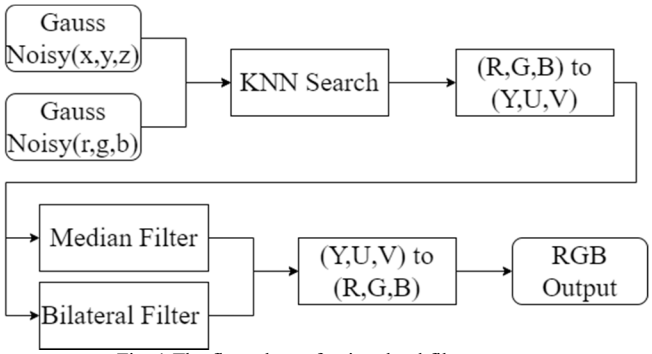

Fig. 1 The flow chart of point cloud filters .

A. Model Definition

A point cloud is composed of discrete points in 3D space, where each point can be represented as $p_i = [q_i, c_i]$. Here, p_i encompasses six pieces of information, namely the positional attribute represented by $q_i = [x_i, y_i, z_i]$, indicating the Cartesian coordinate information of point i. All positional attributes can be collectively represented as $q = [q_1, q_2, \ldots\ldots, q_N]^T$, where N denotes the total number of points in the point set. Based on the preliminary assumption , the positional coordinates are assumed to be noise-free or have already been corrected by other positional denoising algorithms. The other three attributes representing color are denoted as $c_i = [r_i, g_i, b_i]$. The color information in the point cloud data is stored in the RGB format. All color attributes can be collectively represented as $c = [c_1, c_2, \ldots\ldots, c_N]$. Therefore, the entire point cloud collection can also be represented as $p = \{q, c\}$.

Traditional two-dimensional image restoration refers to the problem of restoring a degraded or interfered image to its original form. Building upon this foundation, the color attribute model affected by noise can be simply defined as (1) :

$$d = c + n \quad (1)$$

B. Graph Construction

Due to the discrete and unordered nature of point clouds, mathematical operations can be highly challenging. Therefore, it is necessary to assign a representation that captures the correlation between points. An undirected graph $G = \{\nu, \varepsilon\}$ is defined, where ν represents the set of vertices in the graph, and ε represents the edges that form each connection within the graph.

The K NN method is employed to find neighboring points. This approach is based on the nearest Euclidean distance. By calculating the distances, nine closest points to point p_i are identified and considered as its neighboring points. This method treats each calculation as constructing a new undirected graph $G\{\nu, \varepsilon\}$, where ν represents the nine neighboring points along with point p_i, and ε represents the connections between each point and p_i.

C. Color Space Conversion

A color space is a standardized representation that defines how colors are displayed and typically consists of three parameters. The RGB model is a commonly used color space, where each color is represented based on corresponding spectral components of red, green, and blue. However, color hue, saturation, and brightness cannot be directly obtained from the RGB model. In contrast, the YUV model uses luminance and chrominance as parameters. One advantage of the YUV model is that luminance (Y) and chroma apperception (U,V) are separated, resulting in lower correlation compared to the RGB approach. In typical situations, luminance and chrominance exhibit piecewise smoothness (PWS) compared to the RGB color space. It can use the following formulas for conversion [4] :

$$[Y\ U\ V] = [0.299\ 0.587\ 0.114\ -0.147 \\ -0.289\ 0.436\ 0.614\ -0.515 \\ -0.100\ ][R\ G\ B] \quad (2)$$

$$[R\ G\ B] = [1.000\ 0.000\ 1.140\ 1.000\ -0.369 \\ -0.581\ 1.000\ 2.029\ 0.000\ ][Y\ U\ V] \quad (3)$$

The relationship between the YUV channels and RGB is linear, and the Y channel represents the additive synthesis of RGB, preserving the original high-frequency signal. The U,V channels, on the other hand, are obtained through subtraction operations from RGB. In addition to separating luminance and chrominance, the original colors are also divided into high-frequency and low-frequency components. Therefore, it is easier to achieve noise removal in image processing using this approach.

D. Bilateral Filtering

Bilateral filtering is a spatial filter that has been well-developed and commonly used to address denoising problems in 2D images [6]. It is based on the notion of spatial proximity and color similarity, using a Gaussian kernel function as weights. Points that are close in space and similar in color will have a larger influence on the new color attributes of the current point. The weight formula is as shown in (4) :

$$W_j = exp(-\frac{\|q_i - q_j\|^2}{2\sigma_q^2})exp(-\frac{(d_i - d_j)^2}{2\sigma_d^2}) \quad (4)$$

where q_i represents the coordinates of the current point, q_j denotes the coordinates of the neighboring points obtained through KNN search, d_i represents the color information of the current point, d_j represents the color value of the neighboring points, and σ_q and σ_d are the standard deviations of position and color, respectively.

The formula for bilateral filtering is defined in (5):

$$\hat{c}_i = \sum_{j=1}^{k} \frac{1}{w_j} d_j * w_j \quad (5)$$

Based on the bilateral filtering formula, this paper calculates the product of the neighboring weights obtained through KNN search and uses filters to obtain new values for the Y, U, and V channels. The color-related computations for each channel are performed independently, while the point positions remain fixed. Due to the characteristics of bilateral filtering, the newly obtained values can preserve image features and edges.

E. *Median Filtering*

While processing the noise for the positional properties, it may indirectly introduce errors in the color properties. P oints that have moved to incorrect positions can be seen as color attributes being disturbed by impulse signals. In 2D images, filters can effectively eliminate such noise while preserving the original image details and features.

One of the filters that effectively removes this type of noise is the median filter [5], which is computationally simple and fast compared to other filters. The median filter is defined in (6):

$$Median\,(\hat{c}_i) = c_j\left(\frac{k+1}{2}\right), where\ k = 9 \quad (6)$$

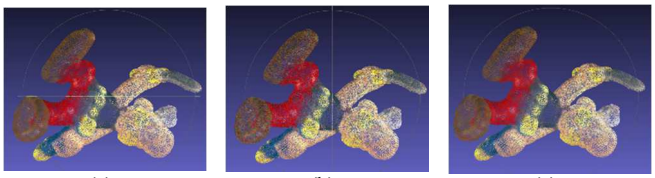
where c_j represents the set of neighboring points obtained through KNN search, and the YUV values of c_j are arranged in ascending or descending order. After sorting, the median of each YUV channel is taken as the new YUV value.

III. EXPERIMENTAL RESULTS

To evaluate the denoising results objectively, this study uses the Peak Signal-to-Noise Ratio (PSNR) as a standard metric. In order to calculate the PSNR values before and after denoising, this study first performed calculations on the color channels of the original image and the comparison image at the corresponding positions. Considering that the denoising results might lead to positional mismatches, if there is no corresponding point at the same position in both images, the nearest neighboring point is selected as the corresponding point. The Mean Squared Error (MSE) is then calculated based on the color differences between the two points. The calculation formulas for PSNR and MSE are as follows in (7) and (8):

$$MSE = \frac{1}{N}\sum_{i=1}^{N} \|c_i - \hat{c}_i\|^2 \quad (7)$$

$$PSNR = 10log_{10}\left(\frac{255^2}{MSE}\right) \quad (8)$$



Where c_i and $\hat{c}_i$ respectively represent the color information of the original point cloud and the color information of the denoised or noise-added points, N is the total number of points in the point cloud collection. The software and hardware platform used in this study are shown in Table 1.

Table 1 The hardware and software platform

Hardware platform	Version
CPU	Intel Core i7-7700
DRAM	DDR4 2666 16G
Software platform	Version
MATLAB	R2019a

A. *Performance of Bilateral Filtering*

In this section, the denoising method is applied to the Greyc dataset of synthetic point clouds to validate the effectiveness of the proposed methods. From Fig. 2, it can be observed that Fig. 2-a and Fig. 2-b depict the original point cloud and the point cloud with color attributes affected by Gaussian noise. After applying the proposed denoising processes, the color noise has been significantly removed, as shown in Fig. 2-c. Furthermore, the positional properties of the entire point cloud data have not been altered, and there has been no increase or decrease in the number of points.

(a) (b) (c)

Fig. 2 Asterix in point cloud model (a) Ground-truth (b)Noisy (c) Result.

Fig. 3 illustrates the appearance of the point cloud after surface reconstruction using the triangulation method. The result shown in Fig. 3-c provides a more intuitive and clear visualization than the image affected by Gaussian noise as shown in Fig. 3-b. The colors on the surface are obtained by averaging the color attributes of the connected three points.

(a) (b) (c)

Fig. 3 Asterix in triangulation method (a) Ground-truth (b)Noisy (c) Result.

In the Greyc dataset, the color attributes of the point cloud were simulated to be affected by Gaussian noise with a noise level of $\mu = 0$ and $\sigma = 20$. The proposed color denoising algorithm in this paper was then applied to restore the point cloud. Table 2 and Table 3 provide a comparison of the MSE and PSNR between the method proposed in this paper and the Tikhonov, TV, and SGW [7] methods.

Table 2 MSE Comparison of Color Denoising Algorithm for Greyc Dataset

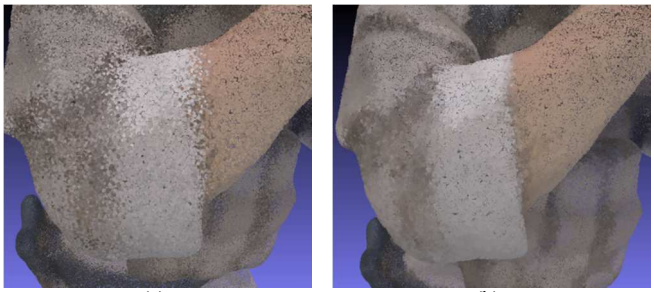
Model	Noisy	Proposed	SGW[7]	Tikhonov	TV
Asterix	361.25	**76.51**	98.2	103.56	279.02
Green Dinosaur	395.78	63.36	**63.03**	63.04	301.5
Jaguar	370.16	**71.29**	76.68	85.83	279.21
Pokemon	311.15	**83.75**	156.1	149.53	241.15
Red Horse	376.13	100.90	**80.64**	82.52	293.32
Average	362.894	**79.16**	94.93	96.896	278.84

Table 3 PSNR Comparison of Denoising Algorithm for Greyc Dataset

Model	Noisy	Proposed	SGW[7]	Tikhonov	TV
Asterix	22.56	**29.31**	28.21	27.98	23.67
Green Dinosaur	22.16	30.12	**30.13**	**30.13**	23.34
Jaguar	22.46	**29.62**	29.28	28.79	23.67
Pokemon	23.21	**28.93**	26.2	26.38	24.31
Red Horse	22.38	28.13	**29.07**	28.97	23.46
Average	22.554	**29.22**	28.578	28.45	23.69

These two indicators objectively demonstrate that the proposed method in this paper performs well in restoring the point cloud compared to the current algorithms. In order to compare the performance of this study, this study compares with other methods namely SGW, GLR, and GTV, which have shown good performance in denoising algorithms. As shown in Table 4 and Table 5, this study slightly outperforms the other algorithms in terms of average denoising performance. It is particularly notable in terms of speed, with an average execution time (AET) that is twice as fast as SGW. As a result this study maintains the denoising performance while improving the speed.

Table 4 Comparison of Color Denoising Based on PSNR



Model	Noisy	Proposed	SGW[7]	GLR[8]	GTV[8]
Asterix	22.56	**29.31**	28.21	28.10	27.56
Green Dinosaur	22.16	30.12	30.13	30.30	**30.34**
Red Horse	22.38	28.13	**29.07**	27.85	28.57
Average	22.37	**29.19**	29.14	28.75	28.82

Table 5 Comparison of Color Denoising Time Based on AET (s)

Model	Proposed	SGW[7]	GLR[8]	GTV[8]
Asterix	0.58	1.06	5.20	211.00
Green Dinosaur	1.06	1.82	11.20	389.00
Red Horse	1.84	3.48	19.50	851.00
Average	1.16	2.21	11.97	483.67

B. Performance of Median Filtering

From Fig. 4-a, after applying position-based denoising, some points affected by Gaussian noise still appear in incorrect positions. These erroneous points on the segmented smooth surface resemble impulse interference.

(a) (b)

Fig. 4 The cuff is disturbed by Gaussian noise (a) two stage filter (b) Result.

(a) (b)

Fig. 5 The Gaussian noise data (a) two stage filter (b) Result

Fig. 4-a and Fig. 5-a demonstrate the results obtained after applying the two-stage filter. Median filtering effectively corrects the color attributes of erroneous points, restoring the surface color of the point cloud to a smoother state, as shown in Fig. 4-b and Fig. 5-b.

Table 6 The comparison of PSNR

	Two Stage Filter	This Proposal
PSNR	24.04	27.85

The PSNR values provided in Table 6 indicate that the position-based denoising algorithm still significantly affects the PSNR in terms of color. In other words, this study effectively addresses the color errors caused by noise interference in the position.

IV. CONCLUSIONS

This study proposes a low-complexity and effective method for denoising point cloud colors and classifying noise, as noise can interfere with color space when acting in different spaces. The proposed algorithms in this paper are based on two-

dimensional image processing techniques, namely median filtering and Gaussian bilateral filtering, both of which are developed specifically for point cloud data under the assumption of position-wise stationary (PWS) properties. By employing K-nearest neighbors (KNN) search to identify a specific number of neighboring points and defining them as correlated data, the algorithm facilitates subsequent filtering operations. In both subjective and objective evaluations, the proposed algorithm demonstrates promising results, surpassing the state-of-the-art techniques in terms of computational speed. Extensive quantitative analysis is conducted on the Grey dataset, where evaluations based on mean squared error (MSE) and peak signal-to-noise ratio (PSNR) achieve satisfactory outcomes. Unlike existing point cloud denoising approaches, this paper focuses on denoising the color attributes of point clouds while preserving the integrity of their positional attributes. In future work, the integration of graph theory and triangulated meshes will be explored to achieve a more accurate representation of neighboring points. This alternative approach, as opposed to KNN, is expected to enhance the precision of the denoising process.

DDR4 is a high-speed memory structure commonly employed in modern medical devices. The benefit of DDR4 architecture enables fast data transmission and efficient data processing, it can effectively reduce the time for responding to medical devices and improve their performance. Therefore, our proposal is to design under Verilog and implement a DDR4 structure in order to transfer the biomedical signals of temperature, electrocardiogram(ECG), and electroencephalogram(EEG) data, furthermore, using ModelSim to simulate and verify the accuracy of the system.

Keywords—DDR4, ECG, EEG, temperature, multi-sensor Verilog, Modelsim

I. INTRODUCTION

With the continuous advancement of modern medical equipment and technological capabilities [1], we now have a plethora of devices capable of detecting human physiological signals. However, these devices are faced with escalating demands such as high-speed data transmission and reduced power consumption. Hence, our research endeavors to design a system that can efficiently receive multiple signals, operate at high speed, and minimize power consumption. This system is intended to address the evolving challenges posed by contemporary medical devices.

Double Data Rate 4 Synchronous Dynamic Random-Access Memory (DDR4 SDRAM) is a type of synchronous dynamic random-access memory with a high bandwidth ("double data rate") interface. The main advantages of DDR4 compare with its predecessor, DDR3, include higher module density and lower voltage requirements, moreover, it has better speed with data transmission. The standard of DDR4 allows for DIMMs with up to 64 GB in capacity. DDR4 works at a voltage of 1.2 V and a frequency between 800 to 1600 MHz. [2]

Electrocardiography is the process of producing an electrocardiogram (ECG), it records the heart's electrical activity through repeated cardiac cycles. Three main components are composed of an ECG: the P wave, which represents depolarization of the atria; the QRS complex, which represents depolarization of the ventricles; and the T wave, which represents repolarization of the ventricles.[3]

Electroencephalography (EEG) is a method to record an electrogram for the spontaneous electrical activity of the brain. EEG can detect abnormal electrical discharges such as sharp waves, spikes, or spike-and-wave complexes in epilepsy patients, thus it is often used to inform the medical diagnosis. EEG can detect epilepsy patients for spatiotemporal (location and time) evolution of seizures and the continuous status of epileptics. It is also used to help diagnose sleep disorders, depth of anesthesia, coma, encephalopathies, cerebral hypoxia after cardiac arrest, and brain death.[4]

II. SYSTEM ARCHITECTURE

In this paper, our objectives are threefold: signal differentiation, data compression, and high-speed transmission. To achieve these goals, our adopted architecture consists of three main components: an adaptive filter, entropy processor, and a DDR4 controller. As depicted in Fig. 1, this diagram illustrates the system architecture of our study. In the subsequent sections, each of these components will be introduced and explained in detail.

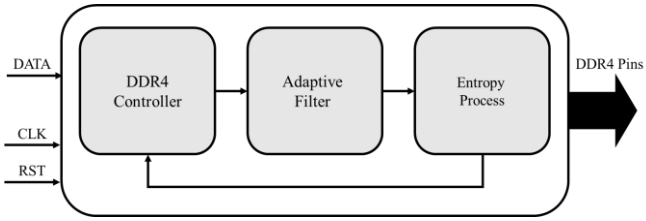

Fig. 1. The system structure of the frame diagram

A. Adaptive Filter

Considering the diverse input sources encompassing body temperature, electroencephalogram (EEG), and electrocardiogram (ECG) signals in this paper, individualized compression processing for distinct signal sources is aimed to be achieved. This approach offers the advantage of enhancing data compression efficiency while reducing system power consumption. Hence, the role of the adaptive filter in the preprocessing stage is of paramount importance. Given the varying bit lengths within our data, we can classify signals by detecting the bit length of the input source, thus achieving improved compression results.

B. Entropy processor

Entropy coding is a data compression technique that represents data efficiently by utilizing probability models and the concept of entropy. The objective of this approach is to reduce redundant information in data, thereby occupying less storage space or transmission bandwidth.[5]

In entropy coding, symbols with higher probabilities of occurrence are assigned shorter codes, while symbols with lower probabilities receive longer codes. The aim is to save space when encoding common symbols and ensure that codes for different symbols do not overlap. The two primary methods of entropy coding are Huffman coding and arithmetic coding. In this paper, we adopt Huffman coding due to its simplicity and good compression efficiency.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

In this paper, we deal with three types of biomedical signals: body temperature, electroencephalogram (EEG), and electrocardiogram (ECG). Since body temperature exhibits relatively small variations within each time unit, we choose to employ the differential coding method for compression. Conversely, EEG and ECG display a high degree of temporal redundancy within each time unit, making Huffman coding an effective choice for achieving compression. Through these selections, we ensure data integrity while achieving efficient compression.

C. DDR4 Controller

To achieve the goal of high-speed transmission, we adopt the DDR4 architecture.[6] To accomplish this objective, designing a DDR4 controller is essential for managing data read and write operations. Throughout this design process, referencing the DDR4's Data Sheet is crucial to ensure accurate operation.

The primary functionalities of DDR4 revolve around executing distinct actions through command instructions, including activating, reading/writing, precharging, and refreshing. In our design, we need to tailor the DDR4 controller based on these fundamental operations to ensure our system executes these actions accurately.

Fig. 2 illustrates a simplified state diagram for DDR4, aiding our comprehension of its operational processes. We will utilize this FSM diagram to craft our DDR4 controller, ensuring smooth transitions between different states to accomplish high-speed data read and write operations.

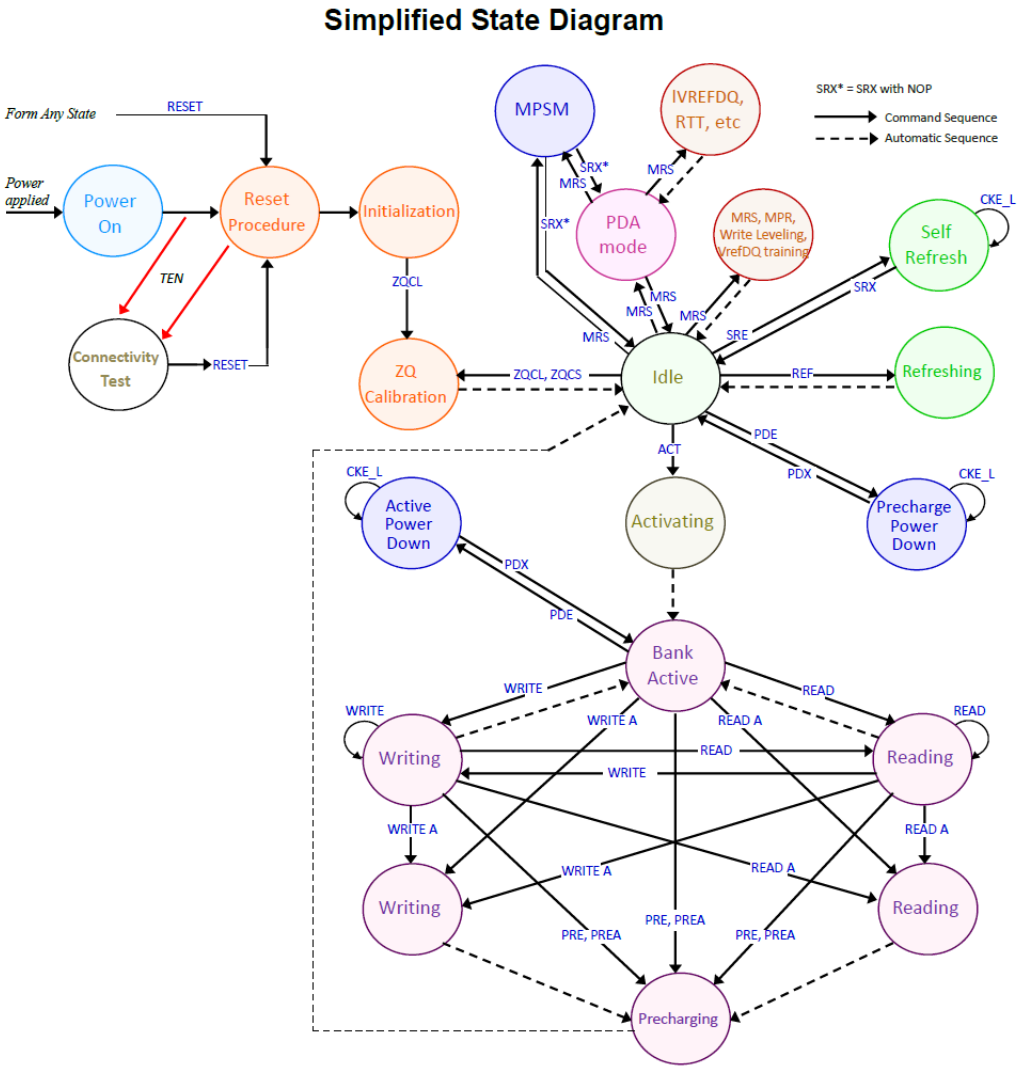

Fig. 2. The DDR4 FSM diagram

III. Simulation Environment and Results

In this study, we opted for the Windows operating system as the platform for execution and simulation, utilizing ModelSim SE 10.5 to create our simulation environment. The choice of the Windows operating system offers a user-friendly graphical interface and an extensive software ecosystem, facilitating development, simulation, and analysis. Selecting ModelSim SE 10.5 as our simulation tool enables us to conduct in-depth analysis of our design.

In the upcoming sections, we will present simulation results for the adaptive filter, entropy processor, and DDR4 controller components. Additionally, relevant data will be introduced to provide detailed explanations and analyses.

Table I presents the power consumption, number of Look-Up Tables (LUTs), and number of flip-flops (FFs) utilized by each component. Additionally, Figs. 3, 4, and 5 display the simulated waveform of each component, providing a clear representation of the relationship between input signals and filtered outputs.

TABLE I. Hardware Resources Consumed by Each Component

	Power	LUT	FF	Gate Counts
Adaptive filter	0.2 W	6	17	0.36 k
Entropy processor	0.94 W	45	35	0.27 k
DDR4 Controller	3.81 W	208	306	1.25 k
Total	4.95 W	259	358	1.55 k

Figure 3 illustrates the output and input of the Adaptive Filter. In this simulation, "data_in" represents the input signal, and for this particular simulation, it uses EEG signals. "state_out" and "data_out" are the output signals. In this design, "state_out" signals 0 to 3 correspond to "IDLE," "body temperature," "ECG," and "EEG" respectively, in sequence. From the simulation diagram, it is evident that the simulation is accurate and correctly represents the intended functionality

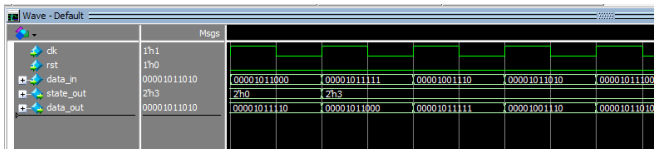

Fig. 3. ModelSim waves of Adaptive Filter processor

Figure 4 displays the output and input of the Entropy processor. In this illustration, "data_in" and "state_in" represent the input signals. "state_in" is derived from the previous stage, the Adaptive Filter, and it indicates the source of the input signal, selecting the corresponding entropy processing method. "data_out" and "length" are the output signals.

For this Entropy processor design, it first subtracts the two consecutive data points. In the mode where the input source is "body temperature," it directly outputs the difference between these two data points. In the modes where the input source is "ECG" or "EEG," the Entropy processor transforms this difference into the corresponding Huffman-encoded value. Table II and III describes the Huffman encoding methods for "ECG" and "EEG."

For this simulation, EEG signals are used. Therefore, it can be observed from Figure 4 that the "state_in" signal is 3, indicating EEG signals. From the simulation diagram, it is evident that the simulation is accurate and correctly represents the intended functionality.

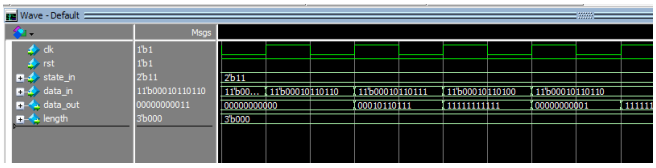

Fig. 4. ModelSim waves of Entropy processor

Figure 5 presents the input and output signals of the DDR4 controller section. Signals like "cke," "actn," "bank_add," "rasn," "casn," "bank_add," and "addr" play critical roles in DDR4 control, and Table IV lists some key DDR4 commands. The design of the DDR4 controller is primarily based on the signal timing provided in the datasheet, with many design details referencing datasheet information. The signals in Figure 5 illustrate the functionality of DDR4 initialization.

In this study, the Terasic HAN Pilot Platform development board was used to test the functionality of the DDR4 controller. This development board offers Nios II software program control, enabling quick hardware testing through software. Figure 6 displays the test results

for data write and read operations, demonstrating successful completion of both write and read functions. This indicates that DDR4 initialization and read/write functions operate as expected.

IV. CONCLUSION

In this paper, we utilized ModelSim for circuit simulation and verification, achieving DDR4 high-speed transmission, automatic classification of sensor signals by the adaptive filter, and corresponding compression. The compression ratios achieved are TEMP:3.6, ECG:2.2, EEG:2.5.

Compared to the work by Y. -J. Huang et al., their system can adaptively handle four different input signals, which is superior to our paper's three signals. However, our research introduced innovations in high-speed data transmission and data compression technologies, providing significant advantages to our system, including reduced power consumption and improved system performance. This makes our system more suitable for addressing modern and diverse application requirements while delivering higher efficiency.

In comparison to the paper by T. -H. Tsai and M. A. Hussain, although their work focused on lossless compression of ECG, our research introduced compression for multiple types of signals, making our system more versatile and functional.

Compared to the paper by L. Kuang, J. Zeng, and P. Georgiou, while their paper also utilized DDR4 high-speed storage, our system excels in terms of functionality and versatility.

In summary, the comparison in Table V clearly outlines the strengths of our paper. Our system excels in processing multiple sensor signals, adaptive filtering, and high-speed transmission capabilities.

TABLE V. COMPARISON WITH OTHER ARTICLES

	This paper	2013[8]	2020[9]	2021[10]
Number of sensors	3	4	1	1
Compression ratios	Temp: 3.6 ECG: 2.2 EEG: 2.5	×	2.77	×
Adaptive filter	✓	✓	×	×
High-speed transmission	DDR4	×	×	DDR4

***Abstract*—This paper presents an image-based target detection and integration algorithm for victim wearing vibrant clothing. The algorithm utilizes image processing and analysis techniques to automatically identify and locate victims, and combines the detected bounding boxes into a larger box. Experimental results validate the effectiveness and accuracy of the algorithm in various environments. The proposed algorithm can be applied in emergency response, disaster management, and surveillance systems, enhancing the efficiency of victim search and rescue operations**

Keywords—victim search, vibrant clothing

I. INTRODUCTION

While mountaineering is undoubtedly a highly enjoyable recreational activity, it also comes with various risks. Adverse weather conditions, slips and falls, rockfalls, and altitude sickness, among others, can lead to mountain accidents. With the increasing popularity of mountaineering in recent years, the number of mountain incidents has also been on the rise. Mountain rescue is an extremely challenging and resource-intensive task. Hindered by terrain, signal, and visibility issues, mountain rescue operations are highly demanding. The dense vegetation and foliage not only obstruct the rescuers' line of sight but also make aerial rescue difficult. Rescue missions are a race against time because once night falls, the rescue operation becomes even more daunting. G. Seeja et al [1] mentioned that the possibility of saving a victim is high only during the first 48 hours, and then the prospect tends to zero. So they developed a Transfer Learning-based Deep Learning approach to identify human victims under collapsed building environments by integrating machine learning classification algorithms. To ensure higher accuracy within a shorter timeframe.

Image processing is a field of study that focuses on analyzing and manipulating digital images using computer algorithms. It involves various techniques and methods to enhance, transform, or extract information from images for a wide range of applications. In this area, Xuewen Wang et al [2] used an algorithm for extracting characters from text regions of natural scene images with complex backgrounds. W. Hoshino et al [3] mounted a wide-angle camera on the drone, which is easy to control in a narrow building space. In some experiments, the drone was equipped with a thermographic camera to facilitate detection of victims. They investigated the effects of each and looked for ways to detect victims more accurately.

H. Liu et al [4] created an innovative air-space integrated system that combines the Remote Satellite System (RSS) and Unmanned Aerial Vehicles (UAVs) to enhance disaster response. Utilizing advanced image analysis and UAV control techniques, they employ fusion algorithms for victim detection, satellite navigation for patrolling, and camera-based navigation for precise aid delivery.

D. Yanguas-Rojas et al [5] presents a control strategy for multiple heterogeneous robots oriented to the assistance in situations of search and rescue from two complementary perspectives, the real time control and the discrete task allocation. This approach takes into account not only the current conditions of the environment and victims but also estimates the future positions of victims and the potential locations of remaining victims.

Under the comprehensive framework outlined in numerous research papers, the potential for implementing the entire system has been enhanced. This includes aspects such as search and localization, path planning, as well as visual analysis techniques, and more. The focal point of this article will be on feature recognition, aiming to address the system's limitations and enhance its capabilities.

The article proposes a method that can quickly search for mountaineers in images, utilizing the functionalities provided by MATLAB. The application areas include computer vision, autonomous driving [6] , medical imaging and many other fields.

II. IMAGE PROCESSING

As shown in Figure1., our proposed system consists of six-part: Input, Pre-Processing, Target Detection, Region Labeling, Region Selection, and Integration of Bounding Boxes. Next, each part will be described in detail.

A. Color Space Conversion

In digital images, colors are typically represented using different color models, such as RGB, HSV, CMYK, and YUV. Each color model has its own advantages and characteristics, and converting between them enables us to extract specific color information or enhance certain features of an image.

C. Liu et al [7] mentioned a fog level detection method based on image HSV color histogram and shows that the HSV model is very suitable for image algorithm processing color perception based on the human visual system. The conversion from RGB to HSV is based on the transformation of the cube model in RGB color space to the cylindrical model in HSV color space is obtained by the following formula:

$$H = \begin{cases} 0, & if\ Min = Max \\ 60 \times \frac{(G-R)}{(Max-Min)} + 60\ (if\ Min = B) \\ 60 \times \frac{(B-G)}{(Max-Min)} + 180\ (if\ Min = R) \\ 60 \times \frac{(R-B)}{(Max-Min)} + 300\ (if\ Min = G) \end{cases} \quad (1)$$

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

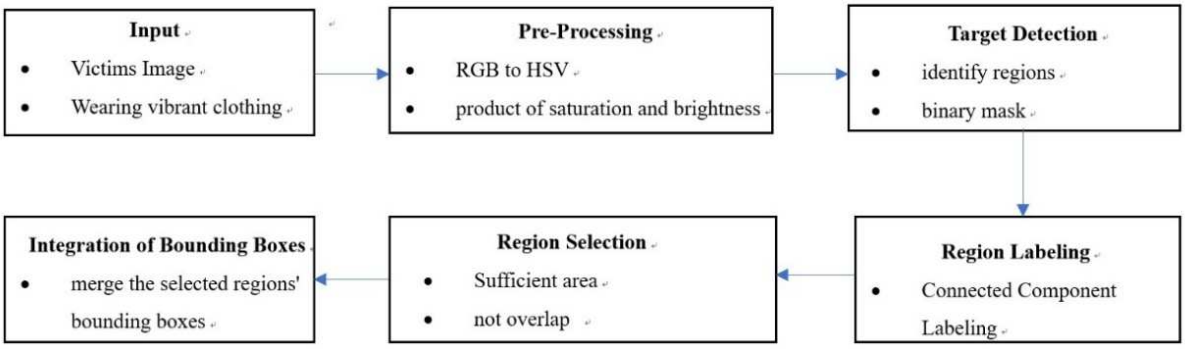

Figure1.The System Flowchart

$$S = \begin{cases} 0, & if\ Max = 0 \\ \frac{Max-Min}{Max} \times 255, & otherwise \end{cases} \quad (2)$$

$$V = Max \times 255 \quad (3)$$

Min is the color channel in RGB where the minimum value is found. It is used to determine the basic color tone of the color. Max is the color channel in RGB where the maximum value is found. It is used to calculate H and determine the color's saturation and brightness.

