DFRN(Ours)	**74.90±0.21**	**64.77±0.22**	**89.34±0.12**	**84.75±0.13**

V. CONCLUSION

In this paper, a dual feature reconstruction network is proposed. The network takes into account information that could lead to inaccurate predictions by using attention masks to further identify distinguishable regions of the target, forcing the classifier to leave its comfort zone and focus its attention on other regions, thus mining more diverse discriminative information. In this paper, we test the classification performance of DFRN on Flowers, CUB and Cars datasets, and the experimental results show that the classification performance of DFRN is significantly higher than that of FRN.

Abstract —**Electroencephalography (EEG) data plays a crucial role in brain science research as it provides valuable insights into the mechanisms of brain functions. Typical EEG research involves conducting experiments, collecting data, and comprehensive data analysis. The success of such complex studies truly hinges on the collective efforts of multiple researchers. An efficient tool is required to facilitate such collaborative research. While many related tools exist, none specifically aim to enhance efficiency across data management, data analysis, and collaboration. To address this issue, we developed and deployed an integrated cloud-based platform for EEG experiment management, collaboration, and data analysis. Verified by practice, our platform facilitates collaboration, simplifies EEG data analysis for researchers not proficient in programming, and boosts the efficiency of overall EEG research.**

I. INTRODUCTION

Electroencephalography (EEG) is a technique that records the electrical activity between neurons in the brain. It provides valuable insights into the mechanisms of various brain activities, such as cognition, memory, sleep, and emotion, and helps neuroscientists unravel the secret of the human brain [1], [2]. As a real-time technique that directly reflects the ongoing conditions inside the human brain, EEG has been widely used in clinical diagnosis and treatment of brain disorders, including epilepsy, Alzheimer's disease, and anxiety [3], [4], [5]. EEG provides valuable information for monitoring and measuring changes in brain activity related to different tasks and contexts, which assist in investigating the mechanisms, structure, and function underlying cognition and behavior.

Both the process of conducting experiments to collect data, and the subsequent analysis of EEG data, are important in neuroscience research. They underpin hypothesis testing and enable the uncovering of new scientific discoveries [6], [7]. Various works are involved in these two procedures, such as experimental design, subject recruitment, data collection, data cleaning, data preprocessing, and data analysis. To ensure the overall success of a neuroscience study, multiple researchers may collaborate concurrently to accelerate the progress of the study in different tasks [8]. Therefore, a platform that can improve the efficiency of each task is critical for accelerating the entire research project.

The collection of EEG data in neuroscience research incurs significant financial costs, including those for equipment acquisition and participant recruitment [7], [9]. Consequently, the collected data represent valuable resources that warrant careful management for data security and to support subsequent analyses. A variety of data management tools have been developed specifically for EEG research [6], [10]. In EEG data analysis, there is an ongoing need for user-friendly, accurate, and efficient tools capable of handling large amounts of EEG data. A range of tools has been developed to assist researchers in effective EEG analysis, including MATLAB-based tools like EEGLAB and FieldTrip [11], [12], and the Python-based package MNE-Python library [13]. These tools enable researchers to tailor their data analysis to their needs, providing a convenient way to accomplish analysis tasks, and given familiarity with the respective programing language. They are less user-friendly and less effective for researchers lacking programming proficiency [14]. Additionally, researchers' varying programming skills could influence their choice of analytical methods. Moreover, the availability of hardware resources, such as computing power, could also limit researchers in their choice of specific analysis strategies. As a

[1] Corresponding Author: Linqing Feng, fenglq@zhejianglab.com

result, the introduction of diverse method choices in research complicates the comparison of results across different research projects [15]. Addressing this issue, Li Dong et al. developed a cloud-based brainformatics platform(WeBarin) [14] designed to store EEG data on a cloud server and provide online computing services, thereby enhancing the efficiency and consistency of EEG analysis. Similar tools are also reported in other studies [16], [17]. In summary, while a host of tools and platforms exist to aid in various aspects of EEG research, the need for a comprehensive solution that combines data management, collaboration, and data analysis remains a key challenge. Addressing this challenge could significantly enhance the efficiency and reproducibility of EEG studies.

Beyond analyzing EEG data, a neuroscience research project involves tasks like experiment arrangement and data collection, which typically require the collaboration of multiple researchers [6], [9]. Providing support to researchers in data analysis alone is insufficient to advance neuroscience research. Boosting the efficiency of other tasks, such as data management, is of equal importance. However, existing EEG analysis tools rarely offer adequate support for these tasks. To bridge this gap, our study presents a cloud-based data analysis collaboration platform designed to streamline EEG data management, enhance research collaboration, and simplify EEG data analysis. The platform provides cloud-based services encompassing data storage, computing, analysis, sharing, and collaboration. This facilitates a more efficient development of EEG-related experiments and aids in the analysis of EEG data to decode the connections between data and brain activity.

II. METHODS

A. Architecture design

The system architecture of this platform, structured on a browser-server architecture, is illustrated in Fig. 1. The backend of the platform resides on a cloud server, allowing users to interact with cloud-based data via a front-end browser. The cloud server comprises an administrative database, an EEG file database, and a computation server, which are used for storing administrative data, storing EEG files, and analyzing and computing large amounts of EEG data, respectively. The platform mainly consists of four core modules: data management, data visualization, data query, and data analysis. Users can upload collected EEG data wirelessly or through a hard drive, with commonly used EEG storage formats in neuroscience research, such as EDF, BDF, and CNT. Following the upload, the data undergoes a simple quality check, whereby accepted data is stored on the file server. For uploaded data, Vue.js [18] front-end display frameworks are used for data visualization. The search function of the platform is built on the Elasticsearch [19] engine, which constructs retrieval indexes based on uploaded files and sorts them based on the similarity of each signal. The platform's analysis function utilizes the MNE algorithm library and enables researchers to upload and share their custom algorithm files for EEG analysis purposes.

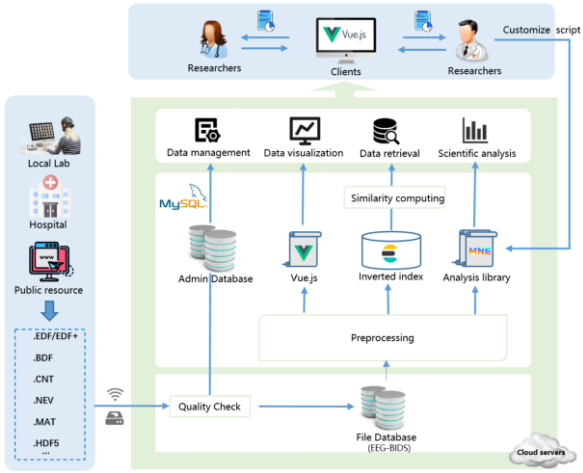

Fig. 1 The architecture of the platform

B. Workflow design

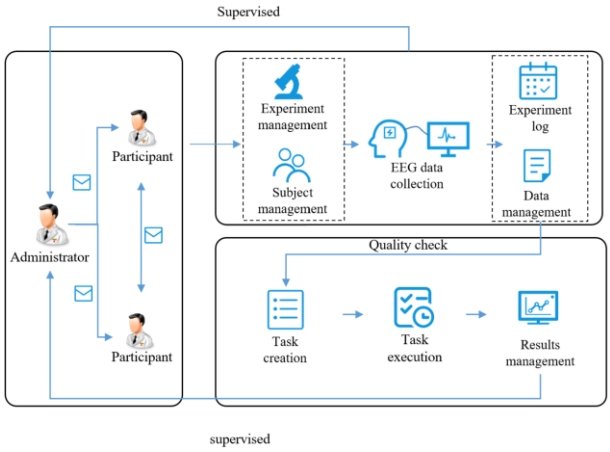

Fig. 2 The workflow of the platform.

The platform is designed with a workflow that encompasses all research processes, assisting researchers in their corresponding tasks. At the initial research stage, the research administrator can assemble their team, with all participants able to coordinate and record their work on the platform. In the

data collection phase, researchers can use the platform to create a project to record relevant information about an EEG experiment, such as the subject's details, and schedule the experiment accordingly. All information linked to the experiment, such as its location, duration, participants, and devices used, can be recorded to the platform for management and retrieval. The data generated from the experiment will also be uploaded to the platform and associated with details such as the experiment operator, subject, and device, making subsequent data management easy.

In the data analysis phase, researchers responsible for data analysis can create corresponding analysis tasks. The platform can provide users with commonly used data analysis support, such as EEG data filtering, time-frequency analysis, and EEG topomap. Researchers can also upload their custom EEG analysis code files for data analysis. The defined analysis tasks will be executed sequentially by the computation server, and the data and results generated in each step will be stored on the platform. Researchers can check them online or download them for further analysis on a local computer.

The experiment administrators can assign tasks to each participant and monitor the progress of each task. They also have operational authority over data, algorithms, and execution results involved in their project. This enables the administrator to ensure the experiments and data acquisition proceeds as planned or choose to share data, algorithms, and results on the platform after the research for communication and comparison.

To boost data analysis efficiency and minimize the impact of individual researchers' programming skills, our platform provides a user-friendly interface (Fig. 4) for data analysis functions. This obviates the need for researchers to write and execute code for relevant algorithms; instead, they simply fill in the corresponding parameters in the analysis algorithm's interface for data analysis. Additionally, researchers can save the defined parameters as fixed schemes, so they do not have to redefine them when performing the same analysis in the future but can instead select the scheme. Researchers can choose to make custom schemes public or private to facilitate other researchers' studies.

III. Results

A. *The EEG platform*

The screenshot of the platform is shown in Fig. 3. Corresponding to the structure diagram, the platform's four core modules can be accessed using the three labels located on the navigator's left-hand side in Fig. 3. The "Experiment" label provides access to the data management and visitation modules, enabling researchers to review and manage the information and data relevant to their EEG experiments. The "TaskList" label links to the data analysis module, allowing neuroscientists to create data processing tasks, such as filtering and time-frequency analysis. Finally, the "SignalSearch" label links to the data retrieval module, permitting users to retrieve EEG files that contain fragments matching their selected target signal.

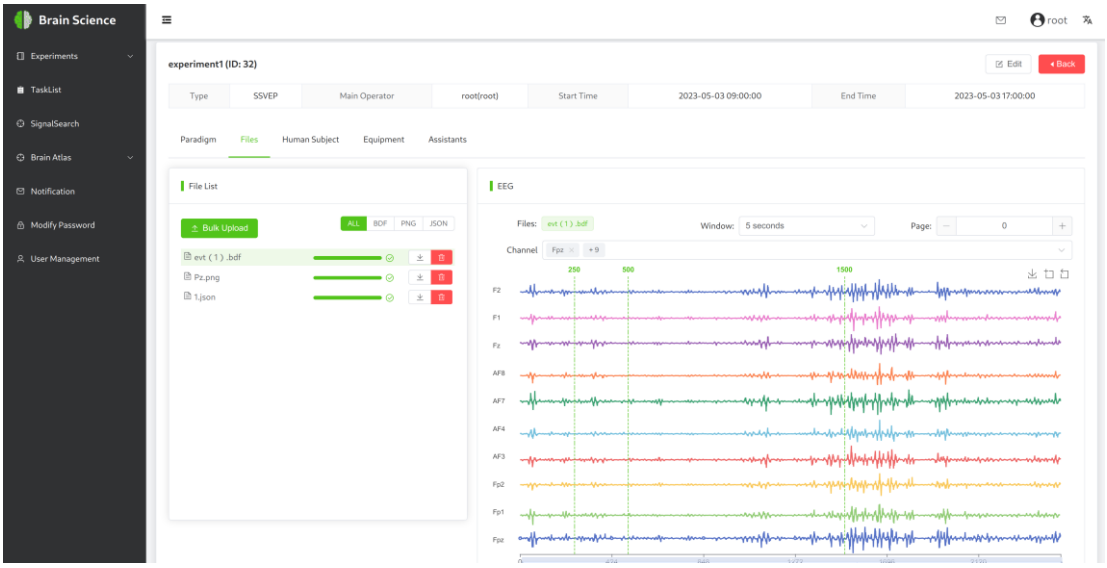

Fig. 3 Screenshot of this platform

C. *EEG analysis design*

Other labels in the platform's navigator are maintenance

modules or functionalities that will be developed in the next version of the platform.

Currently, the platform has been deployed on the server of Zhejiang Lab, for internal testing. Three research teams, totaling 10 researchers, are utilizing the platform to conduct research in a variety of areas, including human steady state visually evoked potential(SSVEP), motor imagery, human sleep, and EEG related to some animal experiments.

B. Comparison with other EEG tools

We conducted a comprehensive comparison of the functional characteristics of the platform developed herein with existing EEG research-related tools, focusing on three key aspects of EEG research: data management (Table 1), collaborative work (Table 2), and data analysis (Table 3). The first rows in each of these tables display the name of the tools. For tools that were not explicitly named in the corresponding research, we represented them by their author's name. Throughout the tables, we referred to the platform developed in this study as "brain science".

Specifically, in the domain of data management, we compared the tools based on their provision of services such as data storage, data retrieval, EEG experiment management, subject management in experiments, and data sharing capabilities with other researchers.

Table 1. Comparison form data management aspect

	Storage	Retrieval	Experiment	Subjects	Share
Musestudio [7]					
mEEG[10]	✓			✓	
DRT[20]					
BrainBase[6]	✓	✓	✓	✓	✓
WeBrain[14]	✓	✓			✓
ReportFlow [21]	✓			✓	✓
BEAPP[16]					
Alphonse's [17]					
Sans Tracas[9]	✓		✓	✓	
Petr's [22]	✓				
brainscience	✓	✓	✓	✓	✓

Regarding workflow support, our analysis focused on whether these tools offered assistance in areas like authority management, data collection, message exchange, and other workflow-related functionalities crucial for conducting EEG research.

Table 2. Comparison form work flow support aspect

	Authority management	Data collection	Messages exchange	Workflow
Musestudio		✓		
mEEG				
DRT				
BrainBase		✓		
WeBrain	✓		✓	
ReportFlow	✓	✓	✓	✓
BEAPP				
Alphonse's				
Sans Tracas	✓	✓		✓
Petr's				
platform				
brainscience	✓	✓	✓	✓

In the context of data analysis, we thoroughly examined whether the analyzed tools provided support for common analysis requirements encountered in EEG research. These requirements encompassed tasks such as format transformation of EEG files, visualization, filtering, classification, and time-frequency analysis. It is important to note that the needs for EEG analysis are diverse, and each tool has its own specific design intentions. Thus, certain less common analysis functions were not exhaustively outlined in the table.

Table 3. Comparison form data analysis aspect

	Transformation	Visualization	Filtering	Classification	time-frequency analysis
Musestudio	✓	✓			
mEEG		✓	✓	✓	
DRT	✓				
BrainBase					
WeBrain		✓	✓		✓
ReportFlow					
BEAPP	✓	✓	✓		
Alphonse's		✓	✓	✓	✓
Sans Tracas		✓			
Petr's		✓	✓	✓	
brainscience		✓	✓		✓

Overall, the majority of existing tools that primarily focus on providing functional support in one or two specific aspects, while few tools offer comprehensive support across all three aspects. DRT, Musestudio, Alphonse's, BEAPP, and Petr's primarily concentrate on data analysis. ReportFlow primarily emphasizes workflow support, whereas mEEG contributes to both data analysis and storage functionalities. WeBrain demonstrates the ability to provide support in multiple aspects, albeit lacking in experiments and subject management.

It is important to notice that some tools are not exclusively designed for the three aspects mentioned above. For instance, ReportFlow primarily focuses on the secure transmission of encrypted EEG reports, while the main purpose of DRT is to transform EEG data structures into a standardized format. Both

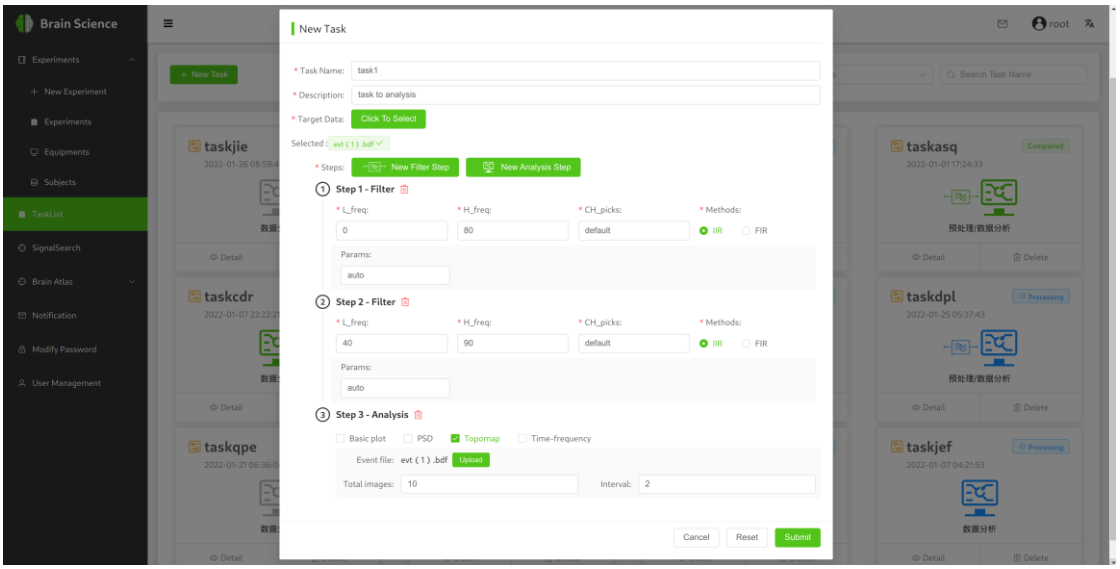

Fig. 4 The UI design of EEG analysis tasks

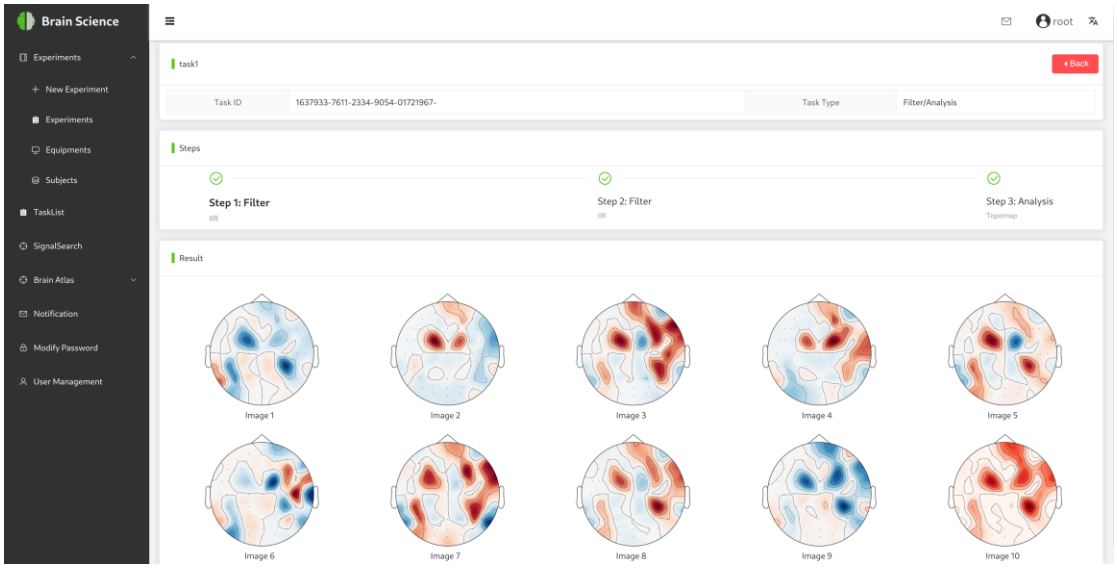

Fig. 5 The results of an EEG topomap task

of these tools, however, are useful for promoting EEG research by addressing specific areas of improvement.

C. An example of an EEG analysis task

Here, we use an EEG topomap task as an example to demonstrate how to analyze EEG data on the platform. Initially, the researcher creates a task in the task module, customizing the task's detailed content through the platform's user interface (Fig. 4). They can then select the "Target data" option and choose the data to be processed by the task. In this demonstration, we use data obtained from an SSVEP experiment conducted by our research team. The signals were captured using a 64-channel EEG recording device with a sampling frequency of 1,000 Hz

Next, filtering operations are added to the task. In this task, we implement an 80 Hz low-pass filter and a 40-90 Hz band-pass filter. Researchers can submit the parameters of two sets of filters in the form to achieve filtering (Fig. 4).

Subsequently, researchers can customize the parameters of the topomap task. These parameters include uploading event-related files, drawing intervals, and the number of image displays (Fig. 4).

Finally, the defined task can be submitted to the computing server, and results will be displayed on the platform in a few seconds (Fig. 5).

IV. Discussion

EEG data collection and analysis are two important steps in neuroscience. While many EEG data analysis tools have been designed and implemented to improve research efficiency, critical tasks such as data collection and experiment management, often involving multiple researchers, require equal attention. Therefore, enhancing collaboration among multiple researchers in different stages of neuroscience research is a fundamental requirement for present-day neuroscience researchers.

This study aims to design and implement a cloud-based EEG data management and analysis platform, providing researchers with cloud storage, and computing capabilities, and fostering multi-person collaboration to enhance neuroscience experiments. The platform facilitates the collection, management, and computation of large batches of EEG data, ultimately enhancing the efficiency of EEG experiments and promoting the development of neuroscience research.

In this study, we designed a workflow that aligns with the process of neuroscience research to facilitate collaborations among researchers. After actual deployment and testing, the platform effectively assisted researchers with their daily EEG experiment work and improved data management efficiency. By designing user-friendly EEG analysis functions, we reduce the need for advanced programming skills in EEG analysis tasks, making these tasks more accessible to new researchers.

Nevertheless, there remains room for further improvement in platform's functionality. Through the internal testing process, we received feedback indicating that the data analysis functions need to be expanded. Despite the implementation of interface operations for data analysis, the platform still needs enhancements to fully meet researchers' analysis requirements. Additionally, the current version of the platform lacks compatibility with the Brain Imaging Data Structure (BIDS) [23] data specification, which will be fixed before it is released to public in the near future. Lastly, to enable analysis of multi-modal neuroscience data, this platform needs to support more types of neuroscience data.

Currently, the platform is only available for internal testing. Nonetheless, we plan to release a public version with enhanced data security modules in the near future, aiming to assist researchers worldwide in their neuroscience research, facilitating academic communications and fostering progress in the field of neuroscience.

V. Conclusions

In this study, we have developed a cloud-based platform dedicated to EEG data management and analysis. This platform equips researchers with cloud computing and storage capabilities, streamlining their work process. In practical application, our platform not only diminishes the complexities of EEG data analysis but also enhances efficiency in data collection and data management. With these benefits, we believe our platform holds substantial potential in propelling the advancement of EEG-related neuroscience research.

***Abstract*—Recent studies in speech processing often utilize sophisticated methods for solving a task to obtain high-accuracy results. Although high performance could be achieved, the methods are too complex and require high-performance computational power that might not be available for a wide range of researchers. In this study, we propose a method to incorporate the low dimensional and the recent state-of-the-art acoustic features for speech processing to predict the speech intelligibility in noise for hearing aids. The proposed method was developed based on the stack regressor on various traditional machine learning regressors. Unlike other existing works, we utilized the results of the digit triplet test, which is usually used to measure the hearing ability in the existence of noise, to improve the prediction. The evaluation of our proposed method was carried out by using the first Clarity Prediction Challenge dataset. This dataset is utilized for speech intelligibility prediction that consists of speech signals output of hearing aids that were arranged in various simulated scenes with interferers. Our experimental results show that the proposed method could improve speech intelligibility prediction. The results also show that the digit triplet test results are beneficial for speech intelligibility prediction in noise.**

I. Introduction

Hearing loss is a widespread and significant problem that affects people's lives. With age and other factors, an individual's hearing function gradually deteriorates, decreasing speech comprehension and communication skills [1], [2]. Hearing loss directly impacts the clarity of an individual's speech. Hearing loss at specific frequencies makes it difficult for individuals to discriminate certain speech sounds, reducing speech intelligibility and comprehension [3]. This effect is further exacerbated by background noise and complex listening environments [4], [5]. As individuals' hearing function gradually deteriorates, they often suffer from physical burdens, further exacerbated by emotional depression due to the inability to communicate effectively with others.

A significant goal of hearing aids is to improve the speech intelligibility of individuals with hearing loss to better participate in social activities, communicate with others, and receive and understand verbal information effectively. Evaluation of hearing abilities takes place through various methods such as audiograms, speech tests, auditory questionnaires, auditory neurophysiological measures, and cognitive tests [6]–[8]. Existing methods for speech intelligibility prediction in hearing aids often rely only on audiograms to represent the status of hearing loss, which has certain limitations.

The traditional audiogram assessments only provide information about hearing sensitivity and frequency characteristics. In contrast, speech comprehension involves more complex auditory and cognitive processes, and audiograms do not fully reflect changes in these aspects [9]. Moreover, audiograms do not provide information about an individual's performance in a given speech environment, which is essential when assessing the speech intelligibility of hearing aids. The effects of environmental noise, speech intelligibility, and individual auditory processing abilities prevent conventional audiograms from providing detailed information on these aspects. To obtain more comprehensive and accurate hearing assessment results in assessing the speech intelligibility of hearing aids, we need to combine other assessment methods, such as the digit triplet test (DTT) as a method of assessing hearing ability in noise.

The DTT has essential applications in assessing speech perception in complex listening environments, such as background noise or competing sounds [10], [11]. The test uses digit triplets to measure an individual's ability to perceive and discriminate speech sounds in the presence of hearing loss, especially in the high-frequency range [12]. By measuring the speech reception threshold (SRT) obtained from the DTT, we can reveal an individual's ability to comprehend speech under adverse conditions and correlate it with the overall speech intelligibility in the real world. Lower SRT values indicate that individuals are more capable of successfully recognizing and discriminating speech in the DTT, which implies a higher level of discourse intelligibility. In addition, the DTT provides practical guidance for hearing aid assessment, selection, and individualized rehabilitation planning by measuring an individual's ability to perceive and discriminate speech at lower levels. It can also predict their overall speech intelligibility in the real world.

The purpose of this paper is to propose a speech intelligibility prediction method that considers the results of the DTT for hearing aids in complex listening environments. Our approach builds on a stacked regressor that combines the functionality of traditional machine learning regressors, including linear regressor, support vector regressor, and random forest regressor. Since the DTT can assess the hearing ability in the presence of noise, we hypothesize that incorporating the results of the DTT into our prediction model has the potential to improve the prediction further.

The paper next consists of five sections. Section 2 includes details of the related work, i.e., hearing condition assessment, baseline of the modified Binaural Short-time Objective Intelligibility (MBSTOI), and speech intelligibility prediction.

TABLE I
SUMMARY OF SPEECH INTELLIGIBILITY ASSESSMENT METHODS

Assessment Methods	Phoneme Tests	Word Recognition Tests	Sentence Intelligibility Tests	Digit Triplet Test
Purpose	Assess discrimination of phonemes, syllables	Evaluate recognition of individual words	Measure understanding of sentences	Assess speech perception in connected speech
Response	Discrimination or identification	Identification or repetition	Repetition or understanding	Identification or repetition
Stimuli	Individual speech sounds or minimal pairs	Isolated words	Sentences	Triplet of connected speech sounds
Types of Tests	Phoneme Discrimination Tests, Phoneme Recognition Tests	Consonant-Vowel Tests	Speech Intelligibility Index, Hearing in Noise Test	Digit Triplet Test
Measurement Outcome	Discriminative thresholds, discrimination accuracy	Word recognition score	Threshold level for speech intelligibility	Accuracy or threshold level for speech intelligibility

Section 3 presents the proposed method, i.e., feature extraction and regression analysis. Section 4 describes the experiments, such as the dataset, evaluation metrics, and results. Section 5 shows the conclusion of our study.

II. Related Work

A. Hearing Condition Assessment

An audiogram measures the sensitivity of an individual's hearing at different frequencies. The threshold of the different sound intensities they can hear is measured by performing a hearing test and drawing an audiogram. The shape and results of the audiogram can provide detailed information about an individual's hearing status. A physician or audiologist can use the audiogram to help determine if there is a hearing loss and its degree and type. Recording the hearing thresholds of individuals at different frequencies plots the audiogram. These hearing thresholds represent the minimum sound intensity that an individual can hear. The pure tone average (PTA) provides the audiogram with a measure of the degree of hearing loss. It summarizes an individual's hearing sensitivity over a specific frequency range. A common way to calculate the PTA is to select frequency points. These frequency points are the most critical frequency ranges for speech and communication. A higher PTA value indicates a higher hearing threshold, i.e., an individual has a lower auditory sensitivity to sound, suggesting the presence of hearing loss.

Existing methods for assessing speech intelligibility with hearing aids include a series of tests to assess an individual's ability to perceive and understand language [11], [13]–[16]. These assessments aim to quantify the degree of speech intelligibility and provide valuable information for diagnosing hearing impairment, assessing treatment effectiveness, and guiding intervention strategies. All of the methods assess an individual's ability to perceive and comprehend language. The acceptable discrimination required by phoneme tests allows for detailed speech analysis but may only partially reflect the challenges faced in complex listening environments. The word recognition tests provide insight into recognition at the lexical level but may not reflect an understanding of communication at the sentence level. The sentence intelligibility tests present higher cognitive and linguistic demands, potentially affecting an individual's ability to understand and accurately respond to the entire sentence, which places a higher cognitive burden on individuals with hearing loss.

The DTT has demonstrated reasonable validity and reliability in assessing speech intelligibility [11]. The DTT presents a series of digraph triplets consisting of three speech sounds [10]. During the test, individuals recognized different digit triplets at different signal-to-noise ratios. By setting different signal-to-noise ratios in the test environment, the DTT provides insight into a person's ability to perceive speech in complex listening environments and helps to assess their overall communication ability more accurately. Compared to isolated phonemes, words, or sentences, the DTT uses a triplet of digital speech with specific phonetic features, and the test results more closely mimic real-life speech intelligibility.

The advantages of the DTT in complex listening environments and for individuals with hearing loss make it a promising option for assessing speech intelligibility in challenging listening conditions. The DTT has higher sensitivity and specificity than other testing methods, allowing for a more accurate assessment of an individual's ability to perceive and discriminate speech sounds. Moreover, the DTT results correlate strongly with audiogram PTA measurements, which serve as an index to assess the degree of hearing loss and reflect an individual's hearing threshold at different frequencies. The correlation with the PTA suggests that the DTT can be used as one indicator to complement the hearing status assessment, providing more comprehensive information for a hearing assessment. The DTT is the ability to capture the individual's ability to perceive the nuances of speech features, thus providing a more comprehensive assessment of the individual's speech intelligibility.

B. Baseline Modified Binaural Short-time Objective Intelligibility (MBSTOI)

The MBSTOI is an improved binaural short-time objective intelligibility index for speech intelligibility prediction in hearing aids. The short-time objective intelligibility (STOI) measures have successfully predicted the intelligibility of noisy speech processed by time-frequency (TF) weighting methods [17]. However, a limitation of STOI is its reliance on monophonic speech signals, which ignores valuable dual-channel

cues available to listeners.

The binaural short-time objective intelligibility (BSTOI) is based on the principles of STOI but introduces some modifications [18]. In BSTOI, the equalisation cancellation (EC) model uses information from binaural cues to simulate how the human auditory system works [19]. During the EC phase, the linear combination of the left and right ears is described by Eq.(1). $x_{k,m}^{(l)}$ is the signal of the TF unit corresponding to the left ear in the m-th time period and k-th frequency bin. The factor λ implements the equalization step in the EC stage.

$$\hat{x}_{k,m} = \lambda \cdot \hat{x}_{k,m}^{(l)} - \lambda^{-1} \cdot \hat{x}_{k,m}^{(r)} \tag{1}$$

The MBSTOI performs independent EC stages at each time range and each frequency band to estimate EC parameters. The MBSTOI improves binaural processing and optimized equalization stages over the BSTOI to more accurately predict speech intelligibility. Such improvements allow MBSTOI to better capture and utilize binaural information in the speech signal and improve the performance of speech intelligibility assessment.

C. Speech Intelligibility Prediction

In the field of hearing aids, predicting the speech intelligibility of listeners is an important research task. Such prediction can be achieved by objective measurements, guiding audiologists in selecting appropriate signal processing algorithms when fitting hearing aids, and providing valuable tools in developing machine learning-based hearing aid algorithms and other speech enhancement methods [20]. The objective measurement of speech intelligibility refers to analyzing various features and attributes of the speech signal. These features can include spectral characteristics of speech, time domain characteristics, and acoustic parameters. By modeling the relationship between these characteristics and listener comprehension, it is possible to predict the speech intelligibility of listeners with hearing loss under listening conditions.

The widespread use of machine learning methods in speech intelligibility prediction is due to their ability to learn patterns and correlations from large-scale speech data and apply them to new data samples for prediction. These methods use large datasets and features to train models to establish associations between features and speech intelligibility. Standard machine learning algorithms include support vector machines, random forests, and deep learning models. Through objective speech intelligibility measures and machine learning methods, audiologists and researchers can better understand listeners' speech intelligibility and select appropriate signal processing algorithms to improve listeners' listening experience.

III. Proposed Method

As the proposed model, the noisy speech after hearing aid processing is taken as input speech for feature extraction. The result of extracted speech features also combines with the bilateral audiogram and the DTT results. The aims to incorporate both audiogram and the DTT is to account for the individual listener's hearing profile and tailor the prediction accordingly. Besides, we use this holistic approach to enhance the accuracy and relevance of speech intelligibility predictions by taking into account the listener's individual auditory capability. After the feature extraction stage, the proposed model concludes with regression analyses to predict speech intelligibility.

A. Feature Extraction

In the feature extraction, we corporate various feature extraction process, including Geneva minimalistic acoustic parameter set (GeMAPS) and its extended version (eGeMAPS), wav2vec2, hidden unit bidirectional encoder representation from transformer (HuBERT), and waveform language model (wavLM). The details of each feature extraction are described in the following section.

1) GeMAPS and eGeMAPS: The open-source toolkit openSMILE incorporates to perform extraction of the GeMAPS and eGeMAPS parameter sets. Our proposed method includes these sets to extract features related to signal-to-noise ratio, spectral envelope, pitch, and temporal dynamics. The valuable information about speech characteristics might capture the relevant factors affecting speech intelligibility in the context of hearing loss perception under complex listening environments. The GeMAPS is a minimalistic parameter set that incorporating essential prosodic, excitation, vocal tract, and spectral features [21], [22]. Meanwhile, the eGeMAPS, as an extended version, includes additional cepstral features to enhance recognition accuracy beyond using only prosodic and spectral parameters.

In detail, the set of features extracted by the GeMAPS includes frequency-related, amplitude-related, and spectral features. Frequency-related features include pitch (measured in semitones), jitter (deviations in F0 period lengths), and formant frequencies. Amplitude-related features include a shimmer (difference in peak amplitudes), loudness (perceived intensity), and harmonics-to-noise ratio (HNR). Finally, Spectral features include:

- Alpha ratio: energy ratio between specific frequency ranges
- Hammarberg Index: ratio of energy peaks
- Spectral slope: regression slopes in frequency bands
- Formant relative energy
- Harmonic difference of the first harmonic to the second harmonic (H1-H2) and the third formant range (H1-A3)

These parameters undergo smoothing using a moving average filter and various functions to generate a set of parameters. These functionals include arithmetic mean, coefficient of variation, percentiles, range, and slope-related measures. Additionally, temporal features, such as the rate of loudness peaks and statistics of voiced and unvoiced regions, provide a comprehensive analysis of speech characteristics. In total, 62 parameters were extracted by GeMAPS.

As aforementioned, the extension of GeMAPS, the eGeMAPS, includes cepstral and dynamic parameters to model the affective states in speech analysis. The eGeMAPS introduces additional parameters, including Mel-frequency cepstral coefficients (MFCCs), spectral flux difference, and formant bandwidth. Functionals like arithmetic mean and coefficient

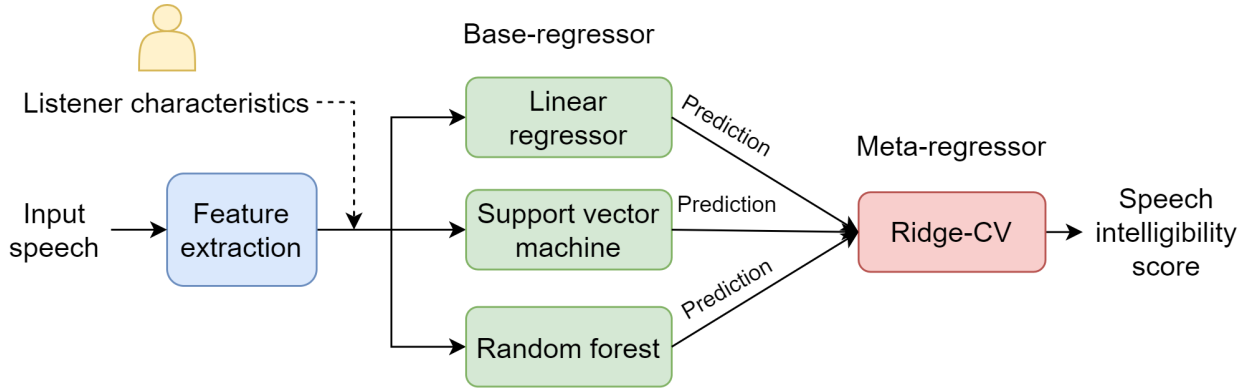

Fig. 1. Block diagram of our proposed method

of variation are applied to these parameters. The eGeMAPS set, combined with the GeMAPS, generates 88 parameters.

2) wav2vec2: The wav2vec2 is a framework of self-supervised learning in representing speech audio that is fine-tuned on transcribed speech [23]. We chose self-supervised learning because predicting speech intelligibility for hearing loss conditions using a speech recognition model only applies in real applications if it can deal with unlabeled data or explicit annotation. Besides, wav2vec2 extracts high-level acoustic features that capture important aspects of the speech signal useful for downstream tasks of predicting speech intelligibility.

The speech features extracted by wav2vec2 include the phonetic and linguistic properties by learning to model the temporal relationship between different phonemes or speech units. These representations encode information about the distinct speech and their temporal patterns, which are crucial for speech intelligibility. The wav2vec2 also captures the prosodic cues such as pitch variation, rhythm, and intonation, which play a role in conveying meaning and syntactic structure. Lastly, wav2vec2 extracts spectral information related to the frequency content, indicating phonetic distinctions and acoustic cues relevant to intelligibility.

3) HuBERT: Another self-supervised learning framework we consider is HuBERT [24]. HuBERT consists of three main components: the feature encoder, transformer encoder, and classification head, which appeared as the extension of wav2vec2. The feature encoder extracts low-level acoustic features from the input signal and converts them into time-frequency representation. Then, the transformer encoder captures the contextual information through unidirectional and bidirectional transformers. Finally, the classification head maps the acoustic features to the predicted speech intelligibility.

Although HuBERT shares the same overall architecture as the pre-trained model, HuBERT introduces enhancements and modifications to improve speech representation learning. It also utilizes larger-context modeling by increasing the context window size during pre-training to capture more long-range dependencies and contextual information in the speech signal. Unlike the unidirectional transformer layers used in wav2vec2, HuBERT incorporates both unidirectional and bidirectional transformer layers. This combination enables the model to effectively capture the local and global context in the speech signal, improve the ability to understand the intricacies of speech, and extract relevant features for speech intelligibility prediction.

4) wavLM: The last self-supervised learning model to learn the representation for speech-related tasks that we consider is the wavLM [25]. It is introduced as the extension of the HuBERT framework that enables the pre-trained model to work on speech recognition and related tasks. We include the wavLM because of the ability to extract fine-grained details within an audio signal. Besides, the wavLM trained using a language modeling objective, resulting in rich representations of speech and its linguistic properties, which can be beneficial for tasks related to speech intelligibility.

In terms of feature extraction to predict speech intelligibility, the wavLM model does not explicitly extract handcrafted features. Instead, it directly operates on the raw waveform data, allowing it to capture complex patterns and dependencies present in the speech signal. The wavLM model learns to encode various aspects of speech intelligibility within its internal representations and capture acoustic features such as pitch, spectral characteristics, phonetic content, and temporal dynamics, among others. In addition, by training on a large corpus of speech data, the WavLM model learns to implicitly extract relevant features for the task at hand, making it a powerful tool for speech intelligibility prediction.

B. Regression analysis

The extracted features were fed to the base-regressor and the meta-regressor to obtain the final speech intelligibility score. While speech is indeed a complex and multidimensional signal, we use the base-regressor, which consists of linear regressor, support vector machines, and random forest, to make predictions. Although linear regression models have been successfully used in various speech-related tasks, in the case of complex listening environments and listener individuals that affect speech intelligibility, the pattern captured by single linear model cannot be adequate. Therefore, we utilize support vector machines and random forests, alongside linear regressor, to capture broader range of relationships and better handle non-linearities in the data. Finally, each of the prediction results

was fed to the Ridge-CV as the meta-regressor and ensemble model to generate the final speech intelligibility score.

IV. Experiment

A. Dataset

The dataset utilized in the experiment is associated with 6 speakers, 10 hearing aid systems from the entrants of the first Clarity Enhancement Challenge, and 27 listeners [26]. The noisy speech in the dataset was generated from the various living room scenarios of sound propagation through the room and interaction to the human head. The target sentences consist of 7-10 words in length with the subset of 1500 utterances [27]. On the other hand, the interferer was recorded from sounds of daily electronic appliances, such as washing machines, vacuum cleaners, and kettles, to demonstrate the non-impulsive noise in the real world condition. Next, to create the consistence scenarios, the position of target speaker, listeners, and interferer is adjusted. For each scene, input signals are convoluted with appropriate geometric room acoustic model and head related transfer function (HTRF) database, which include measurements for hearing aid microphones to create suitable inputs to hearing aid system.

The information about the listeners is also given in the dataset and characterized by the bilateral pure-tone audiograms. The audiogram is specified with average hearing loss in dB in frequency between 2 to 8 kHz. Based on the measurement obtained, there is 1 listener with mild hearing loss (15–35 dB), 9 listeners with moderate hearing loss (35–56 dB), and 17 listeners with severe hearing loss (>56 dB) [28]. The other hearing ability measurement is also provided, that is, the DTT, Glasgow hearing-aid benefit profile questionnaire (GHABP), and Speech, Spatial, & Qualities of Hearing questionnaire (SSQ12). In this paper, more concentration will be devoted to the analysis of audiogram and the DTT results. Since the results of the DTT are not available for several listeners, we remove those data in investigating the speech intelligibility.

There are two tracks provided in the dataset. Track 1 is a closed-set track with the known listeners and hearing aid processors in the training set (4812 responses) and test set (2421 responses). Track 2 is an open set track with one hearing aid processor and five listeners unseen in the training set. The remaining 22 listeners and 9 hearing aid processors are available in both training and test sets, generated (3545 responses). The purpose of including track 2 is to demonstrate how well the method generalizes the prediction to the unseen data. Since the DTT results are unavailable for all listeners, we remove all the data with missing values. The total number of listeners is nineteen people with the characteristics detailed in Table III. Note that due to this removal process, the total number of data for this experiment is less than those in our prior works and the existing works in the Clarity Prediction Challenge [29].

B. Evaluation Metrics

Five universal metrics used for regression task are utilized to assess the results, including Pearson correlation coefficient (ρ_p), Spearman correlation coefficient (ρ_s), root mean square error (RMSE), standard error (SE), and the coefficient of determination (R^2).

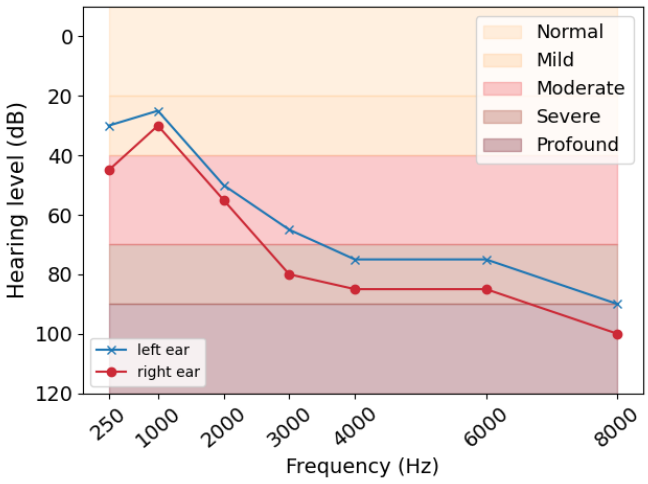

Fig. 2. The audiogram of listener L239. The hearing ability is categorized into severe hearing loss since the average hearing loss level in the audiogram with frequency in {250, 500, 1000, 2000, 3000, 4000, 6000, 8000} Hz is $>$ 56 dB. Additionally, the SRT obtained from the DTT can be categorized as high, which indicates the minimum hearing level to recognize 50% of the digit tests.

The ρ_p assesses the linear correlation between two variables. In the context of speech intelligibility prediction, ρ_p is used to determine the relationship between the actual and predicted speech intelligibility score. The ρ_s is also corporated to measure the association between the actual and predicted speech intelligibility score, even if they have a non-linear relationship. To assess the prediction accuracy, RMSE is corporate. In addition, SE helps to determine the precision of the prediction and reliability of the experiment results. Moreover, R^2 represents the goodness of fit between the predicted and actual intelligibility scores.

C. Results

In this section, we present the results of the experiment using the proposed lightweight machine learning method with several speech features for predicting speech intelligibility. Table II shows the experiment results of the proposed method compared to the baseline MBSTOI [29] in both Track 1 and Track 2. The baseline MBSTOI was developed based on the MBSTOI metric [17] with the hearing loss model developed by Nejime et al. [30]. The speech intelligibility model was built by fitting the output MBSTOI score of the training data with a logistic mapping model with a sigmoid function.

Since we aim at reducing the computational complexity, we experiment on several low dimensional acoustic features (i.e., eGeMAPS) and the embedding features in the state-of-the-art features for automatic speech recognition (ASR) (i.e., wav2vec2, HuBERT, and wavLM). The listener characteristics, such as audiogram and the DTT, were also simplified into categorical data. For audiograms, we use three categories: mild, moderate, and severe. Meanwhile, based on the SRT for the DTT results, we use two categories: low and high. These

Hearing loss level	Moderate	Severe	Moderate	Moderate	Mild	Severe	Moderate	Severe	Moderate	

categories were based on the calculation of the average SRT of all listeners that represents a collective level of speech intelligibility. If an individual's SRT value is significantly higher than the mean value, the individual needs a higher signal-to-noise ratio to discriminate speech accurately. The individual has poor speech intelligibility under specific hearing conditions and may have a hearing loss or hearing impairment. Conversely, an individual with a significantly lower than average SRT value indicates that the individual can discriminate speech accurately at a relatively low signal-to-noise ratio, which implies that the individual has better speech intelligibility and auditory discrimination and may have better hearing ability. Table III shows the categorization of the listener characteristics.

Table II indicates the results from the baseline MBSTOI and the proposed method with three ways to reduce the dimension of the features. For wav2vec2, HuBERT, and wavLM, we extracted the output of the intermediate layer for each second of the speech signal. For instance, if a signal has a 5-second length, then we could extract 1024 $\times$ five dimensional feature. We utilized these features in three ways by 'mean value', 'concatenate', and 'concatenate + feature selection (512)'. The 'mean value' is performed by averaging the extracted feature based on the time stamp. Hence, we only have a vector with 1024 dimensions. The 'concatenate' means that we use all the extracted features, so a vector with 1024 $\times$ number of seconds (#sec.) dimension can be obtained. Lastly, the 'concatenate + feature selection (512)' means after the concatenation, we perform a univariate feature selection by selecting the 512 highest-scoring features based on the training data.

In most cases, the results in the table II have a higher correlation, lower RMSE, and lower SE, which indicates that the proposed method could achieve better results than the baseline MBSTOI. In addition to the higher correlation and lower RMSE, the proposed method could be regarded as a blind or non-intrusive method because the reference speech signal is not required for predicting speech intelligibility. Although the GeMAPS only consists of 62 dimensions, it could be utilized to achieve higher performance compared to the baseline method. The additional 26 extended parameters also positively contribute to improving the prediction accuracy. Comparing the performance of these low dimensional features to the recent state-of-the-art features, the wavLM could achieve the highest performance almost in all evaluation metrics used in the experiment. This finding aligns well with the prior research, which also showed that the wavLM performs better than wav2vec2 and HuBERT on all downstream speech processing tasks [25].

Observing the experiment results we conducted to reduce the feature dimension, we found that averaging the vectors obtained from each speech segment could achieve a higher

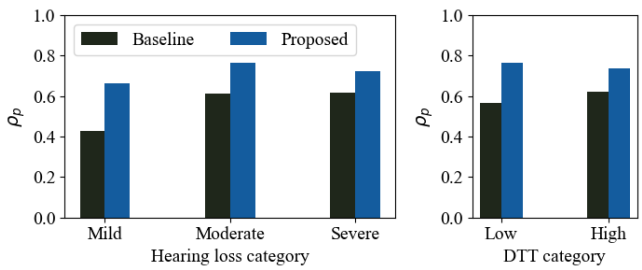

Fig. 3. Correlation analysis on the actual correctness and prediction results based on the listener characteristics: (Left) audiogram, (Right) digit triplet test (DTT)

prediction accuracy. For instance, by using the wavLM feature, the ρ_p of the proposed method (mean value) is 5% higher than the proposed method (concatenate). Similarly, the RMSE is smaller, and the R^2 is higher. The feature selection method in our experiment could not improve the prediction performance. For instance, the prediction by the feature selection using wav2vec2 and HuBERT caused a reduction in the correlation. At the same time, the results show no significant difference ($\rho > 0.05$) compared to those without feature selection.

An in-depth understanding of the hearing status allows for assessing the degree and type of hearing loss. An audiogram is a standard assessment tool that provides detailed information about hearing loss by plotting an individual's hearing levels at different frequencies and volume levels. Meanwhile, the SRT obtained from the DTT provides a direct and operational indicator of an individual's level of speech intelligibility in complex listening environments. Figure 3 shows the results grouped by the audiogram and DTT results. These results indicate that the proposed method could more accurately predict speech intelligibility in all categories of hearing loss conditions. Compared to the analysis of the results by audiogram and the DTT categories, the prediction using the DTT category shows a more stable speech intelligibility prediction for listeners with mild levels of hearing loss than the prediction grouped by the hearing loss category from audiogram.

While this research provides valuable insights into speech intelligibility prediction, we acknowledge certain limitations inherent in the study. First, the dataset used for training and evaluation may be limited and not fully represent the wide range of real-world listener conditions and noisy scene scenarios. To our knowledge, the CPC1 dataset is the only data that includes the DTT results. In the future, it is important to carry out more data collection for additional listeners on a broader range of scenes. Second, the study primarily focuses on the features used in common speech processing, such as in automatic speech recognition or emotion recognition, overlooking potential contributions from other important acoustic features or cues in speech intelligibility perception. For instance, the binaural hearing cues naturally utilized by human ears to recognize speech have yet to be considered. Future research should explore the incorporation of these cues to enhance the accuracy and robustness of speech intelligibility prediction models.

V. Conclusion

We proposed a method incorporating low-dimensional and state-of-the-art acoustic features for speech processing to predict speech intelligibility in noise for hearing aids. The prediction method was developed based on a stack regressor using various traditional machine learning regressors, including linear regressor, support vector regressor, and random forest regressor. Based on the overall results, the proposed method outperformed the previous method, particularly when utilizing wavLM features. The better performance is achieved with the help of the DTT input that is categorized based on the calculation of the average SRT of all listeners, representing speech intelligibility level. Since the proposed method does not require high computational power due to the low dimensional feature and relatively simple machine learning model, it can be considered as a baseline method before going through a further experiment using extensive machine learning models and sophisticated features for speech intelligibility prediction. In future work, we plan to further analyze the phenomena in hearing loss that both successfully and unsuccessfully restored by hearing aids and the effect on speech intelligibility perception.