B. Feature Extraction

H. Xu et al [8] designed a feature extraction method of ophthalmic image. The feature blocks of ophthalmic image are divided, and the window of threshold selection is determined according to the comparison of pixel and threshold range.

The paper uses the product of saturation and brightness of an image as a feature, where the highlighted region represents the location of the victim in the image. This characteristic is characterized by higher feature values

A threshold is set based on this feature map. Pixels with a product greater than the threshold are set to 1 with red color, while pixels below the threshold are set to 0 with the green color, creating a binary mask showing in Figure2. By labeling the connected regions in the mask, the pixels belonging to the same region are grouped together and can be segmented into different areas.

Figure2. Binary Mask

C. Expansion Factor

H. Tian et al [9] mentioned the goal of expansion step is to compute a support plane for each pixel in the image. The idea behind expansion is the fact that the neighboring pixels are very likely to have similar planes. And is able to expand its good plane to its neighboring pixels especially for high resolution images because of the local similarity.

The expansion factor is a parameter used to adjust the size of the detected regions during the victim search algorithm. By increasing the expansion factor, the algorithm enlarges the bounding boxes around the detected regions. This expansion helps to include more surrounding pixels and provide a larger margin of error, increasing the chances of capturing the complete area of the victim.

D. Connected Component Labeling

J. G. Pandey et al [10] present a field-programmable gate array (FPGA) platform based approach for implementing an efficient and improved two-scan equivalence-based connected component labeling algorithm. With the development J. G. Pandey et al [10] present, we can further validate the feasibility of the connected component labeling algorithm and assess its accuracy for application in hardware showing in Figure3.

To remove a lot of noise, the "bwlabel" function is used to calculate the connected components of a binary image, identifying and labeling connected regions showing in Figure4. The binary mask (MASK) is generated based on the product of saturation and brightness and a threshold value called "vividness_threshold". MASK marks which pixels are considered to have a sufficiently high saturation (color vividness) and brightness (luminance), i.e., falling above the threshold. Since victims are defined as relatively larger objects, the "bwlabel" function is used for connected region analysis, where each connected group of pixels is assigned the same label, and the number of labels corresponds to the total number of these connected regions.

After labeling each connected region, we check whether its area is greater than "min_area" and examine if the new connected region overlaps with the previously identified regions. If the overlap exceeds a certain threshold (in this case, 50%), it is considered the same region. Otherwise, the new connected region is added to the list of already identified regions, and those with sufficient area are selected for expansion. The expanded regions are merged into a single bounding box.

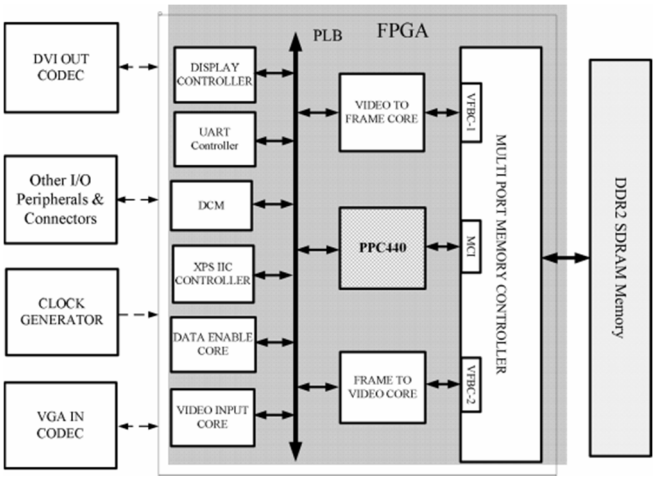

Figure3. System architecture for image acquisition for connected component labeling algorithm[8]

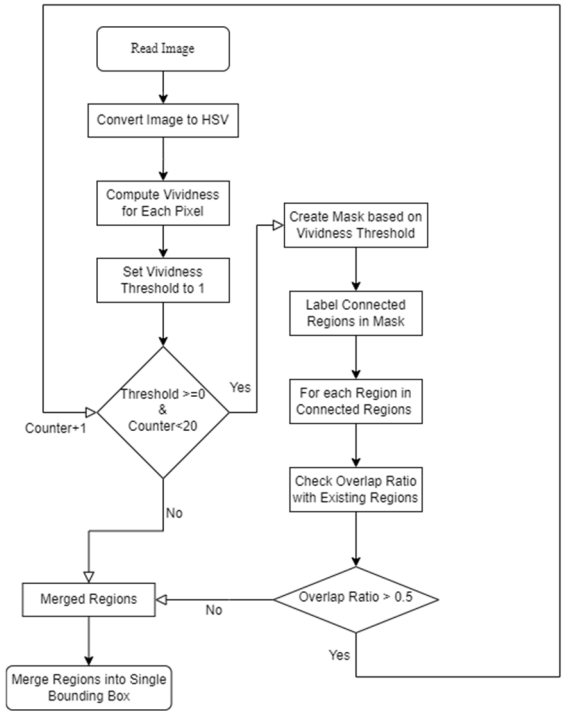

Figure4. Identifying And Labeling Connected Regions

E. *Intergration Of Bounding Box*

We have identified multiple areas with high saturation (color vividness) and brightness in our findings. We generated corresponding bounding boxes for these areas. However, there may be some scattered or overlapping boxes, leading to judgment errors. Therefore, we attempted to merge these boxes into a larger one to highlight the overall region.

Calculated the average position of all box centers and the distance from each box center to the average position are obtained by the following formula:

$$Sum = \sum_{x=x_{min}}^{x_{max}} \sum_{y=y_{min}}^{y_{max}} I(x,y) \quad (4)$$

$$Mean = \frac{1}{NumPixels} \sum_{x=x_{min}}^{x_{max}} \sum_{y=y_{min}}^{y_{max}} I(x,y) \quad (5)$$

I(x, y) represents the pixel value at position (x, y) in the image and "NumPixels" represents the number of pixels within the bounding box.

Then, we excluded boxes that were far from the average position and retained only those close to it. This was done to remove scattered boxes and keep only those in concentrated areas. We used the 'insertShape' function to draw the merged large box on the original image. Additionally, we inserted text next to the large box to display the value of the average threshold. This text serves to provide additional information about the average value of the threshold for identifying these areas with high saturation (color vividness) and brightness (luminance).

III. EXPERIMENTAL RESULTS

Ž. Marušić et al [11] examine the effectiveness of visual search of human observers for the purpose of finding missing/lost persons on aerial imagery. On average they were able to detect 84 target objects and the average recall was 80.43%. Significantly better results were achieved in precision that takes into account false alarms or false detections. Average precision was 90.98% shows in Figure5.

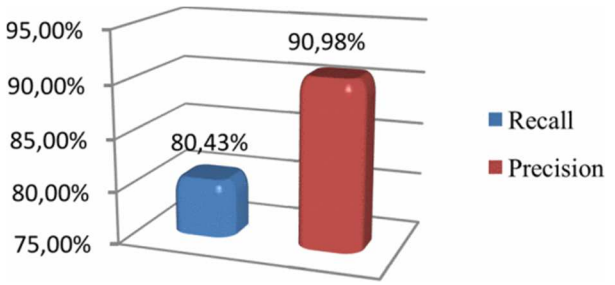

Figure5. Average recall and precision[9]

We present the experimental results of the proposed image-based target detection and integration algorithm for victim search. We evaluated the performance and accuracy of the algorithm using various image datasets and scenarios. The following are our experimental results.

In Figure 5, it is clearly visible to the naked eye that the victim standing in the center of the image is wearing vibrant clothing, making it relatively easier for search and rescue operations as there are no significant obstacles obstructing the rescuers' line of sight. Conversely, in Figure 6, the victim is more likely to be overlooked by the rescuers due to the presence of numerous interfering factors that affect their judgment. However, the experimental results accurately capture the vibrant clothing worn by the victim.

Figure6. Mountain Accident Victim

Figure7. Mountain Accident Victim

IV. CONCLUSION

In this paper, the position of victims in the image is identified using MATLAB. The test results show that the vibrant clothing of the victims can be accurately recognized. However, in cases where the surrounding environment is too complex or the surroundings are more vibrant than the clothing of the victims, the recognition may be distorted. furthermore, due to a lack of photo support and an insufficient number of victim photos available, there is not enough data to populate all the elements of the confusion matrix, including true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN).

In the future, training on the images will be conducted to achieve higher accuracy in identification.

***Abstract*— Point cloud is a point-based representation of three-dimensional data used to describe the geometry of objects or scenes However, due to its large data volume, a point cloud needs to be compressed to reduce the data volume. After point cloud compression, some points may be lost, causing the loss of edge details and the appearance of point cloud holes and outliers, leading to a significant subjective quality decrease and affecting point cloud development in practical applications. In this paper, an effective point cloud repair method is proposed. First, use the mean filter to remove outliers, so that the subsequent point-filling algorithm can avoid errors caused by outliers. Secondly, the point cloud is analyzed by the Delaunay triangulation method. Perform statistical analysis on the areas of all triangles. If an individual triangle has an area larger than the average, it is marked. After comparing the triangles, the coordinates of all the holes in the point cloud can be found, so as to identify the holes in the point cloud. In the hole-filling strategy, the interpolation method is used to average the coordinates and color information of the three vertices of the triangle to obtain the filling point, that is, to complete the restoration of the point cloud data. When evaluating the results, in addition to PSNR, the GraphSim index proposed by Q. Yang was also referred to [1]. This indicator is closer to the subjective evaluation of people and better reflects the subjective evaluation of people. According to the experimental results, the GraphSim of the proposed method can reach 0.363, which significantly improves the point cloud data after V-PCC compression [2].**

I. INTRODUCTION

Point cloud has become an important research direction in computer vision, robotics, autonomous driving, and other fields. The subjective visual quality of the point cloud is crucial in its applications. Therefore, point cloud repair has become a popular research topic. Two common reasons for point cloud holes are identified. Firstly, specialized scanning devices usually acquire point cloud data using 3D laser scanning to obtain 3D data on object surfaces. However, occlusions or scanning surface reflection errors can cause holes in the collected point cloud [3]. Secondly, point clouds typically have a large amount of data and require compression, such as the Motion Picture Experts Group (MPEG) established video-based point cloud compression (V-PCC) standard [2]. The compression standard employed in this study involves storing point clouds in 2D image format to reduce data size, and decoding them back to 3D point clouds when necessary. However, this process will cause a large loss of edge details, which will lead to the loss of information at the edge.

In recent years, several methods have been proposed for repairing holes in point clouds. For instance, Keming Cao et al. [4] utilized V-PCC to annotate the edges of 2D images and then mapped them back to the 3D point cloud to obtain the hole positions. They then mapped the holes onto the XYZ plane and performed a closing operation on each of the three planes to repair the holes. This paper refers to the hole-filling strategy used by Erjie Nie [5], who preprocessed the point cloud using

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Delaunay triangulation. Instead of interpolating the midpoint of adjacent points as in the reference paper, this paper calculated the sum of the areas of all triangles and used the average area as the threshold. When the triangle area is larger than the average area, it is defined as a hole-filling point. The centroid coordinates of the triangle are used as the interpolation point. The process repeats until the area is smaller than the average, indicating that hole filling is complete. This method solves the problem of sparse insertion points in the repair process.

Research structure flow chart: First, denoise the point cloud, and then perform Delaunay Triangulation and interpolation calculation. Finally, analyze the experimental results of the point cloud Fig. 1.

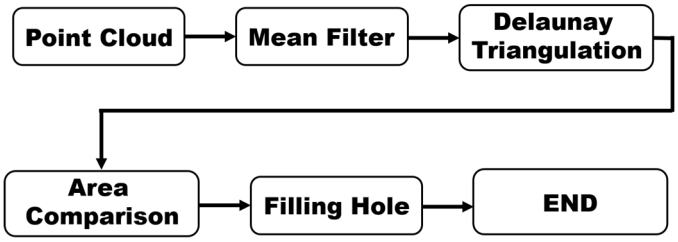

Fig. 1 Research structure Flow chart

II. EXPERIMENTAL METHOD

A. *Denoising for Point Cloud*

The point cloud with holes in this paper was obtained by referring to the method in [6], which uses the MPEG V-PCC's r1 file. Compared to the r5 file, which has better subjective visual performance after reconstruction, the geometry QP and texture QP values in the r1 file were increased from 16 and 22 to 32 and 42, respectively. Increasing the QP values means that the distortion of point cloud compression increases, resulting in poorer performance of details. As shown in Fig. 2 there are significantly many outlier points on the edges of the point cloud, and these outlier points will cause the Delaunay triangulation effect to deteriorate in the subsequent processing. Therefore, point cloud denoising preprocessing is needed to filter out the outlier points.

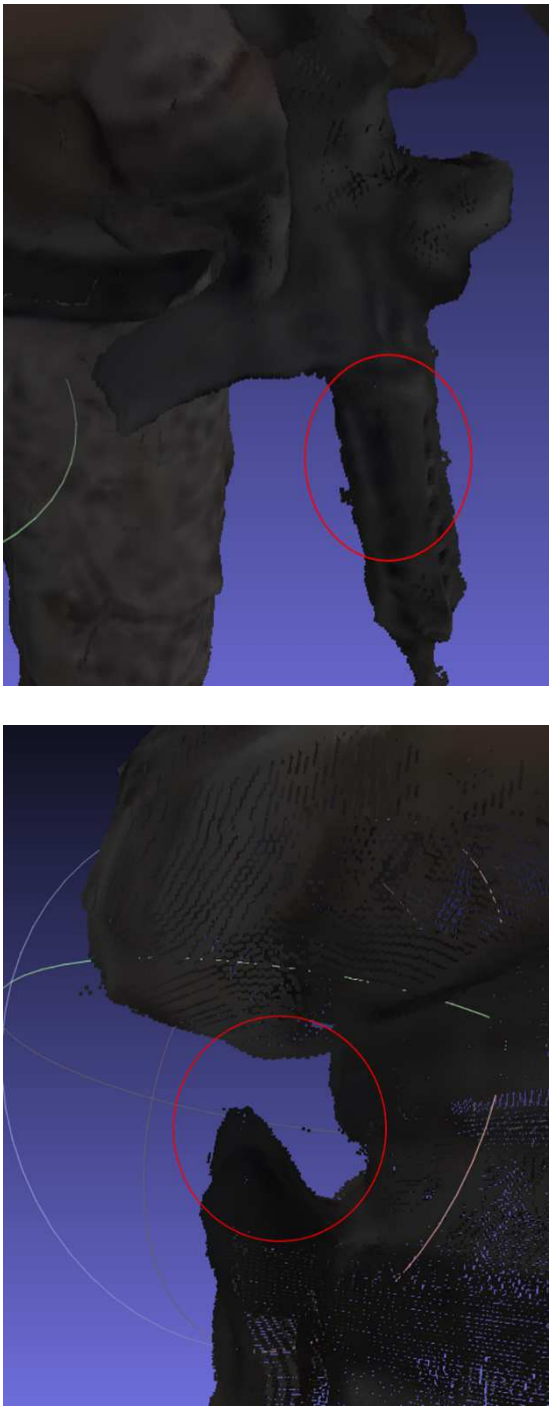

Fig. 2 Point cloud after V-PCC r1 file

Point cloud denoising is a highly popular area in computer vision. The main filtering methods can be classified into several categories[7]. The first type is based on neighborhood analysis, which estimates the similarity of a point and its neighbors. Examples include bilateral filtering, mean filtering, and non-local mean filtering. The second type is based on statistics, such as local median filtering, local averaging, and Bayesian statistics. The third type is based on partial differential equations (PDEs). Since this paper only aims to filter out outlier points instead of complex Gaussian noise, we adopt mean filtering. Compared to other methods, it has lower

computational complexity and is faster. By performing a K-Nearest-Neighbors (KNN) search to find k nearest points(P_i) of the target point P, we obtain the positions of k points and then average them by adding their coordinates. Finally, we replace the coordinates of the target point P with the calculated average value (1). This process moves the outlier points closer to the main body of the point cloud. As shown in Fig. 3, the denoised point cloud has significantly fewer outlier points compared to Fig. 2.

$$P(x) = mean(\sum_{i=1}^{k} P_i(x))$$
$$P(y) = mean(\sum_{i=1}^{k} P_i(y)) \quad (1)$$
$$P(z) = mean(\sum_{i=1}^{k} P_i(z))$$

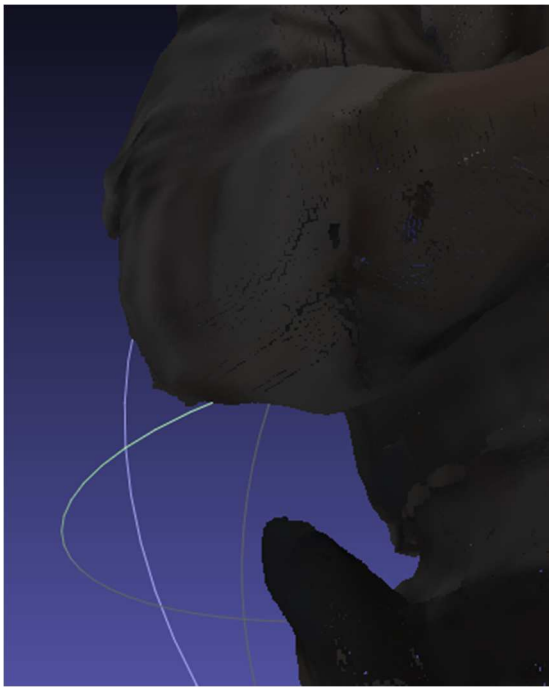

Fig. 3 Point cloud after mean filter

B. Point Cloud Delaunay Triangulation

The purpose of this research is to obtain the geometric relationship between points through the Delaunay triangulation of the point cloud. Unlike 2D images with inherent order, 3D point clouds are disordered, so a method is needed to obtain the computational correlation. As mentioned in [6], slicing the point cloud along the y-axis to obtain a 2D image facilitates computation. In this study, Delaunay triangulation is adopted, which is an important preprocessing technique for numerical analysis and computer graphics. Delaunay triangulation has two advantages: first, it maximizes the minimum angle, resulting in a triangle mesh that is closest to being regular; second, no four points can be cocircular. This method is particularly effective for dense point clouds such as Soldier, as shown in Fig. 4 which displays the results of Delaunay triangulation of the Soldier point cloud.

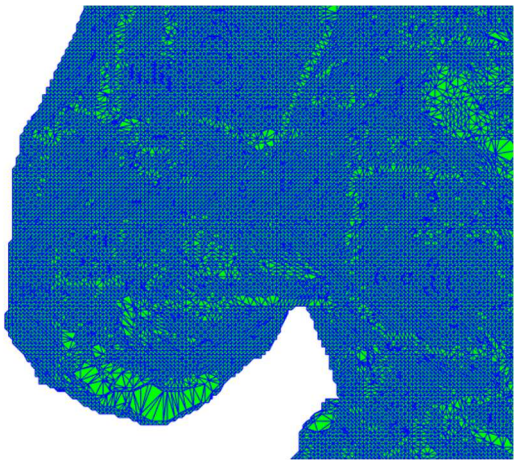

Fig. 4 Point cloud after Delaunay Triangulation

C. Hole Detection

After converting the point cloud into a large number of three-point matrices through Delaunay triangulation, the next step is to detect holes. For a triangle with three points A(x1,y1,z1), B(x2,y2,z2), and C(x3,y3,z3), this paper calculates the area of each triangle and sums them (2), then divides by the total number of triangles to obtain the average area. This value is used as a threshold u and individual triangles with areas greater than the threshold are marked, allowing the coordinates of the holes in the point cloud to be obtained. Fig. 5 shows the hole triangles calculated after comparison.. After multiple attempts, a threshold value of 2 times the average area was found to be most effective, as it can identify large holes while avoiding marking holes that are too small compared to the average.

$$Mean\ Area = Mean(\sum_{i=1}^{n} \frac{1}{2} \left|\overrightarrow{A_iB_i} \times \overrightarrow{A_iC_i}\right|) \quad (2)$$

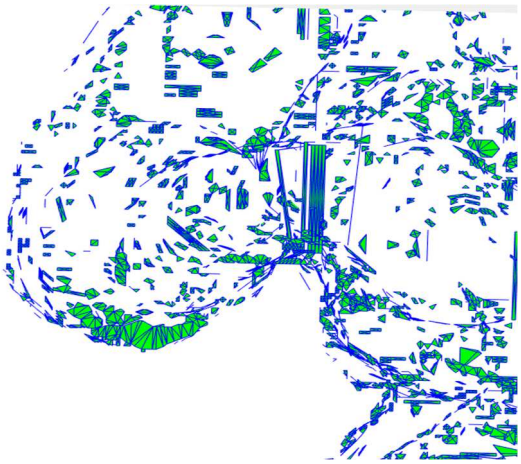

Fig. 5 Hole triangle after area comparison

D. *Hole Inpainting*

In the hole-filling strategy, the coordinates and color information of the three vertices of each triangle are averaged using interpolation to obtain information about the hole-filling points. After adding the hole-filling points, the triangle areas are recalculated and compared with the average area. If any triangle has an area greater than the threshold value, interpolation is continued and the iteration is repeated until all triangles have an area smaller than the threshold, which is considered as the end of hole-filling. By using the above algorithm, the damaged point cloud data can be repaired, and a visually better point cloud can be obtained subjectively. The result is shown in Fig. 6

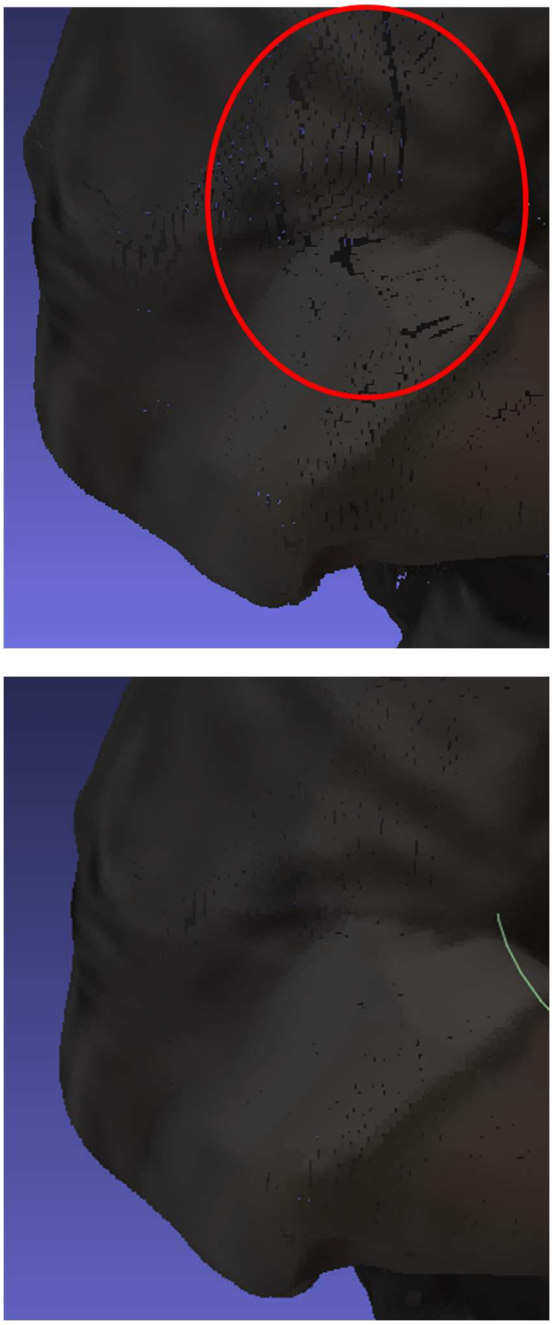

Fig. 6 The inpainting result is compared with the point cloud after denoising in the previous step

III. EXPERIMENTAL RESULTS

In order to verify the effectiveness of the algorithm proposed in this paper, the original data compressed by V-PCC and the data after the algorithm in this paper are calculated and evaluated. In addition to comparing the traditional PSNR, we also referred to the GraphSIM index adopted by [1] for evaluation. The GraphSIM metric takes into account that the human visual system is more responsive to contours and edges. Unlike PSNR, which compares individual points, GraphSIM better balances the expression of structural changes and subjective visual perception. In other words, GraphSIM has significant effects in evaluating subjective visual quality. Table

1 shows the experimental results. Although our proposed algorithm leads to a marginal decrease in PSNR, it notably attains a GraphSIM index of 0.363, surpassing the reference paper by 0.012. This index, being more representative of subjective evaluation, highlights the significant enhancement in visual perception resulting from our approach. As shown in Fig. 6 in the previous section, the proposed algorithm can significantly improve the completeness of the point cloud data in subjective observation.

Table 1: Comparison table with reference studies.

	V-PCC r1 [4]	Proposed
PSNR(Point to Point)	65.9417	64.588
PSNR(Point to Plane)	67.6579	67.4547
Y-PSNR	29.4043	28.86
U-PSNR	43.0417	43.0816
V-PSNR	43.2131	43.2503
GraphSIM	0.349	**0.361**

IV. CONCLUSION

This paper addresses edge damage and outliers that occur during V-PCC by removing outliers and repairing holes. Experimental results show that although there is a slight decrease in PSNR, there is a significant improvement in the subjective indicator GraghSIM. Since the Delaunay triangulation is used in this paper's analysis, the algorithm's performance may decrease when the hole is too large and has a high gradient. Therefore, the proposed method is more suitable for dense point clouds, where the gradient of holes is smaller and direct triangulation interpolation works better. Overall, this paper proposes a new process for point cloud repair, and we will continue to work towards ensuring that the repair method is more complete and improves human subjective visual evaluation in future research.

V. ACKNOWLEDGMENT

First of all, the author would like to thank the organizer for organizing this conference and thank He-Sheng Chou and Ming-Zhan Lee for their guidance. Most importantly, I would like to express my thanks to the three professors Shin-Lun Chen, Ting-Lan Lin, and Mei-Ling Chan for their guidance and suggestions.

†Guangdong Laboratory of Artificial Intelligence and Digital Economy (SZ), China

***Abstract*—Accurate three-dimensional (3D) color models play a crucial role in various emerging applications, such as geographic surveying and mapping, smart cities, and digital twin cities. To achieve high-fidelity representations of large-scale scenes, recent advancements in machine learning techniques and LiDAR-based Simultaneous Localization and Mapping (SLAM) have been instrumental. Leveraging these cutting-edge technologies, this paper presents a sensor-fusion framework that integrates a solid-state LiDAR, an inertial measurement unit (IMU), and a monocular camera. Additionally, a point cloud upsampling technique is introduced into LiDAR SLAM to enhance the density of the point clouds. Within this framework, the LiDAR-IMU odometry accurately estimates the positions and poses of the collected point clouds. Simultaneously, synchronized images are captured and utilized to incorporate texture information into the point clouds. The proposed framework demonstrates its capability to generate highly detailed and dense 3D color models for large-scale outdoor scenes, all within a limited on-site scanning time. Extensive experimental results validate the effectiveness and efficiency of the proposed approach.**

I. Introduction

Accurate reconstruction of large-scale outdoor scenes in three-dimensional (3D) color models is essential for various applications, including geographic surveying, urban planning, smart cities, digital twin cities, and environmental protection. However, outdoor scenes present unique challenges due to their complex and dynamic nature. One of the challenges arises from the sheer size and complexity of outdoor environments. These scenes often consist of numerous objects with diverse shapes and textures, making it difficult to capture and reconstruct them accurately. Moreover, outdoor scenes are subject to changing illumination conditions, which can affect the color and appearance of objects. Additionally, the presence of occlusions caused by trees, buildings, or other obstacles further complicates the reconstruction process.

To address these challenges in dense 3D color reconstruction, researchers have made significant progress by developing advanced algorithms and techniques. In the literature, two main approaches have been proposed: image-based and LiDAR-based methods. In image-based methods, [1] focused on 3D color reconstruction using images, including surround photos of objects or buildings and aerial drone remote sensing images. However, these methods have demonstrated poor performance in larger-scale scenes, limiting their practicality. Recent developments introduced NICE-SLAM [2], which combines Simultaneous Localization and Mapping (SLAM) with Neural Radiance Fields (NeRF) and has shown success in indoor scene reconstruction. Another method, SensatUrban [3], specifically designed for large-scale 3D reconstruction of buildings and cities using aerial drone images, has also been reported. Despite these advancements, image-based methods face challenges in practical deployment, such as the complex planning process for data collection and high computational complexity.

On the other hand, recent breakthroughs in solid-state LiDAR technology have enabled the generation of dense and accurate point clouds for 3D urban reconstruction. For example, the CamVox framework [4] integrates the Livox solid-state LiDAR with a monocular camera using the ORB-SLAM2 Visual SLAM technique. Similarly, R3LIVE [5] utilizes LiDAR Odometry and Mapping (LOAM) and its variants to render model textures. However, the LiDAR-based approach faces challenges in generating realistic 3D models due to the limited scanning time windows in practical applications like post-disaster rescue missions. To tackle this, pioneering works have integrated LiDAR SLAM with deep learning techniques [6] to enhance point cloud density using machine learning-based methods.

In summary, the combination of LiDAR-based approach and point cloud upsampling techniques holds immense promise for achieving large-scale 3D color reconstruction. This approach offers enhanced accuracy in representing geometric structures and effectively captures intricate textures, resulting in the creation of realistic and high-quality 3D city models.

This paper introduces a novel sensor-fusion system that combines both hardware and software components to address the challenges in generating denser 3D color models for large-scale outdoor scenes. The main contributions of this paper are as follows:

1) A novel sensor-fusion system that integrates a solid-state LiDAR, an inertial measurement unit (IMU), and a monocular camera is proposed. This combination of hardware components allows for comprehensive data capture, enabling the generation of more detailed 3D

This work was supported in part by the Shenzhen Science and Technology Innovation Committee under Grant No. JCYJ20190813170803617, the National Key R&D Program of China under grant 2018YFB1800800, the Basic Research Project under Grant HZQB-KCZYZ-2021067 of Hetao Shenzhen-HK S&T Cooperation Zone, Shenzhen Outstanding Talents Training Fund 202002, Guangdong Research Projects under Grant 2017ZT07X152 and 2019CX01X104, the Guangdong Provincial Key Laboratory of Future Networks of Intelligence under Grant 2022B1212010001, the National Natural Science Foundation of China under Grant 41801323. *(Corresponding authors: Man-On Pun (SimonPun@cuhk.edu.cn); Sheng Guo (guogis@126.com)).*

color models.

2) A novel method for upsampling point clouds is introduced. This technique involves dividing the point cloud into patches and representing these patches as neural fields. By integrating these local neural fields into a global surface, the proposed technique achieves upsampling of arbitrary ratios.
3) To validate the effectiveness of the proposed system, a proof-of-concept prototype platform is constructed and tested on the campus of the Chinese University of Hong Kong, Shenzhen. Through extensive data collection and scene reconstruction tests, the experimental results demonstrate that the proposed system can obtain dense 3D color models of large-scale outdoor scenes within limited scanning time windows.

II. Proposed Hardware Framework

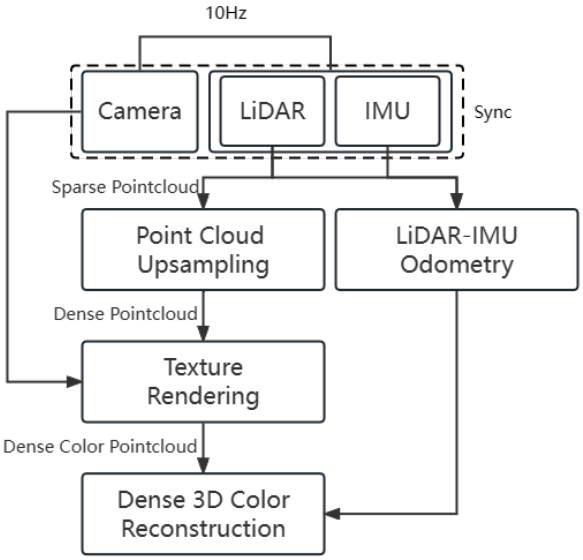

Fig. 1: The proposed framework.

The block diagram of the proposed framework is shown in Fig. 1. Compared to the Visual SLAM backbone of CamVox, the proposed framework is based on LiDAR SLAM that is less susceptible to ambient light, and has higher precision and smaller cumulative errors. The three main components of the proposed framework are the LiDAR-IMU odometry, the texture rendering system and the point cloud upsampling system, respectively. In the proposed framework, data are first collected by the camera and the IMU-empowered LiDAR. After that, the localization information of the point cloud, such as pose and orientation, is estimated using LOAM. In the meantime, the point cloud upsampling system performs upsampling on the point cloud to obtain denser point cloud. After the dense point cloud is generated, the texture rendering module renders the color of each point by matching each point in the point cloud with its counterpart in the image using intrinsic and extrinsic parameters. Finally, the proposed framework reconstructs the dense 3D color model by exploiting the resulting dense colored point cloud and the localization information.

A. LiDAR-IMU-Camera Calibration

1) Intrinsic Calibration: To fuse the images from the camera with the point cloud from the LiDAR, it is critical to align the coordinate systems of the camera and the LiDAR. This paper utilized a chessboard to calibrate the intrinsic and distortion parameters of the monocular camera. More specifically, more than 20 photos of the chessboard from various angles were first taken, covering all the fields of view (FOV). These photos together with the actual size of the black and white squares on the chessboard were used by the cameraCalibrator module from MATLAB to derive the intrinsic and distortion parameters.

We denote by $\mathbf{P}$ and P_d the intrinsic matrix of the camera and the distortion parameters, respectively. $\mathbf{P}$ takes the following form as shown in Eq. (1).

$$\mathbf{P} = \begin{bmatrix} f_u & 0 & c_u \\ 0 & f_v & c_v \\ 0 & 0 & 1 \end{bmatrix}, \tag{1}$$

where $\{f_u, f_v\}$, $\{c_u, c_v\}$ are the focal length set in pixels and the optical center set along the u and v axes in pixels, respectively.

Furthermore, P_d contains five parameters intended for distortion correction as shown in Eq. (2).

$$P_d = (k_1, k_2, p_1, p_2, k_3), \tag{2}$$

where k_i for $i = 1, 2, 3$ are the radial distortion parameters while p_j for $j = 1, 2$ are the tangential distortion parameters. By exploiting P_d, image distortion in the photos can be corrected. Next, the extrinsic matrix will be introduced to perform coordinate system conversion between the camera and the LiDAR.

2) Extrinsic Calibration: We denote by $\mathbf{T}$ the extrinsic matrix that transforms the coordinate system of the LiDAR to that of the camera. The calibration method reported in [7] is employed to derive $\mathbf{T}$ as it is capable of automatic extrinsic calibration in targetless environments by extracting depth-continuous edges and aligning point cloud projections and image edges. Let $\mathbf{X} = [x, y, z, 1]^T$ and $\mathbf{Y} = [u, v, 1]^T$ stand for the coordinates of a point in the coordinate systems of the LiDAR and the camera, respectively. Furthermore, we denote by H_{depth} the z-axis value of a given point in the camera coordinate system, i.e. the depth of this point in the image. The extrinsic matrix $\mathbf{T}$ consists of a rotation matrix $\mathbf{R}$ and a translation vector $\mathbf{t}$ as shown in Eq. (3).

$$\mathbf{T} = \begin{bmatrix} \mathbf{R} & \mathbf{t} \end{bmatrix}, \tag{3}$$

where

$$\mathbf{R} = \begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix}, \quad \mathbf{t} = \begin{bmatrix} t_1 \\ t_2 \\ t_3 \end{bmatrix}. \tag{4}$$

Given a pair of intrinsic matrix $\mathbf{P}$ and extrinsic matrix $\mathbf{T}$, 3D point cloud can be projected onto the corresponding 2D image plane. An extrinsic calibration example is shown in Fig. 2 in which the point cloud is projected onto the image plane with edges being well aligned.

$$H_{depth}\mathbf{Y} = H_{depth}\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} \quad (5)$$

$$= \begin{bmatrix} f_u & 0 & c_u \\ 0 & f_v & c_v \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} r_{11} & r_{12} & r_{13} & t_1 \\ r_{21} & r_{22} & r_{23} & t_2 \\ r_{31} & r_{32} & r_{33} & t_3 \end{bmatrix} \begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix} \quad (6)$$

$$= \mathbf{PTX}. \quad (7)$$

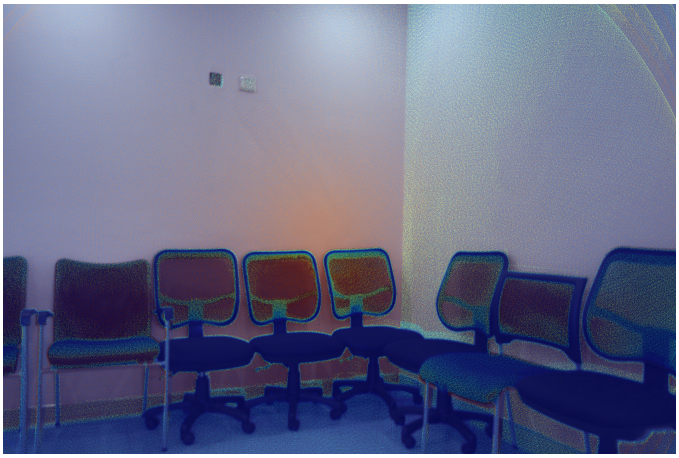

Fig. 2: Visual illustration of an extrinsic calibration example.

B. LiDAR-IMU Odometry

In this paper, the solid-state LiDAR called Livox Avia from DJI is used in our system. We utilize the software package provided by DJI to obtain pose and orientation information from the point cloud. More specifically, the odometry uses an iterative pose optimization method to estimate the LiDAR pose. When an operator performs the feature extraction and selection, it extracts surface and line features using an iterative closest point (ICP) algorithm. Let P_i be the i-th nearest points of P_w from the set of feature points of the w-th frame. We can calculate the edge-to-edge and plane-to-plane residuals according to Eq. (8) and Eq. (9).

$$r_e(P_w) = \frac{|(P_w - P_5) \times (P_w - P_1)|}{|P_5 - P_1|}, \quad (8)$$

$$r_p(P_w) = \frac{(P_w - P_1)^T((P_3 - P_5) \times (P_3 - P_1))}{|(P_3 - P_5) \times (P_3 - P_1)|}. \quad (9)$$

Using the internal IMU of Livox Avia, the odometry is able to eliminate the rotation distortion.

C. Texture Rendering

Next, we proceed to generate dense point cloud. Given the coordinate $\mathbf{X} = [x, y, z, 1]^T$ of a point in the point cloud coordinate system, the coordinate $\mathbf{Y} = [u, v, 1]^T$ of this point in the image coordinate system can be derived from Eq. (5). Since u and v may not be integers, the system will use the nearest integer point as its projection point. In this way, we are able to find the corresponding pixel of this point as well as its color. After each point in the dense point cloud is indexed by the coordinates (x, y, z), the final step is to add the (r, g, b) color information to each point in the point cloud. The resulting data point is recorded in the format of (x, y, z, r, g, b). In order to obtain accurate color information, the LiDAR and camera are synchronized to collect data at a constant frequency, e.g. 10 Hz. Thus, all data samples in the point cloud and images are time-stamped with the dense point cloud inheriting the timestamp of the raw point cloud from the LiDAR, which enables us to match point cloud and images of similar timestamps by using the nearest time registration algorithm. The texture rendering system matches each data point in the point cloud with one pixel in the image before adding the color information (r, g, b) to the matched data point. After rendering the texture of all points in one frame, we can obtain a colored point cloud frame. The rendering procedures discussed above are then repeated for each pair of point cloud and images to generate a sequence of dense colored point cloud frames.

D. Dense 3D Color Reconstruction

Finally, the proposed framework splices the resulting sequence of dense color point clouds into a global map. Let $\mathbf{X_w} = [x_w, y_w, z_w]^T$ and $\mathbf{X_l} = [x_l, y_l, z_l]^T$ be the coordinates in the global and local coordinate systems, respectively. By exploiting the pose and orientation information obtained from the odometry, we can convert the coordinate of a given point in the local coordinate system to the global coordinate system using Eq. (10).

$$\mathbf{X_w} = \mathbf{QX_l} + \mathbf{m}, \quad (10)$$

where $\mathbf{Q}$ is the rotation matrix and $\mathbf{m}$ is the transition vector given as follows:

$$\mathbf{Q} = \begin{bmatrix} q_{11} & q_{12} & q_{13} \\ q_{21} & q_{22} & q_{23} \\ q_{31} & q_{32} & q_{33} \end{bmatrix}, \quad \mathbf{m} = \begin{bmatrix} m_1 \\ m_2 \\ m_3 \end{bmatrix}. \quad (11)$$

By performing the transformation in Eq. (10) on each point in every frame of the dense colored point cloud, the resulting colored points are properly positioned in a global map, i.e. the dense 3D color map.

III. Point Cloud Upsampling

A. Overall Structure

Inspired by the Neural Points reported in [8], the proposed point cloud upsampling module consists of three main sub-modules as shown in Fig. 3.

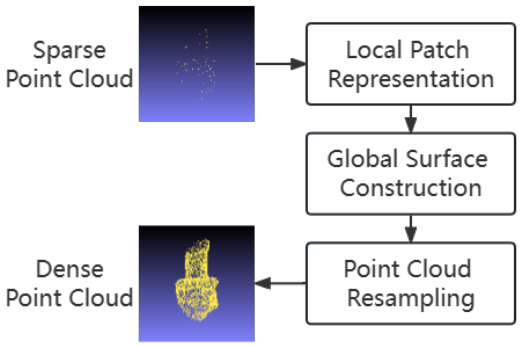

Fig. 3: The structure of the point cloud upsampling module.

B. Local Patch Representation

First, the local patch representation sub-module divides the input, i.e. the sparse point cloud, into patches. Specifically, we denote by $X = \{x_i\}_{i=i}^{I}$ the input, where x_i is the center point. The input is divided into overlapping patches $\{P_i\}_{i=i}^{I}$. For each center point x_i, together with its neighbor points, they are processed by the DGCNN backbone for feature extraction. The DGCNN contains several EdgeConv layers equipped with dynamic graph updates. The resulting local feature f_i is a part of the input into the neural field. In the meantime, the patches are mapped to 2D parametric domain $\{D_i\}_{i=i}^{I}$, which will be used in neural field representation. This mapping is bidirectional and is denoted by $\phi_i : D_i \to P_i$ and $\phi_i^{-1} : P_i \to D_i$. For each 2D point (u_r, v_r), the normal of its corresponding 3D point x_i^r is defined as Eq. (12).

$$Normal_{x_i^r} = \nabla_u \phi_i \times \nabla_v \phi_i. \tag{12}$$

Subsequently, the local patches are converted into local neural fields by using an MLP-based network with the ReLU activation layers to represent ϕ_i. For each 2D parametric coordinates (u_r, v_r) passed into ϕ_i, the local patch representation sub-module performs the positional encoding γ on (u_r, v_r). The resulting positional code and the local feature are fed into the neural implicit function Φ. Mathematically, Φ is shown in Eq. (13).

$$\Phi((u_r, v_r), f_i, x_i) = x_i + \theta_\Phi(\gamma(u_r, v_r) \oplus f_i), \tag{13}$$

where θ_Φ is the MLP stated above. In this way, these discontinuous patches are represented as local neural fields that are continuous.

C. Global Surface Construction

After representing the local neural fields, the global surface construction sub-module combines all these local neural fields into one global continuous surface. Specifically, each input point x in the local neural fields needs to be mapped into the global coordinate system, i.e. the global continuous surface. First, for each x, this sub-module finds its nearest center points denoted by x_k in $\mathcal{X} = \{x_i\}_{i=i}^{I}$. According to the distance between x and x_k, a weighting coefficient c_k can be computed as shown in Eq. (14).

$$c_k = e^{-\alpha_1 ||x - x_k||_2^2}. \tag{14}$$

After obtaining c_k, we can compute the global coordinates of the given point x as shown in Eq. (15).

$$\rho(x) = (\sum c_k \cdot Projection(x, \phi_k))/(\sum c_k), \tag{15}$$

where $Projection(x, \phi_k)$ is the nearest point in ϕ_k to x. After that, the global continuous surface is constructed by applying Eq. (15) to each input point x.

D. Point Cloud Resampling

Finally, the point cloud resampling sub-module is designed to perform point cloud upsampling at any ratio by exploiting resampling on the global continuous surface. Specifically, this sub-module performs resampling uniformly in a 2D parametric domain D_i. Subsequently, each 2D point (u_r, v_r) are mapped onto the 3D local patch as x_i^r. After resampling all the local patches, the union of these sampled points is formed and denoted by $\mathcal{X}_R$ as shown in Eq. (16).

$$\mathcal{X}_R = \bigcup x_i^r. \tag{16}$$

After that, we perform uniform sampling on $\mathcal{X}_R$ and convert them to global coordinate system. The resulting upsampling point cloud is denoted by $\mathcal{Y}_R = \{y_{R_j}\}_{j=1}^{J}$.

IV. Experiments and Results

A. Hardware Prototype

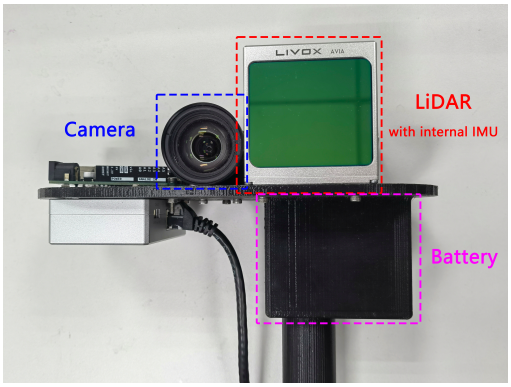

Fig. 4: Prototype of the proposed handheld system.

A handheld system for data collection has been constructed as shown in Fig. 4. The mechanical module of this system is 3D printed. This system includes a power supply unit, a MV-CE060-10UC rolling shutter camera and a Livox Avia LiDAR with an internal IMU BMI088, whose range and angular precision is reported as 2 cm at 20 m and less than 0.05°, respectively. The LiDAR and camera are synchronized before

being deployed to collect data at a frequency of 10 Hz. Furthermore, the internal IMU of LiDAR outputs at a frequency of 200 Hz synchronized with the other two sensors. Thanks to the lightweight of the LiDAR and the camera, the whole system can be easily mounted onto UAVs for geographic surveying and mapping.

The LiDAR is connected to a computer through the Ethernet interface whereas the camera is connected through the USB3.0 interface. The computer used in our experiments runs on the Ubuntu 18.04 64-bit operating system with ROS Melodic installed. In particular, ROS plays the role of data communication and processing center. Data from the LiDAR, the IMU and the monocular camera are received as ROS topics. Because every message in ROS is equipped with a detailed timestamp, these messages can be matched by aligning their timestamps. The proposed system subscribes these topics and processes these synchronized messages to achieve dense 3D color reconstruction.

The experiments of point cloud upsampling were implemented on the PyTorch framework with an NVIDIA GeForce RTX 2080 Ti GPU with 11 GB of memory. The point cloud upsampling model is trained and tested on Sketchfab dataset [9], including 90 training and 13 testing models. In order to avoid GPU memory shortage, the number of points in the input point cloud of each point cloud upsampling operation is set to 256. We divide each input large point cloud into small point clouds of 256 points on which the point cloud upsampling is performed. Finally, we re-fused the resulting upsampled small point clouds into one large point cloud as the final output.

B. Experiment Results

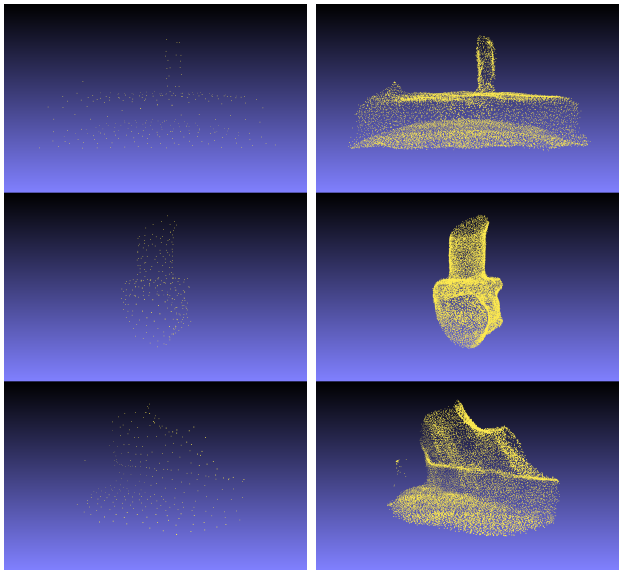

Fig. 5: The results of point cloud upsampling on Sketchfab. From left to right: (a) input point clouds, (b) 64x upsampled point clouds.

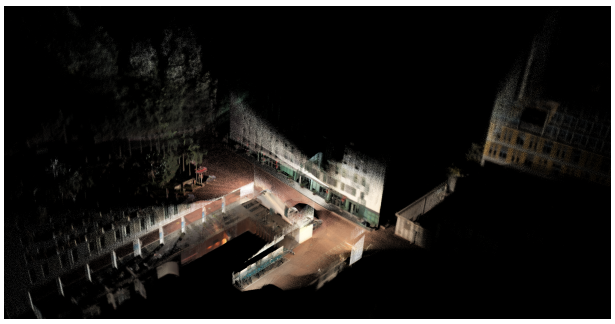
Fig. 5 shows experimental results derived on three examples taken from Sketchfab dataset [9] in which the left column shows the input sparse point clouds and the right column the 64x upsampled point clouds. Inspection of Fig. 5 suggests that the point cloud density has been greatly improved with additional points being generated along the surface of the object, preserving its original shape.

Extensive experiments were conducted in the outdoor environment on the Chinese University of Hong Kong, Shenzhen (CUHKSZ) campus. The collected point clouds were upsampled by a factor of 64. Fig. 6 shows a color picture of the test site of about $120 \times 120m^2$ with multiple buildings of $5-6$ floors. The test site is highlighted with the red boxes in Fig. 6.

Fig. 6: Test site with multiple buildings of $5-6$ floors.



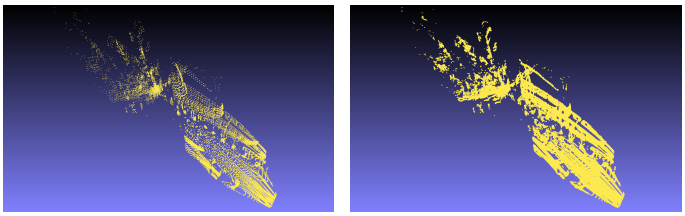


Fig. 7: The raw 3D model without upsampling.

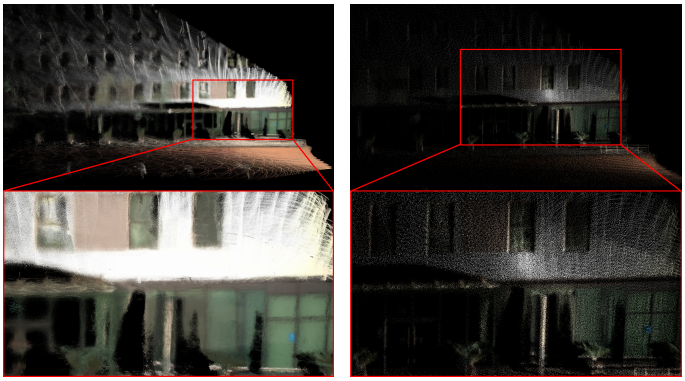
Fig. 8: The corresponding site image captured by the camera.



We limited the scanning time to be less than 100 s that is considered short for such a large scene. The resulting *raw* 3D model *without* upsampling is shown in Fig. 7 whereas the site image captured by the camera over the same area is shown in Fig. 8. Comparison of Fig. 7 and Fig. 8 suggests that the quality of the raw 3D model is far from being satisfactory.

(a) Sparse Point Cloud (b) Dense Point Cloud

Fig. 9: Comparison of 64x point cloud upsampling for a single frame.

Fig. 9 shows the point cloud upsampling result for a single point cloud frame. It is evidenced from Fig. 9 that the number of points has been greatly increased with the original structure of the object being preserved.

(a) With 64x point cloud (b) Without upsampling

Fig. 10: Comparison of 64x point cloud upsampling for a part of the large-scale outdoor scene.

Finally, Fig. 10(a) depicts the results derived from the proposed system. As compared to Fig. 10(b) showing the same area obtained from the conventional methods without upsampling, Fig. 10(a) demonstrates noticeable point cloud density improvement. In particular, if we focus on the zoom-in area inside the red box in both figures, points on the wall in Fig. 10(a) are closely packed without any gaps, forming a continuous surface. This confirms that the proposed point cloud upsampling system performed well with the LiDAR SLAM. It should be emphasized that the amount of input data in both Fig. 10(a) and Fig. 10(b) is identical.

V. Conclusion

In this paper, a sensor-fusion system has been proposed by integrating a solid-state LiDAR (Livox Avia), an IMU and a monocular camera. In particular, a novel point cloud upsampling technique has been developed to obtain denser 3D color maps. By exploiting the LiDAR-IMU-Camera fusion, the resulting reconstruction 3D color models are more precise and informative, i.e. accurate depth and fine texture. Furthermore, compared to the conventional SLAM method, the proposed framework is capable of generating point cloud of much higher density with less scanning time. Extensive experiments have confirmed that the proposed framework is capable of fast and dense 3D color reconstruction, which can be applied in a wide range of applications, such as geographic surveying and mapping, urban planning, smart cities, digital twin cities, and environmental protection.

***Abstract* — This study proposes an assistive system to improve the safety of mobility scooter users. The system autonomously detects potential dangers and avoids accidents using multi-sensors, a single-board computer and active control mechanisms. The working principle includes braking assistance and throttle limitation and the potential benefits of the proposed system are identified. A vector table is constructed by experiment to determine the appropriate distance in which to safely stop the mobility scooter to prevent a collision. The assistive mobility scooter system is tested in the real world to demonstrate its robustness and safety.**

Index terms — Mobility Scooter, Danger Prevention, Safety Enhancement

I. INTRODUCTION

A mobility scooter, a vehicle that allows elderly or handicapped persons to move around. Most mobility scooters are simple to use, slow and suitable for short-distance travel [1, 2]. The demand for mobility scooters among the elderly is increasing worldwide and in Taiwan, the United States and Europe as the elderly population increases [3-6]. Many mobility scooter users view the ability to move as a symbol of health and independence but some elderly users have physical limitations, cognitive impairment, visual impairment or side effects from medication, and much more [2, 3]. The reasons above make users prone to accidents while they drive mobility scooters, epically a high risk of single-vehicle accidents [7-9]. Therefore, a mobility scooter with assistive functions, as shown in Fig. 1, is an important option to increase safety during daily driving [3, 10].

In terms of predicting danger for mobility scooters, many factors are relevant, such as the location, the direction of movement and the relative speed of an obstacle or pedestrian. Moreover, speed control must allow the vehicle to slow down smoothly [11, 12].

Fig. 1. Schematic diagram of a mobility scooter with assistive function modules.

This study collects data for these factors to determine the magnitude of danger using a rule-based model. To uncomplicatedly increase the safety of the mobility scooter user, this study adds multi-sensors and a single-board computer (SBC) with a danger estimation model to create a safer environment for users. The assistive mobility scooter system helps the user by slows the vehicle, stops the vehicle, and alerts the driver.

This paper is organized as follows. Sec. 2 reviews related studies of mobility scooters. The subsystems for the proposed mobility scooter are described in Sec. 3. Sec. 4 presents the rule-based braking method and the results of the experimental tests. Finally, the concluding remarks are given in Sec. 5.

II. RELATED STUDIES

Different types of intelligent mobility scooters have been proposed by previous studies. One study [11] presented a retrofitted mobility scooter for autonomous driving in a closed field for elderly or blind persons. A survey showed that after testing in a closed field, 95 of 99 users were willing to use the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

intelligent-assisted mobility scooter [11]. This study used two LIDAR systems to detect obstacles, map the local area and traced a dynamic virtual bumper for static obstacles and moving pedestrians. Another study [12] based on this study [11] involved driving in an environment with many pedestrians. This system also used two LIDAR systems, but a more complex model was used to prevent the mobility scooter from bumping into pedestrians.

One study [13] used a braking system for an electric scooter to prevent accidents. Ultrasonic sensors detected the distance from an obstacle ahead. The motor was reserved and the rear brake was applied when the distance between the scooter and the obstacle was less than a meter. Another study [14] showed that vehicles with an automatic emergency braking (AEB) have a lower accident rate, and another study [15] showed how the AEB works in a timing table. It also considered speed, force and front distance to increase driver safety. Another study [16] used AEB on a motorcycle, but the brake is currently out-triggered.

This study uses a system that is similar to those previous studies [13] and [15], but instead the static distance is not used to trigger the brake: this study uses a vector table to determine when to activate the braking system. Multi-sensor modules to gather information on distance, speed and throttle position uses a system that is similar to those of previous studies [11] and [15]. The proposed mobility scooter better gather information by integrating sensor modules in a mobility scooter that is currently commercially available.

III. System Overview of Mobility scooter

A. *Specifications*

The base platform for the proposed assistive mobility scooter system is the LY-EW401 that is manufactured by Comfort Orthopedic Co. Ltd. The stock-rated unladen weight of the mobility scooter is 68 kg with a 25 kg battery. The maximum payload is 120 kg and the average range is 30 km. This study adds sensors, microcontroller units (MCUs), a SBC and batteries to increase user safety. The specifications for the mobility scooter before and after the retrofit are summarized in Table 1.

The assistive mobility scooter system is non-destructive: all modules are connected to the mobility scooter using existing joints or glue. Fig. 1 shows all additional modules, such as the power-on module, the motor module, the distance modules, the speed module and. In practice, these function modules can be easily installed on other mobility scooters and calibration is easy.

Table 1. Mobility scooter specification before and after retrofit.

Items	Before Retrofit	After Retrofit
Dimensions (L × W × H)	132 × 62 × 94 cm	
Empty Weight	93 kg	98 kg
Maximum Payload	120 kg	115 kg
Maximum Speed	11 km/h	10 km/h
Range	36 km	30 km
Slope	10 degrees	10 degrees
Working voltage	24 volts	24 and 5 volts

B. *Architecture*

The assistive mobility scooter system uses a master-slave architecture: the master is a SBC and the slaves are MCUs. The SBC is a Raspberry Pi 3B+, which communicates with all MCUs over Wi-Fi via the MQTT protocol. The MCU uses a ATmega328PU as the main processor core. Each module has a MCU, and the system has five modules: a power-on module, a motor module, a front distance module, a rear distance module and a speed module. The system is also connected to the Internet for time calibration and downloads local weather for the user. The architecture for the assistive system is shown in Fig. 2. The SBC and MCUs are described later.

C. *Power-on module*

The power-on module is connected to the battery and all modules. The module detects the battery life and turns the power on or off for each MCU. When the user switches on the mobility scooter, this module is automatically activated. All other modules are powered when the power-on module is activated to ensure that all modules are switched on when the mobility scooter is switched on and switched off when the mobility scooter is switched off.

D. *Motor module*

This module is plugged into the vehicle's throttle to record the behavior of users when driving the mobility scooter. An electromagnetic brake is applied in the mobility scooter, where the braking is automatically activated when the throttle position is set to zero. Therefore, motor module decreases the throttle or provides active braking in an emergency. Throttle adjustment and active braking prevent injury in unforeseen circumstances.

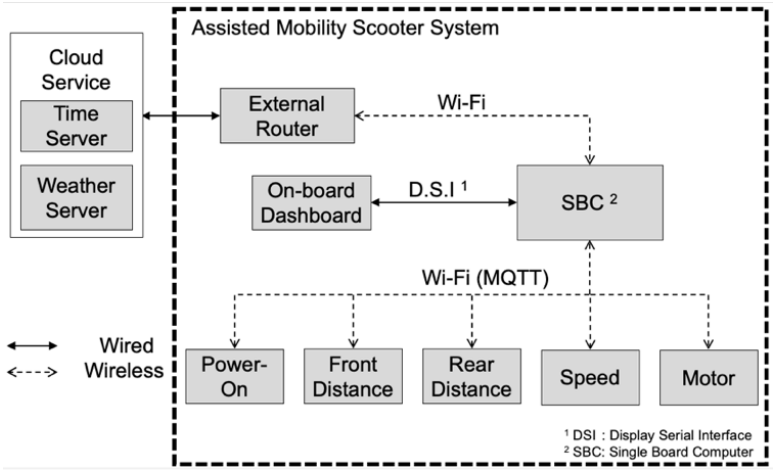

Fig. 2. The architecture for the mobility scooter.

E. Front and rear distance modules

These two modules perceive distance information using multiple HC-04 ultrasonic sensors and a time-of-flight (TOF) infrared sensor. The ultrasonic sensor emits signals and if an obstacle is less than 3 meters ahead, the signal is reflected to the sensor. Once the signal is received, the distance between the sensor and the obstacle could be discovered from the time duration that the signal travel. The front distance module uses five HC-04 ultrasonic sensors and one TOF sensor to detect obstacles in front of the mobility scooter. The effective range of the HC-04 is relatively short so a TOF sensor is additionally installed to extend the effective sensing range ahead to 5 meters. The rear distance sensor uses only three HC-04 ultrasonic sensors because the mobility scooter moves slowly in reverse.

F. Speed module

This module comprises two Hall sensors with ultra-strong magnets (two on the left and four on the right) on the inner side of the vehicle's rear wheels. The vehicle's speed is calculated using the angular velocity in (1):

$$v = \omega \times r \tag{1}$$

where v is the linear speed of the vehicle, ω is the angular velocity, and r is the radius of the rear wheel ($r = 16.5$ cm).

The angular velocity is calculated using the duration between two passing magnets on the rear wheels. The speed is calculated for the right and left rear wheels to ensure an accurate result.

G. Single board computer

The Raspberry Pi acts as the SBC. It has an embedded Wi-Fi chip that functions as a wireless access point (WAP) that allows the MCUs to connect and communicate via MQTT protocol. The Raspberry Pi receives all information that is transmitted from the MCUs and verifies that there is a connection between the SBC and the MCUs. Information is saved in the Raspberry Pi and is viewed on the dashboard or is used for calculations by the danger prevention model.

The onboard dashboard, which is shown in Fig. 3, is 800 × 480 pixels, which accommodates a Raspberry Pi 7-inch touchscreen. This display shows the Wi-Fi status, the time and the weather information on the top left, the brake status on the top right and the distance warning on the bottom right. The lock-unlock button is on the bottom of the dashboard and the speed is shown in the middle of the dashboard.

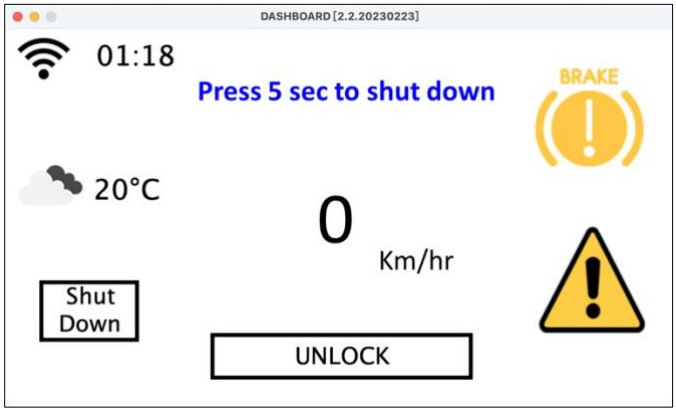

Fig. 3. Onboard dashboard for the mobility scooter.

A throttle lock prevents the user from accidentally activating the throttle. The user locks or unlocks the vehicle by pressing a button and a signal is then transmitted to the motor module via the MQTT protocol. This function ensures the safety of the driver. Most mobility scooters do not display the vehicle's speed, but this system displays the speed on the dashboard.

The warning light on the bottom right activates when an obstacle is close to the front or rear of the mobility scooter. If an obstacle is detected, the throttle is limited via the motor module. The braking indicator on the top right illuminates when the brake is activated by the braking assistance system, which activates when an obstacle is too close to the obstacle. The brake and throttle limiter are discussed in the next section.

IV. Braking Assistance

A. Working principle

When a danger situation is detected, the braking assistant autonomously slows or stops the mobility scooter to prevent an accident. The flow chart for the system is shown in Fig. 4. When the mobility scooter is powered on, the assistive system monitors the speed of the mobility scooter, the front distance and rear distance from obstacles.

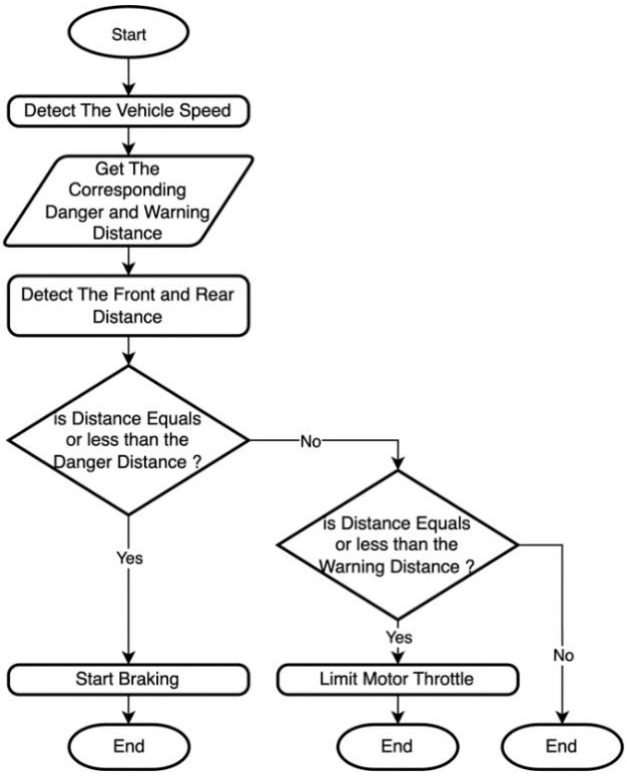

Fig. 4. Flow chart for the mobility scooter.

The assistive system determines the danger distance to a obstacle ahead using the information from Table 2 with the instantaneous speed. If the distance from the obstacle is less than the danger distance, the system activates the brake to stop the mobility scooter. The throttle is limited when the distance to the obstacle exceeds the warning distance. The warning distance is 1 meter longer than the danger distance, as listed in Table 2. The throttle limit value is set to 80% of the current throttle value. The percentage for limited the throttle can be adjust on the setting page, to satisfied the comfort of the user.

Table 2. Danger distance and warning distance versus vehicle speed.