***Abstract*—In the previous study, we proposed image acquisition and deep learning reconstruction using segmented phase-scrambling Fourier transform signals to improve the resolution of magnetic resonance images. Although the previous method achieved an effective resolution improvement for the reconstructed images, aliasing artifacts were generated in the reconstructed images because the segment width and segment skipping space of the previous segmented sampling were uniformly arranged. In this paper, we propose a new segmented signal sampling method in which the segment width and segment skipping space are non-uniformly arranged. Simulation experiments showed that the sampled signals in the proposed method were reconstructed in the deep learning reconstructions and that the qualities of the reconstructed images were compared with those of a uniform segmented signal quantitatively as well as perceptually to verify whether aliasing artifacts occurred. From the experimental results, it was confirmed that the proposed non-uniform segmented sampling could suppress aliasing artifacts while maintaining the reconstruction quality.**

I. Introduction

The magnetic resonance imaging (MRI) is an in-vivo imaging technique that can safely acquire intravital information at high resolution. However, the imaging procedure by MRI takes a long time, such as several tens of minutes. Therefore, accelerating the imaging process while maintaining high resolution is a critical issue for MRI. A super-resolution MRI method using phase-scrambling Fourier transform (PSFT) imaging was proposed by Ito et.al [1], [2]. PSFT [3], [4] is an imaging technique for MRI that applies quadratic phase modulation to the object and has useful features that are not found in Fourier transform (FT) imaging generally used in MRI, such as alias-free reconstruction [5], [6], superior image quality for compressed sensing (CS) [7]–[9]. The iterative algorithm of this super-resolution method is based on one proposed by Gerchberg [10] and estimates high-frequency signals by iterative extrapolation to a band-limited PSFT signal. This method does not sample the signal using a specific sampling pattern but instead restricts the sampling area of the signal domain. Therefore, this super-resolution method is considered to be a kind of acceleration of MRI.

Our previous study introduced a segment-wise signal sampling and skipping approach in which PSFT signals were divided into sub-bands and under-sampled in units of sub-bands to improve the super-resolution method [11]. Under-sampled signals called segmented PSFT signals could be interpolated between segments as well as extrapolated outside of segments. In addition, segmented sampling can obtain higher frequency sub-bands than band-limited sampling such as [1]. Thus, this method can be regard as CS-MRI [12], [13] using segmented sampling, and unrolling model-based deep learning reconstruction [14]–[17] can be used to improve the reconstruction quality. As a result, it was confirmed that the resolution improvement of the segmented sampling was higher than the band-limited sampling. However, aliasing artifacts were generated in the reconstructed images from segmented PSFT signals because the previous segmented sampling uniformly arranged the segment widths and skipping spaces and did not satisfy the incoherent sampling required for CS.

To solve this problem, a non-uniform segmented sampling method in which segment widths and skipping spaces are non-uniformly arranged is proposed to suppress the occurrence of aliasing artifacts in the reconstructed image. In this paper, three non-uniform segmented sampling patterns are described: a non-uniform segment width pattern, a non-uniform skipping space pattern, and non-uniform segment width and skipping space pattern. To verify the effectiveness of the proposed method, simulation experiments were conducted. From the simulation results, it was confirmed that the quality of reconstructed images without aliasing artifact was achieved by using non-uniform segmented sampling.

II. Phase-scrambling Fourier transform imaging

PSFT [3], [4] is a technique in which a quadratic field gradient $\Delta B = b(x^2 + y^2)$ is added to the pulse sequence of general-purpose FT imaging in MRI by synchronizing with the field gradient for phase encoding. The PSFT signal $v(k_x, k_y)$ is represented as follows:

$$v(k_x, k_y) = \iint_{-\infty}^{\infty} \left\{ \rho(x, y) e^{-j\bar{c}(x^2+y^2)} \right\} e^{-j(k_x x + k_y y)} dx dy, \tag{1}$$

where $\rho(x, y)$ represents the spin density distribution in the subject. $\bar{c}$ is the maximum phase modulation value. $\rho(x, y)$

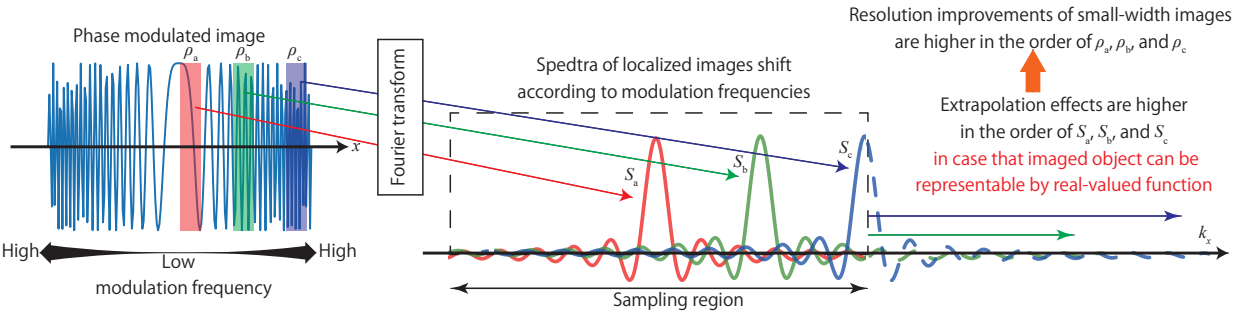

Fig. 1: Super-resolution principle of PSFT signal. ρ_a, ρ_b, and ρ_c are localized small-width images with quadratic phase modulation. The modulation frequencies are higher in the order of ρ_a, ρ_b, and ρ_c. The spectra obtained by applying FT to those small-width images are S_a, S_b, and S_c. Each spectrum is shaped symmetrically with respect to the peak, and the peak position of each spectrum shifts with modulation frequency. The spectra outside the sampling region can be estimated by extrapolation using the symmetrical feature of the spectra. The extrapolation effect is higher for larger shifts, and it is higher in the order of S_a, S_b, and S_c in this figure. Accordingly, the resolution improvements of small-width images are also higher in the order of ρ_a, ρ_b, and ρ_c.

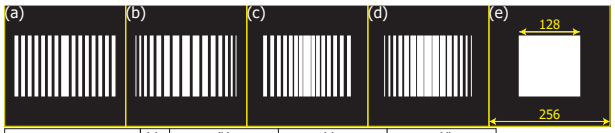
can be obtained by taking the inverse FT (IFT) of $v(k_x, k_y)$ and multiplying the signal obtained by applying IFT by the quadratic phase term $e^{j\bar{c}(x^2+y^2)}$. Since the phase of the object shifts quadratically in the x and y directions, the modulation frequency on the image function increases as the position from the origin of the image space increases, i.e.



$$\rho(x)e^{-j\bar{c}(x^2+y^2)} = \rho(x)e^{-j\{\omega(x)x+\omega(y)y\}}, \tag{2}$$

where $\omega(x) = \bar{c}x$ and $\omega(y) = \bar{c}y$. $\bar{c}$ can be written as $\bar{c} = \pi/(N\Delta x^2)$ from the relation $\Delta x(\partial\omega_x(x)/\partial x)|_{x=N\Delta x/2} = \pi$. In this paper, the phase modulation value c is controlled as follows:

$$c = h\bar{c}, \tag{3}$$

where h is the phase-scrambling parameter. Note that when $h = 0$, the PSFT signal $v(k_x, k_y)$ is equivalent to the FT imaging signal because $e^{-jhc(x^2+y^2)} = 1$. Two methods have been reported so far to acquire a PSFT signal from MRI. One is the addition of coils that generate a quadratic field gradient [6], and the other is the application of frequency modulation to radio frequency pulses while applying a linear field gradient [3].

Consider the phase modulated 1D image and the localized small-width images ρ_a, ρ_b, and ρ_c on its 1D image, as shown in Fig. 1. The spectra of localized images S_a, S_b, and S_c shift in k-space in accordance with the modulation frequency $\omega(x)$, and the shape of each spectrum is symmetric with respect to its peak. $\omega(x)$ is the lowest in the center of the image and increases with increasing distance from the center. When it is assumed that the imaged object can be represented as a real-valued function, the spectrum can be extrapolated to make it symmetric with its peak, which is similar in the half Fourier encoding method [18]. Consequently, the extrapolation effects are higher in the order of S_a, S_b, and S_c, and the resolution improvements are also higher in the order of ρ_a, ρ_b, and ρ_c.

	(a)	(b)	(c)	(d)
number of segments N	15			
width of center segment w_0	16			
widths n-th segment w_n	8	$w_0 - 2n\ (1 \le n \le 7)$	8	$w_0 - 2n\ (1 \le n \le 7)$
n-th skipping spaces s_n	6	6	$n\ (1 \le n \le 7)$	$n\ (1 \le n \le 7)$

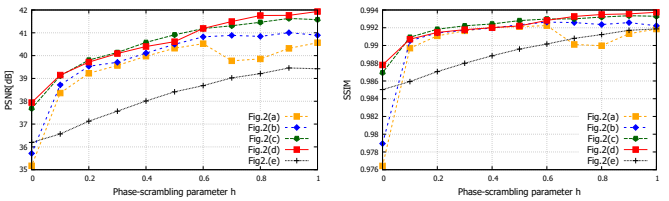


Fig. 2: Uniform and non-uniform segment-based sampling patterns. (a) is the uniform segmented pattern proposed in previous study. (b), (c), and (d) are non-uniform segmented patterns proposed in this study. (b) has non-uniform widths of segments and (c) has non-uniform skipping spaces between segments. (d) is non-uniform segmented pattern both in segment widths and skipping spaces. (e) is the band-limited pattern proposed by Ito et al. [1].

The pattern sizes are 256×256, and the number of under-sampled signals on each pattern is $128 \times 128 = 16384$ points, i.e. the sampling rate is 25%. The phase encoding direction is the horizontal direction.

III. Non-uniform segmented sampling

In the previous study [11], an image reconstruction method that uses segmented PSFT signals was proposed. This method regarded the reconstruction from segmented PSFT signal as an optimization problem of CS. To enhance the resolution improvement effect, Generic-ADMM-Net [14] unrolling alternating direction method of multipliers (ADMM) [19] was used as the deep learning based reconstruction method instead of iterative reconstruction methods. As a result, the resolution of the reconstructed image was higher than that of a band-limited PSFT signal. However, aliasing artifacts were generated in the reconstructed image in our previous study [11] when the phase-scrambling parameter h was the specified values because the segmented sampling pattern was uniform, as show in Fig. 2(a).

To solve this problem, 3 kinds of non-uniform segment-based sampling patterns, as shown in Fig. 2(b) to (d), are

(a) PSNR (b) SSIM

Fig. 3: Evaluation scores of reconstructed images by Generic-ADMM-Net. Abscissa and ordinate are the phase-scrambling parameter h for PSFT and evaluation score of each graph, respectively. Evaluation scores of $h = 0$ on the graphs indicate the results of reconstructing FT imaging signal.

TABLE I: PSNRs[dB] of reconstructed images by ISTA-Net and Generic-ADMM-Net. FT and PSFT denote reconstructions from FT imaging and PSFT signals ($h = 1.0$), respectively. The higher image reconstructed from the FT and PSFT signals under-sampled by the same pattern is underlined. For each reconstruction method, the highest PSNR is bolded.

Usage	ISTA-Net		Generic-ADMM-Net	
patterns	FT	PSFT	FT	PSFT

Fig.2(b)	31.17	31.82	35.71	40.89
Fig.2(c)	33.13	35.17	37.68	41.57
Fig.2(d)	35.14	**35.49**	37.94	**41.93**

proposed. Those non-uniform segment patterns are determined to be non-uniform segment widths and skipping spaces under the condition that the sampling rate, number of segments, and width of the center segment will be the same as Fig. 2. Let w_0 be the width of center segment and N the number of segments. When the right and left segments are symmetrical in segment widths and skipping spaces with the center segment and the number of right segments is equal to the number of left segments, as shown in Fig. 2, the number of segments on one side $\hat{N} = \frac{N-1}{2}$ is an even number. To satisfy the above conditions, the width of n-th segment w_n and n-th skipping space s_n ($1 \leq n \leq \hat{N}$) are determined as follows:

$$w_n = w_0 - \alpha n, \tag{4}$$

$$s_n = \beta n, \tag{5}$$

where α and β are constants for determining the segment width and skipping spacing, respectively. Note that s_n is a space between the n-th segment and the $n-1$-th segment. In this study, we set $w_0 = 16$, $N = 15$, $\alpha = 2$, and $\beta = 1$.

IV. Experimental Results and Discussion

To verify the effectiveness of the proposed non-uniform segmented patterns, simulation experiments were conducted. In this simulation, PSFT signals generated from the MR images were regarded as the signals acquired from the MRI and were under-sampled by using the sampling patterns of Fig. 2. Note that $\bar{c}$ of Eq. 1 is set to 0.614 in this paper because this simulation assumes super-resolution from the under-sampled 128×128 data to 256×256 data. The used images were 570 T2-weighted MRI images of the head (of volunteers who gave consent) from the IXI Dataset [20] and 400 and 170 images were randomly selected for training and testing, respectively. The deep learning reconstruction methods were two unrolling-based deep learning methods, namely, Generic-ADMM-Net [14] and ISTA (Iterative Shrinkage-Thresholding Algorithm)-Net [16]. For training parameters of the two methods, the input size, the number of epochs, the activation function, and the optimizer were set to 256×256, 300, Rectified Linear Unit (ReLU), and Adam [21], respectively. In evaluating the quality of the reconstructed images, the peak signal-to-noise ratio (PSNR) and the structural similarity index measure (SSIM) [22] were used. The simulation was conducted on a computer with an Intel® Core™ i9-11900K CPU (3.5 GHz), 64 GB of RAM, and an NVIDIA GeForce RTX 3090 GPU running Windows 10. The software used was Python 3.7.9, PyTorch 1.11.0, and CUDA ToolKit 11.3. The training times under the above conditions were about 45 minutes on Generic-ADMM-Net and about 2 hours on ISTA-Net.

As shown in Fig. 3, PSNRs and SSIMs of the reconstructed images by using the proposed segmented patterns shown in Fig. 2(b)-(d) are higher than the uniform segmented patterns of Fig. 2(a) in any h. Comparing Fig. 2(b) and (c), (c) has higher scores than (b). Therefore, the reconstruction is improved with non-uniform skipping spaces rather than widths. Furthermore, it is effective to make both widths and skipping spaces non-uniform.

Table I shows the PSNRs using another deep learning method, i.e. ISTA-Net. Even if ISTA-Net is used, the reconstructed images from the under-sampled PSFT signal is also better than under-sampled FT signal except for Fig 2(a). It could be confirmed that non-uniform skipping spaces produced a more effective reconstruction than non-uniform segment widths, and the reconstructed image from the under-sampled PSFT signal by Fig. 2(d) had the highest PSNR. Hence, the non-uniform segmented patterns proposed in this paper can be effective regardless of the unrolling-based deep learning methods.

Fig. 4 shows the reconstructed images and their error maps. The reconstructed images of Fig. 4(c)-(f) had better qualities than the zero-filling image of (b). However, there was a smoothing effect in low luminance regions compared to the full-data, as shown in the enlarged views of Fig. 4(c) and (e). In contrast, the reconstructed image in Fig. 4(d) and (f) does not show smoothing effects like (c) and (e) and are similar to the full-data. In comparison to the error maps in Fig. 4(g)-(k), the error maps of (i) and (k) have smaller errors than (g), (h), and (j). Comparing error maps of Fig. 4(i) and (k), the errors in the central region of (i) are comparable to those of (k), whereas the errors in the outside region of (i) are high. Meanwhile, it is clear that the errors in the outside region of Fig. 4(k) are smaller than other error maps. In other words, the non-

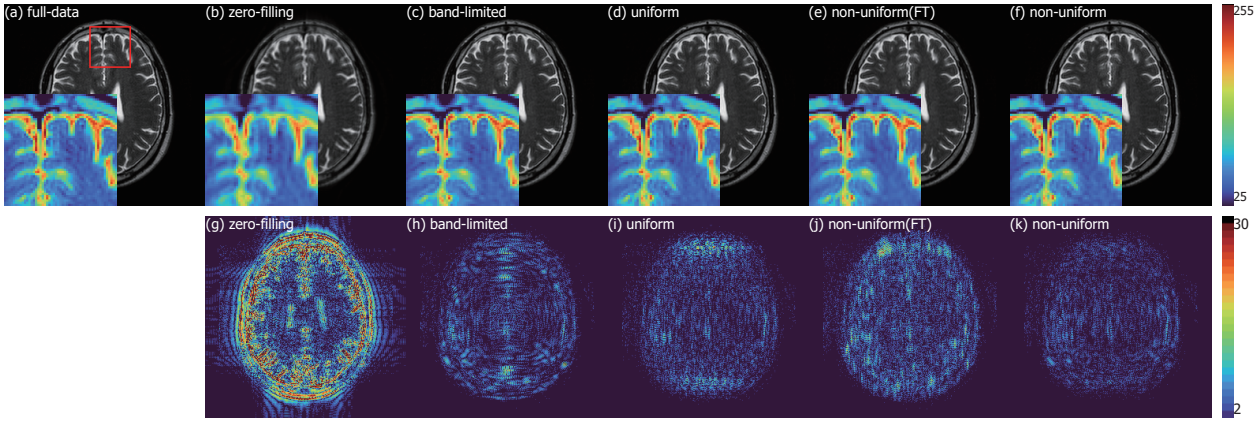

Fig. 4: Reconstructed images by Generic-ADMM-Net and their error maps. Upper row images show full-size images (256×256 pixels) and enlarged views of areas indicated by a red rectangle. Bottom row images show error maps of (b)-(f). (a) shows full-data image. (b) and (c) are zero-filling and reconstructed images from a band-limited PSFT signal, respectively. (d) shows a reconstructed image from under-sampled PSFT signal by the uniform segmented pattern shown in Fig. 2(a). (e) and (f) show reconstructed images from under-sampled FT and PSFT signals by the non-uniform segmented pattern of Fig. 2(d), respectively. h of (b), (c), (d), and (f) is set to 1.0. In (g)-(k), pixels of each error map show the absolute difference between pixels at the same location in the full-data and reconstructed images.

uniform segmented pattern could improve the resolution of the outside region of the reconstructed image without sacrificing the resolution of the central region of the reconstructed image.

Fig. 5 shows profiles of reconstructed PSFT signals and their errors. Comparing the full-data and each reconstructed signal, both Fig. 5(d) and (f) are almost reconstructed to the same profile as the full-data, and it is possible to estimate the unsampled signals from the under-sampled signal shown in Fig. 5(b) and (c). In contrast, the reconstructed signal using the uniform segmented pattern of Fig. 5(d) has large errors at regular intervals, as shown in Fig. 5(e), with particularly large errors in the low-frequency bands such as when the signal index is between 9 and 14. These errors which are regularly generated correspond to the part of the signals not sampled, as shown in Fig. 5(b). The reasons for these errors are considered. The under-sampled signals using the uniform segmented pattern have high coherence, thus introducing aliasing artifacts. In this study, no visible artifacts were observed in the reconstructed images from uniform segmented under-sampled signals by using the deep learning reconstruction method. However, the reason for the errors shown in Fig. 5(e) in the reconstructed signals is considered to be that the aliasing artifacts could not be completely removed even with the deep learning reconstruction method.

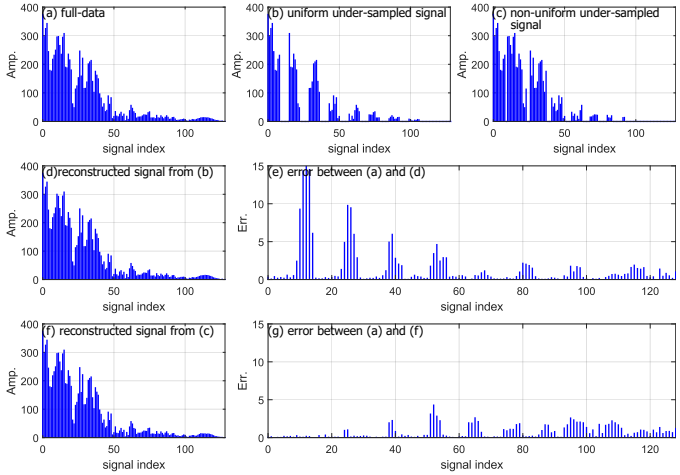

Fig. 5: PSFT signals of reconstruct images. Each profile shows the 127-th row of PSFT signal spectra calculated from Fig. 4(a), (d), and (f). (a) shows full-data signal and (b) and (c) show under-sampled signals using uniform and non-uniform patterns, respectively.(d) and (f) are the reconstructed signals from (b) and (c), respectively. (e) and (g) are errors between full-data and each reconstructed signal.

On the other hand, the errors of the reconstructed signals using the non-uniform segmented pattern shown in Fig. 5(g) were less than 5. In particular, the errors in the low frequency band with a signal index of 20 or less were very small. This is because the non-uniform segmented pattern samples the low-frequency band more densely than uniform segmented pattern. In addition, since the under-sampled signal using the non-uniform segmented pattern is incoherent, the unrolling model-based deep learning reconstruction such as Generic-ADMM-Net seems to perform effectively. However, the errors in the high-frequency band of Fig. 5(g) are slightly larger than those of (e) because the sampling rate in the high-frequency band of the non-uniform segmented pattern is less than that of the uniform segmented pattern. To solve this problem, it is necessary to construct a pattern that can increase the amount of under-sampled signals from the high-frequency band while maintaining the non-uniformity of the segment width and skipping spacing.

V. Conclusion

In this paper, we proposed a segmented sampling pattern in which both the segment widths and skipping spaces were non-uniform to suppress the occurrence of aliasing artifacts and improve the image reconstruction by deep learning reconstruction methods. From the experimental results, it was confirmed that the reconstructed images from under-sampled PSFT signals according to the proposed non-uniform segmented pattern had higher quality than those of the previous uniform segmented pattern regardless of the specific deep learning reconstruction method. Future work will include a validation of the effectiveness of the proposed pattern for complex images including a phase component.

***Abstract* — Depression, a pervasive mental health ailment impacting millions globally, necessitates precise and intelligible predictive methodologies. Physicians encounter formidable hurdles when screening large populations. Despite a plethora of proposed Artificial Intelligence (AI) techniques for depression prediction, creating transparent models remains a formidable challenge. In this investigation, we confront this challenge by constructing prediction models grounded in diverse machine-learning algorithms and employing the Hybrid Feature Selection (HFS) approach, fusing statistical hypothesis tests and LASSO. This process facilitates the identification of pivotal features enhancing the predictive model's efficacy. Consequently, the chosen features serve as inputs for our predictive model, enabling us to harness their predictive potential and delve into their connection with the depression target variable. The ensemble of models encompassed Extreme Gradient Boosting (XGBoost), Light Gradient Boosting, Gradient Boosting, CatBoost, Ada Boost, Linear Discriminant Analysis, Ridge, Random Forest, Extra Trees, Logistic Regression, Decision Tree, K-Neighbors, Naive Bayes Gaussian, and Naive Bayes Bernoulli. These models underwent rigorous evaluation utilizing the Korea National Health and Nutrition Examination Survey (KNHANES) datasets. Our findings reveal that the XGBoost model outperformed its counterparts, achieving the highest accuracy (0.871), AUC (0.927), and F1 Score (0.673). Furthermore, our model sheds light on the intricate relationship between input variables and the predicted outcome, quantifying the influence of each input variable on the result.**

Keywords— machine-learning, Depression, Hybrid Feature Selection, LASSO, XGBoost

I. INTRODUCTION

Depression is a debilitating mental health disorder that affects millions of individuals worldwide. There is a wide range of physical and cognitive symptoms associated with depression, including persistent feelings of sadness and loss of interest or pleasure in activities. Depression can have a significant impact on an individual's daily functioning, quality of life, and overall well-being. Understanding the prevalence, causes, and consequences of depression is crucial for effective prevention, early intervention, and treatment strategies. Depression is a widespread global health issue, with substantial prevalence rates across different populations. According to the World Health Organization (WHO), an estimated 264 million people of all ages suffer from depression worldwide [1]. This staggering figure highlights the magnitude of the problem and the urgent need for effective interventions. Anal the impact the epidemiological data further reveals important insights into the distribution and impact of depression. It is worth noting that depression is more commonly diagnosed in women than in men [2]. Additionally, depression often manifests in early adulthood, with the median age of onset being around 32 years [3]. The disorder can persist chronically or recur episodically throughout an individual's lifespan, leading to long-term impairment and reduced productivity. Research on depression has provided valuable insights in to its multifactorial etiology. The disorder is believed to result from a complex interplay of genetic, biological, environmental, and psychosocial factors. Genetic studies have identified certain genetic variations associated with an increased risk of developing depression [4]. Furthermore, imbalances in neurotransmitters such as serotonin, norepinephrine, and dopamine have been implicated in the pathophysiology of depression [5]. Psychosocial factors, such as stressful life events, childhood trauma, and chronic psychosocial stress, can also contribute to the development and exacerbation of depression [6]. Socioeconomic factors, including low income, unemployment, and limited access to mental healthcare, further compound the burden of depression [7]. In terms of treatment, a range of interventions is available, including psychotherapy, pharmacotherapy, and lifestyle modifications. However, the effectiveness of these treatments can vary depending on individual characteristics and the severity of the depressive symptoms [8]. The experimental results show that the proposed XGBoost model predictive performance while also providing interpretability between input and output. Our model was evaluated against various high-performing machine learning benchmarks including Extreme Gradient Boosting (XGBoost), Light Gradient Boosting, Gradient Boosting, CatBoost, Ada Boost, Linear Discriminant Analysis, Ridge, Random Forest, Extra Trees, Logistic Regression, Decision T

ree, K-Neighbors, Naive Bayes Gaussian, and Naive Bayes Bernoulli.

The main contributions of this work are the proposal of a framework that combines Extreme Gradient Boosting (XGBoost) with Hybrid Feature Selection (HFS) to explore the input-target relationship for depression prediction. Our model demonstrated superior predictive performance, outperforming all evaluated models, with an accuracy of approximately 0.892, AUC of 0.9268, and F1 Score of 0.6729 on the KNHANES datasets.