Vehicle Speed	Danger Distance	Warning Distance
0 ~ 1 km/h	32 cm	132 cm
1 ~ 2 km/h	41 cm	141 cm
2 ~ 3 km/h	64 cm	164 cm
3 ~ 4 km/h	76 cm	176 cm
4 ~ 5 km/h	91 cm	191 cm
5 ~ 6 km/h	105 cm	205 cm
6 ~ 7 km/h	136 cm	236 cm
7 ~ 8 km/h	171 cm	271 cm
8 ~ 9 km/h	212 cm	312 cm
9 ~ 10 km/h	258 cm	358 cm

B. Working theory

To determine the braking distance for the mobility scooter, this study uses a table. The equation is derived using the resistance force. The resistance force is listed in (2) for a dynamic equation for a car using D'Alembert's principle [17]:

$$F_t = F_f + F_i + F_w + F_j \tag{2}$$

where F_t is the total resistance, F_f is the rolling resistance, F_i is the resistance due to a gradient, F_w is the air resistance and F_j is the acceleration resistance. In most cases, a mobility scooter moves slowly; therefore, F_f is regarded as a constant and F_w and F_j are considered as zeros. F_i is defined in (3) as:

$$F_i = m \times g \times \sin\theta \tag{3}$$

where m is the mass of the vehicle and user, g is the acceleration due to gravity, and $\sin\theta$ is the vertical component of the force, where θ is positive for travel up a gradient. The total braking force is expressed as (4):

$$F_{total} = F_f + m \times g \times sin\theta + m \times \beta = m \times a \quad (4)$$

where F_{total} is the total force when braking, β is the vehicle's deceleration under braking and a is the total deceleration due to braking. Using the value for the total braking force that is calculated using Equation (4), the kinematic equation is written as (5):

$$V_1{}^2 = V_0{}^2 - 2 \times a \times S \quad (5)$$

where V_1 is the final velocity, which is 0, V_0 is the initial velocity and S is the braking distance. Using (4) and (5), the braking distance is calculated as (6):

$$S = \frac{-V_0{}^2}{2\times\frac{F_{total}}{m}} = \frac{-V_0{}^2}{2\times\left(\frac{F_f}{m} + g\times sin\theta + \beta\right)} \quad (6)$$

The braking distance is proportional to the square of the initial velocity and is inversely proportional to the sine of the gradient. Mobility scooters are mostly used on flat roads so the resistance due to any gradient is constant at 20 cm. This distance ensures the safety of a mobility scooter that has no gyro sensor.

C. Experimental results

An experiment is shown in Fig. 5 to calculate the distance table for the assistive mobility scooter system. Each distance was measured multiple times, and the experimental procedure is as follows: The mobility scooter was parked a few meters behind an infrared sensor and accelerated to a constant velocity that increased in 1 km/h increments. The mobility scooter then drove at a constant speed until it passed the infrared sensor, and the mobility scooter was then immediately stopped by resetting the throttle. These distances were recorded and used to construct the distance table (Table 2).

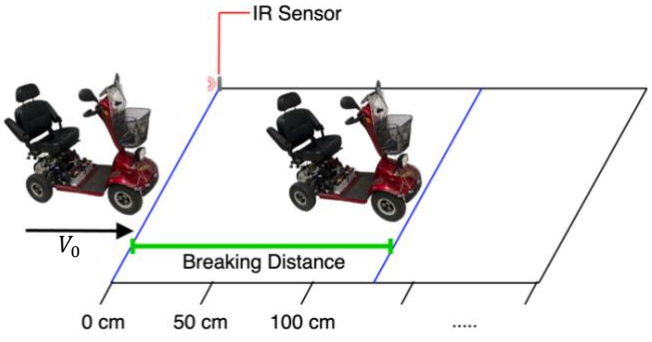

Fig. 5. Schematic diagram of the experiment.

The results of the experiments demonstrate that the assistive mobility scooter safely brakes from 1 to 10 km/h, as shown in Table 2. The experiment was repeated in real-world environments to verify the vehicle's capabilities. The results of one experiment are shown in Fig. 6, for an initial speed of 5 km/h, which is a typical speed for a mobility scooter.

Initially, the vehicle's speed is 5 km/h, the throttle magnitude was 55% and the distance of any obstacles ahead the vehicle is more than 5 meters. The sensor only responds at 5 meters due to the limitations of the detection distance. After a few seconds, the front of the scooter is 191 cm from the obstacle, which is within the warning distance. The system then initiates throttle limitation and the throttle value decreases from 55% to around 44% so the vehicle's speed decreases from 5 km/h to 4.1 km/h. The vehicle does not stop and the front distance quickly decreases to 91 cm from the obstacle, which is less than the safe distance. The system immediately sets the throttle to zero, which activates the brake mechanism and completely stops the vehicle. These results show that the assistive mobility scooter activates the brake in both experimental and real-world environments to prevent a collision.

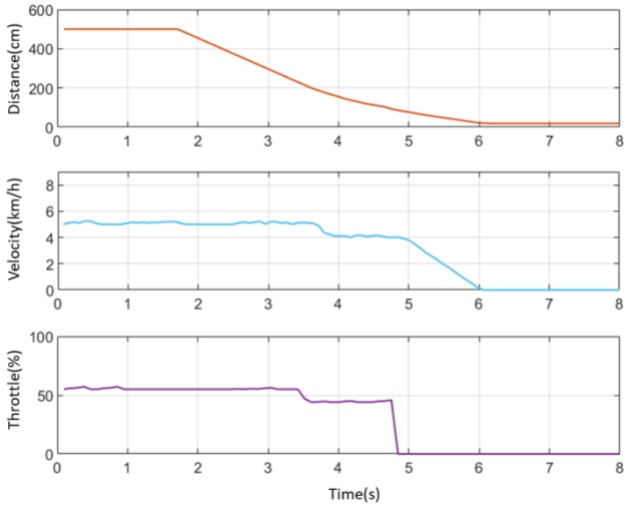

Fig. 6. Timing table for mobility scooter in a real-world scenario.

V. CONCLUSIONS

The assistive mobility scooter system that is proposed by this study enhances safety for users. The system autonomously activates the braking assistant by continuously monitoring information from sensors and comparing them to the corresponding danger distance to prevent accidents. Limiting the throttle when the vehicle approaches the warning distance. This comprehensive approach addresses any physical

limitations or cognitive impairment that users might experience and which increase the risk of accidents for mobility scooters.

This study presents a practical and effective solution to increase the safety of users and increase the sense of independence and well-being. The use of advanced technology and the focus on danger prediction using relevant factors reduces the risk of accidents. Further improvements and real-world evaluations are necessary to optimize the system's performance and to ensure its effectiveness for different environments and scenarios. Mobility scooters are increasingly used by the elderly population and this type of assistive systems significantly improves the quality of life and promotes a sense of health and independence.

Future study will allow participants to experience the assistive mobility scooter and determine the user's reaction, in terms of the warning distance and the braking resistance at high speed. The danger prediction model will also be improved by adding more target obstacles to make the system safer.

***Abstract*—The mainstream ASR error correction system is mainly based on the encoder-decoder structure, by learning the mapping of incorrect text to correct text. Although this approach showed good results in ASR error correction, it mainly solves the spelling errors that occur at high frequencies, while struggling with low-frequency ASR entity errors, especially those entities unseen in the training set. Another downside of the structure is that it may produce undesirable hallucination entities. In this paper, we introduce a DiCODER model for Chinese ASR entity error correction. Specifically, we first retrieve relevant entities from the entity dictionary based on the similarity of the text and phonetic information and then fuse them with ASR text for joint encoding. Next, a controlled decoding strategy utilizing dynamic vocabulary is proposed to generate more reasonable results. Experimental results on three publicly available datasets demonstrate the effectiveness of our proposed method.**

Index Terms: ASR error correction, dictionary knowledge, controllable decoding

I. Introduction

Deep learning-based ASR recognition systems have made significant progress in real-world applications. However, there are still various types of ASR errors in practice, especially entity errors. For example, the named entity "马克黄"("Mark Huang") may incorrectly be identified as "马克谎"("Mark Clung") in "公司分析师马克黄说"("Analyst Mark Huang said"), which will impair downstream tasks such as semantic understanding [1], [2]. Therefore it is necessary to design ASR error correction methods that can effectively handle these errors.

ASR error correction methods can generally be divided into cascaded and end2end categories. The cascaded method first detects the incorrect words and then fixes these words [3]. This method can easily perform error analysis, but it requires both error detection and correction annotations, which is costly in terms of labor. Instead, the end2end method is more labor-efficient through learning the mapping between incorrect and correct text directly. Since its training data is easy to produce (e.g. through TTS-ASR simulations), it is currently the mainstream ASR error correction method [4]–[6].

The end2end approach can give good results for ASR spelling errors, but it is insufficient for ASR entity errors [7]. The reason is that the incorrect entities are often not appearing in the training dataset. Recently, Amazon proposed a KNN memory-based method to address this problem, which shows promising results [8]. However, it requires a large space for storing the episodic memory. [9] incorporates candidate entities into the correction model with a shared context encoder and shows excellent performance for out-of-vocabulary person names. However, It utilizes text edit distance to obtain candidate entities and fails to effectively recall erroneous entities with large textual differences but phonetic similarity. Further, the ASR text and the candidate entities are encoded independently, making them lack direct mutual interactions. On the other hand, the decoder of these end2end model relies on the language model for text generation, which may generate hallucination entities.

To address the above two challenges, we propose a controllable ASR error correction method based on entity-dictionary knowledge. Specifically, we first retrieve the relevant entities from the entity lexicon based on the similarity of character and phonetic information, and later jointly encode the ASR text and the relevant entities, followed by a controlled decoding strategy to fix entity errors and avoid producing unreasonable decoding results. We also propose a hallucination rate metric for measuring the ratio of hallucination entities in correction results. This evaluation metric shows that the quality of error correction can be further improved by our proposed decoding strategy. The experimental results of three publicly available datasets indicate that our method can effectively improve speech recognition quality, especially entity correction performance.

II. Related Work

ASR error correction and ASR entity error correction are two closely related research topics. The former aims to enhance the accuracy of speech recognition by correcting contextual errors in the ASR outputs, which also implicitly fixes some entity errors. The latter, on the other hand, concentrates on rectifying the entity errors to improve the overall quality of ASR transcriptions.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

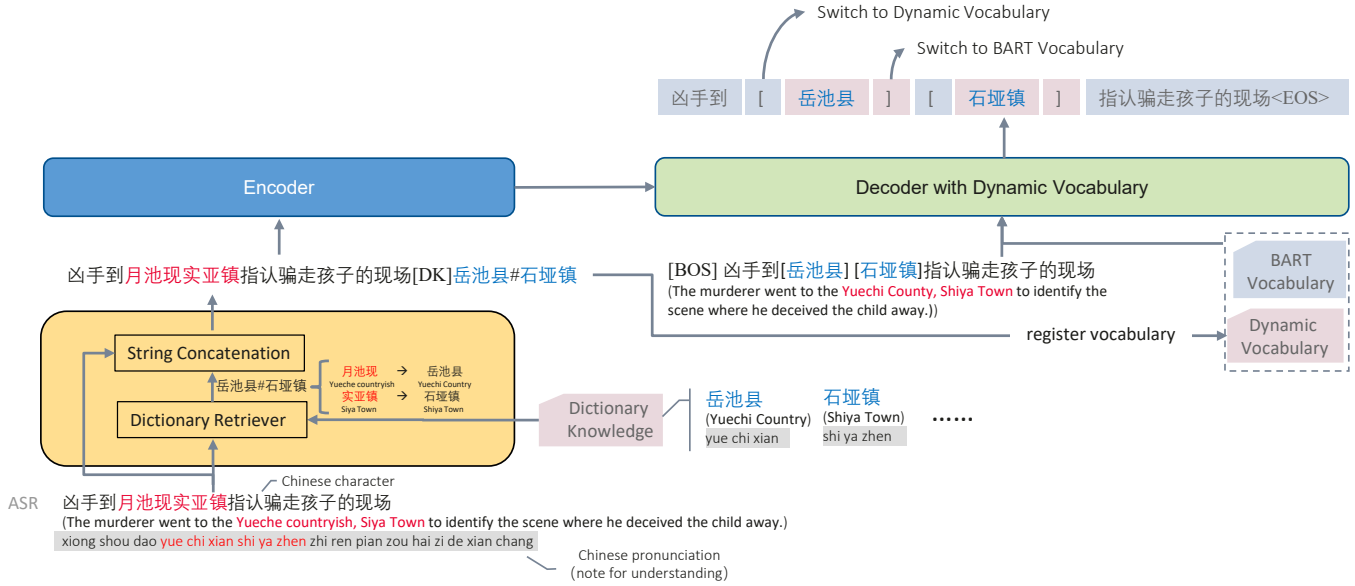

Fig. 1. The overall architecture of the proposed method.

A. ASR Error Correction

ASR error correction methods have mainly adopted a deep learning-based framework. [10] treats ASR error correction as a machine translation task and models it based on the RNN encoder-decoder. [11] replaced the RNN structure with the Transformer structure to further improve the results. Although the above two methods achieved good results on the ASR error correction task, the training of such models relies on a large amount of training corpus. [5] and [12] enhance the generalization performance of such error correction models by initializing the model parameters with BERT or BART pre-trained models, respectively. [7] tackles the problem of misrecognition of near-phonetic characters in English by adding phonetic information to the textual information. [13] solves the problem of recognizing near-phonetic characters in Chinese by adding pinyin information. Further, [14] and [15] introduce phonetic-related pre-training tasks to solve the ASR error correction problem in English and Chinese, respectively. In addition, [16] improves the effectiveness of ASR error correction by modeling the N-best results of ASR output.

B. ASR Entity Error Correction

The topic of this paper is knowledge-enhanced ASR error correction, which is just beginning to be investigated. [8] improves the likelihood of correct entities being decoded by registering text fragments containing entities with external memory, and later using KNN retrieval to obtain candidate entities from memory at each moment of decoding. [17] proposes an approach that draws on existing graph knowledge and finds relevant entities by subgraph matching, followed by ASR entity error correction. While both methods achieve good results in ASR entity correction, such text fragments and related graphs that contain entities are often difficult to obtain in real application scenarios, leading to their limited application. [9] uses two shared-parameter encoders to encode an ASR text and candidate entities such as personal names respectively, then the decoder attends to the encoders by attention mechanism to generate correction results.

III. Approach

The task of our ASR entity error correction can be treated as a functional mapping from X, D to Y, where X denotes text outputs from ASR containing errors, and D is an entity dictionary that contains W entity words. Y is the ground-truth text. As shown in Figure 1, the framework contains the following three parts, including 1) dictionary retriever module: that is a dictionary fuzzy matching module. 2) context encoder module: which encodes ASR text and matching entities corresponding. 3) decoder module: which decodes the character guided by matching entities.

A. Dictionary Retriever

Different from general errors, entity errors cannot be determined according to their context, because entities are very changeable. This is also an important reason why we want to introduce external dictionaries. For example, the model can easily correct “The whether is nice today!” as “The weather is nice today!”, but it is difficult to determine “The murderer went to Siya Town.” or “The murderer went to Shiya Town.”, unless there is a “Shiya” in your mind. Since we cannot determine the wrong location in advance, in order to recall possible right entities, we propose a fuzzy matching method that considers both character and sound shape information to recall all possible entities.

The algorithm 1 summarizes the whole process. At first, a character trie and a sound shape[1] trie are constructed for the entity dictionary. Second, for each text span in the sentence, we retrieve its matching entity words with confidence scores at the character level or pronunciation level. At last, for matching accuracy and computational efficiency considerations, we limit the number of matching results by their confidence scores. In more detail, we constrain the number of matching results from two levels: the number of matching results per span and the total number of matching results. In Figure 1, the output result C of the dictionary retriever is "岳池县" 和 "石垭镇" because they have similar Chinese pronunciations to "月池现" and "实亚镇" in X, respectively.

Algorithm 1: Dictionary Knowledge Retrieval

input : X, an ASR text.
D, an entity lexicon list.
output: C, a retrieved entity list.

```
// Initialization.
charTrie = InitCharTrie()
sscTrie = InitSoundTrie()
for d ∈ D do
    charTrie.add(d)
    sscTrie.add(GetSoundShape(d), d)
// search the character and sound shape
   tries.
C = List()
foreach substring s ∈ X do
    if charTrie.has(s) then
        score = len(s)
        C.add((s, score))
    else if sscTrie.has(s) then
        score = 0
        e = sscTrie.getEntity(s)
        foreach character sc, ec ∈ zip(s, e) do
            sp = GetPinYin(sc)[2]
            ep = GetPinYin(ec)
            if sc == ec then
                score += 1
            else if sp == ep then
                score += 0.6
            else
                score += 0.1
        C.add((e, score))
C.sort(key=lambda x: x[1], reverse=True)
return C
```

B. Context Encoder

We employ a context encoder to encode X and C jointly. In particular, X and C are concatenated into the form X [DK] C, where [DK] denotes special tokens that serve to separate ASR text from retrieved entities. For example, in Figure 1, the fused input is "凶手到月池现实亚镇指认骗走孩子的现场 [DK] 岳池县 # 石垭镇". This concatenated input is subsequently fed into the encoder.

C. Decoder with Dynamic Vocabulary

The commonly used seq2seq model is prone to generate hallucination entities. In Figure 1, the location entity "实亚镇" (Siya Town) is wrongly corrected as "实亚锦" (Siya towne) by baseline method but the ideal entity should be "石垭镇" (Shiya Town). In this case, "实亚锦" (Siya towne) is a hallucination entity, which is created under the language modeling of the decoder.

To alleviate this problem, we propose a controlled decoding strategy to help the decoder ease this kind of miss-corrections. As shown in Figure 1, two different vocabularies were used, one is a common dictionary (here refers to the vocabulary of BART), and the other is the dynamically built vocabulary which only contains the fused input tokens of the context encoder. We do two tasks at the same time when decoding, one is entity recognition, and the model output will enclose the location of the corresponding entity in square brackets; the second task is entity correction. Specifically, at the initial stage of decoding, the decoder uses the common vocabulary to decode until generating the entity start position indicator "[". Next, the decoder uses the dynamic vocabulary to generate the corrected entity followed by the end position indicator "]" generated. After that, it switches back to using the common vocabulary, and this process will repeat until the end of the generation.

IV. Experiments

A. Datasets

TABLE I
Statistics of the datasets. Sents, Avg.L and Dict are the sentence number, sentence average length and the dictionary size of the dataset, respectively.

Dataset	Type	Sents	Avg.L	Dict
Aishell	train	120,098	15.41	
	dev	14,326	15.33	
	test	7,176	15.60	16,470
$\text{MAGICDATA}_{\text{SMALL}}$	train	16,000	10.90	
	dev	2,000	10.69	
	test	1,775	10.74	4,591
$\text{MAGICDATA}_{\text{OOV}}$	train	17,433	10.89	
	dev	1,290	10.87	
	test	1,052	10.85	4,591

In our experiment, we employ three datasets that leverage distinct ASR engines.

1) **Aishell**[3] is an open-source Mandarin Chinese speech corpus that offers audio recordings and their corresponding manual transcriptions [18]. The AISHELL_NER [19] supplies related entity annotations for this dataset. We employ an open-source conformer ASR model [20] to transcribe the audio recordings into ASR texts. These texts are then paired with their manual transcriptions to create an error correction dataset.

2) **MAGICDATA**[4] is an additional Mandarin Chinese read speech corpus. We randomly select a subset of samples and annotate their entities to create the MAGICDATA$_{\text{SMALL}}$ dataset. Subsequently, we employ our commercial ASR service to transcribe the audio recordings into texts.

3) **MAGICDATA$_{\text{OOV}}$** is created by re-splitting MAGICDATA$_{\text{SMALL}}$ into new training, development, and test sets that contain distinct entities. The objective of constructing this dataset is to assess the efficacy of our model on entities that are not present in the vocabulary.

We add "[" and "]" symbols for each entity to indicate their start and end positions within the sentence, then extract these entities from every dataset to form their corresponding entity dictionaries. Table I shows the statistics information of the datasets.

B. Baselines

We compare our methods with the following baselines:

1) **Transformer** [21]: We implement a Chinese version Transformer model for ASR error correction[5]. It is a standard Transformer model with 6 encoder and 6 decoder blocks, trained from scratch.

2) **SC_BART** [5]: BART is a seq2seq language model that has been pre-trained on various denoising tasks [22]. It initially corrupts text using noise functions and then learns to reconstruct the original text. This makes BART well-suited for error correction tasks. The SC_BART uses BART as its base model and fine-tunes it to achieve state-of-the-art results on Chinese ASR error correction tasks. We select a pre-trained BART[6] with 6 encoder and 6 decoder layers as the base model and re-implement SC_BART.

3) **CSC_BART**: Similar to [9], we replicate an entity error correction model that encodes an ASR text and entity candidates separately with two encoders that shared parameters. The model is also initialized with the pre-trained BART.

C. Model training details

The maximum number of matching results per span is set to 1, and the maximum total number of matching results is set to 3. In line with the baseline methods, our model is initialized using BART. The maximum length of the decoder output is set to 64. The initial learning rate is 2e-5. We use the Adam optimizer [23] with a batch size of 32 (the same as the compared methods) and train for 10 epochs. The patience for early stopping is set to 3.

D. Evaluation Metrics

For the error correction task, we evaluate using the sentence error rate (SER) and character error rate (CER). For the entity correction task, after ASR correction, entities are first recognized by a NER tool[7], and then the recall of the entity is calculated using the ground truth.

Furthermore, we have found that hallucinated entities are more disruptive to users and downstream systems than original ASR error entities. This is because a user with background knowledge can infer the correct entity from an ASR error entity, but cannot do so from a hallucinated entity. For instance, if a user already knows the "石垭镇" (Shiya Town) is a town name, he will be aware that the incorrectly recognized "实亚镇" (Siya Town) refers to it due to their similar Chinese pronunciation, but it's hard for him to make this judgment from the generated hallucinated entity"实亚锦"(Siya towne). To measure the degree of hallucination in error correction results, we propose a new metric called the hallucination rate (HR), which is defined as follows:

$$\text{HR} = \frac{\text{number of hallucination entities}}{\text{number of corrected entities by the model}}. \quad (1)$$

The lower value of the HR means less hallucination entities generated and vice versa.

E. Results

1) **Evaluation of ASR error correction**

As shown in Table II, both the SC_BART and CSC_BART methods have varying capabilities for correcting spelling errors. Compared to the results of No correction, the average SER/CER of SC_BART and CSC_BART decreased by 25.31%/2.79% and 26.75%/2.64%, respectively. Compared to SC_BART and CSC_BART, the DICODER$_{\text{CD}}$ further reduces the average SER/CER by 5.95%/0.51% and 4.51%/0.65%, respectively. It is noteworthy that our methods achieve consistent results on datasets produced by different ASR techniques, including the conformer ASR model and our commercial ASR service, demonstrating a reasonable level of robustness.

2) **Evaluation of ASR entity error correction**

On average, the CSC_BART method achieves competitive improvements in entity recall across the datasets, outperforming SC_BART. Compared to CSC_BART, DICODER$_{\text{CD}}$ further improves the average recall by 7.98%, benefiting from the joint encoding of ASR text and candidate entities. Furthermore, the controllable decoding

EXAMPLES OF DIFFERENT METHODS. WE HIGHLIGHT THE ERRONEOUS/CORRECT CHARACTERS IN RED/BLUE FONTS.

Method	**Transcript**	**Retrieved Entity**
No correction	给我拨一个庚橙庆的歌曲。 (Ply a song of Geng Orange Qing.)	
SC_BART	给我播一个庚橙庆的歌曲。 (Play a song of Geng Orange Qing.)	
DiCODER$_{CD}$	给我播一个庚橙庆的歌曲。 (Play a song of Geng Orange Qing.)	
No correction	男一忍受股价被低估。 (Clan stand undervalued shares.)	
SC_BART	难以忍受股价被低估。 (Can't stand undervalued shares.)	
DiCODER$_{CD}$	难以忍受股价被低估。 (Can't stand undervalued shares.)	魏楠; 蚁人 (Kenstan; Ant-Man)
No correction	但直到一二年后的法国阿尔贝为尔冬奥会上。 (But not until the 2012 Winter Olympics in Albertwell, France.)	
SC_BART	但直到一二年后的法国阿尔贝塞冬奥会上。 (But not until the 2012 Winter Olympics in Ashville, France.)	
DiCODER$_{CD}$	但直到一二年后的法国阿尔贝维尔冬奥会上。 (But not until the 2012 Winter Olympics in Albertville, France.)	阿尔贝维尔; 韦尔 (Albertville; Vance)
No correction	凶手到月池现实亚镇指认骗走孩子的现场。 (The murderer went to Yueche countryish, Siya Town to ...)	
SC_BART	凶手到月池现实亚锦指认骗走孩子的现场。 (The murderer went to Yueche countryish, Siya towne to ...)	
DiCODER$_{CD}$	凶手到岳池县石垭镇指认骗走孩子的现场。 (The murderer went to Yuechi County, Shiya Town to ...)	岳池县; 石垭镇 (Yuechi County; Shiya Town)
No correction	涨去科技年内涨超二倍。 (RocketFunTech rose more than two times in a year.)	
SC_BART	思科技年内涨超二倍。 (ThinkTech rose more than two times in a year.)	
DiCODER$_{CD}$	掌趣科技年内涨超二倍。 (PocketFunTech rose more than two times in a year.)	掌趣科技 (PocketFunTech)

strategy can effectively suppress the appearance of hallucinated entities. The average HR on three datasets for DiCODER$_{CD}$ is 27.41%, 18.23% and 1.77% lower than those of SC_BART, CSC_BART, and not using a controllable decoding strategy, respectively. It should be noted that the DiCODER result is from an ablation study in which the controllable decoding strategy was removed from DiCODER$_{CD}$. The DiCODER method adopts a more aggressive approach to correct entity errors, resulting in the improved recall at the expense of HR.

Additionally, we select some noisy entities from the MSRA dataset[8] and add them to our entity dictionary to observe the effect of our method. Figure 2 shows that our proposed method exhibits a certain degree of robustness to these noise.

F. Case Study

To demonstrate the properties of our model, we show several running examples in Table III. From these cases, we can tell that our model is capable to correct both

[8]https://github.com/OYE93/Chinese-NLP-Corpus/tree/master/NER/MSRA

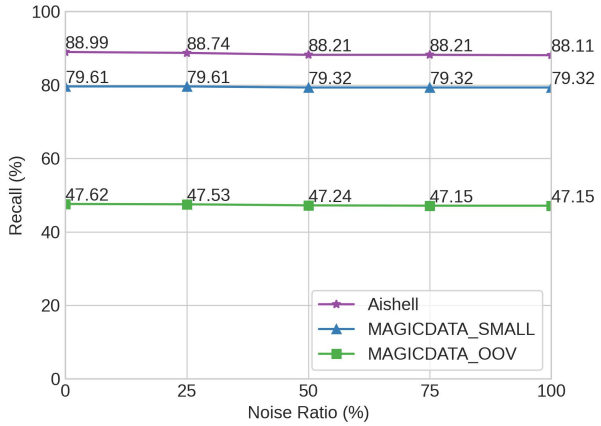

Fig. 2. The entity recall under different noise ratio, which is defined as the ratio of number of noise entities to the number of entities in original dictionary knowledge.

spelling errors and entity errors. The first two examples contain the spelling errors, such as "拨"("Ply") 和 "男一"("Clan"). Benefiting from the language model, both the baseline and our method can deal with this problem by changing "拨"("Ply") to "播"("Play"), "男一"("Clan") to "难以"("Can't")。

Moreover, the last three examples, containing the entity errors, such as "阿尔贝为尔"("Albertwell"), "月池现实亚镇"("Yueche countryish, Siya Town") 和 "涨去科技"("RocketFunTech"). Through leveraging the retrieved entity knowledge, our model can greatly correct these errors. Although the retrieved entity knowledge may contain noise, as seen in the case, the model has some resistance to noise and can tolerate retrieval of entity errors. In sentence "但直到一二年后的法国阿尔贝为尔冬奥会上" ("But not until the 2012 Winter Olympics in Albertwell, France.") the retrieved entities are "阿尔贝维尔; 韦尔" ("Albertville; Vance") by query "阿尔贝为尔; 为尔", where "韦尔" is noise, but it does not affect our error correction results. However, SC_BART relies on the language model alone, generating the hallucination entity "阿尔贝塞"("Ashville") in the results.

V. Conclusions

In this paper, we propose a method to solve the ASR entity error correction problem using entity dictionary knowledge. Experiments on three publicly available datasets show that the method can reduce SER/CER while improving entity error correction performance. However, because the knowledge retrieval component is specially designed for Chinese, it limits the application of our method. In the future, we will extend the retriever to adapt our method to more languages.

A Method of Efficient Synthesizing Post-disaster Remote Sensing Image with Diffusion Model and LLM

Ruizhe Ou, Haotian Yan, Ming Wu, Chuang Zhang
Beijing University of Posts and Telecommunications, China
E-mail: ouruizhe@bupt.edu.cn

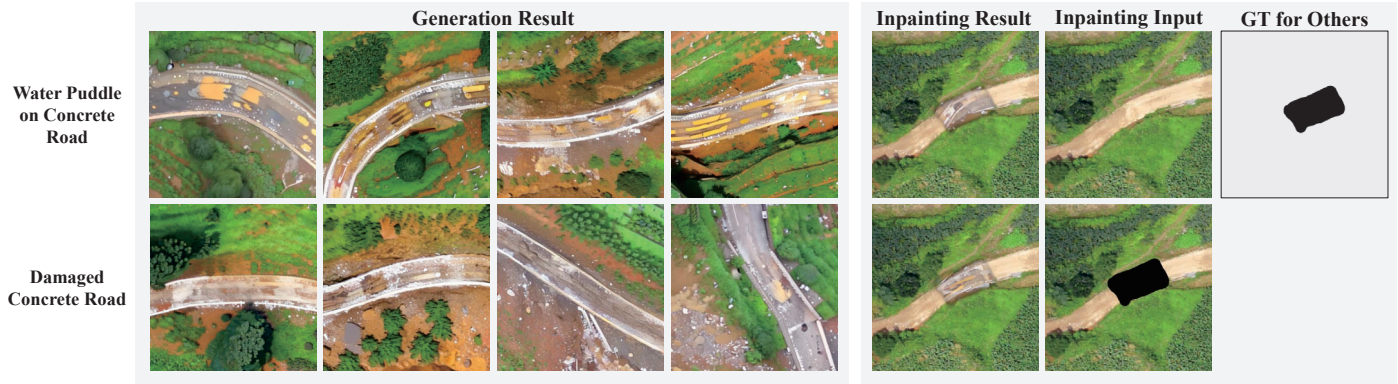

Fig. 1: **Synthesizing Remote Sensing Images Affected by Disaster under Natural Language Guidance with Diffusion Model and LLM.** (1)The images in left block are synthesized in generation manner. The text to the left of the image is condition promtps for synthesizing by the row of images. (2)The images in right block are synthesized in inpainting manner under the same condition of the generation. In addition, synthesizing the images with inpainting manner can obtain the ground truth of disaster as the position label for other interpretation model learning.

***Abstract*—Due to the fact that current deep learning models are typically driven by big data, existing interpretation models for emergency management lack relevant learning data. However, existing pre-trained image generative models cannot directly generate post-disaster remote sensing images without fine-tuning. In this paper, we demonstrate the ability of natural language guidance synthesizing remote sensing imagery affected by disaster by pre-trained image generative model fine-tuned with very few unlabelled images (i.e., less than 100 fine-tuning images) at very low training cost (i.e., one 2080Ti GPU). To trade for lower cost, we embrace the trend of large model, leveraging a pre-trained caption model, GPT-4 and a pre-trained text-to-image Stable Diffusion model for this task. The Stable Diffusion Model, fine-tuned with our method, successfully synthesizes remote sensing images affected by disasters using natural language guidance in both image inpainting and image generation tasks. In addition, the ground truth for other interpretation models learning. With this achievement, our method can synthesize a large amount of data for the emergency management interpretation model to learn when there is less existing data, only unlabelled data and less time, so as to achieve better interpretation performance. Furthermore, our approach highlights the significant of combining human feedback with large models in synthesizing data which is out of the prior knowledge of large model, especially when there is less data available and less computational power available.**

I. Introduction

Due to the unpredictability of disasters and the reliance of existing algorithms on large-scale datasets, there is a lack of learning data for interpretation models[1] serving in emergency management. The pressing issue is how to utilise rapidly advancing image generative models to synthesize post-disaster remote sensing images with limited available data, providing high-quality remote sensing data for interpretation models. Previous disaster remote sensing image synthesis methods primarily include generating disaster-affected remote sensing images by image generative models and inpainting masked position on the image[2] that is not affected by the disaster by image translation model[3]. Nevertheless, the previous methods suffer from several drawbacks: (i) the computational cost of training or fine-tuning an model is exceedingly high; (ii) they required extensive labelled (e.g., mask, class or prompt) data. In this paper, we propose a remote sensing imagery affected by disaster synthesizing method that mitigates all the above problems. Given only a few of unlabelled post-disaster for fine-tuning image generative model, our method can synthesizing high-quality disaster remote sensing imagery under natural language guidance in inpainting way and in

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

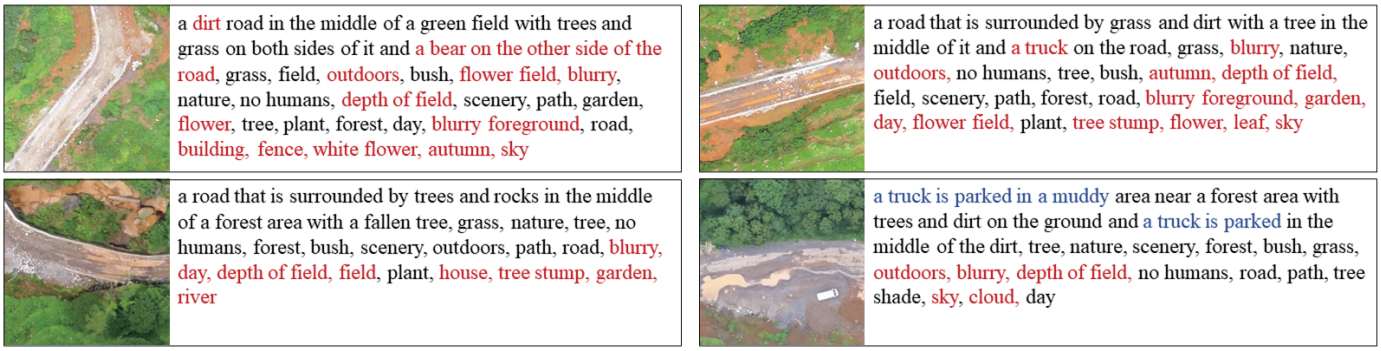

Fig. 2: **The Prompts Captioned by BLIP.** The red words are wrongly captioned by BLIP. There is not semantic information about "remote sensing image" in the prompts captioned by BLIP. Interestingly, The BLIP succeed in captioning the semantic information of small object (e.g, a truck) in a aerial view, which shows BLIP is a very powerful captioning model to caption the semantic information of the object which is not related to disaster.

generation way, as demonstrated at Fig.1. In inpainting way, the label of image which is the mask for inpainting can be the ground truth for other interpretation models training. In generation way, numerous of unlablled post-disaster remote sensing images can be synthesized under natural language guidance.