The findings presented in this study carry significant implications, especially concerning public health outcomes associated with depression. This paper is structured as follows: Section 1 introduces depression, Section 2 discusses related work, Section 3 presents the materials and methods employed, providing comprehensive details on the dataset and overall experimental results, including the configuration and construction process. Section 4 elaborates on the procedure, and Section 5 concludes the paper.

II. RELATED WORK

Artificial Intelligence (AI) has long been proposed as a valuable tool for clinical decision-making in healthcare. In recent years, the use of AI in the healthcare industry has been on the rise, particularly in the development of predictive models for diagnosing and forecasting depression illnesses and diseases. One important area of investigation is the identification of factors associated with depression. Several studies have highlighted the role of genetic factors in susceptibility to depression. For instance, a study by Sullivan et al. (2018) identified specific genetic variations that contribute to an increased risk of developing depression [9]. These findings have shed light on the biological underpinnings of the disorder and have the potential to inform personalized treatment approaches. Psychotherapy, including Cognitive-Behavioral Therapy (CBT) and InterPersonal Therapy (IPT), has also demonstrated effectiveness in the treatment of depression [10]. These therapeutic approaches focus on identifying and modifying maladaptive thought patterns and improving interpersonal relationships, respectively. Additionally, alternative, and complementary therapies, such as mindfulness-based interventions and exercise, have shown promise as adjunctive treatments for depression [11]. Treatment optimization has also been an area of interest. AI and ML algorithms have been used to personalize treatment plans by analyzing patient characteristics, treatment history, and response data. These models can assist in selecting the most suitable intervention, adjusting medication dosages, and optimizing therapy regimens to improve treatment outcomes [12,13]. Additionally, Natural Language Processing (NLP) techniques have been employed to analyze text data, such as social media posts, online forums, and electronic medical records, to gain insights into individuals' experiences with depression and inform mental health interventions [14,15]. By extracting sentiment, linguistic patterns, and thematic information from text, researchers have explored novel ways of understanding the lived experiences of individuals with depression and tailoring interventions accordingly.

III. MATERIALS AND METHODS

The procedures are applied to meet the objectives of this study into three phases (Figure 1). The first phase is concerned with the observation and collection of data and generating training and testing patterns to build features. The second phase is about designing building the prediction model. The last phase includes the predictive performance evaluation measurements and comparison between other benchmark machine learning models.

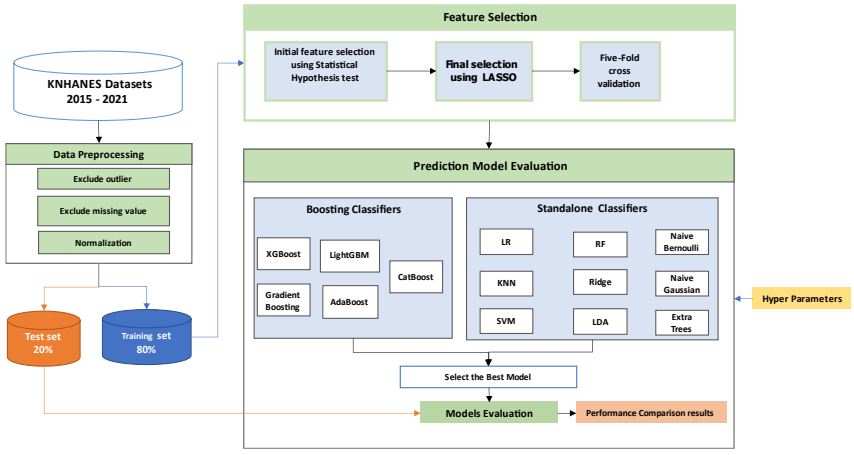

Fig. 1 Experimental design of comparative for hypertension diseases prediction.

A. Data and Preprocessing

The Korea National Health and Nutrition Examination Surv ey (KNHANES) dataset is administered by the Korea Centers for Disease Control and Prevention (KCDC), which publish th e Korea health statistics annually, and microdata are publicly a vailable through the KNHANES website (http://knhanes.cdc.g o.kr) [16]. The dataset includes a broad range of health examin ations of various numbers of diseases, health interviews, nutrit ion surveys, demographic, socioeconomic, dietary, and health- conditions, totaling over 361 features. In this study, we distrib uted across all features from a total of 51,570 individuals' data collected between 2015 and 2021. However, the dataset holds several missing values and outliers that demand attention. Stat istical power is reduced by missing values, and parameters are inaccurately estimated as a result. To produce complete data f or analysis, there are several methods to deal with missing dat a. To prevent model complications, we excluded all the missin g values and outliers. Based on the interquartile range, outliers were removed from the data. apply Hybrid Feature Selection (HFS) to selecting significant features, Furthermore, these sele cted features serve as inputs for the predictive model. To ident ify the most relevant features, we applied the Hybrid Feature S election (HFS) method, which combines statistical hypothesis tests and the least absolute shrinkage and selection operator (L ASSO). This process helped us select significant features that contribute to the predictive model's performance. Subsequentl y, the selected features were utilized as inputs for our predictiv e model, allowing us to leverage their predictive power and ex plore the relationship between these features and the target var iable of depression.

B. Classification Algorithms

The experimental results evaluate various high-performing machine learning benchmarks, including Extreme Gradient Bo osting (XGBoost), Light Gradient Boosting, Gradient Boostin g, CatBoost, Ada Boost, Linear Discriminant Analysis, Ridge, Random Forest, Extra Trees, Logistic Regression, Decision Tr ee, K-Neighbors, Naive Bayes Gaussian, and Naive Bayes Ber noulli. Extreme Gradient Boosting (XGBoost) is a powerful machine learning algorithm that combines the advantages of gradient boosting and random forests. It iteratively trains an ensemble of weak decision tree models, where each subsequent model corrects the errors made by the previous ones. XGBoost is known for its scalability, speed, and ability to handle large and complex datasets [17]. Light Gradient Boosting Machine (LightGBM) is another gradient boosting framework that aims to achieve high efficiency and low memory usage. It utilizes a novel tree-building algorithm called Gradient-based One-Side Sampling (GOSS), which selects the most informative samples for growing trees. LightGBM is particularly suitable for large-scale and high-dimensional problems [18]. Gradient Boosting is a general machine learning algorithm that builds an ensemble of weak models in a sequential manner. Each model focuses on correcting the mistakes made by the previous ones. By combining multiple weak models, gradient boosting can create a strong predictive model. It is widely used in various domains and has proven to be effective in many applications [19]. CatBoost is a gradient boosting algorithm that is specifically designed to handle categorical features effectively. It uses a novel approach called ordered boosting, which combines a set of decision trees in a particular order to exploit the inherent order in categorical features. CatBoost is known for its robustness, accuracy, and ability to handle high-cardinality categorical variables [20]. Adaptive Boosting (AdaBoost) is an ensemble learning algorithm that iteratively combines multiple weak models to create a strong model. It assigns weights to the training instances and adjusts them based on the performance of the previous models. AdaBoost focuses on misclassified instances, making it particularly suitable for tasks with imbalanced classes [21]. Linear Discriminant Analysis (LDA) is a statistical technique used for dimensionality reduction and classification. It seeks to find a linear combination of features that maximally separates different classes while minimizing the within-class scatter. LDA assumes that the data follows a Gaussian distribution and that the classes have equal covariance matrices. It is widely used for pattern recognition and feature extraction [22]. Ridge regression is a linear regression technique that incorporates a penalty term to regularize the model. It adds a term proportional to the square of the coefficients to the loss function, which encourages smaller and more balanced coefficient values. Ridge regression helps prevent overfitting and can handle multicollinearity in the input features [23]. Random Forest is an ensemble learning method that constructs a multitude of decision trees and combines their predictions through voting or averaging. Each tree is trained on a random subset of the training data, and the final prediction is determined by aggregating the individual tree predictions. Random Forests are robust against overfitting, can handle high-dimensional data, and provide feature importance measures [24]. Extra Trees (Extremely Randomized Trees) is another ensemble learning method similar to Random Forests. It builds multiple decision trees using random subsets of features and random thresholds for splitting nodes. Extra Trees

further randomizes the tree construction process by selecting the splitting thresholds at random, without optimization. This randomness often leads to faster training times compared to Random Forests [25]. Logistic Regression is a linear classification algorithm used to model the probability of binary or multiclass outcomes. It uses the logistic function to map the linear combination of features to a probability value. Logistic Regression is widely used in various fields, particularly in cases where interpretability and simplicity are desired [26]. Decision Trees are non-parametric machine learning algorithms that create a flowchart-like model of decisions and their possible consequences. Each internal node represents a feature or attribute, and each leaf node represents a class label or a decision outcome. Decision Trees are interpretable, handle both numerical and categorical data, and can capture non-linear relationships [27]. K Nearest Neighbors (KNN) is a non-parametric classification algorithm that classifies new instances based on their similarity to known instances in the training data. It assigns the class label based on the majority class among its K-nearest neighbors in the feature space. KNN is simple, flexible, and often used for pattern recognition and recommendation systems [28]. Naive Bayes Gaussian is a variant of the Naive Bayes algorithm that assumes the continuous features in the dataset follow a Gaussian (normal) distribution. It uses the Gaussian probability density function to estimate the likelihood of each feature value given in the class. Naive Bayes Gaussian is particularly useful when dealing with continuous data and can handle high-dimensional feature spaces efficiently [29]. Naive Bayes Bernoulli is another variant of the Naive Bayes algorithm that assumes the features are binary or follow a Bernoulli distribution (taking values of 0 or 1). It models the likelihood of each feature value being 1 or 0 independently for each class. Naive Bayes Bernoulli is commonly used in text classification tasks, where binary features represent the presence or absence of certain words in documents [30].

C. Experimental Setup

To optimize the hyper-parameters of various machine learning classifiers, a random search approach was employed using 5-fold cross-validation. The resulting optimized hyper-parameter settings for the baseline classifiers are summarized in Table 1.

D. Evaluation Metrics

For evaluating the NCDs prediction model were trained and evaluated using five-fold cross-validation in this study. The performance of different algorithms for the testing dataset is

Table 1. Searching Space of Hyper-parameters

Model	Parameters	Search Space
Random Forest	adept	(2, 8)
	min_samples_split	(1, 8)
	min_samples_leaf	(1, 8]
	criterion	{'gini,' 'entropy'}
	bootstrap	{True, False}
AdaBoost	learning_rate	(0.1, 1)
	algorithm	{'SAMME.R,' 'SAMME'}
XGBoost	min_child_weight	(1, 10)
	gamma	{0, 0.1, 0.5, 0.8, 1}
	subsample	{0.5, 0.75, 0.9}
	colsample_bytree	{0.5, 0.6, 0.7, 0.8, 0.9, 1}
	max_depth	{2, 8}
	learning_rate	{0.01, 0.1, 0.2, 0.3, 0.5}
LightGBM	min_child_samples	(10, 60)
	reg_alpha	{0, 0.1, 0.5, 0.8, 1}
	subsample	{0.5, 0.75, 0.9}
	colsample_bytree	{0.5, 0.6, 0.7, 0.8, 0.9, 1}
	max_depth	(2, 8)
	learning_rate	{0.01, 0.1, 0.2, 0.3, 0.5}
CatBoost	min_child_samples	(10, 60)
	subsample	{0.5, 0.75, 0.9}
	colsample_bytree	{0.5, 0.6, 0.7, 0.8, 0.9, 1}
	max_depth	(2, 8)
	learning_rate	{0.01, 0.1, 0.2, 0.3, 0.5}

evaluated after the completion of the training phase and was compared using the following performances the confusion matrix for a binary classification problem. As a consideration of this provided information of confusion matrix, performance metric such as accuracy, precision, recall, Specificity, F-measure, and ROC area [31] and [32] which are computed by Eq.1-4. Accuracy is a measure that indicates the proportion of correct results, which includes both true positive and true negative results, in a selected population.

$$Accuracy = \frac{(TP + TN)}{TP + TN + FP + FN} \quad (1)$$

Sensitivity is a measure that represents the probability of a diagnostic test correctly identifying patients who have the disease.

$$Sensitivity\ (Recall) = \frac{TP}{(TP + FN)} \quad (2)$$

Specificity is a measure that represents the probability of a diagnostic test correctly identifying individuals who do not have the disease without giving false-positive results.

$$Specificity = \frac{TN}{(TN + FP)} \quad (3)$$

Precision represents positive predictive value.

$$Precision = \frac{TP}{(TP + FP)} \quad (4)$$

ROC graphs are two-dimensional graphs in which TP rate is plotted on the Y axis and FP rate is plotted on the X axis. An ROC graph depicts relative tradeoffs between benefits (true positives) and costs (false positives) [32].

IV. EXPERIMENTAL RESULT AND ANALYSIS

As illustrated in Figure 1, the proposed experimental design involves three distinct components: (I) data preprocessing (II) features selection and cross validation (III) comparison of machine learning classifiers for the prediction models of Depression. To demonstrate the effectiveness of our proposed model, we compare it to high-performing machine learning benchmarks. We evaluate the model's performance on the test set using three key metrics: area under the curve (AUC) and accuracy and F1 score.

A. The Results of Hybrid Feature Selection

The initial stage of the Hybrid Feature Selection (HFS) process involves utilizing t-test statistical hypothesis tests to determine the null or alternative hypothesis, thereby selecting significant features. Moving on to the second stage of HFS, the least absolute shrinkage and selection operator (LASSO) plays a crucial role in enhancing the predictive capability of models by eliminating irrelevant features that hold no relevance to the target classes. Consequently, these features were eliminated by assigning them to a coefficient of zero. By employing the second stage HFS method, we were able to select a representative set of 32 features from the KNHANES dataset. Furthermore, these selected features serve as inputs for the predictive model.

B. Comparison Results

In this section, the efficient An Extreme Gradient Boosting-based Approach (XGBoost) framework for Depression Disease Prediction is compared with baseline models including Logistic Regression, Support Vector Machines (SVM), K-Nearest Neighbors (KNN), Naive Bayes Gaussian, Naive Bayes Bernoulli, Random Forest, Gradient Boosting, AdaBoost, and LightGBM. The performance of these models is evaluated using the KNHANES dataset and the evaluation metrics used are classification accuracy and area under the Receiver Operating Characteristic Curve (AUC). The data is split into 80%for the training set and 20% for the evaluation set. A 5-fold stratified cross-validation procedure is applied to the training set to prevent overfitting. In this procedure, the dataset is randomly partitioned into five parts, and four folds of the training sets are used to train classification models while the remaining fold is used to validate the model. Table 2 shows the performance of all predictive models in the KNHANES dataset. The XGBoost model achieved the highest accuracy of 0.871 AUC 0.927, and F1 Score 0.673, Naive Bayes Gaussian had lower accuracy scores but still performed reasonably well with accuracy.

Table 2. Performance Comparison of Machine Learning Models

Model	Accuracy	AUC	F1
Extreme Gradient Boosting	**0.871**	**0.927**	**0.673**
LightGBM	0.869	0.925	0.668
Gradient Boosting	0.866	0.923	0.655
CatBoost	0.862	0.918	0.649
Ada Boost	0.861	0.918	0.642
Linear Discriminant Analysis	0.859	0.913	0.649
Ridge	0.858	0.661	0.619
Random Forest	0.855	0.913	0.609
Extra Trees	0.852	0.907	0.599
Logistic Regression	0.838	0.885	0.551
Decision Tree	0.808	0.711	0.541
K-Neighbors	0.784	0.705	0.550
Naive Bayes Gaussian	0.762	0.671	0.424
Naive Bayes Bernoulli	0.776	0.509	0.344

C. Model Interpretability

In this section, we will delve into the interpretation of the XGBoost model employed in our study. Our model enables us to determine the impact of each variable on the model's output, as illustrated in Figure 2. For instance, if age increases, the probability of depression also tends to increase. The features are ordered based on their effects on the prediction, from the highest to the lowest. To ensure interpretability of the XGBoost model in predicting depression among the Korean population, the features were sorted in ascending order of their importance scores. Figure 3 showcases the most useful features identified for depression prediction in the Korean population, including age, age of onset of smoking (BS2_1), frequency of female bullying (BD2_32), body mass index (HE_BMI), and gender. Furthermore, we explored the relationship between these features and the target variable of depression. It is evident that age and gender have a significant association with the target variable. Specifically, being an older male is associated with higher values of the target variable, indicating a higher likelihood of depression. These findings provide valuable insights into the factors that contribute to depression prediction in the Korean population. The identified features shed light on the demographic, behavioral, and physical factors that play a crucial role in understanding and predicting depression.

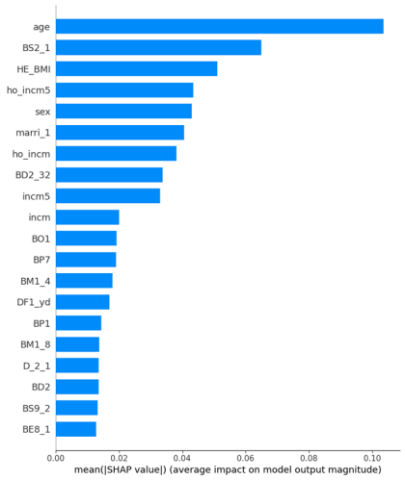

Fig. 2 Illustrates the 20 features that significantly contribute to the models.

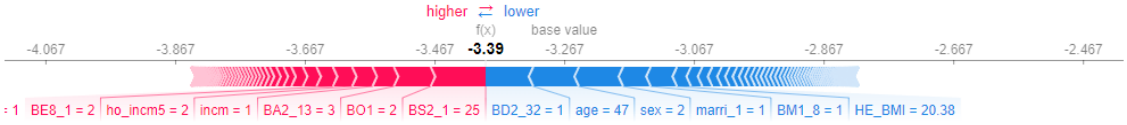

Fig. 3 Features and influence on predicted label for depression.

CONCLUSION

In conclusion, depression presents itself as a significant global public health concern and a primary contributor to suicide rates. Despite the introduction of artificial intelligence techniques for predicting depression risk, the integration of interpretable models remains a formidable hurdle. Our study has illuminated the XGBoost model's capacity to achieve superior predictive performance in comparison to numerous models using the expansive KNHANES dataset, while also offering partial interpretability between input and output variables. Nonetheless, working with the extensive KNHANES datasets required employing a hybrid feature selection (HFS) approach to pinpoint vital features, limited it may still fall short in comprehensively unraveling the intricate nature of depression. Depression's roots are entwined with numerous factors, including genetics, environment, and cultural influences, which these datasets may not fully encompass. Consequently, the model's applicability across diverse populations and contexts may be limited. Furthermore, there exists an opportunity to augment the model's interpretability to delve deeper into the relationship between input and output variables. The proposed XGBoost model harbors the potential to refine the accuracy of depression diagnosis and contribute to a more profound comprehension of this vital domain in public health. Nevertheless, it remains crucial to acknowledge these limitations as we persist in advancing our understanding and management of depression.

***Abstract* — Bioresearch data primarily contain private identifiable information. Thus, to ensure personal information protection, anonymization is required throughout the data collection and storage phases, which necessitates significant efforts to prevent errors. This paper proposes a code system ideally suited for replacing personal identification numbers with unique identifiers. The study further explores a check digit algorithm optimized for minimizing identification errors. The participant identification number, which plays a crucial role in the integrated management of bioresearch data, comprises 10 digits, with the last one serving as the check digit for validating the accuracy of the identification number. Among check digit algorithms available for participant identification number systems, the Verhoeff algorithm has demonstrated superior error detection performance compared to other algorithms. Simulations and applications of the coding system confirmed that the proposed method effectively anonymizes personal identification information with improved accuracy. The method is highly applicable to various scenarios involving the collection and storage of bioresearch data.**

I. INTRODUCTION

Personal data and identity protection are globally recognized as crucial issues. In particular, bioresearch data usually contain personally identifiable information, which when inappropriately disclosed can result in privacy infringement or criminal misuse, with significant socioeconomic impact on individuals [1].

In South Korea, these issues are addressed under the Bioethics and Safety Act. This legislation regulates the permanent deletion of personal information from human biological material donors, promoting anonymization through replacement with an institution-specific identifier (Article 2, Clause 19). Anonymization is mandated throughout all data processing phases when the donor does not provide consent for the inclusion of personal information (Articles 38 and 42–44). Similarly, the Personal Information Protection Act defines "pseudonymized information" as "personal information that is pseudonymized, making it impossible to identify a particular individual without the use/combination of additional information for its restoration to the original state" (Article 2, Clause 1). Anonymized or pseudonymized information serves as a legal and institutional framework for replacing personally identifiable information with unique identifiers either entirely or partially, to prevent donor identification. Within this legal framework, Korean biobanks issue identification numbers generated by anonymization algorithms to ensure personal information protection while collecting and storing human biological materials, genetic information, epidemiological information, and clinical data. These unique identification numbers can be reverse-converted to participant identification numbers by authorized personnel or committee(s). Such an identification number system plays a vital role in data sharing and linkage among healthcare providers and government entities, when providing human biological materials and data to researchers.

Although the accurate identification of each participant is crucial when collecting biological specimens and conducting epidemiological surveys, errors cannot be completely avoided despite careful research design and strict adherence to protocols [2]. The Laboratory Accreditation Checklists of the College of American Pathologists in the United States mandate two patient identifiers prior to specimen collection [3]. However, patient misidentification during laboratory testing remains a significant cause of medical errors [4].

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

Identification errors can occur at any stage of a diagnostic testing procedure [5]. Although electronic systems can effectively reduce error occurrence, cohort study data are often collected from participants' handwritten notes, resulting in frequent errors during the transformation of data from paper into electronic format by data entry personnel [6].

Given these circumstances, check digits can be utilized in computer data processing to automatically detect potential errors in identification numbers as an effective method to reduce the risk of participant misidentification. A check digit is a mathematically calculated digit added to the data to verify whether a valid value has been correctly submitted to the recipient without incurring any alterations to the original data during transmission [7]. The check digit acts as a checksum or error control, and various algorithms have been introduced depending on the purpose and components of the data (e.g., binary, alphanumeric, or decimal). For instance, data composed of decimal numbers (e.g., resident registration numbers, bank account numbers, and product codes) utilize algorithms such as Modular, Luhn, Damm, and Verhoeff to detect errors in the input values.

This study examined the application of personal identification numbers for participant identification in the bioresearch environment and related error detection algorithms. The remainder of this paper is organized as follows: Section 2 provides a brief review of previous studies on the application of check digits. Chapter 3 presents a case study on the use of check digits in composing bioresearch data identification numbers, explaining the identification number system and error detection algorithms. Chapter 4 presents the experimental results obtained from applying check digits. Finally, in Chapter 5, related issues are discussed and examined.

II. Related Research

The check digit automatically verifies the correct arrangement and accuracy of sequentially inputted numbers in complex and dynamic work environments and is widely recognized as a technique that effectively detects errors during manual recording or data transmission.

Error-detection algorithms for input data are widely used and continually improved upon across various fields, including the production and distribution of goods. In particular, check digit systems based on the Luhn algorithm are commonly used because of their simplicity. However, although the Luhn algorithm is effective in detecting transposition errors (e.g., $12 \rightarrow 21$), it is less sensitive to other types of errors because of the simple repetition pattern of the weights [8]. Consequently, alternative algorithms such as the International Standard Book Number (ISBN) [9] and Universal Product Code (UPC) [10] have been developed to address this limitation. More complex algorithms, such as Verhoeff [11] and Damm [12] detect errors in a more precise manner. Moreover, with advancements in computer processing speed, the calculation speed of these algorithms has reached a level that does not significantly impact workflow efficiency.

With the internationalization of distribution systems, UPC has been expanded to the European Article Number (EAN)-13, EAN-8, UPC-A, and UPC-E, depending on the intended use and required number of digits, as part of the global standard (GS1) of barcoding systems, which encompasses various standardized formats [13]. ISBN, a unique identifier for books originally proposed by Foster and Smith in 1966, was officially adopted as the "International Standard Book Number" by the International Organization for Standardization in 1970, as ISO 2108 [9], and is currently used for all published books [14]. It consists of a numeric code broken down into numbers representing the country, publisher, and book number, with the final digit serving as a check digit. To generate the check digit for a 10-digit ISBN, the ISBN Modulus 11 Check is used, which involves a mathematical manipulation, whereby each digit is multiplied by a weight ranging from 1 to 10, to ensure that the resulting number is divisible by 11 without a remainder. Check digits are used in credit cards worldwide. A credit card number typically comprises 10–19 digits that contain account information, along with a single check digit to identify the card issuer. The Luhn algorithm is employed to calculate the check digit [15]. The credit card issuer identification number has been standardized by ISO/IEC 7812-1, and this standard has also been adopted by the International Mobile Equipment Identity (IMEI) for check digit calculation [16].

The National Provider Identifier (NPI), which was adopted in 1996 pursuant to the Health Insurance Portability and Accountability Act (HIPAA), is a 10-digit numeric identifier consisting of a nine-digit serial number and one digit check. It is used to identify healthcare providers in the United States [17]. The check digit of the NPI is calculated using the Luhn algorithm, which is also employed in credit cards and mobile equipment, based on the ISO/IEC 7812-1 standard mentioned above. In the GenomeEUtwin project, the cohort study focuses on twin genetic analysis in Europe, and a numeric code is used to differentiate individual participants. This code

consists of a three-digit country code, serial number, and one check digit [18]. The Generalized Universal Mathematical Method (GUMM) is utilized to calculate the check digit in the GenomeEUtwin project [19].

In summary, the identification numbers used to detect errors that may occur during manual recording and data transmission, are generated by a coding system suitable for the given environment, with the last digit serving as the check digit. The suitability of different check digit algorithms should be evaluated on a case-by-case basis, considering their applicability for the intended use. This study proposes a code system for identifying participants who have donated human biological materials for research in the healthcare field, further exploring the most effective check-digit algorithm to reduce misidentification rates.

III. Materials and Methods

A. *Integrated management of bioresearch data*

This process focuses on the unique identifiers used to anonymize the participants' personal information throughout the process of bioresearch data collection, storage, and utilization. Fig. 1 provides a brief overview of this scenario.

Large-scale biodata collection projects typically exhibit

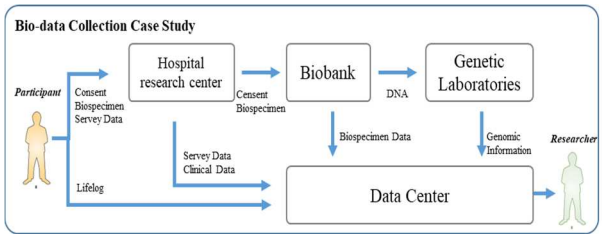

Fig. 1 Flowchart of the integrated system for bioresearch data under study. The data donated by each participant go through various processing stages within multiple organizations before being provided to researchers.

similar organizational structures and roles. The left side of Fig. 1 illustrates the data generation process, in which a voluntary participant visits a hospital or research center to complete a consent form, initiating the data generation process. The participant undergoes an epidemiological survey and clinical examination conducted by the hospital or research center staff and provides biological materials, such as blood or tissues. These donated biological materials are stored in a biobank, whereby genetic laboratories utilize DNA to generate genomic information. The bioresearch data produced through this process are integrated at the data center (bottom right of Fig. 1), to provide convenient access to researchers.

The workflow depicted in Fig. 1 demonstrates that biodata are generated at four different locations, with each location generating and storing different types of data. Because researchers must be able to identify the participant from the data, all bioresearch data and the corresponding participant identification numbers must remain identifiable throughout the data generation and transmission processes. According to the Bioethics and Safety Act, participant identification numbers should be replaced with unique identifiers to ensure anonymization rather than using personally identifiable information directly.

Errors in participant identification numbers can significantly affect subsequent processes within the workflow. These errors often remain undetected until the data reach the final datacenter for integration. Indeed, with data generated and modified at each stage, small errors in the identification numbers from the previous stage are not easily detectable, making arbitrary modifications impossible. This can result in complex quality-control issues.

B. *Participant identification number*

The protection of participants' biodata-related personal information is a major issue being actively researched from various perspectives [20, 21]. The issue of personal information protection in biobanking and health data is not only emphatically covered in mainstream media [22] but also emphasized in the academic literature [23–25]. Specifically, the potential to identify an individual's DNA within a DNA mixture [26] is a significant concern in terms of participant identification within a biobank.

To address these concerns, rigorous anonymity of participant identification numbers is essential. In this context, a participant identification number is defined as "a unique identifier assigned by the data center under the law to replace personally identifiable information, such as resident registration, passport, driver's license, and foreigner registration numbers, to prevent easy recognition when combined with other information." Furthermore, a participant identification number should serve as a mediator to enable bidirectional communication between the participant and both the biobank and bioresearch data for authorized users (or information systems).

The GenomeEUtwin project [18] added specific personal information to participant identifiers, such as singleton, twin, triplet, and quadruplet information, during the collection of genotypic and phenotypic information for twin research in Europe. This was to address end users' preference for identifiers containing eyeball data that they could verify

visually. Literature being scarce on participant identifiers, the current academic literature does not reflect other cohort situations. Korean research projects that collect human-derived materials often include code for specific personal information, such as region, gender, mother-child relationships, and the presence of disease. Including specific personal information in the participant identification number may be convenient for the workflow; however, there is the disadvantage of partial disclosure of personal information to anyone. The Personal Information Protection Act defines personal information as “information that can be used to identify a specific individual when combined with other information, even if the individual cannot be identified with this information alone.” Under the Resident Registration Act, the resident registration number contains unique personal identification information and is composed of 13 digits that disclose personal information such as the holder’s birth date, gender, and region of first issuance,. In response to human rights issues arising from excessive exposure to sensitive personal information, this ID card system was revised in October 2020, with the numbers in the latter part of the resident registration number representing the region replaced by random numbers. Therefore, it is desirable to remove as much identifiable information as possible from the participant identification number, as it is visible to anyone during biodata processing. Even at the expense of convenient visual identification of data during processing, it is necessary to ensure personal information protection.

This paper proposes the use of participant identification numbers that employ random instead of serial numbers, without encoding specific personal information, to minimize the risk of personal information disclosure (Fig. 2). The level

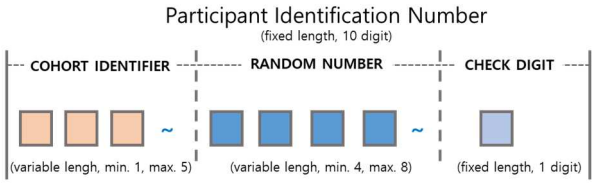

Fig. 2 Composition of the participant identification number scheme.

of personal data protection is enhanced by using numbers that do not follow a specific order or rule. To easily identify the cohort, which refers to the entire process from biodata collection to utilization, only a cohort identifier assigned by the data center is used as a prefix. The data center issues a unique cohort identifier upon request from the cohort research project manager. However, random numbers belonging to each cohort are assigned and managed by the corresponding institution, which further strengthens anonymity. Thus, the proposed system enables the efficient use of the necessary research data while protecting each participant's personal information.

The participant identification number is composed of 10 digits broken down into three parts as follows:

- Cohort identifier: 1 to 5 digits
- Random number: 4 to 8 digits
- Check digit: 1 digit

The All of Us Research Program [27], the world's largest biodata collection project, reportedly has more than one million voluntary participants across the United States. However, given the Korean population of 50 million [28], it is unrealistic to conduct research projects targeting hundreds of millions. Accordingly, to register all domestic bioresearch data in one location, it is reasonable to use nine digits that cover cohort projects with thousands of participants. That is, a 9-digit system that combines a cohort identifier (initial numbers) and random numbers (subsequent numbers) can be used, with the digits for the cohort identifier appropriately designated according to the cohort size. To ensure the accuracy of this 9-digit number, a check digit is added to verify the correct assignment of the identification number. An appropriate check digit algorithm is presented and explained in the following section.

C. Comparison of check digit methods

Table 1 presents common types of digit errors that occur during the generation of numeric code through manual input, as identified by Siddharth [29].

Table 1. Types of errors likely to occur during number code generation process

Category	Error Type	Example
1	Single digit error	1 → 2
2	Single transposition error	12 → 21
3	Twin error	11 → 22
4	Jump transposition error	546 → 645
5	Jump twin error	545 → 343
6	Phonetic error	13 (thirteen) → 30 (thirty)

A single-digit error refers to the case in which only one digit of a number sequence is incorrectly entered. A single transposition error occurs when the nth and (n+1)th digits are replaced by the (n-1)th and nth digits, respectively. A twin error occurs when two consecutive identical digits are

mistakenly entered as two other identical digits. A jump transposition error occurs when the nth and (n+2)th digits are replaced by the (n+2)th and nth digits, respectively. A jump-twin error refers to a case in which the nth and (n+2)th digits are identical and incorrectly entered as two other identical digits. Errors may also occur because of similar sounding numbers in some languages. Examples include the English numbers 16 (sixteen) and 60 (sixty) and German numbers 15 (fünfzehn), and 50 (fünfzig) [11]. In Korean, number pairs that are distinguished by the presence or absence of the final consonant of a syllable, such as 1 (일, il) and 2 (이, i) or 3 (삼, sam) and 4 (사, sa), may sound similar and be entered incorrectly. However, because these cases can be classified as single-digit errors, phonetic errors are not considered separately in this study. In addition to error detection during number code generation, there are also issues concerning data standard compliance, such as inputting nonnumeric characters or values with ten places. These issues can be easily resolved through exception handling during the information system implementation process; hence, they were not considered in this study.

The ISBN-13, Damm, and Verhoeff algorithms, which consider possible errors when generating numerical codes, can be used to generate participant identification numbers. The remainder of this section explains these three check digit algorithms used to generate participant identification numbers.

1) ISBN-13

Every publication is assigned a unique ISBN number. The ISBN was originally introduced by Foster and Smith in 1966 [30] and published as ISO 2108 by the International Organization for Standardization in 1970. An ISBN consists of the numbers α1, α2... α9, and the check digit α10 is chosen to satisfy the weight coefficients W1, W2, W3....W9 (10,9,8,7,6,5,4,3,2). The Luhn algorithm, developed by IBM scientist Luhn [31], assigns weights to the given digits and uses the remainder of the total as the check digit, similar to ISBN-13.

2) Damm algorithm

Unlike the Luhn algorithm and ISBN-13, the Damn algorithm uses an approach based on a more complex mathematical principle [12] of symmetric 10 × 10 two-dimensional array in its calculations.

3) Verhoeff algorithm

Verhoeff conducted an empirical analysis of user-input errors when processing decimal input values in the Dutch postal system. The analysis revealed that 89.26% of the errors were due to transcription (ab) or transposition (ab → ba), accounting for 79.05% and 10.21%, respectively [11]. Based on these analytical results, Verhoeff proposed an algorithm to detect single-digit and single-transposition errors. This method is similar to the Damm algorithm because it uses a two-dimensional array structure.

IV. EVALUATION

The participant identification number, designed for the integrated management of bioresearch data, comprises 9 digits and a check digit, thus allowing the generation of one billion unique identifiers. After generating all types of errors (Table 1) that could occur for these identifiers, we assessed the ability of the ISBN-13, Damm, and Verhoeff algorithms to accurately detect errors in randomly selected identifiers.

The error detection test model was implemented using Python 3.9 and implementation modules were incorporated for each algorithm. The model is executed in a computing environment powered by cloud-based Infrastructure as a Service (IaaS). The system running the model was equipped with an Intel Xeon 2 CPU, 4 GB of memory, and a 128 GB Non-Volatile Memory express (NVMe) storage device.

The comparative test results for approximately 3.5 billion identifiers are summarized in Table 2. All three check digit algorithms detected 100% of the single-digit errors. While the Damm and Verhoeff algorithms detected 100% of the single-transposition errors, ISBN-13 detected only 88.89%. Fenwick noted that ISBN-13 cannot detect adjacent transpositions of two digits with a difference of 5, such as 1 ↔ 6 or 8 ↔ 3 [8]. Given that the weights of all odd and even digits of ISBN-13 are equivalent to 1 and 3, respectively, approximately half of the jump transposition errors (even ↔ even, odd ↔ odd position) cannot be detected. The Damm and Verhoeff algorithms, which use a more complex mathematical approach than the weight-based check digit approach for ISBN-13, exhibited high mean error detection rates of approximately 96%.

For the proposed system, which combines a 9-digit identifier with a check digit to ensure the anonymity of personal information, the Verhoeff algorithm appears to be the most suitable. This method demonstrated a higher detection rate than the other two methods. However, considering the minimal difference in error detection performance between the Verhoeff and Damm algorithms, the latter can also be employed as an alternative depending on specific needs.

Table 2. Error detection rates of the check digit methods for integrated management of bioresearch data.

Error Type	ISBN-13	Damm Algorithm	Verhoeff Algorithm
Single digit error	100%	100%	100%
Single transposition error	88.89%	100%	100%
Twin error	88.89%	96.99%	91.90%
Jump transposition error	0%	92.23%	93.65%
Jump twin error	88.89%	89.67%	93.65%
Mean error detection rate	73.33%	95.78%	95.84%

V. Discussion

Small errors that may occur in identifiers during the collection of health-related information for research purposes (e.g., human biological materials, genetic data, epidemiological information, and clinical examination data) can be difficult to detect, potentially leading to complex quality management issues. Using check digits with participant identification numbers obviates the need for database lookups for verification, enabling easy detection of identifier-related errors throughout the various data processing stages. This approach is highly effective for quality management of bioresearch data. The methods presented in this paper can be applied not only to participant identification numbers, but also to appropriate numbering systems designed to detect input errors in the bio-data management process, such as donation consent forms, epidemiological questionnaires, clinical records, and human biological materials.

The process of collecting bioresearch data involves various stages: obtaining the participant's consent for donation, conducting subsequent clinical examinations, and collecting biospecimens (such as blood or tissue), which are then used to generate human biological materials, such as cells and DNA. DNA is prepared for genomic analysis data and supplied to researchers. The proposed participant identification number, used throughout this complex process of biodata collection, enables the anonymous management of human bio-specimens and associated data, thereby allowing operators at each stage to accurately identify and efficiently verify any input errors.

The research utility of biomedical data has increased in recent years amid the burgeoning big data market and increasing interdisciplinary integration. The establishment of registration systems for searching human biospecimens and the associated data necessary for research, is actively underway. Both academia and government entities are intensely promoting data-driven innovative growth while striving for a balanced tradeoff between data utilization and information protection. Confronted with a surge in information linkage between bioresearch data and collaborative research, the participant identification system for information management was proposed, alongside research on encryption and anonymization technologies, which are expected to provide significant assistance.

VI. Conclusion

This study investigated the use of identification numbers for the tracking of participants who provide bioresearch data, as well as applications of error-detection models. To minimize the risk of personal information exposure, we proposed a method that uses random numbers instead of sequential numbers, obviating the encoding of specific participant information in identification numbers. A check digit was added as the last digit of the participant's identification number to detect errors that may have occurred during manual input or data transmission. In this context, three different check digit methods: the ISBN-13, Luhn, and Verhoeff algorithms were compared. The results show that both the Verhoeff and Luhn algorithms effectively detected errors, significantly outperforming ISBN-13.

Although the check digit is indeed a very useful tool for error detection, it has limited capability for restoring the original information in the event of errors. To overcome this limitation, additional research on the application of Error Correction Codes (ECC) is required. Future research should aim to apply ECC, a concept that has been extensively studied in the field of computer science, to healthcare data. This would help prevent data corruption and alteration, ensure the accuracy and integrity of the data, and provide an important direction for efficient data management.

***Abstract*—This research investigates classification models and data representation techniques to distinguish snoring from non-snoring sounds. Spectrogram images were fed into a pre-trained ResNet18 model, attaining a classification accuracy of 99.00%. The mean and standard deviation of the acoustic feature profiles were extracted from audio features, including spectral features, zero crossing rate, root mean square, and Mel Frequency Cepstral Coefficients (MFCCs). Different combinations of the extracted features were utilized for training various machine learning classifiers to detect whether the audio samples contained snoring sounds. The MFCC features play a significant role in capturing snoring patterns against non-snoring sounds, attaining the highest classification accuracy of 98.50% when coupled with a random forest classifier. In addition, the feature importance list is presented for guiding feature engineering and providing data insights for greater interpretability. These findings emphasize the effectiveness of using statistical values derived from audio signals as features for machine learning-based classification. This work contributes to the field of snoring detection and classification with potential applications in sleep disorder monitoring and diagnosis.**

I. Introduction

According to a statistical analysis conducted by N. Bhattacharyya in 2015, snoring is a widespread phenomenon worldwide, affecting a substantial proportion of the adult population. Specifically, the study revealed that approximately 59.0% of adult men and 46.9% of women experience snoring on at least an occasional basis [1]. The snoring phenomenon can signify a more severe condition in several life aspects, such as health status and relationship strain [2]. The cause of snoring is the relaxation of the throat, narrowing the airway during sleep [3]. The vibration of the soft tissues in the airway creates the sound of snoring. It can be a sign of a serious condition called obstructive sleep apnea (OSA), which is characterized by pauses in breathing while asleep and a significant decrease in blood oxygen levels. OSA is linked to different health issues, such as high blood pressure, heart disease, stroke, and diabetes [4], [5]. In addition, it could also affect daytime fatigue, reduce cognitive function, and decrease quality of life. Snoring and OSA are more common among men, overweight people, and those over 40 years old. Other factors contributing to snoring and OSA include smoking, alcohol consumption, nasal congestion, and sleeping position [6]. The classification task in snoring detection enables the development of automated systems for snoring analysis. The INTERSPEECH 2017 ComParE Snoring Challenge [7] involved the classification of snoring sounds, aiming to explore and understand the different mechanisms and characteristics of snoring related to various sources of OSA.

The ability to accurately identify the sound of snoring and non-snoring is also very important for early diagnosis in the medical process. Several tools are used to diagnose snoring conditions, including questionnaires, physical examinations, and sleep tests. The results provide crucial information for developing appropriate treatment plans. The majority of snoring and non-snoring classification research over the recent decade has been around the applications of artificial intelligence (AI) and machine learning (ML) techniques. Adesuyi *et al.* represented sound signals by spectrogram images and input into a 2D-CNN model for the classification of snoring and non-snoring sounds but the classification accuracy was poor [8]. The same group later proposed the 1D-CNN network incorporated with the numerical extracted features for the same classification task, resulting in a high-performance accuracy of 99.7% [9]. A number of published works describe the importance of signal processing in extracting features from snoring sound for classification purposes. The selection of appropriate features is critical as it directly impacts the performance and accuracy of the classification models [10]. Recent evidence has indicated that sound signal features in the domain of music information retrieval (MIR) garnered significant interest in the feature extraction process [9]. These features include the mel-frequency cepstral coefficients (MFCCs), short-time Fourier transform (STFT), zero-crossing rate (ZCR), and spectral features.

In this study, a range of audio features commonly employed in the analysis of snoring sounds is provided with data representation to capture the sound characteristics. The binary classification of snoring and non-snoring is carried out using two approaches of data representation as inputs for deep learning and classical machine learning models, respectively, detailed as follows:

- Spectrogram images are the data represented inputs for the pre-trained ResNet18 model.
- Statistical values of extracted audio features are the data represented inputs for machine learning classification

models.

The remaining sections of this paper are structured as follows. Section II outlines the methods used in this study, which include details on the dataset, data representation techniques, and classification models. Section III presents the results and discussion regarding the classification performance of each data representation technique and classification model. Lastly, Section IV summarizes the study and explores potential directions for future research.

II. Method

A. Snoring and Non-snoring Dataset

There are 1,000 sound samples in the dataset, separated into two groups: snoring sounds and non-snoring sounds [11]. Each class consists of 500 samples. These sounds were collected from various online sources and were previously used to create a binary classification model of snoring and non-snoring sounds. The length of each pre-processed sound sample is one second. Among the 500 snoring sound samples, there are 363 sound samples without any background noise acquired from children, adult men, and adult women. The remaining 137 samples include snoring sounds accompanied by other non-snoring sounds in the background. The 500 non-snoring samples were made up of different ambient noises typically heard around a person who snores. These sounds were gathered from ten different categories, containing 50 samples per category. The categories include sounds of a baby crying, a clock ticking, a door opening and closing, complete silence or the faint sound of a vibrating gadget, a toilet flushing, emergency vehicle sirens, rain and thunderstorms, streetcar sounds, people talking, and background television news. Fig. 1 presents example visualizations of the waveforms for snoring and non-snoring sounds.

In this work, the dataset was divided into three subsets by ratios of 60:20:20 for training, validating, and testing, respectively. The same training and testing datasets were utilized in the machine learning and deep learning experiments to ensure comparable evaluation of their performance. For deep learning with spectrogram representations, 60% of the data were assigned for training (600 samples), 20% for validating (200 samples), and the remaining 20% for testing (200 samples). For machine learning using extracted audio features, the same split ratios of 60:20:20 were applied.

B. Data Representation

1) Spectrogram: Transforming a sound signal into a spectrogram involves applying a Fourier transform to the signal. During this process, the time-domain signal is transformed to the frequency domain. As a result, the signal is represented as a sequence of frequencies along with their corresponding magnitudes over time. The resulting spectrogram can be visualized as a 2D plot, with the intensity of each pixel indicating the magnitude of the frequency component at that point in time. The spectrogram images of snoring sound in Fig. 1 are illustrated in Fig. 2.

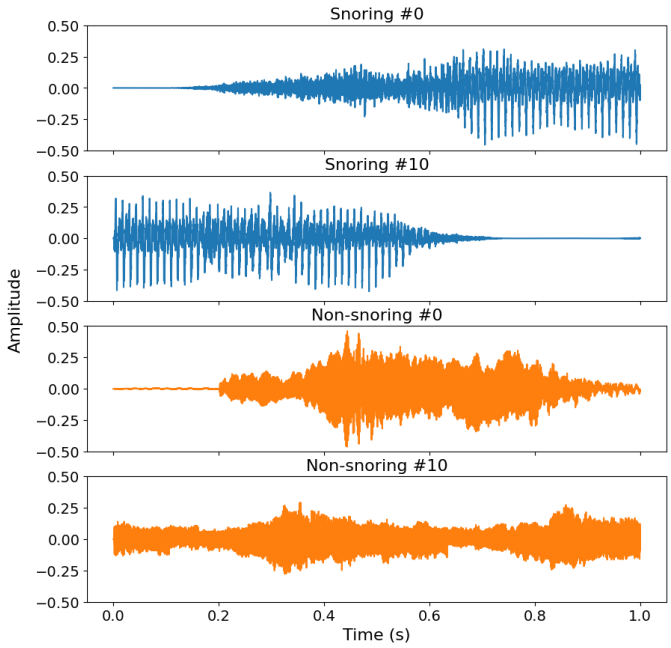

Fig. 1. Examples of snoring waveforms (blue) and non-snoring waveforms (orange), providing the visualization of physical features underlying the audio data

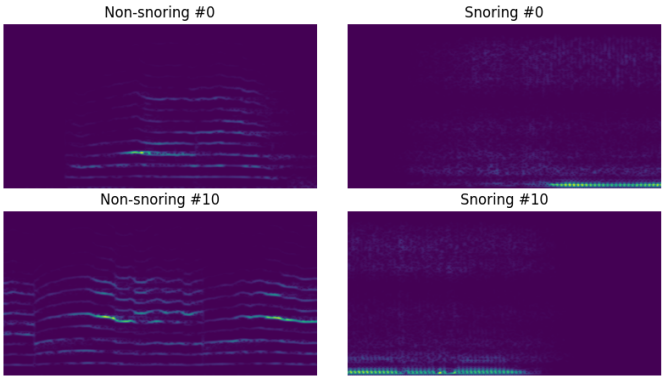

Fig. 2. Spectrogram images generated from snoring sounds (right) and non-snoring sounds (left).

2) Audio Features: Signal data processing typically involves identifying and extracting physical features from the signals, such as frequency, amplitude, and phase. Selecting and applying appropriate techniques for feature extraction in signal data can provide insight into the underlying patterns that can be used for further analysis or modeling.

- *Mel-frequency cepstral coefficients (MFCCs)*: The MFCCs are a common feature extraction technique used to analyze sound signals. The process involves breaking audio into small frames and then applying mathematical operations to each frame [12]. These operations involve multiplying a window function, followed by a Fourier transform. This sequence of steps converts the signal from the time domain to the frequency domain. The resulting spectrum is passed through a set of Mel filters,

and the logarithm of the Mel-filter bank energies is taken to produce Mel frequency. A Discrete Cosine Transform (DCT) is applied to the Mel frequency coefficients to obtain a set of cepstral coefficients representing the spectral envelope of signals. Previous studies have reported that adopting MFCCs as extracted features works well for snoring identification [11], [13], [14].

- *Root Mean Square (RMS)* is often used to characterize the waveform of audio amplitude. The RMS of an audio signal intensity, I, is defined in (1):

$$\text{RMS} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}|I_i|^2} \tag{1}$$

where n is the number of signal data points in an individual window, which was set to 2,048 with the sliding size of 512 [9]. $i = 1, ..., n$ is the index of signal intensity across a window. In the case of snoring, RMS can be used to identify the intensity representing the loudness of the snoring signal.

- *Zero Crossing Rate (ZCR)* is the rate at which the signal crosses the zero level [15]. In the case of snoring, ZCR can be used to identify the periodicity of the snoring sound.
- *Spectral Centroid* is a measure of the center of mass of the spectrum. It provides information about the frequency at which the energy of the signal is concentrated [15]. In the case of snoring, spectral centroid can be used to identify the dominant frequency or range of frequencies associated with a snoring sound.
- *Spectral Bandwidth* is a measure of the spread of the spectrum around the spectral centroid. It provides information about the width of the frequency distribution of the signal [15]. In the case of snoring, spectral bandwidth can be used to identify the overall spectral content of snoring sound.
- *Spectral Rolloff* is a measure of the frequency at which the spectrum falls to a certain percentage of its maximum value. It provides information about the high-frequency content of the signal [15]. In the case of snoring, spectral rolloff can be used to identify the upper-frequency limit of snoring sound.

In summary, the feature extraction of snoring sound can provide useful information about the characteristics of the sound, which can be helpful in the diagnosis of sleep disorders and other health conditions.

C. Classification Models for Snoring Sound

This work aims to develop classification models to distinguish between snoring and non-snoring sounds. Two different approaches for data representation and subsequent classification approaches were investigated. ResNet-18 was employed to demonstrate the power of deep learning, particularly by highlighting its capability to eliminate the need for any feature extraction process. Furthermore, it also aimed to compare with traditional machine learning, which required feature extraction steps. The explanation of these two approaches was detailed as follows:

1) Deep Learning with Image Representation Inputs: The snoring sound dataset was transformed into spectrograms to extract visual representations of the audio signals. Image data representations of snoring and non-snoring sounds were fed into the Fast.ai deep learning framework [16]. The pre-trained ResNet18 model is used as a feature extractor [17], employed the Adam optimization function with the defaulted learning rate of 10^{-7}. The initial learning rate was determined using the **`lr_find`** function provided in the Fast.ai framework to optimize the classification performance. The model is fine-tuned in the training process by adjusting the learning rate based on the initial learning rate. Specifically, a fine-tuning step consisting of 10 epochs at a learning rate of 2×10^{-6} is implemented. This fine-tuning process was configured to automatically stop and save the model when the classification performance discontinue improvement. This fine-tuning step aimed to optimize the model performance and enable it to improve the classification between snoring versus non-snoring sounds.

2) Machine Learning with Feature Extracted Inputs: Statistical features are extracted from the snoring sound samples to capture relevant information. Specifically, the mean and standard deviation of the extracted audio features were calculated. These statistical features, along with their corresponding labels (snoring and non-snoring), are used to construct a dataset for training the machine learning models. Different classification algorithms available in PyCaret [18], including Random Forest (RF), Support Vector Machine (SVM), and *k*-Nearest Neighbor (KNN) are utilized. The dataset is split into training and testing sets same as the dataset for the deep learning approach. Model hyperparameters are optimized using the technique of 20 folds cross-validation with randomized parameters.

III. Results and Discussion

In this work, the performance of the classification for snoring and non-snoring sounds is presented. The classification models, developed using both machine learning and deep learning approaches, are evaluated using the accuracy metric. Spectrogram images and numerical extracted features are used as input data for deep learning and machine learning, respectively. This study aims to explore the strengths and capabilities of various data representations. The accuracy of classification performance in various scenarios of models and features is investigated as shown in Table I. In addition, the advantages and disadvantages of each approach for snoring and non-snoring sound classification are discussed in Table II.