To achieve this feat, embracing the trend of large mode, we divide this task into three steps:

1) Caption textual prompts remote sensing image affected by disaster to obtain the semantic information of the image.
2) Optimize prompt with human feedback and GPT-4[4] to supply the semantic information of disaster.
3) Fine-tuning Stable Diffusion Model[5] with optimized prompts and post-disaster remote sensing image to capture the image-specific appearance.

Finally, we achieve synthesizing remote sensing image affected by disaster with fine-tuned Stable Diffusion Model under natural language guidance in both image inpainting manner and image generation manner. These results showcase the generality, versatility, and quality of our method in synthesizing out-of-domain data of the large model. We additionally conduct an ablation study, highlighting the effect of each element of our method. We summarize our main contributions as follows:

1) Illustrating a pioneering method for synthesizing post-disaster remote sensing images.
2) Presenting a novel way to cost-effective data augmentation using pre-trained large model.

II. Related Work

A. Image Generative Models and Fine-tuning Strategy

1) Diffusion Models (DMs): DMs[6]–[9] have become state-of-art image generative image. The core premise of Diffusion Model is to initialize synthesizing with a randomly sampled noise $\mathbf{x}_T \sim \mathcal{N}(0, \mathbf{I})$ then iteratively denoise it in a learned fashion, until it is synthesized into a learning image $\mathbf{x}_0$ intermediate step satisfies:

$$\boldsymbol{x}_t = \sqrt{\alpha_t}\boldsymbol{x}_0 + \sqrt{1-\alpha_t}\boldsymbol{\epsilon} \tag{1}$$

where α_t being the hyperparameter of noise-adding process t (i.e., diffusion process), $\boldsymbol{\epsilon}$ is the standard Gaussian noise.

However, these models evaluate and optimize in pixel space, result in slow inference speed and excessively high computational costs.

2) Latent diffusion model (LDM): LDM[5] is one of the DMs, which performs in the latent space, while incorporating a cross-attention[10] mechanism into the denoising process for conditioning the synthesize process. LDM achieves powerful and flexible synthesis conditioning input by introducing a domain specific encoder τ_θ to project conditioning input y to an intermediate representation $\tau_\theta(y)$, which augmenting backbone via a cross-attention layer.

3) Stable Diffusion Model (SDM): SDM, a LDM trained on the LAION-5B[11] dataset that contains 5.85 billion high-quality image-text pairs, has exhibited impressive results in various generative tasks. Users can synthesize realistic high-resolution images using only a text prompt describing the desired scene. However, for synthesizing post-disaster remote sensing imagery, Stable Diffusion requires fine-tuning on post-disaster remote sensing images to achieve better performance.

4) SDM Adpator - Hypernetworks: Hypernetworks[12] involves training an auxiliary network to generate the weights of main network. In 2021, NovelAI introduced a new approach to control model generation, which apply a single small neural network without changing any other part of generation model, either a linear layer or multi-layer perceptron, at cross-attention layer of the larger network to modify hidden states. Since the Hypernetworks is smaller, training is fast and demands limited computational resources. Training Hypernetworks as adaptor inserting into Stable Diffusion model instead of directly fine-tuning it, the computational overhead can be significantly reduced.

B. Iamge Captioning

BLIP: Bootstrapping Language Image Pre-training[13], a novel vision-language pre-training (VLP) framework for vision-language understanding and generation, including image-text retrieval and image captioning. The pre-trained

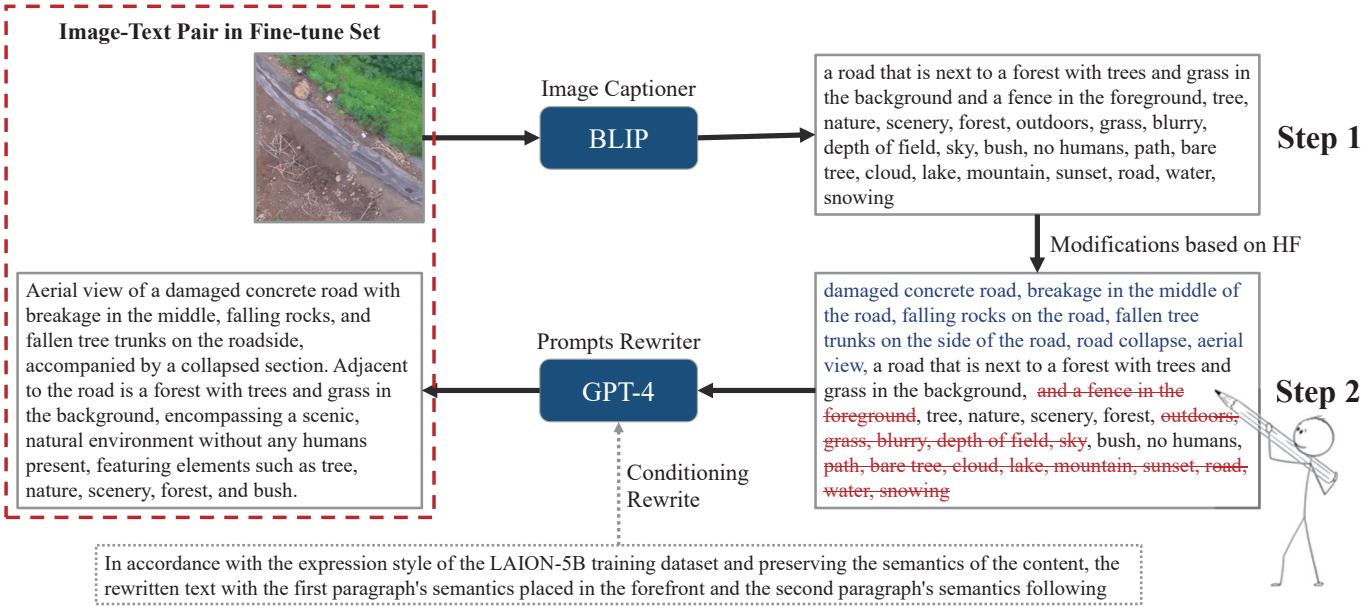

Fig. 3: **The Process of Image Captioning of Our Approach.** In step 1, the semantic information of the object in the image is captioned by BLIP. In step 2, with the help of human feedback, the errors in captioned prompts are removed and supplement the semantic information of disaster at the beginning of the prompts. The bottom statement circled in a box is the prompts for GPT-4 to rewrite prompts for the image according with the writing style of the Stable Diffusion Model training dataset.

model demonstrated poor performance in post-disaster remote sensing image captioning tasks, as evidenced by the results presented in Fig.2. Given the limited availability of post-disaster remote sensing images and the absence of any textual annotations within these images, we must consider the potential detrimental effects of catastrophic forgetting when directly fine-tuning a pre-trained BLIP model to gain a better captioning performance.

In light of the challenge, we propose an alternative approach in this paper, wherein we incorporate validated human feedback to tune the captioned prompts. This enables us to retain the semantic information derived from the BLIP while introducing prompts that align with the specific semantic context of post-disaster remote sensing image.

III. OUR METHOD

In order to achieve efficient post-disaster remote sensing image synthesis, we choose to embrace the large models, that is, to use pre-trained large models as much as possible, with as little fine-tuning as possible. We divide synthesizing task into three steps:

1) Captioning semantic information of the image by BLIP to get prompt words that contain as much semantic information as possible, even if they contain errors.
2) Optimize prompts with human feedback and GPT-4. Remove the errors in captioned prompts and supple the semantic information of disaster. GPT-4 is then used to rephrase the prompts using the writing style of the LAION-5B dataset while maintaining semantic integrity.
3) ine-tuning Stable Diffusion Model with Hypernetworks to minimize fine-tuning cost. The fine-tuning data contains optimized prompts and the images

A. Captioning

In captioning, the pre-trained model we used is a open-source *BLIP w/ ViT-L* model that trained with 129 million images, with ViT-L[14] as the vision backbone.

B. Optimize prompts with Human Feedback and GPT-4

The process is shown in Fig.3. We optimize the captioned prompts based on human feedback (HF). Human experts can directly remove prompts they perceive as defective and supplement with concise terms or natural language expressions to describe disaster-related information they deem missing. When adding the missing disaster-related information, human experts should first describe the characteristics of the disaster-affected locations, and then, centred around these damaged locations, gradually expand their descriptions outward. Examples of human experts supplementing missing disaster descriptions can be found in Fig.3. The prompts composed by human are positioned at the beginning of the captioned prompts to increasing their weight.

To mitigate potential biases in image descriptions due to language usage issues on the part of human feedback, we utilise the GPT-4 as a rewriter for the human-introduced prompts. The GPT-4 maps its original expression to that of the Stable Diffusion model training dataset, ensuring that the adjusted prompts comply with the prior knowledge of the pre-trained Stable Diffusion Model. By adopting this method, we generate the prompts that combine the rich semantic

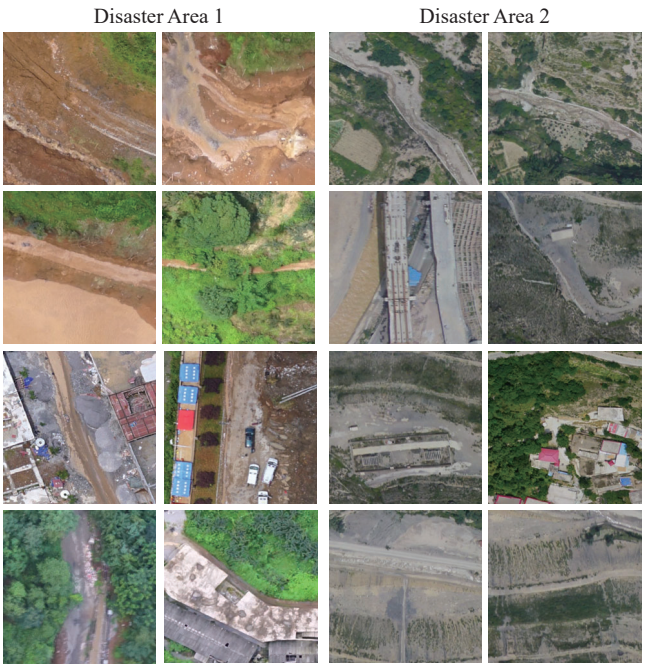

Fig. 4: **The Images that were Filtered Out.** A. The images that unable to identify the road; B. The images that unable to identify damage; C. The images with cluttered backgrounds; D. Blurry and low quality. Moreover, The geographical features of remote sensing images in different regions are different (i.e., the color, the distribution, etc.)

information provided by the BLIP model and the natural language information introduced through human expert feedback. Furthermore, these prompts are articulated in a manner that is readily comprehensible by the Stable Diffusion model.

C. Fine-tuning Stable Diffusion model with Hypernetworks

We utilize a simplistic three layers fully connected neural network, designated as an adaptor for Stable Diffusion to lower fine-tuning cost. The Hypernetworks are inserted into the cross-attention layers of the Stable Diffusion model, where the dimensions of key and value vector are 640, 768, 1024 and 1280. The dimension of the hidden layer of Hypernetworks we used is three times of the dimension of the input layer and output layer, as it called $[1, 3, 1]$ Hypernetworks. We initialized it with XavierNormal[15] which initializes weights with Gaussian noise centred at 0 and sets biases to 0.

IV. EXPERIMENT

A. Dataset

In this study, we utilized drone-captured remote sensing imagery from two regions, namely Disaster Area 1 and Disaster Area 2, as the dataset for our study. In order to improve the quality of fine-tune data, the image that unable to identify the road, unable to identify damage, cluttered background and blurry will be removed. Fig.4 is the example of images that have been filtered out. After filtering, compared to the number of images in the Stable Diffusion model training set, only very little data is available for our fine-tuning. The size of fine-tuning set is showed in Table.I.

TABLE I: Size of Fine-tuning Set

Area No.	Scale	With disaster	Without disaster	Tot.
1	Std.	37	61	98

To explore the generalization of our model, we added total 170 remote sensing images without disaster that contains 49 images with smaller scale from Disaster Area 1 and 60 images with same scale from Disaster Area 2 to the inpainting set. The size of inpainting set is showed in Table.II

TABLE II: Size of Inpainting Set

Area No.	Scale	Without disaster	Tot.
1	Std.	61	170
1	Smaller	49	
2	Std.	60	

B. Implementation details

The $[1, 3, 1]$ Hypernetworks was trained using 98 remote sensing images affected by disaster for 20,000 steps. When training, we unload VAE[16] and CLIP[17] from VRAM. Experimentally, We employed a training strategy of gradually decreasing the learning rate in stages, where a larger learning rate was used at the beginning to activate learning and then lowered artificially as the training progressed to ensure model convergence. Specifically, the learning rate adjustment strategy was as follow:

$$lr_s = \begin{cases} 5e-5 & 0 \le s \le 100 \\ 5e-6 & 100 \le s \le 1,500 \\ 5e-7 & 1,500 \le s \le 10,000 \\ 5e-8 & 10,000 \le s \le 20,000 \end{cases}$$

where s stands for step. The version of pre-trained Stable Diffusion is 2.1. All the experiments are conducted on ONLY ONE GPU - NVIDIA 2080Ti.

C. Ablation Study

1) Prompts optimization: To validate the effectiveness of the prompts optimization based on human feedback, we conducted three sets of ablation experiments. In these experiments, the remote sensing images affected by disaster are synthesized by the Stable Diffusion Model that is fine-tuned with $[1, 3, 1]$ Hypernetworks based on the prompts synthesized in three ways. In the results, as shown in Fig.5 of these three ablation experiments, it can be observed:

- Only using captioned prompts for fine-tuning, the fine-tuned Stable Diffusion Model do not support natural language guidance, as the expression format of captioned prompts significantly differs from that of natural language.

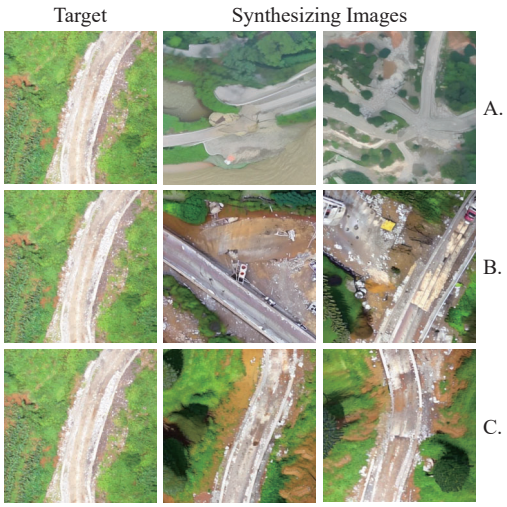

Fig. 5: **Effectiveness of prompts optimization.** A. The images were synthesizing by the model fine-tuned with captioned prompts; B. The images were synthesizing by the model fine-tuned with hand-writing prompts; C. The images were synthesizing by the model fine-tuned with the prompts with our prompts optimization method.

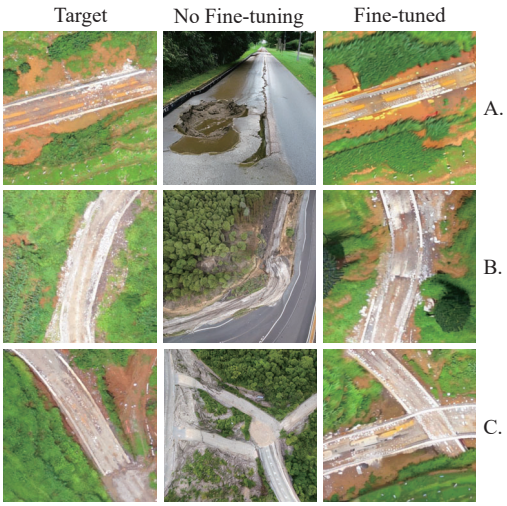

Fig. 6: **Effectiveness of fine-tuning.** A. The images synthesized under "water puddle on concrete road" guidance; B. The images synthesized under "damage concrete road" guidance; C. The images synthesized under "the concrete road is broken in the middle".

- Only using human-composed prompts for fine-tuning, the synthesized images are relatively chaotic in areas other than the damaged parts, as the inability of human-composed prompts to comprehensively describe semantic information of the images used for fine-tuning.

The model that fine-tuned using prompts that synthesized with our method produces best results. It successfully synthesizes remote sensing images affected by disasters similar to the expected images, and also realizes the synthesis guided by natural language.

TABLE III: Fine-tuning Comparison

Fine-tune	FID	SSIM
No Fine-tuning	83.22	0.18
Fine-tuned with $[1, 3, 1]$ Hypernetworks	83.42	**0.31**

D. Fine-tuning

To demonstrate the effect of fine-tuning on the output images, we synthesize images using the Stable Diffusion Model with or without the fine-tuning. we calculated the Fréchet Inception Distance (FID) and Structural Similarity Index (SSIM) between the synthesized images and those containing the same damage semantics. The FID assesses the distribution similarity between two images, with a lower value indicating better. The SSIM measures the similarity in structure between two images, where a higher value suggests better similarity.

With the SSIM value in Table.III almost doubling after fine-tuning, which indicates that fine-tuning brings an enhancement of structural similarity between the synthesizing images and the reference images.

In addition, we observed that the pre-trained Stable Diffusion model struggles to effectively differentiate between semantic information related to specific damage forms, such as collapse and breakage, resulting in the generation of relatively similar images. A comparison between rows B. and C. in Fig.6 substantiates our conjecture regarding the model's inability to accurately distinguish between the distinct types of road damage.

E. Generalization of Synthesising by Inpainting

We conducted inpainting experiments on the images with small-scale from same area and and the images with scale same as learning image from different area to assess the generalization capability of the model.

Observing Fig.7 to analyze the generalization of the model. When using smaller-scale remote sensing images containing more information and applying the same textual prompts as used for large-scale images, the model is struggle for inpainting as the condition. It may simply inpainting the mask with surrounding pixels. For Inpainting on the image of the same scale but from different area, the synthesized image aligns the guidance prompts, but there are some conflicts between the edges of the synthesized content and the input remote sensing images.

F. Limitations

Trading for low fine-tuning cost, all the processes in our method perform at word level or pixel level, the model only learned small amount of semantic information and the feature information of the learning data. Furthermore, based on the assumption that there is less data available for the task,

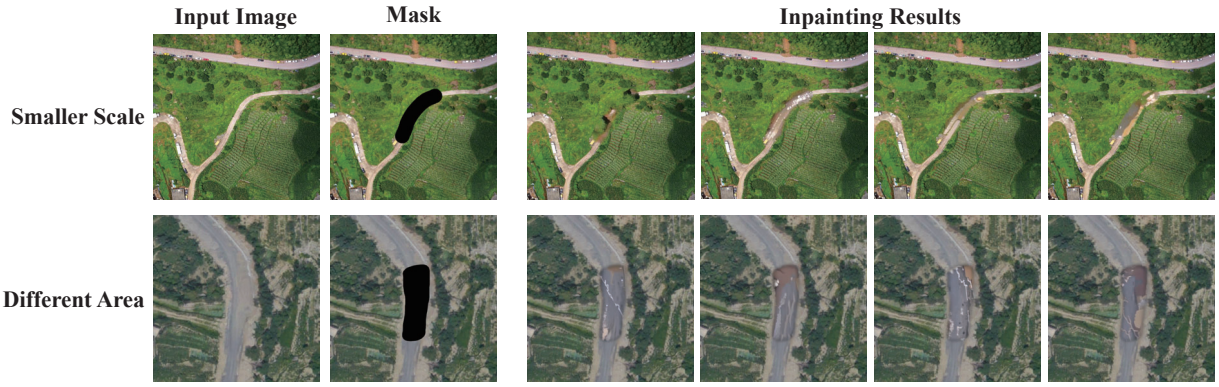

Fig. 7: **Results of Synthesis in the Context of Our Method, Demonstrating Model Generalization Capability.** The synthesized results showcased in this figure are generated using an inpainting technique on images that are devoid of any disaster-related semantics information. The images in the upper row are the outcomes of synthesis performed within the same geographical area, albeit at smaller scales. Conversely, the images in the lower row are the results of synthesis carried out within distinct geographical areas, while maintaining a consistent scale.

the result is that the distribution of synthesizing remote sensing images affected by disaster is quite similar to the learning ones. Considering these two limitations, the model fine-tuned with our method struggles in synthesizing the image via inpainting manner that inpaint on the image containing more semantic information or different semantic information.

V. Conclusions

In this paper, we propose a method to synthesize remote sensing image affected by disaster with Stable Diffusion and GPT-4 under natural languadge guidance in the condition that the data is limited and the data is unlabelled.

To achieve this feat, we firstly synthesize the textual prompts for the image and treat it as the label for training. In our method, a text prompt is captioned by BLIP at the beginning, then by introducing hand-writing prompts through human feedback, we supplement the disaster impact semantics missing in the captioned prompts. GPT-4 is finally used to map the human-feedback-modified prompts to the expression format of the pre-trained Stable Diffusion model's training dataset. After obtaining textual prompts, the images and the prompts are combined to fine-tune Stable Diffusion Model to capture the appearance of remote sensing image affected by disaster. The model fine-tuned with our method succeeds in synthesizing remote sensing images under natural language conditioning in both image inpainting manner and image generation manner.

The model fine-tuned with our method only takes one 2080Ti-GPU and less than 100 images to complete fine-tuning. However, trading to low training cost, the model struggles in synthesizing the image with different scale or containing different senmantic information from the learning dataset.

Based on the fact that interpretation models in emergency management often need to interpret specific types of disasters with only a small amount of data for learning and in a short time, our method can synthesize a large amount of data for the emergency management interpretation model to learn when there is less existing data and time, so as to achieve better interpretation performance. With this achievement, our approach highlights the significant of combining human feedback with large models in out-of-domain data synthesis tasks (e.g., prompt synthesis and image synthesis), especially when there is less data available and less computational power available.

Acknowledgment

I would like to give my sincere thanks to my supervisor, with patience, gave me lots of valuable advice. Then, I also appreciate my family and friends, they support me a lot during my research.

***Abstract*—Wireless network communication has the characteristics of broadcasting and bandwidth limitation, which makes it difficult for devices in the wireless network to obtain high-quality privacy protection and service. The difficulty of achieving both privacy and service quality exacerbates the challenge of privacy-oriented content caching optimization. To solve this problem, coded caching technology offers a new way, but there is little research on the integration of this technology with privacy protection. We propose a privacy-protecting coded caching framework named PCC for mobile Information-Centric Networks (ICNs). Firstly, we discuss the privacy leakage problems existing in the uncoded caching techniques of ICNs and propose an effective adversary model and a privacy protection strength evaluation model for caching in ICNs based on the Shannon cipher system. Secondly, we design a content encoding mechanism based on machine learning to solve the privacy leakage issue in caching, relying on a framework that predicts changes in network fluid nodes. We further propose a joint optimization problem for content caching and privacy protection and propose a privacy-oriented coded caching algorithm called PCC. Compared with existing solutions, our solution not only provides an improvement in privacy protection, but also achieves performance improvements in latency, throughput, and bandwidth savings.**

I. Introduction

Thanks to advances in wireless communication and AI, we've seen a surge in smart mobile devices and apps in wireless networks. These services aim for high-performance, secure, privacy-oriented digital manufacturing, causing massive traffic on the networks. Cisco's annual report[1] forecasts that global wireless network device connections will rise from 8.8 billion in 2018 to 13.1 billion by 2023, reflecting a 1.48-fold overall growth. This surge in mobile services and Device-to-Device(D2D) connections pose twin challenges of cache efficiency and data privacy preservation due to limited bandwidth and poor privacy protection. To mitigate these issues, content caching has been widely researched to lower delay and network traffic.

The ICNs [2] architecture has been proposed to address these limitations. In ICNs, nodes assume varying roles including data consumer, content provider, and forward relay, supporting content-centric services in mobile networks [3]. Content request involves a data consumer seeking content by name, the network identifying providers and maintaining a route between consumer and providers via the forward relay, and providers returning the requested content. ICNs provide a seamless user experience during location changes and allow proactive content caching, reducing content access latency. However, the design incurs privacy issues [4], [5]. Therefore, devising a cache mechanism preventing privacy leaks while accommodating mobile communication demand is optimal.

Traditional uncoded caching strategies cache uniformly-sized content chunks at the network edge. However, their inability to adapt to network dynamics results in inefficient cache resource utilization and compromised privacy [6]. Coded content caching, a potential alternative, has spurred research in mobile services [6]–[9] and data privacy [10]–[13]. Coded caching employs network coding to encode multiple content chunks into packets for distribution [6]. Unlike uncoded chunks, coded packets can simultaneously satisfy multiple users' requests via a broadcast channel. By increasing transmission capacity and reducing delivery latency, coded caching has gained traction in wireless mobile networks [7], [8]. Specifically, [14] proposed the MATO-CAD algorithm, which utilizes user encoding caching, for the delivery of AR video content in the network. Yet, existing coded caching studies have limitations. For example, [6] leaves cached content uncoded until transmission, causing low cache utilization due to redundancy. [9] equally treats content in the coding phase, overlooking content features and relevance, leading to inefficient cache resource utilization.

Unencrypted content broadcasted over wireless networks faces significant privacy risks. V. Leung et al. [11] suggest a new eavesdropping scheme and propose a cooperation-based passive eavesdropping approach that goes unnoticed by victims. In response, authors in [10] propose a strategy for selecting interference jammers and relay nodes from intermediate nodes to improve eavesdropping attack security. In [12], they suggest XOR-based secure coded caching in wireless Ad Hoc networks, demonstrating that coded caching simplifies reactive routing and achieves near-perfect secrecy for D2D file transmissions. Moreover, [13] presents secure coded caching for cloud network storage. However, these strategies overlook network dynamics, impeding practical deployment in D2D-based networks, and require trusted nodes and secure channels to transmit decoding coefficients—a strict prerequisite for D2D-based mobile ICNs.

To counter these issues, we suggest a new coded caching mechanism aimed at jointly optimizing service performance and privacy protection. The main contributions are as follows:

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

1) We present an adversary model for XOR-secured caching, proving that with lesser cached coded content, privacy equals uncoded policy. We also offer a threat-quantifying privacy model.
2) We address data privacy by carefully devising a machine learning-based content coding architecture that integrates representational learning and deep belief networks(DBN).
3) Leveraging proposed architectures, we formulate the joint optimization problem of performance and privacy, developing a privacy-focused coded caching algorithm for optimization and protection without trusted nodes or secure channels.
4) We design a series of simulations to compare our algorithm with the state-of-the-art approaches [15][16]. Results demonstrate our algorithm outperforms state-of-the-art solutions in terms of privacy protection intensity, latency, throughput and resource consumption.

II. Related Works

Several papers have contributed to uncoded and coded caching mechanism designs. [17] introduced a novel uncoded caching network topology that focuses on a combination network with end-user caches. [9] examined decentralized coded content cache placement in heterogeneous networks, highlighting the throughput advantages of coded strategies. [18] proposed novel caching schemes based on erasure codes to achieve low latency in distributed coded storage systems.

Comparatively, [19]proposed a joint MDS codes and weighted graph based coded caching policy to minimize the fronthaul load. [20] suggested a knapsack optimization-based content caching protocol for intelligent traffic networks, enhancing cache utilization of roadside units. [21] proposed a matrix completion-based method for accurate content popularity prediction and cache placement. [12] discussed a decentralized coded caching technique using XOR operations for improved secrecy and simplified routing. [22] proposed a privacy-preserving design to resist quantum attacks in intelligent traffic networks. [4] proposed a privacy-aware caching solution to counter timing attacks in ICNs, albeit sacrificing service performance.

In a prior work [16], we proposed a novel fluid-based structure for 5G ICNs integrated with Device-to-Device communications. We employed an optimal centralized algorithm aimed at minimizing content access latency and caching resources for multimedia services. Further, an optimal coded content caching solution was proposed, leveraging a DBN [23]. This fluid-based model helped simulate state transitions of nodes under coded content caching. A cloud-assisted caching algorithm was designed, encompassing a code content selection mechanism and an optimal coded content distribution, to enable low-latency, cost-effective caching for mobile nodes. However, many studies, including ours, overlooked privacy performance for data and users in the mobile environment.

III. System, Adversary and Privacy Model

A. Preparations

In our model, each mobile node is equipped with D2D interface and caching capabilities, which makes it possible to build a cache-enable D2D network [24]. We consider unicast-based request packet forwarding strategy [25]. From a service perspective, according to [16], we assume that such mobile nodes play any of the three roles: *consumer*, *producer* and *forwarder*, each role follows the same definition in [16]. Besides, we assume the contents are divided into multiple chunks with equal size [16]. The requesting rate $q(i)$ of each chunk follows the Zipf distribution with parameter ρ. The Random Way Point (RWP) model is employed for mobility description. We assume that an adversary can eavesdrop and decipher all of the ciphertexts in the consumer request packet.

B. File Recover with Coded Packets

For capacity analysis, we represent the library of contents by a set $\mathscr{F} = \{\boldsymbol{f}_1, \boldsymbol{f}_2, ..., \boldsymbol{f}_m\}$, where m is the total amount of content. We assume that each content f_i contains k number of chunks as $\boldsymbol{f}_i = \{p_{i,1}, p_{i,2}, ..., p_{i,k}\}$. Since the content is rich in the real-world system and the popularity of different content is disparate, coding everything together is infeasible. Therefore, we consider a classification-based coding strategy and divide all of these chunks into K different categories. Besides, we denote $\mathscr{L} = \{\boldsymbol{l}_1, \boldsymbol{l}_2, ..., \boldsymbol{l}_K\}$ as the set of all coded categories and for the category j we have $\boldsymbol{l}_j = \{l_j^1, l_j^2, ..., l_j^{N_j}\}$, $j \in [1, K]$ as the set of chunks in class j where $N_j = |\boldsymbol{l}_j|$ is the size of $\boldsymbol{l}_j$. According to [9], for each class, we randomly select chunks from set $\boldsymbol{l}_j$ with probability 0.5 and then mix the selected chunks via the XOR operation to create a coded packet. The total amount of coded packets is $2^{N_j} - 1$. The i-th coded packet of category j can be represented as:

$$g_j^i = \sum_{n=1}^{N_j} a_j^n l_j^n = \boldsymbol{a}_j \boldsymbol{l}_j^T \tag{1}$$

where $\boldsymbol{a}_j = [a_j^1, a_j^1, .., a_j^{N_j}]$ is a vector, and each of its components follows a binary random distribution where $\boldsymbol{a}_j$ is a uniformly distributed vector of coding counters with binary elements and the summation is carried over Galois Field (GF) of two elements (0,1). In this way, if the mobile nodes find a set of nodes in the forward path with enough coded packets containing N linearly independent coded vectors, they can collaborate to decode the chunk. As shown in Fig. 1, considering the content set of the current network is $\{A, B, C, D, E\}$, we assume that node n_0 contains the coded content $\{B \oplus C \oplus E\}$. If n_0 requests content A, it will need uncoded content packet A or $\{A \oplus B \oplus C \oplus E\}$ for decoding A. Thus, n_0 sends out the request packet containing the *Counter Vector* $(1,0,0,0,0)$ and $(1,1,1,0,1)$ to the neighbor n_1. The receiving node n_1 does not contain the asked packets. Since n_1 contains $\{B \oplus E\}$, decoding the requested packet will only need any one of the packets A, $\{A \oplus B \oplus C \oplus E\}$, $\{A \oplus B \oplus E\}$ and $\{A \oplus C\}$. Thus, n_1 forwards the request with vectors $(1,0,0,0,0)$, $(1,1,1,0,1)$, $(1,1,0,0,1)$ and $(1,0,1,0,0)$ to next hop n_2 which has coded packet $\{A \oplus C\}$. n_2 passes the $\{A \oplus C\}$ to n_1, and n_1 obtains the

$\{A\oplus B\oplus C\oplus E\}$ by combining the $\{A\oplus C\}$ and $\{B\oplus E\}$. Then, n_1 returns the asked $\{A\oplus B\oplus C\oplus E\}$ to n_0 and n_0 decodes the A with $\{A\oplus B\oplus C\oplus E\}$ and $\{B\oplus C\oplus E\}$.

Based on above discussion, each mobile node can decodes the required p-th chunks via N_j linear independent packets. The decoding process can be represented by a equation $\sum_{i=1}^{2^{N_j}} b_j^i g_j^i$, where $b_j^i \in GF(2)$ denotes whether to perform the XOR operation with coded packet g_j^i over the decoding process. Then, we substitute the equation (1) into $\sum_{i=1}^{2^{N_j}} b_j^i g_j^i$ and we have $\sum_{i=1}^{2^{N_j}} b_j^i \boldsymbol{a}_j \boldsymbol{l}_j^T = \boldsymbol{v}_p \boldsymbol{a}_j$. Intuitively, we have vector $\boldsymbol{v}_p = \sum_{i=1}^{2^{N_j}} b_j^i \boldsymbol{l}_j^T$ and requiring 1 only for p-th component in vector $\boldsymbol{v}_p$ and 0 for other components.

C. Adversary Model

In this subsection, we will introduce the privacy security of the coded caching and then describe the adversary model of coded caching privacy. We can consider the XOR coded process as the encoding function of the Shannon cipher system. According to [12], if a consumer caches k coded packets, that means there are at most 2^k possible random keys (*Counter Vectors*) can be built. So the XOR coded caching strategy provides asymptotic perfect secrecy.