A. Image Data Representation

The conversion of audio signals into spectrograms enables the capture of significant patterns and variations associated with snoring sounds. The classification model for snoring and non-snoring sounds, based on the ResNet18 pre-trained model, achieved an astonishing accuracy of 99% using spectrogram

TABLE I
CLASSIFICATION PERFORMANCE OF VARIOUS MODEL PIPELINES WITH VARYING DATA REPRESENTED FEATURE SETS AND CLASSIFICATION MODELS

Data Represented Features	Models	Accuracy
Spectrogram images	ResNet18	**99.00%**
Spectral (Centroid+Bandwidth+RollOff)	RF	89.00%
	SVM	61.50%
	KNN	87.00%
Spectral+RMS+ZCR	RF	94.00%
	SVM	73.50%
	KNN	89.50%
MFCCs	RF	**98.50%**
	SVM	90.50%
	KNN	96.50%
MFCCs+Spectral+RMS+ZCR	RF	97.50%
	SVM	94.50%
	KNN	98.00%

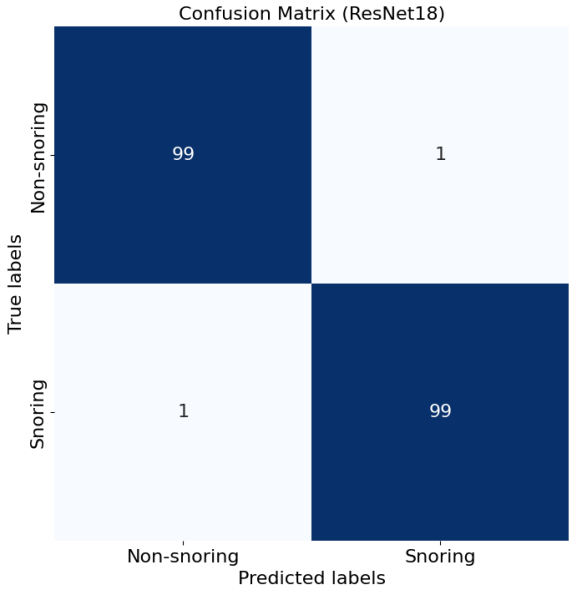

Fig. 3. Confusion Matrix of the snoring and non-snoring sound classification accuracy using the ResNet18 pre-trained model. The spectrogram images, serving as the input training dataset, are processed to predict the class labels.

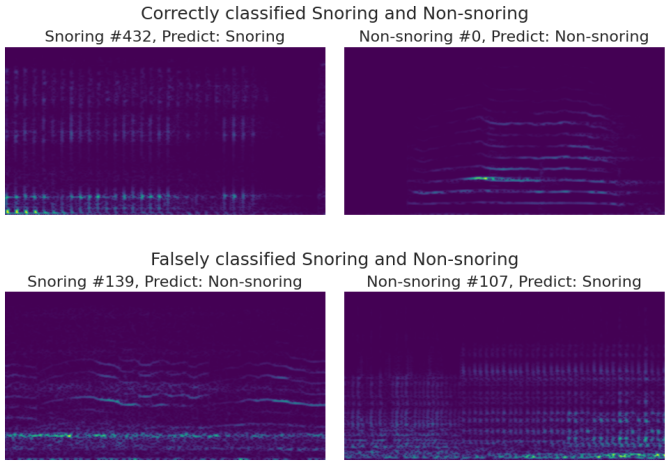

Fig. 4. Correctly (top) and falsely (bottom) classified image data representations for snoring (left) sound and non-snoring (right) sounds.

images as input data. The experimental results showed a significant improvement over the previous study conducted by Adesuyi *et. al.* that achieved an accuracy of 86.80% using their proposed 2D-CNN model [9]. The combination of fine-tuning and learning rate searching on the Fast.ai platform contributed to the higher classification accuracy achieved in this study. In addition, the pre-trained model has shown to be very helpful, as it provides a starting point by using knowledge gained from training on large datasets. It can also serve as a feature extractor which can save computational costs and time [19]. The confusion matrix is visualized to compare the predicted classes with the actual classes, as shown in Fig. 3. These results highlight the potential of deep learning and the effectiveness of spectrogram representation in accurate separation. However, there are missing predictions in classifying between snoring and non-snoring, possibly due to the represented image characteristics. The correct classification results are illustrated in the top part of Fig. 4, while the false classification results are shown in the bottom part of Fig. 4. This struggle can occur due to similarities in patterns, noise, or artifacts in the spectrogram.

B. Extracted Feature Representation

This section focuses on classifying snoring and non-snoring sounds using various audio features. These features include Mel-frequency cepstral coefficients (MFCCs), zero-crossing rate (ZCR), root mean square (RMS), and spectral features. The collected features are first extracted in the form of series data and are commonly used in audio classification. Especially for MFCC features, there are 20 orders of MFCC features extracted from the raw audio. These features were used as input series data in a 1D-CNN model, which resulted in a classification accuracy of 99.7% [9]. In this work, statistical values of the mean and standard deviation of those features are computed to create representative data inputs for classification. The classification of snoring and non-snoring is performed using three machine-learning models, including Random Forest (RF), Support Vector Machine (SVM), and *k*-Nearest Neighbor (KNN). The input datasets are separated into four scenarios, composed of four different sets of features. The performance of the classification models is evaluated using the accuracy score as shown in Table I. The results indicate the role of feature selection in audio classification. The feature set of spectral features shows that the RF model achieves the highest accuracy of 89.00%. In contrast, the SVM model exhibits lower accuracy at 61.50%, while the KNN model performs well with an accuracy of 87.00%. These findings suggest that the RF model is good at using spectral features to classify, but the SVM model may struggle because of the

TABLE II
COMPARISON OF ADVANTAGES AND DISADVANTAGES OF SNORING AND NON-SNORING CLASSIFICATION APPROACHES.

Approach	Advantages	Disadvantages
2D-CNN model using spectrogram images	- Captures temporal and frequency information. - Provides visual representation for pattern identification.	- Increases computational complexity and memory requirements for generating spectrogram images. - Lacks interpretability in terms of the physical features of the audio waveforms.
1D-CNN model using extracted audio features	- Extract features containing information on spectral, temporal, and amplitude characteristics. - Eliminates the need for additional pre-processing steps.	- Obtains limited capacity to capture complex spectral patterns compared to spectrogram-based approaches.
Machine learning models using statistical input features	- Simplifies input representation and reduces dimensionality. - Enhances efficiency for computational processing. - Utilizes the physical characteristics extracted from the audio waveforms.	- Potentially loses information due to the summarization process. - Not fully capture the dynamic and temporal nature of snoring and non-snoring sounds via the acquisition of statistical features alone.

linear separation assumption. Expanding the feature set by including Root Mean Square (RMS) and Zero Crossing Rate (ZCR) results in improved performance for all models. The higher accuracy demonstrates the power of combined features of spectral, temporal, and amplitude-based features of audio classification. When considering the Mel Frequency Cepstral Coefficients (MFCCs) as the features, the RF model achieves an impressive accuracy of 98.50%. This suggests that extracted MFCC features capture important characteristics of the audio signals that enable the classification model to achieve high-performance accuracy. Furthermore, combining MFCCs with spectral, RMS, and ZCR features leads to further improvement in classification performance. This combination is specifically employed to investigate the importance of different features in distinguishing between snoring and non-snoring sounds. The MFCC features capture the spectral characteristics of the audio signals. The spectral features provide additional insights into the distribution of energy across different frequency bands. The integration of RMS and ZCR features allows the consideration of the temporal and amplitude-related properties of the sound signals. The list of feature importance, as ordered in Fig. 5, was used for training an RF model where the predominant features were found based on the average values of MFCC features. Those MFCC features seem significant in capturing patterns related to snoring and non-snoring sounds. Other features, such as the standard deviation of spectral rolloff and ZCR, also enhance the classification performance.

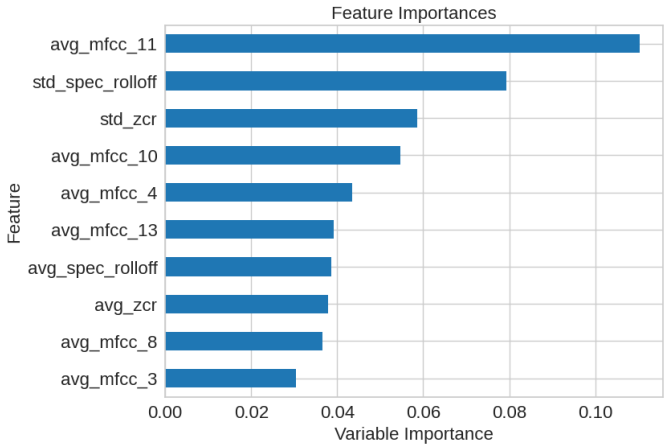

Fig. 5. The feature importance for training the Random Forest Classifier model is listed in descending order. The most important statistical features of the extracted series include the average of 11th MFCC, the standard deviation of spectral rolloff, the standard deviation of ZCR, the average of 10th MFCC, the average of 4th MFCC, the average of 13th MFCC, the average of spectral rolloff, the average of ZCR, the average of 8th MFCC, and the average of 3rd MFCC. For the hyperparameter tuning process, a 20-fold cross-validation approach is employed using randomized parameter sets.

IV. CONCLUSION

The outcomes of snoring and non-snoring sound classification using different data representations and classifiers are examined. This work contributes to understanding feature selection and suggesting appropriate model pipelines for this binary classification task. The deep learning model yields an accuracy of 99.00% using spectrogram images as the data represented input along with the application of the ResNet18 pre-trained model. For classical machine learning approaches, the features are extracted from audio waveforms, and statistical values are computed accordingly for use as input data. The best results are obtained when the MFCC feature is used in combination with the RF model, achieving an accuracy of 98.50%. This approach achieves comparable performance to a pre-trained deep learning model while offering the advantage of reduced computational resources and time in the data preparation and training processes. In addition, the results emphasize the benefit of statistical feature extraction from audio waveforms over the image-based data representation, which is mainly the ability to interpret the results and algorithmic simplicity. Further studies are demanded to explore powerful feature engineering techniques and classification models to improve the solutions to snoring detection and other audio signal classification problems.

Un-Rectifying in ReLU Networks and Applications

Shih-Shuo Tung,* Ming-Yu Chung,† Jinn Ho,* and Wen-Liang Hwang *
* Institute of Information Science, Academia Sinica, Taiwan
† National Taiwan University, Taiwan

***Abstract*—Most learning algorithms for deep neural networks (DNNs) employ gradient descent or block coordinate descent, which involves the direct application of a non-linear activation function throughout the course of optimization, such that only the input and output of the activation function are optimized. By contrast, the "un-rectifying" technique expresses a non-linear point-wise (non-smooth) activation function as a data-dependent variable (activation variable), which means that the activation variable along with its input and output can all be employed in optimization. The fact that the ReLU network in this study was un-rectified means that the activation functions could be replaced with data-dependent activation variables in the form of equations and equality constraints. We also demonstrate it is possible to optimize a network based on the augmented Lagrangian approach. In experiments and comparisons with other methods addressing classification and compressed sensing recovery problems, the proposed approach makes it easier to learn a network to a given degree of accuracy within a small number of epochs.**

I. Introduction

DNN training methods include the popular back-propagation algorithm and its variants, block coordinate descent (BCD), and the alternating direction method of multipliers (ADMM). The BCD approach involves decomposing a problem into sub-problems to be solved cyclically with the remaining blocks fixed according to their most recent updates. The ADMM approach searches for saddle points of augmented Lagrangian functions via primal and dual variable updates, wherein the updating of primal variables is based on the BCD approach.

In this study, we employed un-rectifying in our implementation of the augmented Lagrangian method in order to investigate the issue of convergence in learning an L-layer ReLU network, represented as follows:

$$\mathcal{M}_L = M_L \rho M_{L-1} \dots \rho M_1, \tag{1}$$

where ρ refers to ReLU and M_i is an affine transform, the linear portion of which is $\mathbf{W}_i$ and the bias is $\mathbf{b}_i$ [1], [2].

The learning problem in (1) can be formulated in a manner that allows the application of alternating optimization whenever a single block of variables is minimized, while leaving the other variables fixed. Below, we illustrate this approach using an example involving a three-layer DNN $\mathcal{M}_3 = M_3 \rho M_2 \rho M_1$ with the following three-splitting formulation:

$$\begin{cases} \min_{\mathbf{U}_1,\mathbf{V}_1,M_1,M_2} \ell(\mathbf{Y}, M_3\mathbf{V}_2) + S(\mathbf{V}_1,\mathbf{V}_2,\mathbf{U}_1,\mathbf{U}_2) \\ +T(M_1,M_2,M_3) \\ \mathbf{V}_1 = \rho\mathbf{U}_1, \mathbf{V}_2 = \rho\mathbf{U}_2 \\ \mathbf{U}_1 = M_1\mathbf{X}, \text{ and } \mathbf{U}_2 = M_2\mathbf{V}_1, \end{cases} \tag{2}$$

where ℓ is the loss function, ρ is the non-linear activation function, and S and T are regularization functions. The equality constraint is approximated using the penalty method with penalty parameter γ.

Nearly all approaches to DNN learning treat the non-linear activation ρ as a function, such that ρ is not directly involved in optimization [3], [4]. Most theoretical studies on convergence in DNN learning have assumed that if ρ is not a smooth activation function, then it must be approximated. By contrast, the un-rectifying technique [5] expresses point-wise CPWL function ρ as a data-dependent variable. For example, $a = \rho z$ becomes $a = dz$, where d is a data-dependent variable (i.e., its value is dependent on the value of z). Un-rectifying makes it possible to use d in optimization in the same way as other variables. It is from this perspective that we explore DNN learning using the augmented Lagrangian approach under the framework of the Conn, Gould, and Toint algorithm [6].

Un-rectifying ReLUs introduces an input-dependent diagonal matrix of entries $\{0, 1\}$, such that for input $\mathbf{x}$,

$$\mathbf{D}_\mathbf{x}\mathbf{x} = \rho\mathbf{x} \tag{3}$$

with the following constraints:

$$\begin{cases} \mathbf{0} \le \mathbf{D}_\mathbf{x}\mathbf{x}, \\ (\mathbf{I} - \mathbf{D}_\mathbf{x})\mathbf{x} \le \mathbf{0} \\ \mathbf{D}_\mathbf{x} = \mathrm{diag}(\mathbf{d}) \text{ with } \mathbf{d} = [d_i \in \{0,1\}]_i. \end{cases} \tag{4}$$

In other words, $\rho\mathbf{x}$ can be equivalently expressed as $\mathbf{D}_\mathbf{x}\mathbf{x}$, where $\mathbf{D}_\mathbf{x}$ satisfies (4). In [7], [8], the learning model in (1) using the un-rectifying approach achieved global convergence by relaxing the domain of the un-rectifying variables (variables replacing the activation functions) from integer to real values. This transforms a combinatorial problem into a real-domain problem, thereby making it possible to solve the problem of learning an un-rectifying network via constrained optimization. Meanwhile, applying the CGT-algorithm involves introducing data-dependent slack variables to convert inequality constraints into equality constraints.

This paper presents an alternative approach to the conversion of inequalities into equations using non-linear operations without introducing data-dependent slack variables. The first two contributions of this paper pertain to technical enhancement of the CGT-algorithm for ReLU networks:

- We amend the assumption of the CGT-algorithm (referring to as CGT-extension) in coping with continuous constraints (with mild assumptions pertaining to the first and second derivatives on constraint functions). We

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

demonstrate that the CGT-extension can reach global convergence to critical points of problems.
- We demonstrate that the equality constraints introduced by un-rectifying ReLUs satisfy the CGT-extension, which means that ReLU networks can be trained to critical points. Replacing ReLUs with equality constrained functions avoids the need to introduce massive data-dependent slack variables. This is a dramatic improvement over the un-rectifying representation of ReLUs in [7] when dealing with large datasets and deep networks.

We compared the performance of the proposed CGT-extension, BCD, ADMM, and Adam (state-of-the-art back-propagation algorithm) in training fully-connected networks in terms of classification and compressed sensing recovery using the MNIST, fashion-MNIST, and set11 datasets:

- The CGT-extension method was more robust than BCD and ADMM in selecting initial weights and the number of layers within a fixed number of epochs. The CGT-extension method generally required more time than did back-propagation methods in the execution of a single epoch; however, CGT-extension provided a considerable advantage in terms of accuracy within the first few epochs, while achieving average execution times lower than those of the Adam algorithm.

The remainder of the paper is organized as follows. Section II briefly reviews related works. Section III presents the un-rectifying representation of a ReLU network and solutions by which to learn the networks. Section IV outlines experiments and comparisons with other methods and provides a demonstration of numerical convergence by the proposed algorithm. Concluding remarks are presented in Section V.

II. Related Works

A. Deep learning algorithms

Our review of deep learning algorithms deals with the gradient descent approach, alternating minimization (block coordinate descent), and the alternating direction method of multipliers (ADMM), as these are most widely used methods with theoretical support. The back-propagation algorithm [9] and its variants are the most popular deep learning algorithms, due to their adaptability to all types of feed-forward neural networks. However, this approach is susceptible to gradient instability and most of the methods designed to deal with this issue necessitate setting an appropriate range of values for the updating of parameters (particularly the learning rate). Other techniques that counter gradient instability are reviewed in [10].

Deep learning problems can be formulated using the two-splitting and three-splitting approaches, which allows the application of alternating optimization whenever a single block of variables is minimized, while the other variables remain fixed [3]. The fundamental principle underlying two-splitting and three-splitting is the introduction of auxiliary variables to separate highly-coupled DNN structures into separate sub-components and equality constraints [11]–[13]. The penalty method is then used to transform the constrained problem into an un-constrained problem, in which equality constraints are replaced as penalty terms in the objective function.

The ADMM approach, which is closely related to the augmented Lagrangian approach, has recently received considerable attention for DNN learning, due to its ease of implementation and proven effectiveness in optimizing sums of simple but non-smooth convex functions in situations where high accuracy is not a strict requirement [14]. The convergence of non-convex ADMM under a 2-block linear constrain is outlined in [15]. Recent breakthroughs in convergences of non-convex ADMMs under multi-block linear and multi-affine constraints are respectively presented in [16] and [4]. Thus, the DNN problem can be formulated/approximated as a non-convex optimization problem with multi-affine constraints [4] [17].

B. CGT-algorithm

Conn, Gould, and Toint [6] considered the problem of finding a local minimizer for the following function:

$$f(\mathbf{x}^1, \mathbf{x}^2)\colon \mathbb{R}^n \to \mathbb{R}, \text{ where } \mathbf{x}^1 \in \mathbb{R}^{n_1} \text{ and } \mathbf{x}^2 \in \mathbb{R}^{n_2} \quad (5)$$

where $n = n_1 + n_2$ and $(\mathbf{x}^1, \mathbf{x}^2)$ must satisfy

$$c_i(\mathbf{x}^1, \mathbf{x}^2) = 0,\ 1 \le i \le m. \quad (6)$$

There is no constraint on $\mathbf{x}^1$, and any component x_j of $\mathbf{x}^2$ must satisfy the following simple bounds:

$$l_j \le x_j \le u_j \quad (7)$$

where $u_j > l_j$, $l_j \in \mathbb{R}$, and $u_j \in \mathbb{R} \cup \{\infty\}$. Here, B is used to denote the convex set of $\mathbf{x} = (\mathbf{x}^1, \mathbf{x}^2)$, wherein $\mathbf{x}^2$ satisfies (7). The CGT-algorithm is a global convergence algorithm[1], which solves problems involving equality constraints and variables with simple bounds, in situations where the objective and all of the constraints are twice-continuously-differentiable (that is, f and c_i are in $\mathcal{C}^2$).

The Lagrangian function and augmented Lagrangian function of (5)-(7) with respect to constraints $\{c_i\}$ are respectively written as follows:

$$L(\mathbf{x}, \lambda) = f(\mathbf{x}) + \sum_{i=1}^{m} \lambda_i c_i(\mathbf{x}), \quad (8)$$

and

$$L_\mu(\mathbf{x}, \lambda) = f(\mathbf{x}) + \sum_{i=1}^{m} \lambda_i c_i(\mathbf{x}) + \frac{1}{2\mu} \sum_{i=1}^{m} c_i(\mathbf{x})^2, \quad (9)$$

where $\{\lambda_i\}$ are the Lagrangian multipliers.

Global convergence of the CGT-algorithm can be achieved for problems in which the following three conditions are assumed:
(AS1) Objective $f(\mathbf{x})$ and constraints $\{c_i\}_i$ are twice-continuously-differentiable for $\mathbf{x} \in B$.

[1]Global convergence means that the iterators generated by the algorithm from any initial point converge to limit points for which necessary conditions of optimality hold.

(AS2) The iterators $\{\mathbf{x}^{(k)}\}$ under consideration lie within a closed, bounded domain, $\Omega \subset B$.
(AS3) J denotes the variables (with indices) in $\mathbf{x}^1$ and the variables (with indices) in $\mathbf{x}^2$, such that $i \in J$ implies that variable x_i is in $\mathbf{x}^1$ or $\mathbf{x}^2$ with a value strictly in the interior of the closed interval $[l_i, u_i]$.

The template of the CGT-algorithm is given in Algorithm 1. The CGT-algorithm solves (5)-(7), provided that the primal-

Algorithm 1 CGT-algorithm solving (5)-(7)

Input parameters: the Lagrangian multipliers $\mu^{(0)}$ of equality constraints and stopping conditions ω^* and η^*, $Iter$ (the maximum number of iterations), the value of ρ^0.
Let α denote primal variables and let $\mathbf{c}$ denote the vector of all equality constraints.
Set $k = 0$, $\omega_0 = \omega^{(0)} = 1$, $\eta_0 = \eta^{(0)} = 1$, and $\tau = 0.01$, as suggested in [6].
repeat
    repeat
        $\alpha^{(k)} \leftarrow$ Update primal variables α with fixed Lagrangian multipliers $\bar{\mu}^{(k)}$.
    until $\|\mathbf{P}(\alpha^{(k)}, \nabla_\alpha L^{(k)}_{\rho^{-1}})\| \leq \omega^{(k)}$
    if $\|\mathbf{c}(\alpha^{(k)})\| \leq \eta^{(k)}$ **then**
        [Test for convergence and update Lagrangian multiplier estimates].
        if $\|\mathbf{P}(\alpha^{(k)}, \nabla_\alpha L^{(k)}_{\rho^{-1}})\| \leq \omega^*$ and $\|\mathbf{c}(\alpha^{(k)})\| \leq \eta^*$ **then**
            Return.
        end if
        [Update dual variables by using (10)].
        $\rho^{(k+1)} = \rho^{(k)}$; $\beta = \min((\rho^{(k+1)})^{-1}, 0.1)$; $\omega^{(k+1)} = \omega^{(k)}\beta$; $\eta^{(k+1)} = \eta^{(k)}\beta^{0.9}$.
    else
        [Reduce the penalty parameter ρ^{-1} (or increase ρ)].
        $(\rho^{(k+1)})^{-1} = \tau(\rho^{(k)})^{-1}$.
        $\bar{\mu}^{(k+1)} = \bar{\mu}^{(k)}$; $\beta = \min((\rho^{(k+1)})^{-1}, 0.1)$.
        $\omega^{(k+1)} = \omega_0\beta$ and $\eta^{(k+1)} = \eta_0\beta^{0.1}$.
    end if
    Increase k by one.
until $k \geq Iter$

Remark 1. The value of $\rho^{(k)}$ is a non-decreasing function of k. The updating of dual variable μ associated with constraint $c(\alpha) = 0$ is performed as follows:

$$\mu^{(k+1)} \leftarrow \mu^{(k)} + \rho^{(k)} c(\alpha^{(k)}). \tag{10}$$

Remark 2. The initial values are as follows: ρ_1 and ρ_2 (1), ρ_3 and ρ_4 (100), c_1 (0.001), and c_2 (10^{-6}).

variable update converges to a critical point of (9) over B.

C. Learning using data-dependent slack variables

When employing the un-rectifying approach, the ReLU function becomes a data-dependent variable, which can be analyzed in the same manner as other variables. It is represented through the introduction of activation variable d with a value in $\{0, 1\}$. Variable d can be used to indicate the activeness of the ReLU. The value of d is set to 1 when the input is a positive scalar, and otherwise equal to 0. Note that using discrete values for the activation variable could hinder optimization, due to the fact that the discrete domain can render a combinatorial problem for which solutions cannot be efficiently derived. In the context of optimization, variable relaxation refers to the relaxation of discrete variables by replacing discrete values with continuous values. This kind of relaxation can be applied to (4), as long as the solutions to the original problem are equivalent to the problem with relaxed variables. Below, we review [7], in which it is asserted that relaxing the domain of the activation variable from discrete to a continuous closed interval $[0, 1]$ enables the application of the CGT-algorithm to train DNNs to achieve globally convergence to critical points of (5)-(7).

The inequalities in (4) can be converted into equations satisfying (6) through the introduction of data-dependent slack variables, which would double the number of variables for a given input (compared to the size of ReLUs). For each i, we obtain

$$\begin{cases} d_i x_i - s_i = 0, \\ (1 - d_i)x_i + t_i = 0, \\ d_i \in \{0, 1\}, \\ t_i, s_i \geq 0. \end{cases} \tag{11}$$

Slack variables t_i and s_i are associated with component x_i of input $\mathbf{x}$. Constraint $d_i \in \{0, 1\}$ is then relaxed to $d_i \in [0, 1]$, yielding

$$\begin{cases} d_i x_i - s_i = 0, \\ (1 - d_i)x_i + t_i = 0, \\ d_i \in [0, 1], \\ t_i, s_i \geq 0. \end{cases} \tag{12}$$

Un-rectifying involves replacing the ReLU function with a variable in a discrete domain. Relaxation involves relaxing the domain of the variable, which allows it to be treated as a continuous variable. This cannot be regarded as a smoothing of the ReLU function, because most smoothing technique involve a trade-off between accuracy and computational efficiency. From another perspective, unless un-rectification and relaxation are applied to a ReLU, the status of the function is discrete (i.e., active or in-active), with a value depending exclusively on the input of the function. Un-rectifying and relaxing a ReLU transforms the function into a constrained continuous variable. This facilitates optimization by allowing continuous variables to be optimized in the same way as other variables, based on its most recent input and output values.

III. Learning un-rectified networks

We first consider the regression problem used to learn a 2-layer representation $\mathcal{M}_2$ from N training data $\{(\mathbf{x}_j \in \mathbb{R}^{N_0}, \mathbf{y}_j \in \mathbb{R}^{N_2})\}_{j=1}^N$. Imposing the Frobenius norm on the

weight matrices to stabilize the outputs with respect to input perturbation [5] renders the least squares regression problem as follows:

$$\sum_j \|\mathbf{y}_j - \mathcal{M}_2\mathbf{x}_j\|^2 + \frac{c_1}{2}(\|\mathbf{W}_1\|_F^2 + \|\mathbf{W}_2\|_F^2), \tag{13}$$

where $c_1 > 0$ is a parameter, $\mathbf{W}_i \in \mathbb{R}^{N_i \times N_{i-1}}$ are weight matrices, and $\mathbf{x}_j \in \mathbb{R}^{N_0}$ is the input. We un-rectify the ReLU in $\mathcal{M}_2$ by replacing ρ with data-dependent diagonal matrices $\mathbf{D}_j$ and add the term $\frac{c_2}{2}\sum_j \|\mathbf{D}_j\|_F^2$ to (13), in which the value of c_2 is small enough that its effect on the solution of (13) is negligible. We should see that including the term produces a unique closed-form solution of variables in $\mathbf{D}_j$, where $\mathbf{D}_j$ is defined as

$$\mathbf{D}_j M_1\mathbf{x}_j = \rho M_1\mathbf{x}_j \tag{14}$$

and the i-th diagonal entry of $\mathbf{D}_j$ is denoted as

$$d_{ji} = \begin{cases} 1 & \text{if } (M_1\mathbf{x})_i = (\mathbf{W}_1\mathbf{x}_j + \mathbf{b}_1)_i > 0, \\ 0 & \text{else.} \end{cases} \tag{15}$$

By introducing a small deviation of $\epsilon > 0$ from 0, we then formulate the constrained optimization problem with the aim of obtaining $\mathbf{W}_1, \mathbf{b}_1, \mathbf{W}_2, \mathbf{b}_2, \{d_{ji}\}, \{z_{ji}\}$ at critical points of the following:

$$\text{(P1)} \begin{cases} \sum_j \|\mathbf{y}_j - M_2\mathbf{D}_j M_1\mathbf{x}_j\|^2 + \frac{c_1}{2}(\|\mathbf{W}_1\|_F^2 + \|\mathbf{W}_2\|_F^2) \\ +\frac{c_2}{2}\sum_j \|\mathbf{D}_j\|_F^2, \\ \text{subjected to} \begin{cases} -d_{ji}(M_1\mathbf{x}_j)_i + \max(0, z_{ji}) = \epsilon, \\ z_{ji} = (M_1\mathbf{x}_j)_i, \\ d_{ji} \in [0,1]. \end{cases} \end{cases}$$

The data-independent variables are $\mathbf{W}_1$, $\mathbf{b}_1$, $\mathbf{W}_2$, and $\mathbf{b}_2$, whereas the data-dependent variables are d_{ji} and z_{ji}, where $j = 1, \cdots N$ and $i = 1, \cdots, N_1$. If $\bar{\lambda}_{ji} \in \mathbb{R}$ and $\bar{\mu}_{ji} \in \mathbb{R}$ respectively denote the Lagrangian multipliers of the first and second constraints in (P1), then the augmented Lagrangian function for (P1) can be written as follows:

$$\begin{aligned} &\sum_j \|\mathbf{y}_j - M_2\mathbf{D}_j M_1\mathbf{x}_j\|^2 + \frac{c_1}{2}(\|\mathbf{W}_1\|_F^2 + \|\mathbf{W}_2\|_F^2) \\ &+ \frac{c_2}{2}\sum_j \|\mathbf{D}_j\|_F^2 + \sum_{ji}[\bar{\lambda}_{ji}(-d_{ji}(M_1\mathbf{x}_j)_i + \max(0, z_{ji}) - \epsilon] \\ &+ \frac{\rho_1^2}{2}\| - d_{ji}(M_1\mathbf{x}_j)_i + \max(0, z_{ji}) - \epsilon\|^2] \\ &+ \sum_{ji}[\bar{\mu}_{ji}(z_{ji} - (M_1\mathbf{x}_j)_i) + \sum_j \frac{\rho_2^2}{2}\|z_{ji} - (M_1\mathbf{x}_j)_i\|^2] \\ &+ \sum_{ji} \iota_{[0,1]} d_{ji}, \end{aligned} \tag{16}$$

where $\rho_1^2 > 0$ and $\rho_2^2 > 0$ are parameters and $\iota_{[0,1]}$ is the indicator function of $[0,1]$. To simplify the notation, we let $\bar{\theta} = \{c_1, c_2, \rho_1^2, \rho_2^2\}$, $\bar{d} = \{d_{ji}\}$, $\bar{z} = \{z_{ji}\}$, $\bar{\lambda} = \{\bar{\lambda}_{ji}\}$ and $\bar{\mu} = \{\bar{\mu}_{ji}\}$ and let $L_{\bar{\theta}}$ denote the above augmented Lagrangian function.

The primal variables in $L_{\bar{\theta}}$ include unbounded variables $\mathbf{W}_2$, $\mathbf{b}_2$, $\mathbf{W}_1$, $\mathbf{b}_1$, $\bar{z}$, where $\mathbf{b}_i$ are bias terms, and simple bounded variables $\bar{d}$. All primal variable except $\bar{z}$ can be alternatively updated to reach a local minimum of the augmented Lagrangian function in (reverse) from layer 2 to layer 1 when dual variables are fixed. This is evidenced by the fact that the augmented Lagrangian function is a strongly quadratic convex function when viewed as a function of any of the above variables except for $\bar{z}$ with the other variables fixed.

We can streamline the derivation of learning an L-layer ReLU network $\mathcal{M}_L\colon\ \mathbb{R}^{N_0} \to \mathbb{R}^{N_L}$ from input data, as in the 2-layer case. Consider learning an L-layer ReLU network $\mathcal{M}_L\colon \mathbb{R}^{N_0} \to \mathbb{R}^{N_L}$ based on $\{(\mathbf{x}_j, \mathbf{y}_j) | \mathbf{x}_j \in \mathbb{R}^{N_0}, \mathbf{y}_j \in \mathbb{R}^{N_L}\}_{j=1}^N$ input data. After un-rectifying ρs using data-dependent diagonal matrices $\{\mathbf{D}_j^1, \cdots, \mathbf{D}_j^L\}$ with constraints for input $\mathbf{x}_j$, we impose regularization on the Frobenius norm of weighting matrices, and introduce the quadratic term $\sum_{j,k} \|\mathbf{D}_j^k\|^2$, such that a unique closed-form solution to $\mathbf{D}_j^k$ can be obtained. Thus, the problem of learning (1) can be formulated as the process of seeking $\{\mathbf{W}_k\}_k, \{\mathbf{b}_k\}_k, \{\mathbf{D}_j^k\}_{k,j}$, and $\{z_{ji}^k\}_{i,j,k}$ as critical points for

$$\text{(PL)} \begin{cases} \sum_{j=1}^N \|\mathbf{y}_j - \mathcal{M}_L\mathbf{x}_j\|^2 + \frac{c_1}{2}\sum_{l=1}^L \|\mathbf{W}_l\|_F^2 \\ \qquad + \frac{c_2}{2}\sum_{j=1}^N \sum_{k=1}^{L-1} \|\mathbf{D}_j^k\|_F^2 \\ \text{subjected to} \begin{cases} -d_{ji}^k(M_k\mathbf{D}_j^{k-1}\cdots\mathbf{D}_j^1 M_1\mathbf{x}_j)_i \\ \qquad + \max(0, z_{ji}^k) = \epsilon, \\ z_{ji}^k = (M_k\mathbf{D}_j^{k-1}\cdots\mathbf{D}_j^1 M_1\mathbf{x}_j)_i, \\ d_{ji}^k \in [0,1], \end{cases} \end{cases}$$

where $j = 1, \cdots, N$, $k = 1, \cdots, L-1$, i is layer-dependent where $i = 1, \cdots, N_k$, c_2 is a very small value, and $\mathbf{D}_j^k = \mathrm{diag}([d_{ji}^k]_i)$. The augmented Lagrangian function can be obtained from the objective function and the first two sets of constraints. Analogous to the 2-layer case, the global convergence of L-layer ReLU networks learning can be derived by alternately updating the primal variables to reach critical points of the augmented function of (PL) with Lagrangian multipliers fixed.

Analogous to (2), problem (PL) can be formulated using the three-splitting approach. The CGT- algorithm that is used to solve the three-splitting formulation is similar to its counterpart algorithm in [7], omitted in the current study.

IV. Experiments

In Section IV-A, we choose the initial weights and numbers of layers by which to train networks (1) effectively. In Sections IV-B and IV-C, we compare the respective performance of classification and compressed sensing recovery problems involving a three-layer ReLU network $\mathcal{M}_3$ (fully-connected network with hidden layers comprising $1,000$ hidden units), using full-batch training, including MNIST, fashion-MNIST, and set11 (natural images) datasets as well as the initial weights and number of layer discussed in Section IV-A.

In this section, CGT-extension denotes the proposed method; BCD denotes the block-coordinate-descent method with three-

splitting formulation [3][2]; dlADMM denotes the ADMM method proposed for deep learning [18][3]; and Adam denotes the Adam optimizer (Pytorch optimization package), which is a state-of-the-art implementation of the back-propagation algorithm. The parameters unique to each method were carefully selected or set at default values to enable fair comparisons.

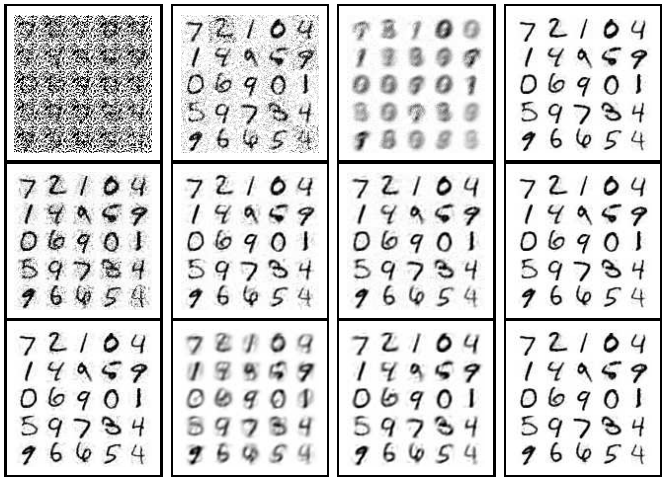
A. Initialization phase

Initial weights are typically obtained via sampling from an independently identically distributed (i.i.d) zero-mean Gaussian random variable of given variance. To provide a fair basis for comparison, we first conducted experiments aimed at determining the variance of an i.i.d. zero-mean Gaussian random variable for initial weights that work well with all selected methods. To access robustness against the number of hidden layers, we also conducted experiments using various numbers of hidden layers using the following simulation:

Let $Y \in \mathbb{R}^{784\times 60{,}000}$ denote the output of a two-layer ReLU network using the MNIST dataset as an input. Let $X \in \mathbb{R}^{784\times 60{,}000}$ denote the input and let σ denote the ReLU activation functions. Note that $Y = \bar{W}_2\sigma\bar{W}_1X$, where $\bar{W}_1 \in \mathbb{R}^{784\times 784}$ and $\bar{W}_2 \in \mathbb{R}^{784\times 784}$ are Gaussian matrices. Each element in a matrix was sampled from an i.i.d. Gaussian random variable with the mean set at zero and standard deviation set at one.

We then trained three-layer and eight-layer ReLU networks, $\mathcal{M}_3$ and $\mathcal{M}_8$, with $1,000$ hidden units in each hidden layer based on objective functions $\|X-\mathcal{M}_3Y\|_F^2$ and $\|X-\mathcal{M}_8Y\|_F^2$, where the training input is Y and output is X. We then compared the performance of the resulting networks when the initial weights were sampled from the i.i.d. zero-mean Gaussian random variable with the standard deviation of the weights respectively set at 0.1, 0.05, and 0.01.

Figures 1 and 2 compare the reconstruction quality of an image from the MNIST dataset using various initial weights and numbers of hidden layers.



B. Classification

Both the MNIST [19] and Fashion-MNIST datasets contain ten classes of images, including $60,000$ training samples and $10,000$ testing samples with 784 features each. The loss function was deterministic cross-entropy loss. The number of learning epochs was set at 200 and the batch size was set at $60,000$. The learning rate of the Adam optimizer was at 0.001 for both MNIST and Fashion-MNIST datasets.

Figures 3 and 4 respectively present curves indicating the testing accuracy of the baselines and CGT-extension method. The CGT-extension method outperformed the baseline values for both datasets. Table I lists the time required to complete classification of the MNIST and Fashion-MNIST datasets. The CGT-extension method achieved high accuracy classification in fewer epochs than was required by the other methods. Note that

Fig. 1: Image recovery performance based on reconstruction using three-layer network $\mathcal{M}_3$ based on (a) BCD, (b) dlADMM, (c) Adam, and (d) CGT-extension methods. The standard deviations in the initial weights were as follows: (first row) 0.1, (second row) 0.05, and (third row) 0.01. Only the CGT-extension method generated recognizable images regardless of the standard deviation. Standard deviation of 0.01 was deemed acceptable for the BCD method and 0.05 was acceptable for the others.

(a) BCD (b) dlADMM (c) Adam (d) CGT-ext

Fig. 2: Image recovery performance in terms of reconstruction using eight-layer network $\mathcal{M}_8$ based on (a) BCD, (b) dlADMM, (c) Adam, and (d) CGT-extension methods. The standard deviation in the initial weights were as follows: (first row) 0.1, (second row) 0.05, and (third row) 0.01. Only the CGT-extension method generated recognizable images regardless of the standard deviation. Standard deviation of 0.01 was deemed acceptable for the BCD method and 0.05 was acceptable for the others.

CGT-extension required far more time than did the Adam in increasing accuracy from 0.96 to 0.97. This indicates that the learning times could be reduced by implementing two methods within a hybrid system in which CGT-extension is used in the early stage and the Adam optimizer is used at later stage.

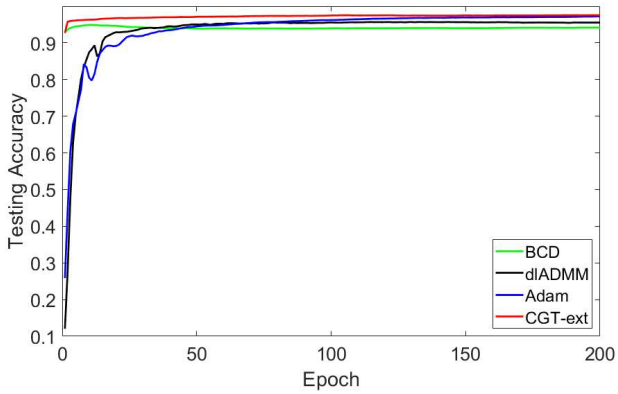

Fig. 3: Classification performance when applied to the MNIST dataset. BCD and CGT-extension methods both achieved accuracy of 0.9 in the early stage. In subsequent iterations, CGT-extension increased steadily towards 1.0; however, the BCD method improved little. Note that the curves of dlADMM and Adam rose slowly. The CGT-extension method converged far more quickly than did the Adam optimizer; however, the ultimate performance was similar.

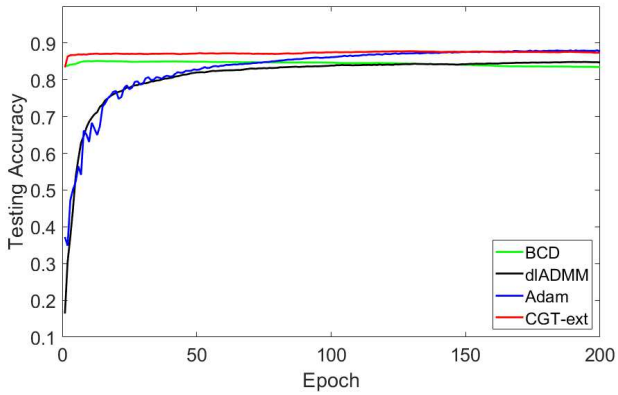

Fig. 4: Classification performance when applied to the Fashion-MNIST dataset. BCD and CGT-extension methods both exceeded 0.8 in the early stage. In subsequent iterations, CGT-extension increased steadily towards 0.9; however, the BCD method improved little. Note that the curves of the dlADMM and Adam methods did not rise as quickly as those of the CGT-extension and BCD methods. The CGT-extension method converged far more quickly than did the Adam optimizer; however, the ultimate performance was similar.

C. Compressed sensing recovery

For a given $m \times n$ sensing matrix $\mathbf{A}$ in which $m < n$ and measurement $\mathbf{y} \in \mathbb{R}^m$ with $\mathbf{y} = \mathbf{A}\mathbf{x}$, the compressed sensing recovery problem involves recovering the sparsest signal $\mathbf{x} \in \mathbb{R}^n$ from $\mathbf{y}$. This is an ill-posed inverse problem, as $n > m$, where the CS ratio is defined as $\frac{m}{n}$. In the current study, we adopted the approach proposed in [20]–[22] in which a DNN learns a deep ReLU network mapping sparse vectors from measurements, where sensing matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$ is a Gaussian random matrix with elements sampled from i.i.d. Gaussian random variables with zero mean and variance $\frac{1}{m}$. Our training data was $(\mathbf{A}^+\mathbf{Y}, \mathbf{X})$, where $\mathbf{X}$ was an array with sparse vectors in the columns, $\mathbf{A}^+$ was the pseudo-inverse of $\mathbf{A}$, $\mathbf{A}\mathbf{A}^+ = \mathbf{I}$, and arrays $\mathbf{Y}$ and $\mathbf{X}$ were related to each other via $\mathbf{Y} = \mathbf{A}\mathbf{X}$. The ReLU network $\mathcal{M}_3$ (three-layer, each hidden layer with 1000 hidden units) was learned with the aim of optimizing the least-squares regression problem as follows:

$$\|\mathbf{X} - \mathcal{M}_3\mathbf{A}^+\mathbf{Y}\|_F^2. \tag{17}$$

$\mathcal{M}_3$ is un-rectified and then learned using Algorithm 1. In testing, we obtain the vector of $\mathbf{y}$ with respect to $\mathbf{A}$ via forward-inference using $\hat{\mathbf{x}} = \mathcal{M}_3\mathbf{A}^+\mathbf{y}$. We compared $\mathcal{M}_3$ derived using various learning methods in terms of compressed sensing recovery performance using experiments based on the MNIST and set11 datasets.

In the MNIST dataset, n was set at 784 and the value of m varied (10, 25, 100, or 200). Note that these values respectively correspond to CS ratios of 1%, 3%, 13%, and 26%. The number of learning epochs was set at 300 and the batch size was set at $60,000$. Figure 5 illustrates the reconstruction errors in terms of MSE versus CS ratio in the recovery of MNIST testing data. Figure 6 illustrates the perceptual quality of the reconstructed images. Consistent with the numerical results shown in Figure 5, the visual quality of the reconstructed images improved with an increase in the number of measurements.

Experiment using Set11 used natural images for CS recovery. The 91 images in [22] were used for training[4]. Patches (32×32 pixels) were extracted from the luminance components of the images using a stride of 4 in each dimension. The total number of training patches was $117,242$. The 11 images in Set11 were used for testing. $58,523$ testing patches were obtained in a manner similar to that used in the extraction of training patches. The size of image patch n was set at 1024 px and the size of m varied (10, 51, 102, 153, 256, or 512 px). Note that these values respectively correspond to CS ratios of 1%, 5%, 10%, 15%, 25%, and 50%. Let $\mathbf{X}$ and $\mathbf{Y}$ denote the sets of training patches and their respective measurements. Three-layer ReLU network $\mathcal{M}_3$ was learned using $\mathbf{Y}$ as the input and $\mathbf{X}$ as the desired output. The number of epochs was set at 500 and the batch size was set at $117,242$. Reconstructed (testing) images were obtained by averaging the overlapped patches and then measuring the

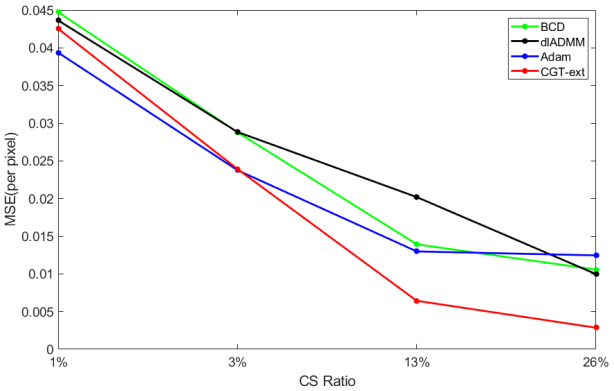
Adam	55.4	76.4	111.8	**209.8**	74.6	95.4	115.0	**146.8**
CGT-ext	48.1	**71.2**	**94.2**	1082.6	50.8	50.8	**73.9**	441.8



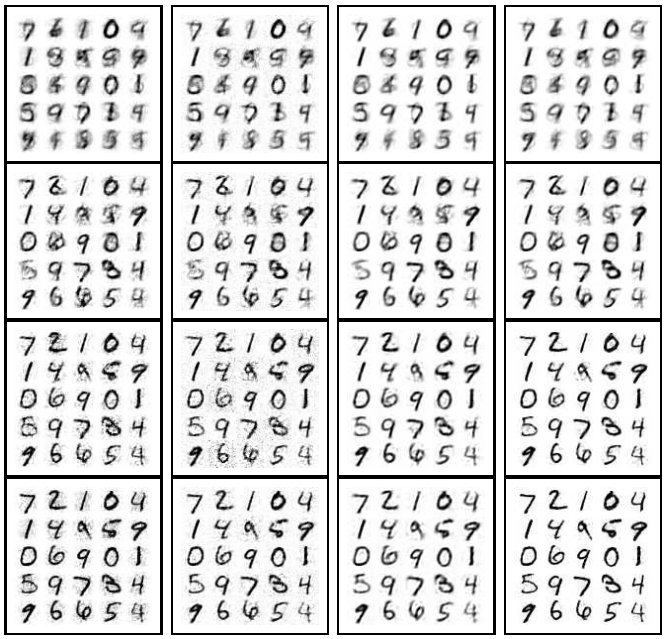


Fig. 5: Comparison of average MSE (per pixel) from MNIST testing images versus CS ratio for a compressed sensing recovery problem with the learning rate of the Adam optimizer set at 0.001, the BCD and dlADMM parameters set at default values, and the initial CGT-extension parameters set int accordance with Remark 2 in Algorithm 1.

(a) BCD (b) dlADMM (c) Adam (d) CGT-ext

Fig. 6: Quality of images reconstructed from (a) BCD, (b) dlADMM, (c) Adam, and (d) CGT-extension methods. CS-ratio: (first row) 1%, (second row) 3%, (third row) 13%, and (fourth row) 26%. When the CS ratio fell below 26% (corresponding to $m = 200$), the Adam optimizer and the CGT-extension methods achieved perceptual quality superior to that of the BCD and dlADMM. Nonetheless, at a CS ratio 26%, all four methods yielded images of consistently high perceptual quality.

average peak-to-noise ratio (PSNR) in Table II. CGT-extension achieved the best performance regardless of CS ratio. Figure 7 presents images ($Parrot$) reconstructed with the CS ratio set at 10% and 50%. The perceptual quality matched the results in Table II. Overall, the CGT-extension method (CS ratio = 50%) preserved more of the details, while providing sharper edges. At a CS ratio of 10%, the perceptual quality of the BCD and proposed methods were roughly the same.

TABLE II: Average PSNR(dB) in the recovery of images in Set11 using varying CS ratios (best performances in bold).

Method	CS ratio					
	1%	5%	10%	15%	25%	50%

V. Conclusions

This paper demonstrates that deep learning problems can be solved using the augmented Lagrangian approach, based on our extension of the algorithm originally developed by Conn, Could, and Toint. Note that this conclusion is based on the application of un-rectification without introducing additional data-depependent slack variables, which would otherwise hamper the applications of this technique to large datasets and deep neural networks. Un-rectifying a ReLU network makes it possible to formulate a learning problem as a non-convex optimization problem with activation variables corresponding to un-rectifying ReLUs relaxed to data-dependent variables within domains confined to closed segments, and constraints expressed as continuous functions. We demonstrate that un-rectifying networks allows global convergence to local optima when the updating of primal variables is subjected to alternating minimization. We compared the performance of the proposed scheme with other state-of-the-art deep learning

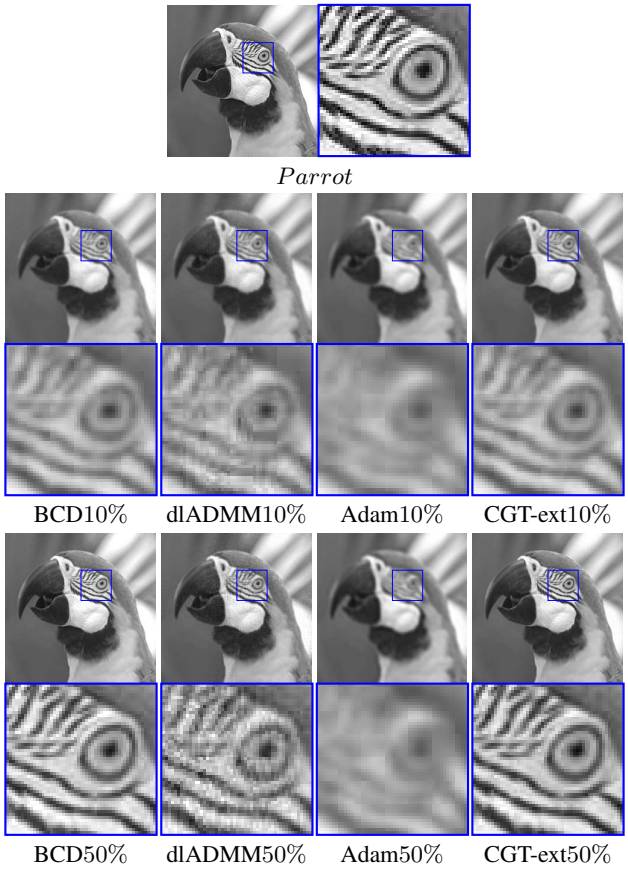

Fig. 7: Perceptual quality of reconstructed images in Set11 dataset with CS ratio set at 10% and 50% with the learning rate of the Adam optimizer set at 0.001 and the BCD and dlADMM parameters set at default values.

methods for classification and compressed sensing recovery problems. Our theoretical results assume a batch input. The question of whether theoretical results could be derived using mini-batch inputs is a subject worthy of further study.