Unfortunately, this security mechanism will be broken by adversaries under our previous assumptions. We assume that the adversary can eavesdrop on the *Counter Vectors* which is sent by the consumers. The exposed *Counter Vectors* can help the adversary infer what the user requested. As shown in Fig. 1, the adversary eavesdrop that the *Counter Vectors* of the request packet are $(1,0,0,0,0)$ and $(1,1,1,0,1)$. Based on this, the adversary can directly infer that the content requested by the user is A. Let's consider a more general case, suppose the consumer caches k linearly independent coded packets and generates a request for the chunk $p_{i,j}$ which cannot be decoded by local caching. The set of *Counter Vectors* sent by the consumer must contain uncoded packets vector, such as $(1,0,0,0,0)$ or $(0,1,0,0,0)$. The adversary can filter out these uncoded vectors from the set of *Counter Vectors*. If the adversary gets only one uncoded vector, the consumer request can be inferred directly. If there are multiple uncoded vectors obtained by the adversary, the adversary can still narrow down user requests to a small range. According to linear algebra theory, the average number of uncoded vectors sent by the consumers is $1+\frac{N-1}{2^{N-k+1}}$ where N represents the total number of chunks encoded together. This means that encoding more chunks together (larger N) will result in a smaller number of uncoded vectors under a given caching capacity of each node.

Since the uncoded packet directly expose the privacy of user request, we believe that users should avoid requesting uncode packets directly and instead request coded content.

D. Privacy Model

Under the new adversary model, we find that the crux of privacy protection depends on the number of uncoded vectors. The more chunks that are encoded together, the better the privacy protection performance. So, we can assume that for the adversary, different coded vectors are equivalent. The adversary cannot distinguish which chunk is requested by the consumer based on the coded vector.

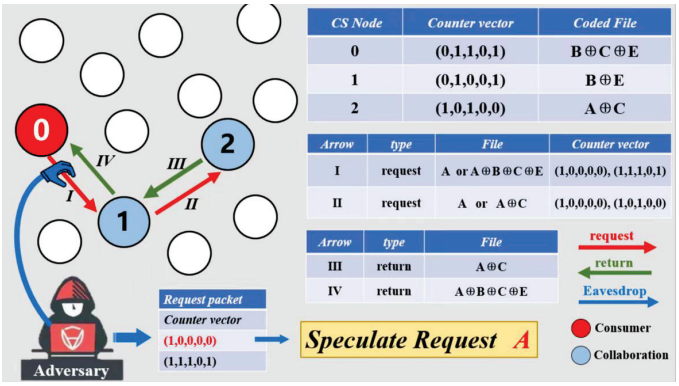

Fig. 1. D2D network decoding example and potential adversary model

We use entropy as the quantitative performance of privacy intensity which is positively correlated with the number of uncoded vectors $|\mathscr{A}|$. We denote $H(\mathscr{A})$ as the function of privacy intensity which is represented as:

$$H(\mathscr{A}) = -\sum_{i=1}^{|\mathscr{A}|} p_i(\mathscr{A}) \log p_i(\mathscr{A}) \tag{2}$$

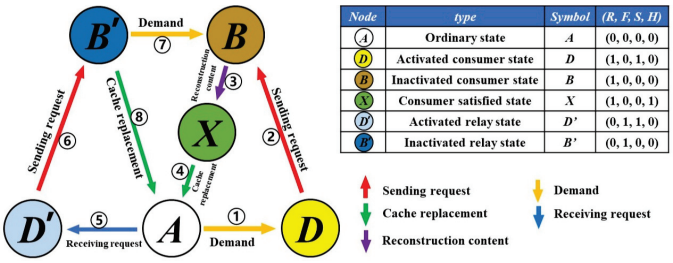
where the $p_i(\mathscr{A}) = 1/|\mathscr{A}|$ and the privacy intensity can be rewritten as $H(\mathscr{A}) = \log|\mathscr{A}|$. The privacy intensity of the original XOR mechanism is $\log N$. This indicates that when we encode more chunks together, the privacy intensity $\log N$ is better. Thus, the issues of coded caching deployment and coded content selection have a significant impact on data privacy.

IV. The Architecture of Coded Content Caching

A. Fluid-based Architecture

We discuss the basic concepts of the fluid-based model for a given class $\boldsymbol{l}_j$. For detailed information, please refer to our early work [16], we have four roles for mobile nodes: **Consumer**, **Relay**, **Provider** and **Ordinary**. We use the following four bits, 1 represents existence:

- **Request bit** (R): consumer for the chunk
- **Forward bit** (F): relay for the chunk
- **Spread bit** (S): able to spread the request to neighbor
- **Have bit** (H): capable of decoding the corresponding chunk



Unlike the [16] which considered the non-coded scenarios, we in this paper model six possible node states:

- **Ordinary state** $\boldsymbol{A}$ (R=0, F=0, S=0, H=0)
- **Activated consumer state** $\boldsymbol{D}$ (R=1, F=0, S=1, H=0)
- **Inactivated consumer state** $\boldsymbol{B}$ (R=1, F=0, S=0, H=0)
- **Consumer satisfied state** $\boldsymbol{X}$ (R=1, F=0, S=0, H=1)
- **Activated relay state** $\boldsymbol{D'}$(R=0, F=1, S=1, H=0)
- **Inactivated relay state** $\boldsymbol{B'}$ (R=0, F=1, S=0, H=0)

Each node in network is one of the six states, hence the sum of all nodes of each state is constantly equal to the total number of nodes in networks, namely:

$$A(t)+D(t)+B(t)+X(t)+D'(t)+B'(t)=1 \tag{3}$$

Further, we build a fluid-based model to describe the dynamics of those nodes. The transition of 6 states and 8 possible

Node	type	Symbol	(R, F, S, H)
A	Ordinary state	A	(0, 0, 0, 0)
D	Activated consumer state	D	(1, 0, 1, 0)
B	Inactivated consumer state	B	(1, 0, 0, 0)
X	Consumer satisfied state	X	(1, 0, 0, 1)
D'	Activated relay state	D'	(0, 1, 1, 0)
B'	Inactivated relay state	B'	(0, 1, 0, 0)

Fig. 2. Possible state transitions of nodes in coded content caching

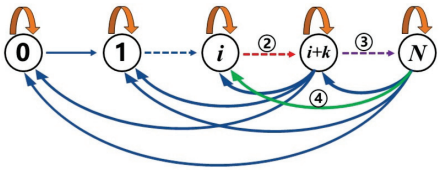


Fig. 3. The state space of the Markov chain for decoding

types of state transitions (represented by the dotted/solid line with an arrow) can be interpreted as Fig. 2.

The conversion rate of the above 8 transition processes is summarized in Table 1. According to Fig. 2 and Table 1, we can obtain the following O.D.E functions:

$$\dot{A}_j = X_j(t) + 2B'_j(t)/\mathbb{H} - \beta_j A_j(t) - A_j(t)\left(D_j(t) + D'_j(t)\right) \quad (4)$$

$$\dot{D}_j = \beta_j A_j(t) - D_j(t) \quad (5)$$

$$\dot{B}_j = D_j(t) - B_j(t)/\mathbb{H} + \beta_j B'_j(t) \quad (6)$$

$$\dot{X}_j = B_j(t)/\mathbb{H} - X_j(t) \quad (7)$$

$$\dot{D'}_j = A_j(t)\left(D_j(t) + D'_j(t)\right) - D'_j(t) \quad (8)$$

$$\dot{B'}_j = D'_j(t) - \beta_j B'_j(t) - 2B'_j(t)/\mathbb{H} \quad (9)$$

$$\boldsymbol{U}_j|_{t=t_0} = U_{j,t_0} \quad (10)$$

Where $\boldsymbol{U}_j$ represents the system state of the class j. Given the initial value U_{j,t_0} by

$$U_{j,t_0} = \left(A_j(t_0), D_j(t_0), B_j(t_0), X_j(t_0), D'_j(t_0), B'_j(t_0)\right)$$

B. Accuracy of the O.D.E Approximation

To validate the accuracy of proposed O.D.E function, we use the ndnSIM based on NS3 to simulate the real NDN environments and conduct a series of tests. Specifically, we build an NDN network with 1000 mobile nodes moving arbitrarily over a 3000 × 3000 square area. The RWP mobility model is used and its velocity range is set to $[3, 10]$m/s. Consider 10 different contents which are 10s long and consist of 5 chunks. All chunks are encoded randomly. The caching capacity of each mobile node in NDN is set to 5 chunks large.

TABLE I
STATE UPDATE AND CONVERSION RATE OF TRANSITIONS

Transition	State update	Conversion rate
1	(0,0,0,0) → (1,0,1,0)	$\beta_j A_j(t)$
2	(1,0,1,0) → (1,0,0,0)	$D_j(t)$
3	(1,0,0,0) → (1,0,0,1)	$B_j(t)/\mathbb{H}$
4	(1,0,0,1) → (0,0,0,0)	$X_j(t)$
5	(0,0,0,0) → (0,1,1,0)	$A_j(t)\left(D_j(t) + D'_j(t)\right)$
6	(0,1,1,0) → (0,1,0,0)	$D'_j(t)$
7	(0,1,0,0) → (1,0,0,0)	$\beta_j B'_j(t)$
8	(0,1,0,0) → (0,0,0,0)	$2B'_j(t)/\mathbb{H}$

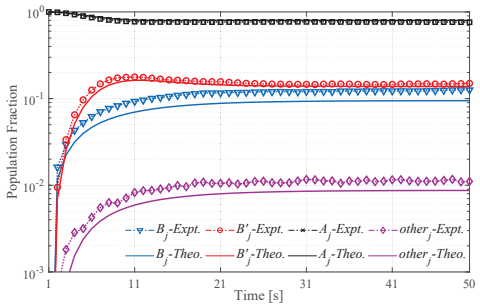

Fig. 4. Population fraction evolution in experimental and theoretical contexts

To eliminate the randomness, we repeat 20 times with different random seeds and take the average of the results. Fig.4 shows the comparison between theoretical and experimental values of the system evolution. Our model converges well with the simulation results. Hence, we can conclude that our model indeed describes the realistic system evolving.

C. Learn-based Content Coding Architecture

In this subsection, we first design a representation learning method based on word2vec to complete the embedding process, and then propose a four layers DBN for coded caching selection. We consider the wireless mobile network as shown in Fig. 5(a). We collect the chunk request records of all nodes and sort the records of each node in chronological order as the representation learning training set as shown in Fig. 5(b). We consider the records sequence of each node as the *text* and each record as the *word* of the *text*. Thus, we use the representation learning in Fig. 5(c). The representation learning model has three layers, the input layer selects z records before and after a specific record p, with each record corresponding to a request of a specific chunk. For all chunks, we initialize them with a N-dimensional vector $\boldsymbol{v}(p)$ with random value. Hence, the input layer contains $2z$ vectors with N-dimensional. In the projection layer, we calculate the sum of $2z$ vectors as the projection which can be expressed as $\boldsymbol{w_v} = \sum_{i=1}^{z}\left[\boldsymbol{v}_i^-(p) + \boldsymbol{v}_i^+(p)\right]$ where $\boldsymbol{v}_i^-(p)$ represent the i-th chunk in front of p and $\boldsymbol{v}_i^+(p)$ represent the i-th chunk behind. The output layer is a Huffman tree which is constructed based on the request frequency of each chunk. In the Huffman tree, each leaf node corresponds to a specific chunk, and each non-leaf node corresponds to a softmax function. This tree-based structure is a basic hierarchical softmax. For any $\boldsymbol{w_v}$, there always exists a path in the Huffman tree. The principle of this process is to calculate the probability of chunk p in a given context $\boldsymbol{w_v}$ which is derived as

$$P(p|w_v) = \prod_{x=1}^{n} P\left(d_x^w | \theta_{x-1}^w\right) \quad (11)$$

where $\theta_{x-1}^{\boldsymbol{w}}$ is the vector of x-th softmax function on the path and $d_x^{\boldsymbol{w}}$ is a binary result which is calculate by input $\theta_{x-1}^{\boldsymbol{w}}$ into x-th softmax function. If the reach leaf p'=p, give positive feedback on the path; otherwise, give negative feedback. As shown in Fig. 5(d), once the representations of chunks are learned by CBOW model, we use k-means clustering to divide the contents into K categories.

When the clustering is completed, we can obtain the coded packet by XOR process. We consider category $\boldsymbol{l}$ has N different

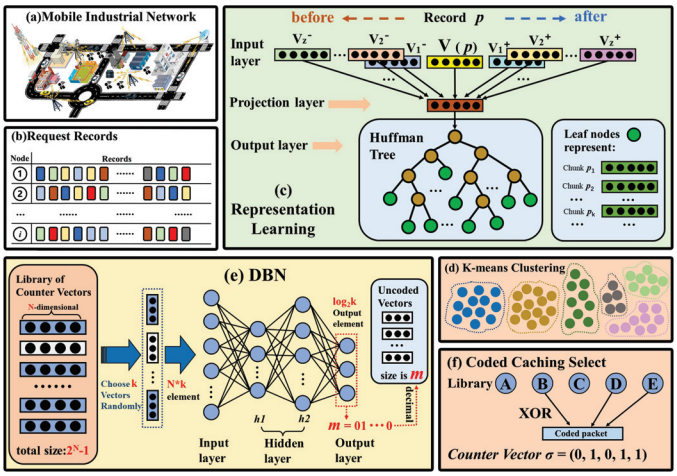

Fig. 5. The learning-based content coding architecture

chunks and each node caching k number of coded packets in this category. The total number of coded packets in this category is 2^N, how to choose k independent packets from such a large number of libraries to ensure privacy performance, is tough work. Thus, we propose a four layers DBN for coded caching selection. Fig. 5(e) illustrates the structure of DBN. The input layer consists of $k*n$. h_1 and h_2 consist n neurons and k neurons, respectively. And the size of output layer is $\lceil \log_2 k \rceil^+$, where $\lceil \cdot \rceil^+$ represents ceil. We randomly select k independent coded packets from the library as input and take the number of uncoded vectors as the label. Thus, we can obtain a large number of (input, label) pairs as our training set. We use this training set to train DBN in the forward and backward directions. Finally, as shown in Fig. 5(f), we use the trained DBN to guide decisions such as coded caching selection and replacement.

V. Joint Optimization of Performance and Privacy

A. Problem Formulation

Coded content caching balances the popularity of different contents and decouples the associativity of each chunk. Therefore, we need to consider "how many independent coded packets need to be cached?". For i-th mobile node, we denote $\eta_i = (k_1^i, k_2^i, ..., k_j^i, ..., k_{K_c}^i)$ as caching policy, where k_j^i indicates the number of independent coding packets in category j. The average number of coded packets cached in all nodes is equal to $\sum_{j=1}^{K_c} \bar{k}_j$. According to our previous assumptions, the more linear independent packets, the higher performance of data privacy and the less hop of content retrieve. However, we can't infinitely cache the coded packets. Thus, the objective function of the joint optimization problem for coded caching can be formulated as the tradeoff between delay, privacy and resource consumption, which can be represented as:

$$J_\eta = \sum_{j=1}^{K_c} J_\eta^j = \sum_{j=1}^{K_c} \left(\phi B_\eta^j \left(T_\eta^j \right) - \varphi H \left(\mathscr{A}_\eta^j \right) + \psi \bar{k}_j \right) \tag{12}$$

where $B_\eta^j(T_\eta^j)$ represents the value of $B_j(t)$ under the coded caching policy η at time T_η^j, T_η^j is the time when $B_\eta^j(t)$ reaches the peak value, namely $\{T_\eta^j | B_\eta^j(T_\eta^j) = \max_t B_\eta^j(t)\}$. k_j is the total scale of coded content in category j. ϕ, φ and ψ are the weight parameters where $\phi + \varphi + \psi = 1$. Thus, we can formulate the optimization as follows.

$$\boldsymbol{min} \quad J_\eta \tag{13}$$

$$\boldsymbol{s.t.} \quad \sum_{j=1}^{K_c} k_j^i \le C_i \quad \forall i \tag{14}$$

where C_i indicates the caching capacity of node i.

B. Optimal Control

In this subsection, we will discuss how to minimize the objective J_η by regulating the coded caching policy η. According to equation (12), J_η is separable for the caching category, we can consider the sub-problem J_η^j instead.

$$J_\eta^j = \phi B_\eta^j \left(T_\eta^j \right) - \varphi H \left(\mathscr{A}_\eta^j \right) + \psi \bar{k}_j \tag{15}$$

According to equation (15), we have the following lemma.

Lemma 5.1: When $B_\eta^j(T_\eta^j)$ and $H(\mathscr{A}_\eta^j)$ are continuous with respect to $\bar{k}_j$, we have J_η^j continuous with respect to $\bar{k}_j$.

The proof of Lemma 1 is intuitive. Since J_η^j is a linear function of $B_\eta^j(T_\eta^j)$ and $H(\mathscr{A}_\eta^j)$, we have J_η^j is continuous with respect to $\bar{k}_j$ based on the above condition.

Since the continuity of $H(\mathscr{A}_\eta^j)$ can be obtained from equation (2), here we focus on the continuity of $B_\eta^j(T_\eta^j)$. To simplify the description of O.D.E function (6)-(12), we rephrase the population fraction of each state with corresponding lowercase letter, such as b for $B(t)$, $\dot{b}$ for $\dot{B}(t)$.

$$\begin{aligned} \dot{a}_j = {} & x_j(t) + \alpha_j b'_j(t) - \beta_j a_j(t) \\ & - a_j(t) \left(d_j(t) + d'_j(t) \right) \end{aligned} \tag{16}$$

$$\dot{d}_j = \beta_j a_j(t) - d_j(t) \tag{17}$$

$$\dot{b}_j = d_j(t) - \gamma_j b_j(t) + \beta_j b'_j(t) \tag{18}$$

$$\dot{x}_j = \gamma_j b_j(t) - x_j(t) \tag{19}$$

$$\dot{d'}_j = a_j(t) \left(d_j(t) + d'_j(t) \right) - d'_j(t) \tag{20}$$

$$\dot{b'}_j = d'_j(t) - \beta_j b'_j(t) - \alpha_j b'_j(t) \tag{21}$$

where $\alpha_j = (\mathbb{H} - 1) / \left(\sum_{i=1}^{\mathbb{H}-1} i \right)$ and $\gamma_j = 1/\mathbb{H}$. Let $\boldsymbol{f}_j$ denotes as $(f_{a_j}, f_{d_j}, f_{b_j}, f_{x_j}, f_{d'_j}, f_{b'_j})$, which are the right side of the (15)-(20). According to (3), we have $(a_j, d_j, b_j, x_j, d'_j, b'_j) \in [0,1]^6$. Therefore the Jacobian of $\boldsymbol{f}_j$ is bounded and satisfy the Lipchitz condition. According to (14), we can limit our focus on state evaluation of $(b_j(t), b'_j(t))$.

$$\dot{b}_j = d_j(t) - \gamma_j b_j(t) + \beta_j b'_j(t) \tag{22}$$

$$\dot{b'}_j = d'_j(t) - \beta_j b'_j(t) - \alpha_j b'_j(t) \tag{23}$$

where β_j is constant and only related to the popularity of $\boldsymbol{l}_j$. As we can see, $b_j(t)$ and $b'_j(t)$ are the monotonically decreasing in terms of γ_j and α_j respectively. Hence, we know that $b_j(t)$ and $b'_j(t)$ are monotonically decreasing with the respect to $\bar{k}_j$.

Assume $\boldsymbol{\omega}_j^{(1)}(t) = (b_j^{(1)}(t), b_j'^{(1)}(t))$ and $\boldsymbol{\omega}_j^{(2)}(t) = (b_j^{(2)}(t), b_j'^{(2)}(t))$ are the trajectories of equation (24) and (25) under different caching policies η_1 with $\bar{k}_j^{(1)}$ and η_2 with $\bar{k}_j^{(2)}$. With loss of generality, we assume $\bar{k}_j^{(1)} > \bar{k}_j^{(2)}$, and denote $\Delta\gamma_j = \gamma_j^{(1)} - \gamma_j^{(2)}$ and $\Delta\alpha_j = \alpha_j^{(1)} - \alpha_j^{(2)}$. According to (17), we have following inequality.

$$||\boldsymbol{\omega}_j^{(1)} \left(T_\eta^j \right) - \boldsymbol{\omega}_j^{(2)} \left(T_\eta^j \right)||_2 \le C T_\eta^j \sqrt{\Delta\gamma_j^2 + \Delta\alpha_j^2}$$

where $C = \sqrt{2}(2+\beta_j)$. Since $\boldsymbol{f}_j$ is bounded, and T_η^j is finite, we have $b_j(T_\eta^j)$ continuous with respect to $\bar{k}_j$, where γ and α are continuous with respect to $\bar{k}_j$.

Fig. 6 shows the variation of $B_\eta^j(T_\eta^j)$, $H(\mathscr{A}_\eta^j)$ and J_η^j with respect to $\bar{k}_j$, where ϕ=0.1, φ=0.5 and ψ=0.4. In addition, the setting of other experimental parameters is the same as in *Section 3.B*. We can see $B_\eta^j(T_\eta^j)$ is monotonically decreasing and $H(\mathscr{A}_\eta^j)$ is monotonically increasing, which also proves the previous conclusion with $\bar{k}_j$. This explains the fact that the more coded packets cached in the mobile nodes, the fewer *consumers* are in the networks, and the better privacy performance of each node. For the value of objective function J_η^j, we can see the corresponding curve firstly experience a decreasing trend and then increase with respect to the $\bar{k}_j$. This is because as the cache fraction increases, the cost of networks cache increases linearly and other terms decrease exponentially, which results in the total increase. Therefore, we can find the optimal $\bar{k}_j$ and J_η^j through numerical calculation. Based on the numerical results, the optimal caching strategy is to let each mobile node cache 5 coded packets under the parameter settings.

Algorithm 1: PCC Algorithm

Input:
Choose the condition numbers ϕ, φ, $\psi \in (0,1)$;
Cloud Center Side:
foreach *time-slot T* **do**
  Collect the records of mobile nodes and $\boldsymbol{U}$;
  Chunks embedding, get K_c categories;
  foreach *category j* **do**
    Calculate the optimal cache policy $\boldsymbol{\eta}_j$;
    Train the DBN$_j$;
  end
  Broadcasts $(\boldsymbol{\eta}, \textbf{DBN})$ to all mobile nodes;
end
Mobile Nodes Side:
foreach *time-slot T* **do**
  Upload $\boldsymbol{U}$ and request records;
  Deployment the coded caching based on $(\boldsymbol{\eta}, \textbf{DBN})$;
end
final

C. Practical Algorithm

We assume that there is a cloud center (e.g. data center) that periodically (the update interval is T) collects the request records of each mobile node in the wireless mobile network system. The cloud maintains request records of each node and orders them by time. Further, the request history set is divided into a series of parts $\{data, label\}$ in a maximum interval $2z$ which contains the context records as the data and predicted record as the label. Therefore, the cloud will use the CBOW model to complete the embedding and get the representation vector of each chunk. Then, we use the learned vectors and K-means to divide the chunks into K_c categories. According to current network status $\boldsymbol{U}_j$, the cloud calculates the coded cache policy η at set intervals. The cloud needs to train the corresponding DBN for each category. After obtaining the optimal η and DBNs, the cloud server broadcasts them to all nodes through the access point (e.g. base station), and then the mobile nodes perform the deployment of coded caching based on η and DBNs. The above process is implemented by the pseudo code of **Algorithm 1**.

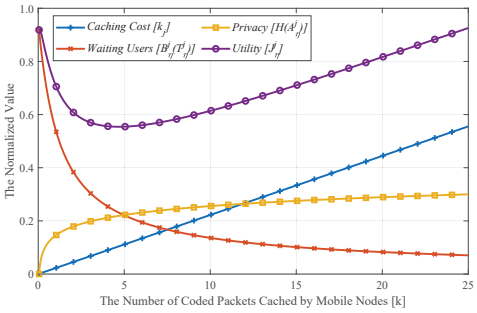

Fig. 6. The normalized value varies with the number of coded packets k_j^i

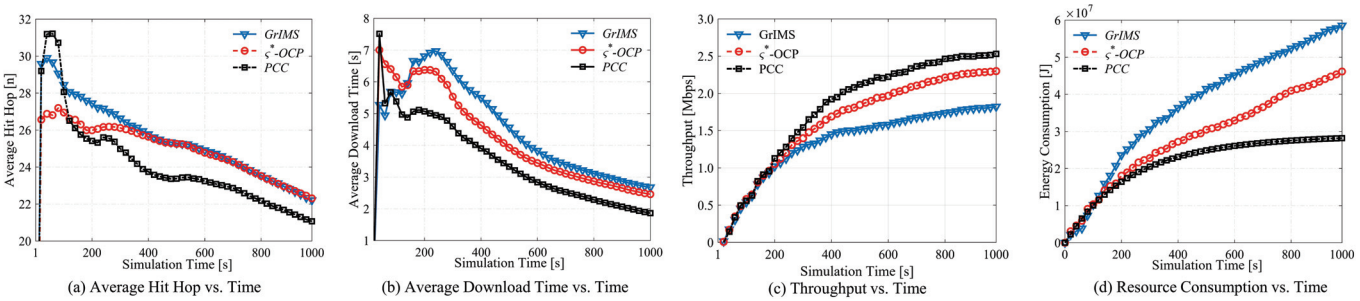
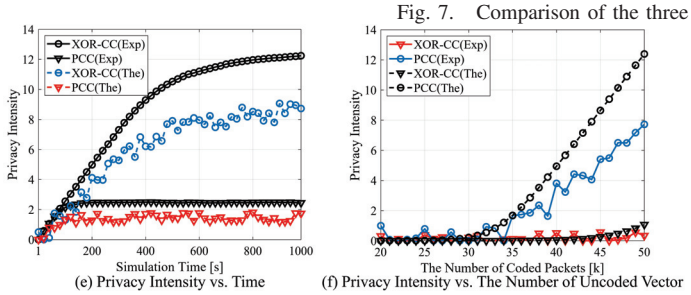
VI. Performance Evaluation



A. Experimental Settings

The parameters setting of RWP model are the same with *Section 3.B*. We use network simulator 3[1] which is a discrete-event network simulator for Internet systems to drive our simulation. We deploy a 3000*3000 m^2 quadrate simulation scenario with 200 mobile nodes and set the simulation time to 1000s. Besides, we adopt 1000 different contents and each of the contents contains 10 chunks. The playback length of each video chunk is 2 seconds. The user's request for content follows the Zipf distribution with parameter ρ = 0.8. The caching size of each node is set to 1×10^5 MTUs, where each MTU equals to 1500B. In such cases, we set that the mobile node can store 300 content chunks at most. We employ the K-means to cluster the content into 100 categories, and a central server broadcast the categories and coding strategy η to all mobile nodes. We assign random initialization coded caching to each mobile node. We also deploy two network providers that contain all of the coded packets. The simulation is deployed on a full-fledged laptop equipped with AMD R9 5900HX, 32G, RTX 3080.

B. Network Performance



We evaluated the performance of our solution in terms of average hit hop, average downloading time, throughput, and energy consumption. We compared the performance with two state-of-the-art solutions: ς^*-OCP [16], and GrIMS [15] in the wireless mobile network system. Where ς^*-OCP is a strategy that uses a centralized server to adjust the deployment of network cache on mobile nodes. By setting a "cache time" for each piece of content, the strategy optimizes network cache deployment, ensuring that cache content that exceeds the set time is replaced. GrIMS is a centralized network cache deployment strategy that takes into account energy consumption. This strategy, through a cloud controller, adjusts

[1]https://www.nsnam.org/

(a) Average Hit Hop vs. Time (b) Average Download Time vs. Time (c) Throughput vs. Time (d) Resource Consumption vs. Time

Fig. 7. Comparison of the three algorithms on AHH, ADT, TP, RC

(e) Privacy Intensity vs. Time (f) Privacy Intensity vs. The Number of Uncoded Vector

Fig. 8. Comparison of the PCC and XOR algorithms

network cache based on the cache energy consumption and resource utilization rate of each mobile node, thus optimizing deployment. It prioritizes the replacement of cache content that has high energy consumption and low utilization. The comparison metrics are shown as follows:

Average hit hop (**AHH**): The average hop of finding all packets for decoding. **Average downloading time** (**ADT**): The average time interval between sending out requests and obtaining enough coding packets. **Throughput** (**TP**): The amount of data transmitted successfully from one node to another in a given time period. **Resource Consumption** (**RC**): The total resource consumption of all forwarding and caching operations during the simulation.

According to Fig7(a), we can see that *PCC* works best on **AHH**, and the **AHH** decreases by about 2 hops. The superiority of *PCC* is because the coded content caching reduces the likelihood of redundant replicas. Assuming five distinct content chunks with each node caching one, the likelihood of two nodes caching identical content is 1/5 in uncoded caching, whereas in coded caching with approximately 2^5 linearly independent coded contents, it drops to $1/2^5$.

Fig7(b) shows *PCC* is the lowest **ADL** of three caching solutions varying with the simulation time. All curves begin with a brief period of shock and then slowly decrease over time. This is because the node movement causes the system to be unstable at the beginning. As time pass by, the cache space is gradually optimized for full utilization and cache configuration, which reduces the **ADT**.

As shown in Fig7(c), the **TP** of three solutions first go through a rapid ascent and then stabilize. we can see *PCC* is superior to the other two algorithms in the whole time domain. Our method can greatly improve the throughput of the network, and its performance is improved by 10% and 38% respectively compared with the other two methods.

In addition, Fig7(d) shows *PCC* outperforms than ς^*-OCP and GrIMS at 1000s by about 24% and 47%. Because the decrease in **AHH** reduces the resource consumed by forwarding, the cache space can be more effectively utilized by caching encoded content.

C. Privacy Performance

For privacy protection, we test the variation of privacy intensity in two dimensions which are simulation time and the number of coded packets t. We test both theoretical and experimental results of XOR-CC [12] and our algorithm. XOR-CC designs a network coding-based coded caching scheme for distributed storage, using XOR operations to code all network content. However, lacking pre-encoding content classification, its service performance degrades significantly with a large amount of content.

Fig8(e) shows experimental and theoretical privacy intensity experience rapid growth, and then tend to stabilize around 800 seconds. While our algorithm deviates more from theoretical results in experimental cases, it still demonstrates an impressive improvement in privacy intensity, achieving nearly a 400% enhancement, which is almost an order of magnitude increase.

As per Fig8(f), our method's privacy protection rapidly increases when coded packets reach about 30. Despite the large deviation between theoretical and experimental results, it outperforms XOR-CC across all time frames, enhancing data privacy intensity by roughly 400% compared to XOR-CC.

VII. Conclusion

This paper proposed a coded caching scheme for joint optimization of coded caching deployment and data privacy. We propose an effective adversary model for the current XOR-based secure coded caching and present a privacy model to quantify its threat. We based on the *fluid-based architecture* proposed a *learning-based content coding architecture* which integrates representational learning and DBN. We design a privacy-oriented coded caching algorithm that jointly optimizes performance and privacy, ensuring data privacy protection and caching optimization without relying on trusted nodes or secure channels. Our algorithm's excellence is confirmed by numerous simulation results. With our model's ability to depict data propagation under diverse transmission strategies, our future work plans to develop efficient ICN forwarding strategies to reduce transmission delays and save energy costs associated with transmission and caching.

***Abstract* —Meter classification in converter station lays the foundation for the subsequent detection-related tasks, however, training excellent meter classification models takes a large quantity of data and computing resources. Aiming to solve this problem, a fine-grained meter classification method based on multi-modal knowledge transfer is proposed. Firstly, the multi-modal knowledge of the Contrastive Language-Image Pre-training (CLIP) model is transferred to provide a more general visual representation for fine-grained features extraction. Secondly, a Task Space Mapping Unit (TSMU) is designed to improve the transfer ability of the multi-modal knowledge. Finally, a new transfer learning strategy is proposed on this basis to achieve a better transfer performance. The experimental results show that our method can achieve higher accuracy than its counterpart in significantly less train time under both fully supervised and few-shot settings, which verifies the its superiority in capturing fine-grained features and reducing training cost.**

I. INTRODUCTION

With the construction and development of power system, the importance of intelligent detection and analysis of power transmission and transformation equipment is increasing [1]. The converter station is used to complete the conversion of alternating current and direct current, which plays an important role in the high voltage direct current system. At present, with the popularization of automatic inspection technology such as panoramic monitoring system and inspection robot, converter station has gradually shifted to unattended mode [2]. However, because of the significance of converter station in the power grid, the inspection requirements for converter station are becoming much higher [3].

There are various types of meters in the converter station, such as oil level gauge, lightning arrester and SF6 meter. These meters are the focus of the converter station inspection which is the foundation of subsequent meter recognition and defect detection [4]. However, training a fine-grained meter recognition model is still a challenging problem. On the one hand, the similar appearance of different meters in converter station poses a challenge for their recognition which requires the model to have a strong ability to capture the fine-grained characteristics about meters. On the other head, influenced by the traditional pre-training paradigm, most existing mainstream fine-grained classification models are pretrained on ImageNet datasets and takes a large quantity of data and computing resources to transfer to downstream tasks of other domains.

In recent years, multi-modal pre-training technology has developed rapidly which effectively improves the performance of the model and reduces the training cost in downstream tasks [5]. Inspired by the application of multi-modal pre-training representation and the thought of deep transfer learning, this paper proposes a fine-grained meter classification method based on Multi-modal Knowledge Transfer with transformer architecture (MKTformer) to leverage the more universal multi-modal representation for fine-grained feature extraction of meters in converter station. The main contribution of this paper can be summarized in three folds:

1. We propose MKTformer, a fine-grained classification method which transfer the underlying general multi-modal knowledge of CLIP for fine-grained feature extraction and interaction in meter classification.
2. We design a TSMU module based on the CLIP representation which provides a latent space between source domain and target domain to improve transfer

efficiency of multi-modal knowledge.

3. We propose a new transfer learning strategy which further boosts the performance of multi-modal knowledge transfer in fine-grained meter classification.

II. Related Works

A. Fine-grained Visual Classification

The purpose of Fine-Grained Visual Classification (FGVC) is to distinguish subclasses from the coarse-grained category. Early works mainly adopt sophisticated Convolutional Neural Network (CNN) architecture for fine-grained feature extraction. Lin et al. [6] used two CNNs as feature extractors and provided a more complex feature interaction by introducing a bilinear feature fusion. Krause et al. [7] achieved a promising result with a large amount of noisy data for training the model. In recent years, with the popularity of transformer architecture in Computer Vision (CV), the self-attention mechanism has shown its superiority in fine-grained feature extraction and interaction. In [8], He et al. proposed part selection module and introduced contrastive feature learning to enhance the fine-grained feature extraction ability of transformer. Chen et al. [9] proposed a deformable patch module to address the corrupted semantics of objects and improve the effect of fine-grained recognition. The latest study by Wang et al. [10] of fine-grained meter classification adopted the transformer architecture and the above schemes of deformable patch as well as contrastive feature learning in fine-grained meter classification.

To sum up, these models rely on more complex structures or need more training data for fine-grained feature extraction which make the training process expensive. Meanwhile, [10] only improve the meter classification model on the level of general architecture while have not fully considered the characteristics of meter recognition itself. Based on the fact that distinctions of meters lie in the scale marks and text on the meter's dial, we transfer the multi-modal knowledge of CLIP which has shown potential in Optical Character Recognition (OCR) to boost the performance and save the cost of training fine-grained meter classification model.

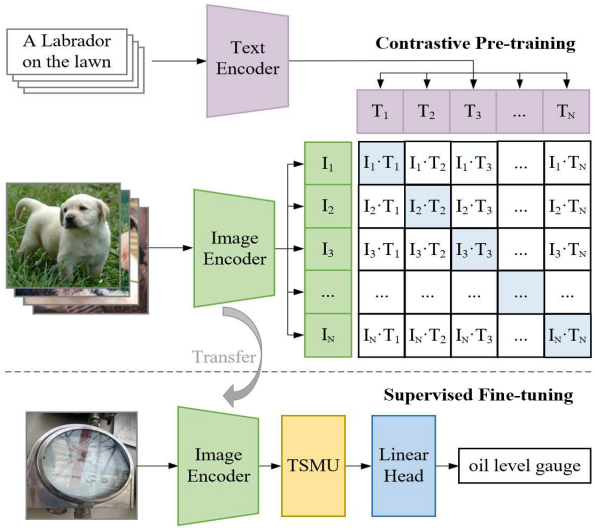
B. Transfer Learning with Multi-modal Knowledge

In order to reduce the training cost and the resource wastes caused by training models repeatedly in downstream tasks, researchers began to use multi-modal data such as natural language for pre-training general representation, which is called Vision-Language Pre-training (VLP) [5]. In recent years, VLP has begun to influence the traditional pre-training paradigm of CV models. Sariyildiz et al. [11] introduced a proxy task in which visual representation is learned as a by-product and can transfer to different CV tasks. A novel VLP method VirTex was proposed by Desai et al. [12], they used image captioning for visual representation learning and transferred the pre-trained image encoder to downstream tasks. However, due to the limitation of pre-training scale, the performance of the above models in downstream tasks still lags behind the most advanced CV models. In order to further improve the performance of VLP models, CLIP [13] was pre-trained on 400 million image-text pairs which enables the task-agnostic encoders of CLIP to learn universal knowledge representation and powerful ability for transferring. A series of subsequent works leverage the task-agnostic encoders for different downstream tasks. [14] and [15] studied the effect of introducing CLIP features into the task of image captioning and show the superiority of it. Conde et al. [16] fine-tuned the CLIP model and used it to perform fine-grained art classification.

The most related works to this paper are [14] and [16]. Different from [14], this paper studies the transfer learning for fine-grained classification instead of image captioning. Meanwhile, this paper focus on leveraging and enhancing the transfer performance of multi-modal knowledge in the domain of meter recognition which makes it distinguish from [16].

III. Method

we elaborate the MKTformer model in this section and the overview of our method is shown in Fig. 1.



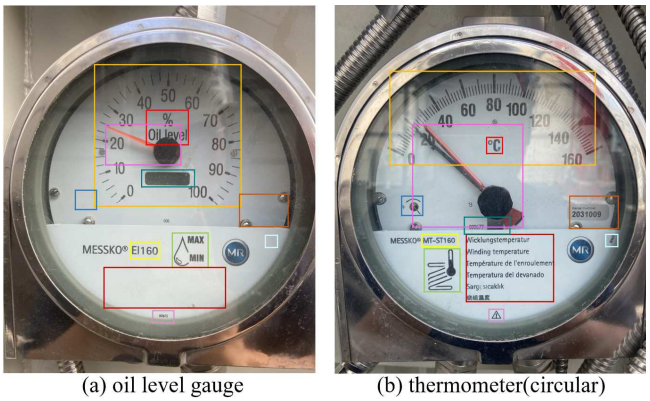


Fig. 1 Overview of the MKTformer.

A. Knowledge Representation of CLIP

CLIP jointly learns the image and text encoder using a large-scale dataset containing 400 million image-text pairs by pairing the correct image-text pairs [13]. Thanks to the large scale pretraining, the model of CLIP has obtained the abundant multi-modal knowledge about various visual and linguistic

conceptions, which enables both the image and text encoder can adapt to a wide range of downstream tasks across different modalities. In this paper, we focus on transferring the image encoder to leverage the multi-modal knowledge.

The recent work has shown the image encoder of CLIP can effectively save the training cost including training data and computing power [14]. In addition, the distinction of meters usually lies in the scale marks and text on the dial as shown in Fig. 2, while CLIP has achieved promising results in OCR which also benefits the extraction of text-related fine-grained features [13]. These factors inspire us to transfer multi-modal knowledge in the image encoder of CLIP for better extracting the fine-grained features of meters in converter station.

(a) oil level gauge (b) thermometer(circular)

Fig. 2 the distinction of different meters is on the dials.

B. *Multi-modal Knowledge Transfer*

Since the multi-head attention has brought advantage to transformer-based models in fine-grained classification in recent years, we use the ViT-B/16 image encoder of CLIP as the backbone of the MKTformer model to leverage the underlying multi-modal knowledge for fine-grained feature extraction. The structure of the backbone is shown in Fig. 3.

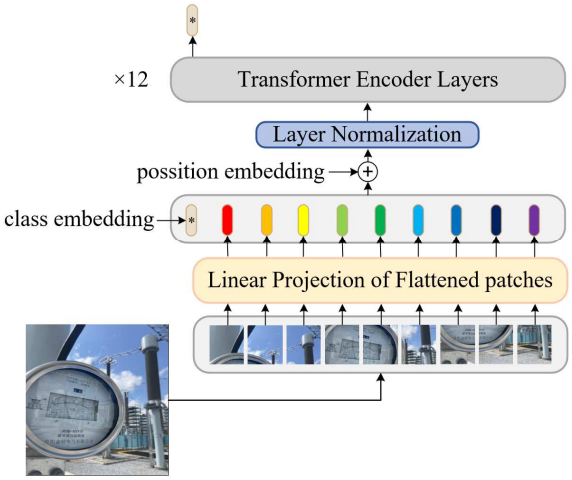

Fig. 3 Structure of the ViT image encoder in CLIP.

Different from the vanilla ViT in [17], the ViT encoder in CLIP adds a layer normalization after position encoding and uses a different initialization scheme. The ViT encoder firstly divides the input image into several image patches and embeds these patches. After that, class embedding and position embeddings are added. Then, these embeddings are passed to a series of transformer encoder layers composed of multi-head self-attention and feed-forward network for feature extraction and interaction, the calculating process of each transformer encoder layer can be written as:

$$z_l' = \mathrm{LN}\left(\mathrm{Multihead}\left(z_l\right)\right) + z_l \tag{1}$$

$$z_{l+1} = \mathrm{LN}\left(\mathrm{FFN}\left(z_l'\right)\right) + z_l' \tag{2}$$

Where z_l is the input of lth transformer encoder layer; LN(·) is layer normalization; FFN(·) is a feed-forward network; multihead(·) is multi-head self-attention which is calculated as:

$$\mathrm{Multihead}\left(\mathbf{Q},\mathbf{K},\mathbf{V}\right) = \mathrm{Concat}\left(\mathbf{H}_1,...,\mathbf{H}_\mathbf{h}\right)\mathbf{W}^\mathbf{O} \tag{3}$$

$$\mathbf{H}_\mathbf{i} = \mathrm{Attention}\left(\mathbf{Q}\mathbf{W}_\mathbf{i}^\mathbf{Q},\mathbf{K}\mathbf{W}_\mathbf{i}^\mathbf{K},\mathbf{V}\mathbf{W}_\mathbf{i}^\mathbf{V}\right) \tag{4}$$

Where $\mathbf{W}^\mathbf{O}$ is the linear transformation matrix, $\mathbf{H_i}$ is the result of self-attention in the ith head; $\mathbf{W}_\mathbf{i}^\mathbf{Q}$, $\mathbf{W}_\mathbf{i}^\mathbf{K}$ and $\mathbf{W}_\mathbf{i}^\mathbf{V}$ are the projection matrices of the ith head; Attention(·) is scaled dot-product attention which can be calculated as:

$$\mathrm{Attention}\left(\mathbf{Q},\mathbf{K},\mathbf{V}\right) = \mathrm{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}}\right)\mathbf{V} \tag{5}$$

Where $\mathbf{Q}$,$\mathbf{K}$ and $\mathbf{V}$ represent the query, key and value respectively; d is the dimension of $\mathbf{Q}$ and $\mathbf{K}$.

In this way, each image is encoded with multi-modal knowledge. Finally, the class embedding output by the last transformer encoder layer containing global information is used as the feature vector to represent the image and pass to the TSMU module for classification, which transfers the multi-modal knowledge into the task of meter classification.

C. *Task Space Mapping Unit*

For fine-tuning the image encoder of CLIP, the source domain of the pre-training task and the target domain of the downstream task correspond to different feature spaces, which can be unfavorable for the transfer performance when we used it directly for meter classification [14]. Therefore, in order to make full use of the multimodal knowledge in CLIP, inspired by recent research achievements in transfer learning [18], we design a TSMU module to smooth the mapping process and improve the performance of multi-modal knowledge transfer as shown in Fig. 4.

The TSMU module learns to map the output of the task-agnostic image encoder from the feature space of the source domain into that of the target domain. Firstly, in order to realize

the basic mapping, TSMU provides a latent vector space between the feature space of source domain and target domain by using a Fully Connected layer (FC layer). Secondly, we introduce Dropout regularization to alleviate the overfitting problem and further improve the classification accuracy. Thirdly, the activation function is introduced to increase the nonlinearity of the mapping, which can be written as:

$$\mathrm{QuickGELU}(x)=\frac{x}{1+e^{-1.702x}} \tag{6}$$

Where x is a feature vector representing the input image.

Meanwhile, the output of the network is adjusted to a suitable range by using layer normalization in order to stabilize the training process of the network. Finally, the effect of TSMU is further improved by selecting the appropriate length of latent feature vector and the number of FC layers.

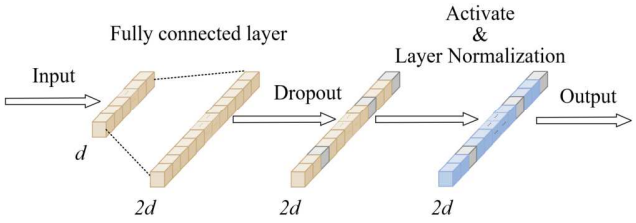

Fig. 4 Structure of the TSMU module.

D. Transfer Learning Strategy

In order to reduce the training cost and improve the transfer efficiency of the model, we design a new transfer learning strategy for fine-tuning based on multi-modal knowledge and TSMU module.

Firstly, we use the ViT-type CLIP image encoder to construct the basic model. The image encoder can encode the images with multi-modal knowledge with its multi-head self-attention mechanism. In addition, a task-specific head is added for meter classification.

Secondly, we insert the TSMU module between the backbone and the task-specific head. TSMU module takes the output of the image encoder and maps it into the latent vector space to raise the transfer efficiency.

Finally, we optimize the parameters in groups. The parameters of CLIP image encoder with a higher level of optimization is optimized with a smaller learning rate, and the random initialized parameters of TSMU and classification head are optimized with a larger learning rate.

IV. Experiments and Analysis

In this section, we evaluate the effectiveness of MKTformer model and its key components on the Converter Station Meter Classification Dataset (CSMC Dataset).

A. Dataset and Settings

CSMC Dataset: The images of the converter station meters in this dataset were collected manually and included different light and weather condition such as full light during daytime, insufficient light at dusk, illumination of the station at night, and others. The dataset consists of 4550 images including five types of meters: thermometer (circular), thermometer (square), lighting arrester, oil level gauge and SF6 meter. The ratio of training set and test set is 9:1, and the distribution of samples of training set and test set is shown in Fig. 5.

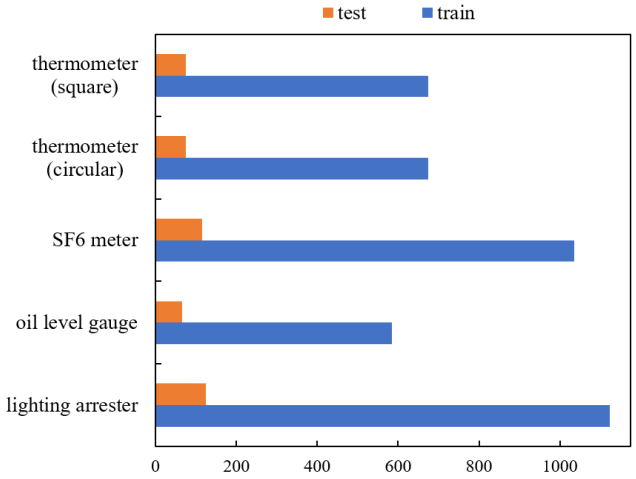

Fig. 5 The distribution of samples in CSMC Dataset.

Experiment settings: We used the PyTorch 1.10.0 framework for experiment and used a single NVIDIA GeForce RTX 3060 Laptop GPU to train and test our model. We trained our model with a batch size of 8 for 30 epochs and Adam optimizer with initial learning rate 10^{-5} for backbone's parameters and 10^{-3} for parameters of TSMU and head.

Evaluation metrics: In this work, we explore better trade-off between accuracy and training cost for fine-grained classification, so we adopt top-1 accuracy (Acc) and training time (Time) as our primary metrics. Meanwhile, we also provide parameters (Params) and floating point operations (FLOPs) to measure the complexity of different models.

B. Comparison Experiment

We train different models under the fully supervised setting to verify the effectiveness of MKTformer, in which models are trained with full training data. The comparison result is shown in Table 1. The experimental result shows our model has a similar complexity to ViT while the accuracy of MKTformer can reach 99.3%, which is significantly higher than other models. In addition, the MKTformer only need significantly less training time to achieve a higher accuracy. The result verifies that our method can effectively improve the

classification accuracy while significantly reduce the computing resources consumed during the training process.

TABLE I PERFORMANCE COMPARISON OF FULLY SUPERVISED SETTING

Methods	*Param*	*FLOPs*	*CSMC Dataset*		*BDC Dataset*	
	(M)	*(G)*	*Acc(%)*	*Time(h)*	*Acc(%)*	*Time(h)*
Szegedy et al. [19]	25.1	17.7	89.2	2.3	78.1	1.8
Howard et al. [20]	4.2	0.2	95.9	1.2	84.3	1.0
Dosovitskiy et al. [17]	88.1	17.6	97.4	1.5	88.9	1.3
He et al. [8]	80.5	14.2	97.8	1.6	89.5	1.2
Chen et al. [9]	46.1	6.9	98.1	1.8	88.7	1.3
Wang et al. [10]	72.3	12.5	98.0	1.6	89.8	1.4
Our method	87.4	17.6	99.3	0.4	90.6	0.5

Then in order to further test the potential and applicability of our method in the domain of electric power vision [1], we evaluate our method on the Bolt Defect Classification Dataset (BDC Dataset) which represents another type of fine-grained classification problem in the power system, the result is also shown in Table 1. The result has shown that the MKTformer can also significantly shorten the training time while achieve higher accuracy, which verifies its effectiveness in the task of bolt defect classification where the pictures have lower quality and the categories are more difficult to recognize.

In order to study the data requirement of training MKTformer, we fine-tune the MKTformer and vanilla ViT under the few-shot setting for comparison, in which models are trained with limited data, the result is shown in Table 2. The accuracy of MKTformer under three settings is significantly higher than vanilla ViT pre-trained on ImageNet. Specially, our model can achieve an accuracy of 97.1% with only 0.5% of the training data, which is 6.4% higher than vanilla ViT. This result verifies MKTformer can effectively reduce data requirements for training fine-grained meter classification model.

TABLE II PERFORMANCE COMPARISON UNDER LIMITED TRAINING DATA

Methods	*Data Proportion(%)*	*Acc(%)*	*Time(h)*
Dosovitskiy et al.	0.1	75.8	0.8
	0.2	82.8	0.6
	0.5	90.7	0.6
Our method	0.1	80.8	0.3
	0.2	87.5	0.2
	0.5	97.1	0.1

C. Ablation Experiment

Before the ablation experiment, we first evaluate the design of the TSMU module. The performance of different TSMU settings is shown in Table 3. Firstly, it can be seen that different settings have little influence on the complexity of the model. Secondly, the settings of Dropout, layer normalization, and activation function can effectively improve the accuracy of MKTformer in downstream tasks. Thirdly, the length of latent vector has different degrees of influence on the effect of TSMU, which reaches the best when the length of the feature vector is twice the length of the input vector d. Finally, when there are more FC layers, the model is prone to overfitting, so the TSMU in this paper contains only one FC layer.

TABLE III PERFORMANCE COMPARISON OF DIFFERENT TSMU SETTINGS

TSMU settings	*Param(M)*	*FLOPs(G)*	*Acc(%)*	*Time(h)*
Default	87.4	17.6	99.3	0.4
No dropout	87.4	17.6	99.1	0.6
No layer normalization	87.4	17.6	98.2	0.6
No activation function	87.4	17.6	99.0	0.6
Length of latent vector: 0.5d	86.5	17.6	98.6	0.8
Length of latent vector: d	86.8	17.6	98.9	0.5
Length of latent vector: 2d	87.4	17.6	99.3	0.4
Length of latent vector: 4d	88.6	17.6	99.2	0.5
Number of FC layer: 1	87.4	17.6	99.3	0.4
Number of FC layer: 2	89.7	17.6	97.8	0.8

Then in order to study the effect of each component of our method, we implement ablation experiment, the result is shown in Table 4. Firstly, after introducing CLIP features containing multi-modal knowledge, the training time is greatly shortened and classification accuracy is raised. Secondly, adding TSMU module on the basis of multi-modal knowledge can further shorten the training time and improve the accuracy. Finally, optimizing the parameters in groups can further improve the accuracy of meter classification, which verifies the effectiveness of our method and indicates that MKTformer achieves a better precision-resource consumption balance.

TABLE IV PERFORMANCE COMPARISON OF MKTFORMER

Multi-modal knowledge	*TSMU*	*Transfer learning strategy*	*Acc(%)*	*Time(h)*
-	-	-	81.7	6.3
√	-	-	98.7	0.8
√	√	-	99.0	0.4
√	√	√	**99.3**	**0.4**

D. Qualitative Experiment

In order to show the performance of MKTformer intuitively, we use Grad-CAM [21] technology to visualize the heat map of different models, as shown in Fig. 6. The first column shows the original images, the second column shows the heat map generated by vanilla ViT and the last column shows the heat map generated by MKYformer. The result shows that

MKTformer can capture more valid fine-grained features of meters especially about text or scale marks on the dial, which verifies our model has the ability to learn key fine-grained features of meters.

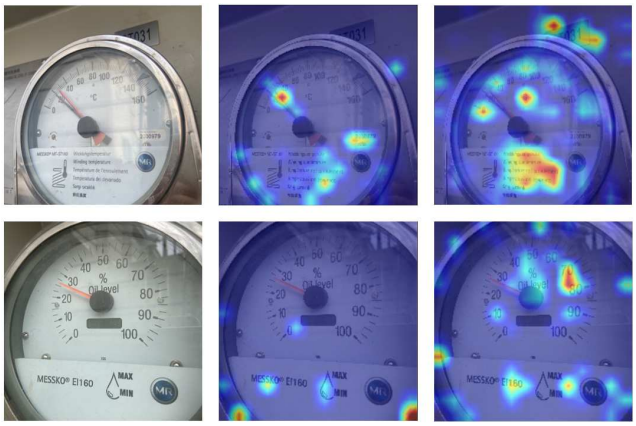

Fig. 6 The distribution of samples in CSMC Dataset.

V. CONCLUSION

This paper proposes a fine-grained meter classification method based on multi-modal knowledge transfer which is called MKTformer. The core idea of MKTformer is leveraging the more universal underlying knowledge learned in multi-modal pre-training to enhance the ability of fine-grained features extraction. We also design an auxiliary TSMU module and a new transfer learning strategy to further boost the transfer performance. The MKTformer has strong ability to capture fine-grained features of meters and can effectively reduce the training cost of fine-grained meter classification model. We will further explore meter recognition and their defect detection with multi-modal knowledge in the future.

***Abstract*—In recent years, deep learning has achieved significant success in various computer vision tasks, notably in image classification. Nonetheless, labeled data is frequently insufficient in real-world applications, presenting significant impediments to the efficacy of deep learning models. This issue is especially pronounced in few-shot image classification tasks. To alleviate the above problem, we propose to augment features in few-shot image classification to increase sample diversity. This is achieved through learning and fitting the features' distribution, generating pseudo-data based on the distribution, and ultimately augmenting the features. Specifically, the adherence of the sample to the Gaussian distribution is learned using both local and global information, and then feature data is generated based on the distribution for feature augmentation. We evaluated the proposed method on four benchmark datasets, and the experimental results show that our method achieves state-of-the-art performance compared to prevailing few-shot image classification methods in most experimental settings.**

I. Introduction

With the widespread application of deep learning technology, image classification has garnered significant attention in the field of computer vision. However, traditional image classification tasks typically necessitate a large amount of labelled data to train the model, which is infeasible for many practical applications. Particularly in some few-shot application scenarios, such as medical image diagnosis and military target recognition, there is often a scarcity of labelled data available for training. Moreover, obtaining and annotating data is also highly time-consuming and costly. Therefore, the accurate classification of images in situations with few samples has evolved into a pivotal research issue. More and more researchers are exploring how to use a small number of labelled samples to learn discriminative information and generalise it to novel classes. To this end, researchers have proposed many methods for few-shot learning, including meta-learning, transfer learning, metric learning, feature learning, feature augmentation, etc. These methods can help the model learn more feature information from a limited quantity of labelled data, thereby improving classification accuracy.

Metric-based methods are a classic approach for few-shot image classification. These methods learn a metric that effectively reduces the distance or increases the similarity between the same class, while increasing it between different classes. However, the effectiveness of the metric is hampered by insufficient feature information extraction or misaligned features between the two ends of the metric.

Due to the limited number of images and classes in few-shot datasets, the diversity of tasks during training is greatly restricted, which has a significant impact on the model's performance. One clear manifestation of this phenomenon is that the model's performance improves significantly when the experimental setting changes from 1-shot to 5-shot. To alleviate the problem of scarce samples in classification tasks, feature augmentation-based methods have received widespread attention. Traditional data augmentation produces new samples by transforming existing data through techniques like flipping, scaling, and cropping. Some newer methods of data augmentation employ generative adversarial models and encoder-decoders to train networks and generate new data. However, the generated data is not ideal due to the influence of data and augmentation methods, which affects the model's generalization ability.

The Feature Map Reconstruction Network (FRN) [1] proposed by Wertheimer et al. is one of the classic few-shot algorithms based on metric learning. By placing support features of the same class in a feature pool, the FRN uses the support features in the pool to reconstruct unseen query features. The reconstructed query features are then evaluated with the original, and their distance is used as the classification criterion. The FRN offers the benefits of a straightforward model structure, commendable performance, swift convergence, and a limited number of parameters. Consequently, we present our suggested feature augmentation network, which employs this technique to improve model performance by augmenting sample features, increasing sample diversity and complementing the existing features.

To summarise, our work makes a triple contribution:

- We propose a feature augmentation network that learns both global and local information of sample features to fit the feature distribution and achieve feature augmentation.
- We verify the effectiveness of the proposed method on three fine-grained datasets and one coarse-grained dataset. The results show that our method achieves state-of-the-art performance in most cases.
- We validate the generalisability of the proposed approach through comparative experiments of adding feature augmentation networks in different network structures, and

consistently improve the network performance.

II. Related Work

A. Data Augmentation-Based Methods

In deep learning models, data augmentation is a highly utilized approach that can effectively enlarge the dataset's sample classes and quantities to a certain extent. In the early stages, data augmentation methods used simple geometric transformations to create new samples from the original sample data [2], which helped to prevent the network model from overfitting during the training process. Traditional methods of data augmentation comprise image rotation, mirror flipping, scaling, cropping, deformation, and adding noise, etc [3], [4], [5]. These approaches can generate varied effects by adjusting parameters such as rotation angle, scaling ratio and cropping size.

With the ongoing advancements in few-shot learning, numerous data augmentation algorithms are continually being proposed. These can be broadly categorised into two groups: data synthesis and feature augmentation. Data synthesis techniques employ generative networks to create fresh data, which is then used to expand the sample space. One extensively studied method for data generation is the use of Generative Adversarial Networks (GANs). This approach trains the network to generate samples that more closely resemble the real data, thereby increasing the size and diversity of the existing dataset and improving the generalisation performance of the model [6], [7].

Feature augmentation methods augment the feature space of samples by utilizing a feature generator, thereby improving the generalization performance of feature extractors. Dixit et al. [8] introduced the Attribute-Guided Augmentation (AGA) model for image attribute-guided synthesis. This model projects image samples onto an attribute space and trains the encoder-decoder of the model to generate images with varying depths and poses. Schwartz et al. [9] proposed a data augmentation method based on an enhanced auto-encoder. This approach extracts variations and disparities among instances of training classes and employs these distinctions to generate new samples. These newly generated samples are then used to train a linear classifier. Chen et al. [10] proposed the TriNet model based on an encoder-decoder architecture, which maps samples to a semantic space and learns the concepts of samples within this semantic space. By introducing noise and finding nearest neighbors in the semantic space, the model performs sample augmentation, and then maps back to the visual space to obtain more augmented samples.

Although some current methods for data augmentation have been developed, they mostly concern general feature creation rather than focused global and local feature information generation. Therefore, we propose our approach to address this gap.

B. Metric-Based Methods

1) Distance/Similarity-based methods: This method assumes that there is a way to measure the distance or similarity between samples in the feature space. The classifier's parameters are learned by reducing the distance between samples belonging to the same class and increasing the distance between samples from different classes. Vinyals et al. [11] proposed a matching network model based on memory and attention mechanisms, which learns the nearest neighbor classifier in an end-to-end manner and uses cosine similarity as the final classification criterion. Li et al. [12] proposed a deep nearest neighbor neural network based on the recent scenario training mechanism. The network replaces the image-level feature metric in the last layer with image-to-class measures based on local descriptors and trains them end-to-end. BSNet [13]combines two types of similarity measures, cosine similarity measure and relation measure, to form a bipartite similarity measure module. It calculates similarity scores separately for each type of measure and then takes the average as the final metric to learn more discriminative features in fine-grained images.

2) Prototype-Based Methods : This method regards each class as a prototype (such as class center or mean value), and learns the parameters of the classifier by minimizing the distance between each sample and its corresponding class prototype. A pioneering metric-based approach is the prototype network model proposed by Snell et al. [14]. This model uses a convolutional neural network to nonlinearly map sample features to an embedding space, and uses the mean of embedding vectors of support set samples as class prototypes. It predicts the sample class by calculating the distance between the embedding vector of the query set sample and the class prototype. In the latest metric-based few-shot learning methods, COMET [15] learns multiple embedding functions, each corresponding to an image segment or concept, and constructs multiple concept prototypes accordingly to adapt to fine-grained classification. CovaMNet [16] uses the second-order feature representation of samples in each class to calculate prototype vectors. PHR [17] uses three levels of feature embeddings to represent each sample: local features, global features, and semantic features, and updates prototypes by superimposing the three features with different weights.

3) Network Metric-Based Methods: This method uses labeled samples to learn the parameters of the classifier and metric network, and improves the performance of the network through iterative learning strategies. Sung et al. [18] proposed a relational network based on deep neural networks, which includes two modules: the embedding module and the relation module. The embedding module is responsible for extracting and encoding the image features of the support set and the query set, and the relation module takes these two features as inputs and output the matching score between two images. Hilliard et al. [19] introduced a new network structure consisting of different stages trained end-to-end, including the feature stage, relation stage, and classifier. This method replaces the static measurement method and compares classes by training the network. LCCRN [20] for few-shot fine-grained image classification. This method can distinguish crucial discriminative local information with high similarity by

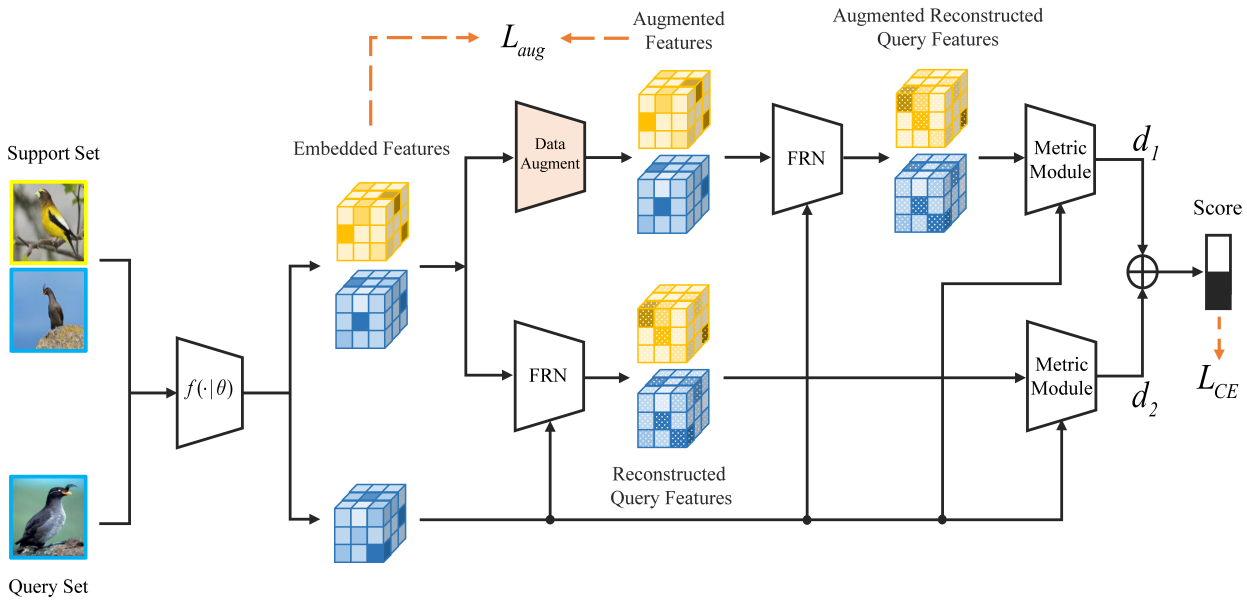

Fig. 1. Architecture diagram of the feature augmentation network

measuring cross reconstruction of different features.

III. Proposed Method

A. Problem Formulation

Few-shot image classification problem usually divides the dataset into training set D_{train}, validation set D_{val} and testing set D_{val}, which are used for the training of the model, the evaluation of the model in the training stage, and the final trained model test.

The N-way K-shot is a common setup in few-shot image classification tasks, where N denotes the number of classes in a task and K denotes the number of labeled samples in each class. For different stages, the corresponding classification tasks are constructed using the above sub-datasets, and each classification task contains a support set and a query set. The number of support set images is $N \times K$. N classes are randomly selected from the sub-dataset and then K images are randomly selected from each class. The number of query set images is $N \times M$, where M is the number of images randomly sampled from the remaining images in the category corresponding to the supporting set. Taking the metric learning-based few-shot training process as an example, during the training stage, the model learns sample features and model parameters from labeled support samples on the training set D_{train} and performs classification on unlabeled query samples, optimizing the model based on the classification loss. The learned model is evaluated using the validation set D_{val} to select the model's hyperparameters. Finally, the optimal model is saved. In the testing stage, the model's performance is tested on the testing set D_{test} to obtain the final classification accuracy.

B. Architecture Overview

As shown in Figure 1, the proposed Feature Augmentation Network consists of five main components. The first component is the Feature Embedding Module, denoted as $f(\cdot \mid \theta)$, which aims to extract deep features from the image samples to capture rich information. The second component is the Feature Reconstruction Module, denoted as FRN, which is used to generate reconstructed query features. The third component is the Feature Augmentation Module proposed in this context. In this module, the learned sample features are fitted to a Gaussian distribution and generate augmented features for subsequent training. The fourth component is the Metric Module, which measures the distance between the reconstructed features and query features as the final criterion for classification. The final component is the Network Loss, which includes the calculation of cross-entropy loss L_{CE} to measure the difference between the true labels and predicted labels, and an additional loss L_{aug} that computes the difference between the augmented features and original support features to constrain the augmented features.

C. Feature Augmentation Module

The proposed Feature Augmentation Module, as illustrated in Figure 2. The embedded features of the samples obtained from the embedding module $f(\cdot \mid \theta)$. The dimension of the features is $[K, 640, 5, 5]$, where K represents the number of samples from the same class, corresponding to the shot number in the N-way K-shot few-shot classification task. The value 640 denotes the number of channels, and [5, 5] represents the width and height of the features. Then, the input features are divided into two parts and processed by two different structures to generate features. The adoption of both fully connected networks and convolutional networks is motivated by their respective capabilities in capturing global and local

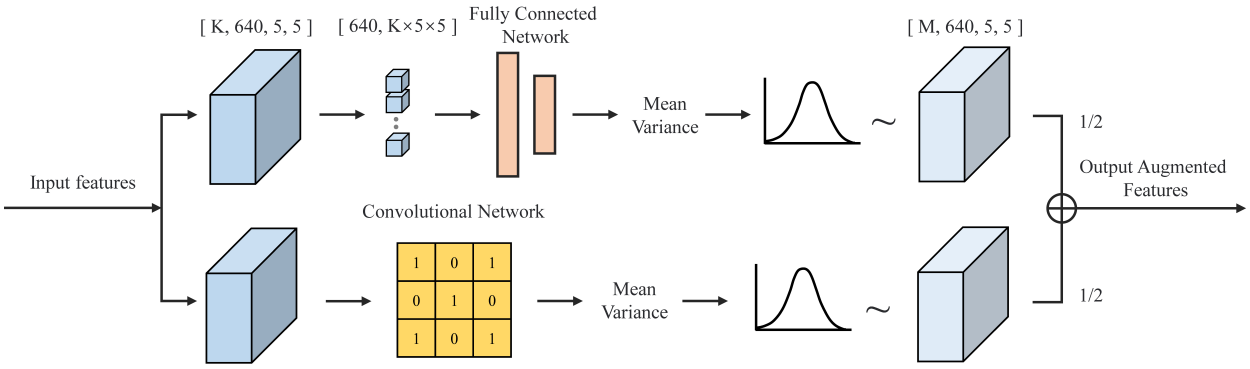

Fig. 2. Architecture diagram of the feature augmentation module

information. The fully connected network establishes global connections, capturing global information, while the convolutional network enables local connections, capturing local information. Therefore, by utilizing both network structures, we can consider both global and local information in the generated features, which better conforms to the distribution requirements.

For the upper part of the structure, the input features undergo dimension transformation, where features from different images belonging to the same class are gathered into a feature pool. This aggregation collects feature vectors across positions and images into a single feature pool, resulting in a dimension change from [K, 640, 5, 5] to [640, K×5×5]. This transformation has the benefit of alleviating the impact of K-shot on the classification task, especially when the shot is 1. The fully connected network in this part consists of two fully connected blocks, each containing two fully connected layers. ReLU activation functions are applied after each fully connected block to introduce non-linearity to the structure. The two fully connected blocks are responsible for learning the mean and variance of the feature distribution for this specific class:

$$\mu_{FC}^{i} = h_{\phi}^{1}\left(X_i\right), \tag{1}$$

$$\sigma_{FC}^{i} = h_{\phi}^{2}\left(X_i\right), \tag{2}$$

where μ_{FC}^{i} represents the mean of the features obtained by passing the transformed features of class i through the fully connected network, σ_{FC}^{i} represents the variance of the feature obtained by passing the transformed features of class i through the fully connected network, $h_{\phi}^{n}(\cdot)$ denotes the corresponding fully connected block, and X_{i} represents the transformed features of class i.

Then, we use the mean and variance to fit the Gaussian distribution to the features of this class, and finally, we randomly generate sample features based on this distribution:

$$q\left(\mathcal{A}_{FC}^{i} \mid X_i\right) = \mathcal{N}\left(\mu_{FC}^{i}, \sigma_{FC}^{i}\right), \tag{3}$$

Where $q\left(\cdot \mid \cdot\right)$ is the distribution function, $\mathcal{A}_{FC}^{i}$ represents the class distribution fitted based on the mean and variance obtained from the features of the i-th class after passing through the fully connected layers, and $\mathcal{N}\left(\cdot \mid \cdot\right)$ denotes the Gaussian distribution function.

$\mathcal{A}_{FC}^{i}$ can be generated using the following equation:

$$\mathcal{A}_{FC}^{i} = \mu_{FC}^{i} + \sigma_{FC}^{i} * \varepsilon, \varepsilon \sim \mathcal{N}(0, I), \tag{4}$$

where $\mathcal{N}(0, I)$ is a standard normal distribution.

The lower part consists of two convolutional blocks, each containing two convolutional layers followed by a batch normalization layer and a ReLU activation function. This structure is used to normalize the data and introduce non-linearity to the features. The two convolutional blocks learn the mean and variance of the distribution for the samples of the same class:

$$\mu_{CN}^{i}{=}g_{\varphi}^{1}(X_i), \tag{5}$$

$$\sigma_{CN}^{i}{=}g_{\varphi}^{2}(X_i), \tag{6}$$

where μ_{CN}^{i} represents the mean of the i-th class sample features after passing through the convolutional network, σ_{CN}^{i} represents the variance of the i-th class sample features after passing through the convolutional network, and $g_{\phi}^{n}(\cdot)$ represents the corresponding convolutional block.

Then, the feature distribution is modeled by fitting a Gaussian distribution based on the variance and mean. Finally, the sample features are randomly generated using this distribution:

$$q(\mathcal{A}_{CN}^{i}|X_i) = \mathcal{N}(\mu_{CN}^{i}, \sigma_{CN}^{i}), \tag{7}$$

$\mathcal{A}_{CN}^{i}$ represents the class distribution obtained by fitting a Gaussian distribution based on the mean and variance of the features from the i-th class after passing through the convolutional layers.

$\mathcal{A}_{CN}^{i}$ can be generated using the following equation:

$$\mathcal{A}_{CN}^{i} = \mu_{CN}^{i} + \sigma_{CN}^{i} * \varepsilon, \varepsilon \sim \mathcal{N}(0, I), \tag{8}$$

After the aforementioned two parts of the network structure, two sets of fitted features are generated, each with a feature dimension of [M, 640, 5, 5], where M represents the number of augmented features generated for the current class. At this point, the two sets of features respectively possess the global and local information of the current class features. Subsequently, the two types of features are combined through

VFD [28]	68.42±0.92	82.42±0.61	57.03±0.86	73.00±0.66	-	-
Ours	**74.02±0.22**	88.37±0.13	58.19±0.22	**76.73±0.17**	**74.58±0.21**	**89.75±0.13**

summation and averaging, resulting in a set of augmented features that encompass both global and local information:

$$\mathcal{A}^i = \frac{\mathcal{A}^i_{FC} + \mathcal{A}^i_{CN}}{2}, \tag{9}$$

After the feature augmentation module, the augmented features are obtained for each support class. The augmented features of the support set and the query features are fed into the FRN reconstruction module for feature reconstruction, resulting in augmented reconstructed query features $\bar{Q}^{aug}_c$. Simultaneously, the original support features and query features are fed into the FRN module for feature reconstruction, resulting in reconstructed query features $\bar{Q}_c$. The detailed reconstruction process of FRN can be referred to in reference [1].

After obtaining the reconstructed features, the Euclidean distance is used to measure the distance between the two types of support features and the original query feature separately:

$$d_{c,1} = \left\|\bar{Q}^{aug}_c - Q\right\|^2_F, \tag{10}$$

$$d_{c,2} = \left\|\bar{Q}_c - Q\right\|^2_F, \tag{11}$$

$$d_c = d_{c,1} + d_{c,2}. \tag{12}$$

By using the aforementioned distances, the final classification probabilities can be obtained:

$$P\left(y_i = c|x_i\right) = \frac{\exp\left(-\tau d_{c,i}\right)}{\sum\limits_{c' \in C} \exp\left(-\tau d_{c',i}\right)}, \tag{13}$$

Where τ is a learnable hyperparameter that adjusts the range of the metric distances.

During the training phase, the cross-entropy (CE) loss is utilized as the loss function to optimize the model:

$$L_{CE} = -\frac{1}{m}\sum_{i=1}^{m}\left(\mathbf{y}_i^T \log\left(p_i\right)\right), \tag{14}$$

where y_i represents a one-hot vector, p_i represents the predicted probability vector, and m represents the number of query samples.

In addition, an augmented feature constraint loss L_{aug} is introduced to enforce the similarity between the augmented features and the original features:

$$L_{aug} = \left\|\mathcal{A}^i_p - X^i_p\right\|^2_F, \tag{15}$$

where $\mathcal{A}^i_p$ represents the prototype of the augmented features generated from the support features of class i, and X^i_p represents the prototype of the support features of class i.

The final loss is obtained by combining the loss L_{CE} and the loss L_{aug}:

$$Loss = L_{CE} + kL_{aug}, \tag{16}$$

where k is used to adjust the impact of the loss L_{aug} on the overall loss.

IV. EXPERIMENTS

A. Datasets and Preprocessing

We conduct experiments on four popular benchmark datasets: CUB-200-2011 (CUB), Stanford Dogs (Dogs), Flowers, and mini-ImageNet. The CUB dataset is consistent with the dataset used in FRN [1], where images are pre-cropped to the provided bounding boxes. All datasets were divided into training, validation, and testing sets in a ratio of 2:1:1.

B. Implementation Details

All our experiments follow the standard settings for few-shot image classification and utilize the Conv-4 and ResNet-12 backbone networks.

The Conv-4 [31] network consists of four convolutional blocks, each containing a convolutional layer, a batch normalization layer, a ReLU non-linear activation layer, and a max pooling layer. The input image size is 3×84×84, and the output feature size is 64×5×5. The ResNet-12 [31] architecture

includes four residual blocks, each composed of a convolutional layer, a batch normalization layer, a ReLU non-linear activation layer, and a max pooling layer. The input dimension is 3×84×84, and the output feature dimension is 640×5×5. We adopt the 10-way 5-shot setting for training, 5-way 5-shot setting for validation, and 5-way 1-shot and 5-way 5-shot settings for testing. The SGD optimizer is used with an initial learning rate of 0.1 and momentum of 0.9. The models are trained for a total of 1200 epochs. During the validation phase, the model is validated every 20 epochs, and the parameters achieving the best performance are saved. In the testing phase, the final test accuracy is obtained by averaging the accuracy over 10,000 randomly selected tasks.

C. Experimental Results

To validate the effectiveness of our proposed method, we conduct experiments and compare with state-of-the-art methods under the 5-way 1-shot and 5-way 5-shot experimental settings. Table 1 presents the experimental results on the CUB, Dogs, and Flowers datasets using the Conv-4 backbone network. Table 2 shows the experimental results using the ResNet-12 backbone network. Since some methods did not evaluate the Flowers dataset in their original papers, certain cells in the table are left blank and marked with "-". Table 3 displays the experimental results on the mini-ImageNet dataset using the ResNet-12 backbone network. The highest value in each column is indicated in bold, and the second highest value is underlined.

From Table 1, it can be observed that the proposed method achieved the best or second-best performance in most cases, except for the 5-way 5-shot setting on CUB and the 5-way 1-shot setting on Dogs, where it performed slightly lower than FRN. On the CUB dataset, the proposed method outperformed the second-best FRN by 0.97% in the 1-shot setting and by 0.82% in the 5-shot setting. According to the comparative experiments in Table 2, the proposed method achieved the maximum accuracy in all cases except for the Dogs dataset, where it slightly underperformed compared to FRN. On the Flowers dataset, compared to the second-best FRN, the proposed method improved the accuracy by 0.86% in the 1-shot setting and by 0.75% in the 5-shot setting. Furthermore, in Table 3, the proposed method demonstrated excellent performance compared to state-of-the-art methods in the mini-ImageNet dataset experiments under the same settings.

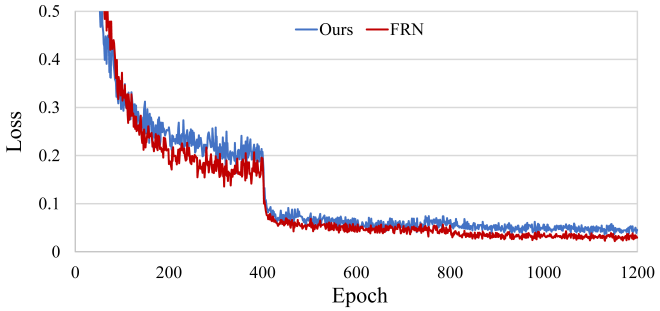

Fig. 3. The training loss of our method and FRN on the CUB dataset.

Overall, the comparative experiments with current state-of-the-art methods in few-shot image classification demonstrate that the proposed method achieved the best or second-best performance in nearly all cases, confirming its effectiveness.

As shown in Table 4, to demonstrate the effectiveness of the proposed feature augmentation module, the module M_{aug} was added to three network architectures: ProtoNet, RelationNet, and Baseline++. Comparative experiments were conducted on the Conv-4 backbone network under the 5-way 1-shot and 5-way 5-shot settings. The three network models were adjusted accordingly following the structure shown in Figure 1. The generated augmented features and the original support features were processed in separate branches, and the scores from both branches were combined as the final score. Additionally, the loss function L_{aug} was added to encourage the similarity between the prototypes of the generated augmented features and the original support features. The comparative experiments on the three datasets revealed consistent performance improvement after incorporating the feature augmentation module, further confirming the effectiveness of feature augmentation.

To demonstrate how our proposed data augmentation network enhances the model, Figure 3 presents the loss alteration between ours and the FRN during the training stage. In the figure, our approach shows a higher loss in contrast to FRN. When considered together with the experimental results, our approach becomes more difficult to train due to the data augmentation and yields a slightly higher loss than FRN. However, the generalisation of the model improves and performs better on novel class.

V. CONCLUSION

In this paper, we propose a new feature augmentation network structure that learns to fit the distribution of features from both global and local information of the image in a learnable way, and then increase the diversity of samples by randomly generating sample features. Numerous experiments demonstrate that our proposed method performs competitively or outperforms to existing few-shot classification methods on four popular benchmark image datasets.

***Abstract*—Few-shot image classification aims to provide accurate predictions for novelty by learning from a limited number of samples. Classical few-shot image classification methods usually use data augmentation and self-supervision to compensate for the lack of training sample, and introduce migration learning and meta-learning to pre-train the model or accelerate the model optimization, which improves the classification performance of the model. However, with a small amount of labeled sample data, these methods cannot meet the requirements of the model's ability to characterize sample features, resulting in a model that is highly susceptible to overfitting problems. In this paper, we propose a Dual Feature Reconstruction Network (DFRN) for few-shot image classification. The network constructs the double feature vector by two modules, in which the first-level feature module generates an attention mask based on the image to make the feature vector characterize more of the target region, and the secondary feature module interferes with the feature vector to improve its generalization performance. In addition, the network also enhances the classification performance of the model by considering the contextual information of the support classes through an auxiliary loss function. Through extensive experiments, the network proposed in this paper achieves excellent performance on Flowers, CUB and Cars datasets and outperforms other reference fine-grained image classification methods such as FRN.**

I. Introduction

Although traditional deep learning models have surpassed human recognition levels in image classification tasks [1], [2], [3], e.g. residual network [4] have outperformed humans in recognition accuracy on ImageNet [5] datasets. But it also exposes the potential problem of image classification models relying on large-scale training data. In contrast, humans make effective use of prior knowledge to learn new things quickly. Drawing on the human approach to rapidly learn new things, few-shot image classification has received widespread attention.

Few-shot image classification aims to provide accurate predictions for new things by learning from a few labeled examples. The most frequently used of the existing few-shot image classification methods is the metric-based learning approaches. Metric learning calculates the distance between two samples by using a given distance function to obtain the similarity. Commonly used distance metric functions are Euclidean distance, cosine distance and Manhattan distance. Existing metric learning-based methods for classifying few-shot images are divided into the following three main parts.

Improving feature embedding space. Deep nearest neighbor neural network [6] uses local features of samples to construct a local feature space of classes and predict the class to which a query sample belongs by the similarity between the query sample and the class. The neural network-based task adaptive projection enhancement proposed by Yoon et al. [7] extracts sample features through an embedding module, learns a class reference vector for each class, and projects the sample features and the class reference vector using a mapping matrix to project into a task-relevant classification space. Wu et al. [8] proposed a location-aware network to collect information from different locations in a location-aware manner through a double correlation attention mechanism to obtain global information about the features.

Improving class prototypes. In the few-shot image classification task, Snell et al. [9] proposed a prototype network in which the support sample features of the same class are averaged by means of an averaging operation to obtain the class prototype of that class. Kim et al. [10] proposed a method for generating class prototypes using a variational autoencoder, which removes the distracting noise from the samples in the original dataset, retains the most valuable information of the images, and classifies the generated class prototypes using the k-Nearest Neighbor algorithm. Wu et al. [11] proposed a few-shot image classification method based on a capsule network, in which the weights of the supported samples are obtained by a classifier, the class prototypes are the weighted averages of the supported samples, and finally the similar samples are placed close to each other and the different samples are placed far away from each other using a triadic loss function.

Sung et al. [12] proposed a relational network that outlawed the traditional distance function and used a neural network to construct a relational module to measure the distance between each query sample and the support sample. Deep Earth Mover's Distance [13] split the whole image into multiple blocks and used Earth Mover's Distance to calculate the distance between the query sample and the support sample blocks. Qiao et al. [14] proposed a transductive scenario adaptive metric to construct pairwise constraints and regularization priors for each task, converting the task optimization process into a standard semi-definite programming problem, and obtaining its closed solution. For the transduced features, compare the similarity between the query sample and each support sample, and the similarity between the support sample and each query sample, which is a two-way similarity measure to complete the prediction of the query sample. Existing methods based on few-shot image classification ignore class-level knowledge. To address this problem, Chen et al. [15]

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

proposed an explicit class knowledge propagation network, which uses an instance graph to learn into a relational representation of samples through a comparison module, compresses the instance-level graph to generate a class graph, models the relationship between different classes, and describes the relationship between class through a correction module to obtain a more discriminative. Finally, the class knowledge representation is combined with the instance-level samples for query sample inference.

However, existing methods for few-shot image classification only convert features into feature vectors by means of an averaging operation on information at different locations in the image, without taking into account the fact that a simple averaging operation can make the feature vectors susceptible to the influence of the irrelevant background of the image during the transform process. In this paper, we propose a dual feature reconstruction network. The network takes into account real-world interference situations and uses attention masks to identify distinguishable regions of the target, thus learning more diverse feature information. And the risk of overfitting is further avoided by considering contextual information of the support classes through an auxiliary loss function.

II. Related Work

A. Metrics Learning

In the same space, samples with small differences are closer to each other, and samples with large differences are farther away from each other, and it is through this feature that metric learning determines the category to which the query sample belongs. Commonly used metrics in few-shot image classification include cosine distance, Euclidean distance, Manhattan distance, etc. In addition to the above commonly used metrics, more effective metrics have emerged in recent years to further improve the classification performance of the model. Das et al. [16] proposed a multilayer neural network, which performs knowledge transfer in two phases: feature extraction and distribution. In the first stage, the relative features are used to obtain the discriminant space, and the model is utilized to predict the variance of each class. Then the Mahalanobis distance of the mean class representation is computed to perform the categorization. In the second stage, a category agnostic transformation from the mean class-mean representation to the class prototype representation is learned. Few-shot Learning with Graph Neural Network [17] is the first application of the concept of graph neural network in few-shot image classification, which contains two parts, the embedding module and the GNN module, where the embedding module extracts the deep features of the samples. The nodes in the GNN module are the deep features and the edges represent the degree of similarity between the nodes, according to the degree of similarity the corresponding adjacency matrix is computed, and finally the classification of query samples is achieved. Li et al. [18] proposed Deep Nearest Neighbor Neural Networks to classify the samples using the local features of the samples, which form a local feature space of the classes, and classify the query samples by comparing the similarity relationship between the query samples and the classes.

To the best of our knowledge, metric learning nowadays mainly focuses on a single similarity metric, which is highly susceptible to metric bias and leads to poor classification performance of the model. Therefore, in the metric module of DFRN, we utilize the query feature vector and the secondary feature vector obtained from the dual feature module to compute the similarity, while considering the influence of the first-level feature vector obtained from the dual feature module, which mitigates the risk of overfitting and further improves the classification accuracy of the model.

B. Loss Function

The loss function usually calculates the difference between the predictions and ground truths, and the neural network is trained by minimizing the difference obtained from the loss function. Li et al. [19] proposed a double-crossing loss function by adding a penalty term on the basis of the cross-entropy loss function, which reduces the probability of the category assignment error and mitigates the effect of the gradient vanishing on classification. Wu et al. [20] proposed a triple loss function that reduces the distance between similar samples and increases the distance between dissimilar samples. The loss function in MeTAL [21] is modified in the inner loop under the guidance of the current task requirements, which enables the loss function to adapt to each task more efficiently and improves the generalization ability of the model.

Different from the above methods, we have multiple loss functions in our proposed DFRN, in which the classification loss of the first-level feature vector is only used to compute the attention mask, and throughout the training process, we update the network parameters by using the combined back-propagation of the classification loss of the secondary feature vector and the ternary auxiliary loss to further optimize the embedding module.

III. Theoretical Basis

In this section, we first define the few-shot learning problem. Then, we describe the DFRN in detail.

A. Problem Definition

The dataset for a few-shot image classification task is usually divided into a train set T_{train}, a test set T_{test} and a validation set T_{val}, which are mutually exclusive to each other. Their corresponding label sets are denoted as $\mathcal{L}_{\text{train}}$, $\mathcal{L}_{\text{test}}$ and $\mathcal{L}_{\text{val}}$, respectively.

In the training phase, C different classes are randomly selected in the training set and K different images are randomly selected from each class to form the support set $S = \{(x_e, y_e)_{e=1}^{N}$, where x_e is the e image in the support set and y_e is its label. Then, a portion of the remaining training samples in each class is randomly selected as the query set $Q = \{(x_p, y_p)_{p=1}^{M}$, where x_p is the p image in the query set and y_p is its label. Thus, the few-shot image classification task is often referred to as a "C-way K-shot" task.

B. Dual Feature Reconfiguration Network

In this paper, we propose a Dual Feature Reconstruction Network (DFRN) for few-shot classification with Feature Map Reconstruction Network (FRN) [22]. The details of the DFRN module are as follows:

1) Embedded Module: The embedding module is used to generate the deep features of the input support samples and query samples. The support sample features are aggregated to generate the support feature matrix. Given the support sample x_e and the query sample x_p, the support sample feature t_e and the query sample feature h_p are obtained through the embedding module f_θ the calculation formula is shown as follows:

$$t_e = f_\theta(x_e) \in \mathbb{R}^{a\times h\times w} \tag{1}$$

$$h_p = f_\theta(x_p) \in \mathbb{R}^{a\times h\times w} \tag{2}$$

where a denotes the number of channels, and h and w denote the height and width of the feature map. Then, the support sample features t_e are reconstructed as $d = h \times w$ dimensional local descriptors, and for each class, the k support sample features from class $c \in C$ are aggregated together and represented by the support feature matrix $S_c \in \mathbb{R}^{kd\times a}$.

2) Feature Reconstruction Module: The feature reconstruction module generates support feature reconstruction by reconstructing the support feature matrix in a ridge regression manner. The support feature matrix is fed into the feature reconstruction module and a closed-loop solution are found by means of ridge regression to reconstruct the support feature matrix into support feature reconstruction, which is calculated as shown below:

$$t_e^{'} = \gamma Q S_c^T (S_c S_c^T + \lambda I)^{-1} S_c \tag{3}$$

$$t_e^{'} = \gamma Q (S_c^T S_c + \lambda I)^{-1} S_c^T S_c \tag{4}$$

where γ and λ are learnable parameters, γ and λ are set to e^α and e^β to ensure their non-negativity, and α and β are learnable hyperparameters, which are initialized to zero. The computational equation is shown below:

$$\gamma = \frac{kd}{c} e^\alpha a \tag{5}$$

$$\lambda = e^\beta \tag{6}$$

We can find that Eq.(3) and Eq.(4) are equivalent in terms of results, but we still compute the support feature reconstruction in these two ways. The reason for this is that the performance consumption caused by computing the transpose of the matrix and the inverse of the matrix is different. When $a > kd$, it is recommended to use Eq.(3). This is because the most performance-consuming step is the computation of the transpose of the $kd \times kd$ matrix. When $a < kd$, it is recommended to use Eq.(4). because the most performance-consuming step in this case is solving the inverse of the $d \times d$ matrix. The support feature reconstruction is fed into the dual feature module to further explore and exploit the space of feature maps to mine richer information. For the query sample feature, the query feature vector $h_p^{'}$ is obtained by global average pooling.

3) Dual Feature Module: The dual feature module extracts a double feature vector for support feature reconstruction and consists of a first-level feature module and a secondary feature module. The first-level feature module is used to generate attention masks and thus identify important regions, while the secondary feature module is used to simulate real-world interference situations, so that the classifier can focus on non-comfortable regions, dig deeper and utilize the feature maps, and learn more diverse discriminative information. It is worth noting that the first-level feature vector is only used for model training. Based on the support feature reconstruction $t_e^{'}$, two copies of it are fed into the first-level feature module and the secondary feature module, and two feature vectors are output. The first-level feature vector $t_{e-1}^{'}$ is obtained through the first-level feature module, and the secondary feature vector $t_{e-2}^{'}$ is obtained through the secondary feature module. First, an attempt is made to obtain the attention mask T_a of the first-level feature module, which is calculated as shown below:

$$T_a = arg\max_T(E(F(t_e^{'}, T), y)) \tag{7}$$

where y is the true label supporting the feature reconstruction, T is the entire region of the sample, F is the classifier and $E(\cdot,\cdot)$ is a measure of the classifier prediction accuracy. L_{flat} is used to express the accuracy of the classifier prediction and is calculated based on the average mask $T_0 = 1/h \times w$ updated attention mask T_a of the secondary feature module, as shown below:

$$T_a = T_0 + \mu \frac{\partial L_{flat}}{\partial T}|_{T_0} \tag{8}$$

where μ is the step size. Note that the attention mask T_a is obtained by back propagation. The average mask T_0 is applied to the support feature reconstruction to obtain the secondary feature vector. The calculation formula is shown below:

$$t_{e-2}^{'} = \textstyle\sum_{i,j} t_e^{'} T_0 \tag{9}$$

where (i, j) represents the spatial location of the support feature reconstruction. The first-level feature vector can be calculated directly based on the attention mask and the support feature reconstruction, and the calculation formula is shown below:

$$\begin{aligned} t_{e-1}^{'} &= \textstyle\sum_{i,j} T_a t_e^{'} \\ &= \textstyle\sum_{i,j} (T_0 + \mu \frac{\partial L_{flat}}{\partial T}|_{T_0}) t_e^{'} \\ &= \textstyle\sum_{i,j} T_0 t_e^{'} + \sum_{i,j} \mu \frac{\partial L_{flat}}{\partial T}|_{T_0} t_e^{'} \\ &= t_{e-2}^{'} + \mu \triangle t_{e-2}^{'} \end{aligned} \tag{10}$$

From Eq.(10), it is clear that the first-level feature vector is a small perturbation combination of the secondary feature vector and noise, which helps to mitigate the risk of overfitting. It is worth noting that the first-level feature vector is only used for the training of the model.

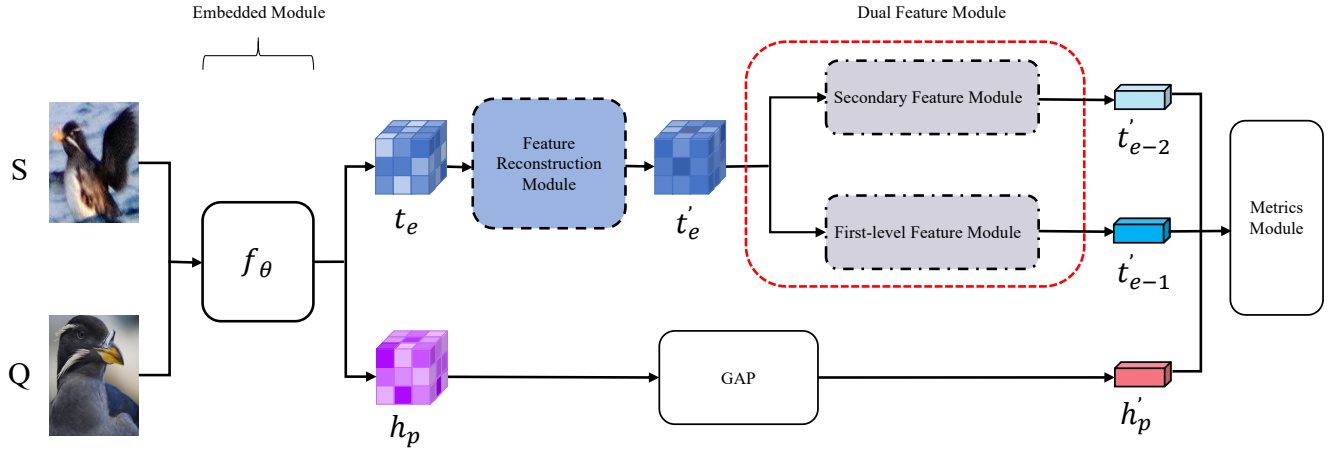

Fig. 1. DFRN network. The proposed network consists of an embedded module, feature reconstruction module, dual feature module and metrics module. The embedded module extracts the features t_e and h_p of the support sample and query sample respectively. The support sample feature t_e is passed through the feature reconstruction module to get the reconstructed feature of the support sample $t_e^{'}$. The feature vector $h_p^{'}$ of the query sample is the query sample feature h_p obtained by the Global Average Pooling(GAP). $t_e^{'}$ undergoes a dual feature module to obtain the first-level feature vector $t_{e-1}^{'}$ and the secondary feature vector $t_{e-2}^{'}$. The metrics module uses the cosine distance to calculate the similarity score of the secondary feature vector $t_{e-2}^{'}$ and the feature vector of the query sample $h_p^{'}$, so as to realize the classification of the query sample. This example illustrates the 1-way 1-shot learning process.

4) Metrics Module: The metric module outputs the similarity scores of the query samples and the support samples. The query feature vector and the secondary feature vector are fed into the metric module, and the cosine similarity is used to measure the similarity score between them to achieve the classification of the query samples.

5) Loss Function: The formula for calculating the classification loss of the first-level feature vector is shown below:

$$L_{level-1} = -\log p(y = c|x)t_{e-1}^{'} \tag{11}$$

where y is the label of the support sample and $p(y = c|x)$ is the Softmax probability. It is important to note that $L_{level-1}$ is only used to calculate the attention mask and is not used for parameter updates. The formula for calculating the classification loss of the secondary eigenvector is shown below:

$$L_{level-2} = E(F(t_{e-2}^{'}, T), y) = \sum_{i=1}^{n} -p\log(p_i) \tag{12}$$

where p_i is the predicted probability of the i class and n is the number of classes. In addition, an auxiliary loss function is invoked to further learn a more compact metric space by considering the contextual information of the support classes. We design a triple $(q, S_e, S_e^{'})$, where q denotes the distribution of a query, S_e is the distribution of a class matching q in the support set and $S_e^{'}$ is the distribution of the remaining classes, and the auxiliary loss function is calculated as shown below:

$$L_{aux-KL} = \sum_{p=1}^{n}\sum_{e=1}^{m}[(q\log\frac{q}{S_e}) - (q\log\frac{q}{S_e^{'}})] \tag{13}$$

Throughout the training process, the loss function is a combination of the classification loss of the secondary feature vector and the auxiliary loss function, which is calculated as shown below:

$$L_{train} = L_{level-2} + L_{aux-KL} \tag{14}$$

In this paper, gradient descent is used to optimize the L_{train}, and the L_{train} is back-propagated to update the network parameters and further optimize the embedding module.

IV. Experiments Result

A. Dataset

For the experiments in this chapter, three commonly used fine-grained datasets were selected: Flowers-102 (Flowers), Stanford-Cars (Cars), and CUB-200-2011 (CUB). In the remainder of this chapter, short symbols in parentheses are used to indicate.

Flowers dataset [23] contains 102 classes of flowers, and the categories of train/validation/test are divided into 60/20/22 in this paper. Cars dataset [24] contains 196 classes of cars, in which the train/validation/test categories are divided into 130/17/49 in this paper. The CUB dataset [25] contains 200 species of birds, and the categories of train/validation/test in this paper are 100/50/50.

B. Implementation Details

To evaluate the method in this paper, 5-way 1-shot and 5-way 5-shot classification tasks were performed, respectively, with Conv-4 as the backbone network. Conv-4 consists of 4 contiguous 64 channels convolution blocks, each consisting of a 3×3 convolution, a batch normalization, and ReLU nonlinear layers. The input image size is 84×84 and the output feature map size is 64×5×5. The experiments in this chapter train the model by SGD optimizer with an initial learning rate set to 0.1. During the training period, standard data enhancement methods are used. The number of iterations for the experiments is 800

under Conv-4. The final test results were obtained with 10,000 experiments during the testing period and 95% confidence intervals were reported.

C. Classification Performance

To verify the effectiveness of DFRN, the experiments use Conv-4 as the backbone to demonstrate the classification performance of each few-shot image classification method on Flowers, CUB and Cars datasets regarding 5-way 1-shot and 5-way 5-shot settings. As shown in Table I and II, the accuracy of the DFRN method is improved over all other methods.

TABLE I
CLASSIFICATION PERFORMANCE OF EACH METHOD AT 5-WAY 1-SHOT ON FINE-GRAINED DATASETS. THE BOLDED PARTS ARE THE METHODS PROPOSED IN THIS PAPER.

Method	5-Way 1-shot Accuracy(%)		
	Flowers	CUB	Cars
PrototypeNet	64.22±0.25	62.83±0.25	48.43±0.22
DN4	70.41±0.95	54.23±0.61	59.80±0.71

D. Ablation Study

In this section, an ablation study is performed to test the effectiveness of the dual feature module and the auxiliary loss function on the CUB and Cars datasets using different backbone networks, and the experimental results are reported in Table III. The composition of the ablation methods in this section is set up as follows:

NAFRN: In the DFRN method, only the dual feature module is used for the experiments, and the other parts are set up in the same way as the FRN method settings.

AFRN: In the DFRN method, only the auxiliary loss function is used for the experiments, and the settings of the other parts are the same as those of the FRN method.

From the experiment results in Table III, it can be seen that the DFRN method achieves the best classification performance and that NAFRN and AFRN achieve the best classification performance compared to the baseline method FRN in 5-way 1-shot and 5-way 5-shot.

TABLE III
CLASSIFICATION PERFORMANCE OF ABLATION EXPERIMENTS UNDER THE CONV-4 SETTING ON FINE-GRAINED DATASET.

Method	5-Way 1-shot Accuracy(%)		5-Way 5-shot Accuracy(%)