***Abstract* — Assessing the difficulty of a Yoga pose is a challenging task, often dependent on individuals' subjective judgement or consultation with professionals to choose poses that fit their needs. In this study, a preliminary difficulty calculation method for estimating the difficulty of Yoga poses is proposed, and it is applied to the Yoga poses in the proposed system in order to provide a user-friendly difficulty reference. OpenPose is applied in the system to detect user's movements and extract the key-points information. In the experimental results, seven users are inquired to participate in practicing Yoga by the proposed system, and they are asked to provide the difficulty levels rating from 1 to 5. These subjective difficulty levels are used to compare the estimated difficulty levels. The results indicate a positive correlation between the subjective and estimated difficulty results.**

***keywords* — Yoga, difficulty, complexity, duration time, stability, angle difference, Euclidean distance, level.**

I. INTRODUCTION

Yoga is one of the most popular exercises nowadays. It requires less time and doesn't need to have large space, making it convenient for daily exercise at home. Yoga helps people maintain physical health and is suitable for all ages of users. There are numerous poses in Yoga, and each pose may vary in difficulty. However, the difficulty of Yoga poses is subjective and varies from different people. In this research, a preliminary method for estimating the difficulty of Yoga poses is proposed and applied to the Yoga poses in this system. It is used to provide a more objective difficulty assessment, allowing users to choose Yoga poses are more suitable for them in a more straightforward way.

In the system, the OpenPose [1-2] is applied for human body detection. OpenPose is applied in a wide research fields, such as self-learning system [3-4], exercise analysis [5], and medical applications [6]. This paper focuses on the design of a self-learning system for Yoga training. OpenPose is an open source library [7] provides various pose models for body detection, and the BODY25 model is used in this system. The 25 key-points of the human body can be extracted through the BODY25 model as shown in the Fig. 1, the key-points and skeleton information are rendered on the image of instructor.

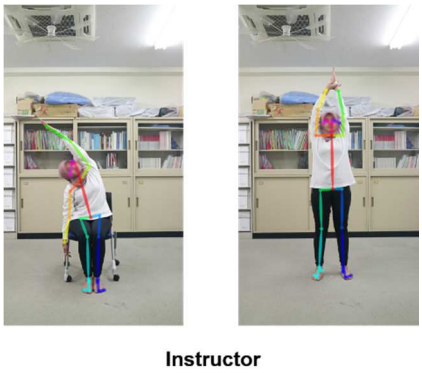

Fig. 1. Examples of BODY25 model detection

II. RELATED WORK

The five Yoga poses are provided from [3]. For each pose, only the main key-points is selected called selected key-points in [8]. The selected frames such as initial frame, keyframes and sync frames in each pose are defined in [9]. This research is an extended work of [10], the standard duration time, time distribution, the definition of static and dynamic regions of each pose is proposed. In [11], the researchers classified ten Yoga poses on six models, and they utilized angle information by using the tf-pose algorithm to extract the key-points of the poses. In [12], the researchers proposed a Yoga pose correction system, gave users suggests to help them correct their pose.

III. PROPOSED METHOD

In the method, we use instructor's video to analyze the difficulty of each Yoga pose.

A. Elements of Estimation

In the proposed estimation method, there are three elements are considered to measure the difficulty of Yoga poses: complexity (**CP**), duration time (**DT**), and stability (**SB**).

From the 25 key-points extracted by OpenPose, key-points 3, 4, 6, 7 (upper body) and 10, 11, 13, 14 (lower body) [8] are selected as target key-points to observe the movement variations. CP is defined based on the number of the target key-points required in the pose, as shown in TABLE I. The more key-points are needed, the more body parts need attention during the Yoga.

TABLE I. COMPLEXITY OF EACH YOGA POSE

Pose	Complexity (CP)
Mountain	4
Seat_1	4
Seat_2	4
Side_bend	4
Warrior	8

In Yoga, we have divided the sequence into dynamic and static regions, and defined the movement time for each movement region as duration time [10]. When the required DT is longer, the user needs more concentration.

The stability is analyzed separately for the upper and lower body. In the upper body, the angle difference (AD) is calculated for each selected key-point, while in lower body, the Euclidean distance (ED) is calculated for each selected key-point as follows:

$$AD = \theta^{C}_{T(\alpha)} - \theta^{C}_{T(\beta)} \tag{1}$$

$$ED = \sqrt{\left(x_\alpha - x_\beta\right)^2 + \left(y_\alpha - y_\beta\right)^2} \tag{2}$$

In Eq. (1), the angel of the selected key-point (T) is relative to the center key-points (C) which are 2nd, 5th (upper body) and 9th, 12th (lower body). In Eq. (2), the x, y are the coordinates of the selected target key-points. In both equations, the subscripts α and β are the index of the instructor's frames will be discussed in the following chapters.

The angle difference values in the upper body and the distance values in the lower body of each selected key-point are summed up, referred to the total angle difference (TAD_{upper}) and the total distance (TD_{lower}) as follows:

$$TAD_{upper} = \sum_{i=0}^{N} \left| AD_{selected[i]} \right| \tag{3}$$

$$TD_{lower} = \sum_{i=0}^{N} ED_{selected[i]} \tag{4}$$

In Eq. (3) and Eq. (4), the N is the number of selected key-points in each Yoga pose.

According to different considerations regarding static poses and dynamic poses, the estimation method is divided into static poses difficulty estimation and dynamic poses difficulty estimation.

B. Static Poses Difficulty Estimation

The difficulty estimation of each static pose in the Yoga is as follows:

$$Difficulty_S = CP * \sqrt{DT_{Si}} * \begin{cases} SB_{s,upper} \\ SB_{s,lower} \end{cases} \tag{5}$$

In Eq. (5), the DT_{Si} is the duration time of each static region, the stability calculation is mapped to two situations (upper and lower body).

Fig. 2 shows an example of evaluating the stability of a static pose in the Warrior pose. In static poses, the stability is calculated by comparing the keyframes of the instructor with the 0th frame of the Yoga pose, to assess the stability of the static pose in the Yoga, the stability of upper body ($SB_{s,upper}$) and stability of lower body ($SB_{s,lower}$) can be obtained from Eq. (1) and Eq. (2) respectively, which α is 0 and β is 280. In a Yoga video, since there are multiple static regions, there will be multiple static difficulty values and stored into a list after calculation.

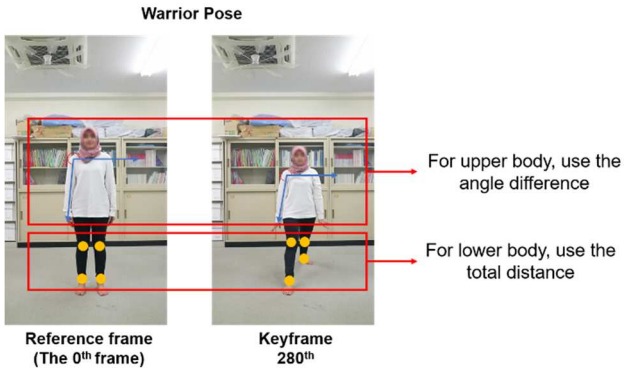

Fig. 2. Schematic of static poses difficulty estimation

C. *Dynamic Poses Difficulty Estimation*

The difficulty estimation of each dynamic pose in the Yoga is as follows:

$$Difficulty_D = CP * \sqrt{DT_{Di}} * \begin{cases} SB_{D,upper} \\ SB_{D,lower} \end{cases} \quad (6)$$

In Eq. (6), the DT_{Di} is the duration time of each dynamic region, the stability calculation is different from static poses, the pose velocity in the dynamic regions is considered as shown in Fig. 3.

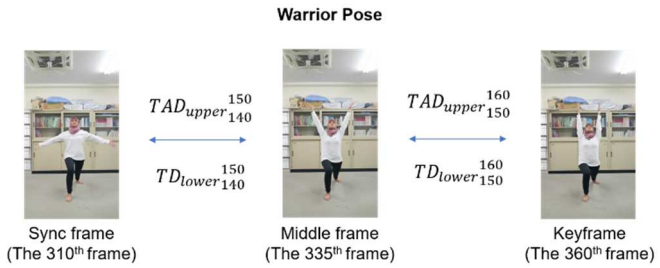

Fig. 3. Schematic of dynamic poses difficulty estimation

The specific frames (initial/key/sync frames) have defined in [9]. In a dynamic region, an additional frame is considered by including a middle frame to measure the pose speed as the dynamic stability. In Fig. 3, there is a dynamic region from the 310th frame to the 360th frame of Warrior pose. In this region, the total angle difference of the upper body and the total distance of the lower body are separately calculated between the sync frame and the middle frame, as well as between the middle frame and the keyframe. Then, these values are used to determine the stability of the upper and lower body in the dynamic region as the formula follows:

$$SB_D = \begin{cases} \frac{TAD_{upper}{}^{Middle}_{Start} + TAD_{upper}{}^{End}_{Middle}}{frame\ number}, upper\ body \\ \frac{TD_{lower}{}^{Middle}_{Start} + TD_{lower}{}^{End}_{Middle}}{frame\ number}, lower\ body \end{cases} \quad (7)$$

In Eq. (7), the frame number is the index difference of selected frame plus 1, in Fig. 3, the frame number is 51. $Start$ is the index of the initial frame or sync frames, $Middle$ is the index of the middle frame, and End is the index of the keyframes.

In a Yoga video, since there are multiple dynamic regions, there will be multiple dynamic difficulty values and stored into a list after calculation.

D. *Difficulty Normalization and Level Transformation*

Because the upper and lower body have different considerations and calculation methods for static and dynamic poses. After difficulty calculation, it needs to do the data normalization. The difficulty data normalization flow is as follows:

Step 1: Merge the body difficulty lists of static and dynamic poses in each Yoga pose, resulting in four merged lists as shown in Fig. 4.

Step 2: Normalize the difficulty values in each merged list to a range of 0 to 1.

Step 3: Divide each normalized merged list into segments based on the number of static and dynamic regions in each Yoga pose.

Step 4: Calculate the sum and average of each list.

Step 5: Finally, each Yoga pose will have four floating-point difficulty values representing the overall upper and lower body static difficulty, overall upper and lower body dynamic difficulty respectively.

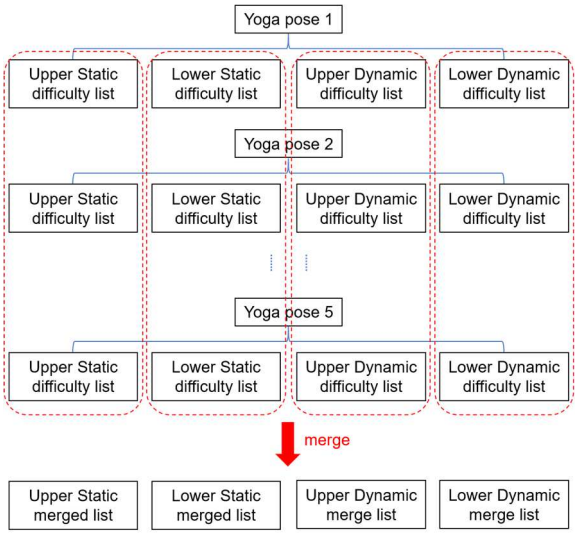

Fig. 4. Difficulty data merge flow

However, not all Yoga poses perform both upper and lower body parts. According to the TABLE II, the overall difficulty of body parts is selected in each Yoga pose. For example, the

overall upper body static and dynamic difficulty is selected in Mountain pose.

TABLE II. SELECTED OVERALL BODY DIFFICULTY OF EACH POSE

Pose	Selected Overall Body Difficulty
Mountain	Upper
Seat_1	Upper
Seat_2	Upper
Side_bend	Upper
Warrior	Upper and Lower

After selecting the corresponding body part difficulty, the overall body static and dynamic difficulty are averaged as pose difficulty, then, the pose difficulty is transformed into pose level ranging from 1 to 5 according to the TABLE III. This provides a more straightforward difficulty reference for users to choose the Yoga poses.

TABLE III. POSE DIFFICULTY TO LEVEL TRANSFORMATION

Pose	Pose Level
$0 \leq$ pose difficulty < 0.2	1
$0.2 \leq$ pose difficulty < 0.3	2
$0.3 \leq$ pose difficulty < 0.4	3
$0.4 \leq$ pose difficulty < 0.5	4
pose difficulty ≥ 0.5	5

IV. EXPERIMENTAL RESULTS

In the experimental results, five Yoga poses named Mountain (arm stretching and bending forward), Seat_1 (lateral stretching with both hands combined performed on chair), Seat_2 (lateral stretching with one arm performed on chair), Side_bend (long-time held side bend pose) and Warrior (full-body stretching movement) are used to estimate the difficulty. For Mountain, Seat_1, Seat_2 and Side_bend, they focus on the upper body movements, only the upper body difficulty is selected. However, for Warrior, it requires the coordination between the upper and lower body, both upper and lower body difficulties are selected.

In TABLE IV, it presents the dynamic and static difficulty for each Yoga pose, categorized into upper body (**U.**), lower body (**L.**) and the sum of the difficulty (**S.**). In the dynamic analysis of Warrior pose, the sum of the body difficulties exceeds 1, but the limit is 1. Therefore, it is reassigned as 1.

After obtaining the sum of body difficulties, the average difficulty of static and dynamic analysis is calculated to obtain the pose difficulty (**PD.**). Then, according to the TABLE III, the pose levels for each Yoga pose are determined as 2, 2, 2, 3, and 5 respectively.

TABLE IV. ESTIMATED DIFFICULTY OF EACH POSE

Estimated Difficulty							
Pose	Static			Dynamic			PD.
	U.	L.	S.	U.	L.	S.	
Mountain	0.12		0.12	0.33		0.33	0.225
Seta_1	0.23		0.23	0.36		0.36	0.295
Seat_2	0.17		0.17	0.41		0.41	0.29
Side_bend	0.45		0.45	0.17		0.17	0.31
Warrior	0.28	0.36	0.64	0.74	0.43	1	0.82

To compare the estimated pose level in this research, seven male users (M1~ M7) are invited to perform the Yoga poses and provide the subjective pose level from 1 to 5 as shown in TABLE V. According to the survey, the user's subjective pose levels are 2, 2, 2, 2, 3.

TABLE V. USER'S SUBJECTIVE DIFFICULTY LEVEL

Pose	Subjective Difficulty (1 ~ 5)				
	Mountain	Seat_1	Seat_2	Side_bend	Warrior
M1	2	2	3	4	4
M2	3	2	2	1	3
M3	2	2	2	1	3
M4	1	2	2	1.5	1.5
M5	3	2	2	2	2
M6	2	3	2	3	4
M7	2	2	3	1	4
Avg.	2.14	2.14	2.29	1.93	3.07
Round	2	2	2	2	3

To better observe the estimated pose levels and user's subjective pose levels, Fig. 5 shows the trend of the two data. It can be seen that in Mountain, Seat_1, and Seat_2 poses, the estimated pose levels are equal to the user's subjective experience. In Side_bend and Warrior poses, although there is some difference, the trends of the two data are similar.

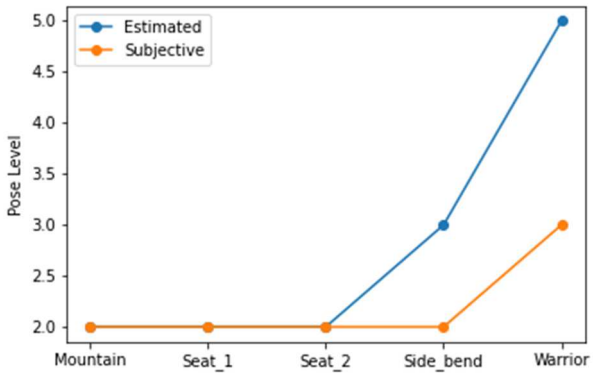

Fig. 5. Pose level trend between estimated and subjective results

V. Conclusions and Future Work

This study proposes a preliminary Yoga pose difficulty estimation method by considering key-points, movements duration time and the stability of the Yoga poses. The estimated pose levels are provided as a reference for users. The experimental results compare the estimated pose levels with the users' subjective experience, and it show the similarity in each other.

The difficulty estimation in this study applies on the Yoga instructor videos in the system, and the estimated difficulty results are relative. It will be better to improve the estimation method to be a more comprehensive approach and apply on more external Yoga data. In the user's survey, there are all young people, which may lead to the user survey a bias. It will be better to invite more middle-aged or elderly users to take the survey, make the user survey more diverse and comprehensive.

***Abstract*—This paper describes automatic music emotion recognition (MER) that aims to estimate the valence and arousal (V/A) scores of a piece of piano music. The emotion is multifaceted in nature; it is rendered by various features that are often mutually dependent and inherent in music composition and performance. A basic approach to MER is to train a deep neural network (DNN) that extracts latent features representing the emotion as a whole and estimates the V/A scores, using only a limited amount of audio data with imbalanced V/A annotations. Such a black-box approach, however, suffers from limited performance and interpretability. To overcome these limitations, in this paper we propose a multimodal multifaceted MER method that fuses various kinds of musically-meaningful symbolic and acoustic features extracted from both MIDI and audio data, respectively, based on the expert knowledge of musical psychology. More specifically, our method separately extracts the affective features representing the rhythm, dynamics, melody, harmony, and tone color of a piano piece as the main factors affecting the emotion and integrates them with a self-attention mechanism that can learn the complicated cross-modal relationships. The experiments using the common EMOPIA dataset showed that the proposed model achieved the state-of-the-art V/A classification accuracy of 69.2% and that the multimodal and multifaceted feature fusions contributed to the performance improvement.**

I. Introduction

Music emotion refers to the affective information conveyed through music and is considered the essence of music itself. It is thus necessary to analyze music data from both objective and subjective viewpoints. As well as automatic music transcription (AMT), music emotion recognition (MER) has been a long-standing fundamental task in the field of music information retrieval (MIR) [1], because it plays a crucial role in emotion-based personalized music retrieval and recommendation systems. The abstract nature of the emotion and the expensive cost of collecting subjective annotations, however, pose a challenge to the development of MER methods.

Music emotion is multifaceted and multimodal in nature; various features of music composition and performance may implicitly interact to render an emotion in a sophisticated manner unique to the musical piece. This makes deep learning (DL) methods [2]–[4] hard to learn a consistent mapping from a specific type of music representation (e.g., score, lyrics, or audio) to the overall emotion of the piece, resulting in the limited performance of the valence and arousal (V/A) estimation. To mitigate this problem, for instance, Berardinis et al. [5] separately extracted affective acoustic features from the vocal, bass, drum, and the other parts of a music signal obtained with a source separation method. Zhao et al. [6] separately extracted text and acoustic features from the text (i.e., lyrics and track and artist names) and audio data and fused them one by one with a cross-modal attention mechanism. However, these existing methods still have some problems: on the one hand, these methods have high requirements for experimental data and can only be applied to specific music; on the other hand, the performance and interpretability of these methods are still unsatisfactory.

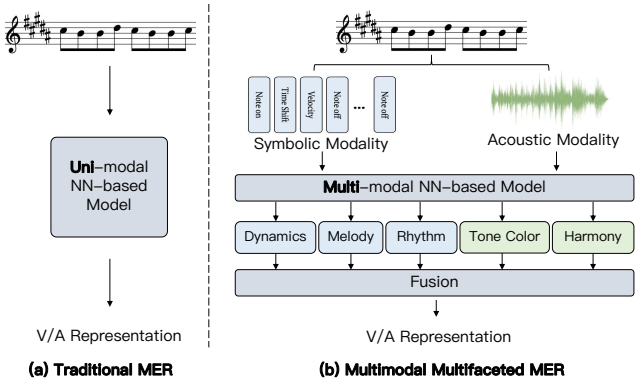

Fig. 1. Comparison between the conventional and proposed approaches.

For interpretable MER, we refer to the investigations of affective features in the fields of music psychology and affective computing. Laukka et al. [7], for example, proposed a human perception model for instrumental music and found that six factors, i.e., dynamics, rhythm, timbre, register, tonality, and structure, characterize the emotional expression of music. Renato [8] revisited this issue from a computational perspective and found eight factors useful for MER, i.e., melody, harmony, rhythm, dynamics, tone color, expressivity, texture, and form. These findings were supported by several empirical studies and experimental results [9], [10]. The superiority of a multifaceted approach was also shown in [11], [12].

In this paper, we propose a multimodal multifaceted MER method for piano music that fuses various kinds of musically-meaningful symbolic, and acoustic features separately extracted from MIDI and audio data, respectively (Fig. 1). Using the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

findings of musical psychology for the network design, a deep neural network (DNN) is expected to be trained effectively with a limited amount of multimodal data. Specifically, our method separately extracts affective features regarding particularly important five factors, i.e., rhythm, dynamics, melody, harmony, and tone color. At the heart of our method is to use a self-attention mechanism that can learn the complicated relationships between different factors and modalities for integrating the extracted features in a weighted manner depending on the musical piece. We show that the proposed approach can achieve the state-of-the-art performance of V/A estimation on the public dataset called EMOPIA [13].

II. Music Emotion Revisited

This section describes five major factors that are considered to play key roles in emotional expression in piano music and which aspects of emotional content are affected. Our theory is based on the findings of recent MER studies and the knowledge in music psychology.

Rhythm refers to the temporal organization and pattern of notes and rests. It determines the timing and duration of each note, creating a sense of pulse, meter, and musical flow. Rhythmic information is usually described as beat, tempo, or accentuation. Rhythm is considered one of the most important elements in emotional expression, it is mainly associated with both the excitement and the happiness of the music.

Dynamics refers to the variations in volume and intensity. It involves the manipulation of loudness and softness to create expressive and emotional effects. It adds depth, contrast, and nuance to the musical interpretation, allowing the pianist to shape the phrases, highlight melodic lines, and create a dramatic impact. Dynamics is also related to the power and intensity of the music and the variation of dynamics may influence the positiveness of the music.

Melody refers to the main musical line or theme that carries the expressive and melodic content of the composition. The prominent sequence of notes stands out and captures the listener's attention. The melody is usually played in the right hand and encompasses the memorable aspect of the music. It carries the emotional and narrative essence of the piece, often conveying a sense of beauty, expression, and storytelling. The melodic elements therefore influence the valence and arousal scores of the emotional expression.

Harmony refers to the simultaneous sounding of multiple notes to create chords and chord progressions. It involves the vertical aspect of music, where different pitches are combined to form harmonious sounds. Harmony provides the foundation and support for the melody, adding depth, richness, and complexity to the overall musical texture. It establishes the tonal framework and creates a sense of stability, tension, and resolution. Harmonic arrangement significantly contributes to the mood, character, and emotional impact of the piece. Major chords are usually related to positive emotions, while minor chords to negative emotions. The complexity of harmony can also be related to the tension and instability of the emotional expression.

Tone color or timbre refers to the unique character of a sound. It is a distinct combination of harmonics, overtones, and how sound is shaped and perceived. Tone color adds richness, variety, and individuality to the musical expression. It can vary according to the specific piano used, the technique employed by the pianist, and the musical context. For example, playing the same note on different parts of the piano keyboard or using different levels of touch can produce different tone colors. Tone color plays a significant role in conveying emotions, creating contrasts, and highlighting musical ideas. Brighter tone color is related to positive or exciting emotions.

Based on the research of Renato et al. [8], we selected some music features that are most suitable for representing the five major factors and designed our model for interpretable piano music emotion recognition.

III. Proposed Method

This section describes the proposed MER method that can consider the multifaceted and multimodal nature of music emotion (Fig. 2). The key feature of the proposed method is to separately analyze the major factors that form the emotion and integrate them in a data-adaptive manner. Our method is implemented on a standard multi-branch DNN consisting of three separate feature extraction branches, the feature fusion module, and the classifier.

A. Melody, Rhythm, and Dynamics Analysis for MIDI Data

We assume that the melody, rhythm, and dynamics factors are originally encapsulated in the symbolic domain (musical score), where these factors have close connections to the distributions of note pitches, locations, and velocities, respectively. Most existing MER methods, however, have dealt with only audio data, where such score-originated factors are treated together with audio-originated factors in a mixed way. In this study, we aim to explicitly learn the statistical patterns of notes from musical scores in a musically-meaningful manner faithful to the findings of music psychology.

As a score representation that plays a crucial role in MER, we use the standard MIDI-like representation. A musical score is serialized as a token sequence, where each note consists of the "note-on", "note-off", and "velocity" tokens and the "time shift" token represents the time interval between notes.

To learn contextual relationships and structural information from MIDI data, we use a recurrent neural network (RNN). Because symbolic music datasets with emotion are severely limited in size, we use as a relatively simpler structured model the bidirectional gated recurrent unit (Bi-GRU) instead of the bidirectional long short-term memory (Bi-LSTM) network to avoid overfitting. Our model consists of two stacked units with 256 hidden layer units each. This computation process can be simply described as follows:

$$\overrightarrow{h_t} = \mathrm{GRU}(\mathrm{token}_t, \overrightarrow{h}_{t-1}), \tag{1}$$

$$\overleftarrow{h_t} = \mathrm{GRU}(\mathrm{token}_t, \overleftarrow{h}_{t+1}), \tag{2}$$

$$h_t = \mathrm{Concat}(\overrightarrow{h_t}, \overleftarrow{h_t}). \tag{3}$$

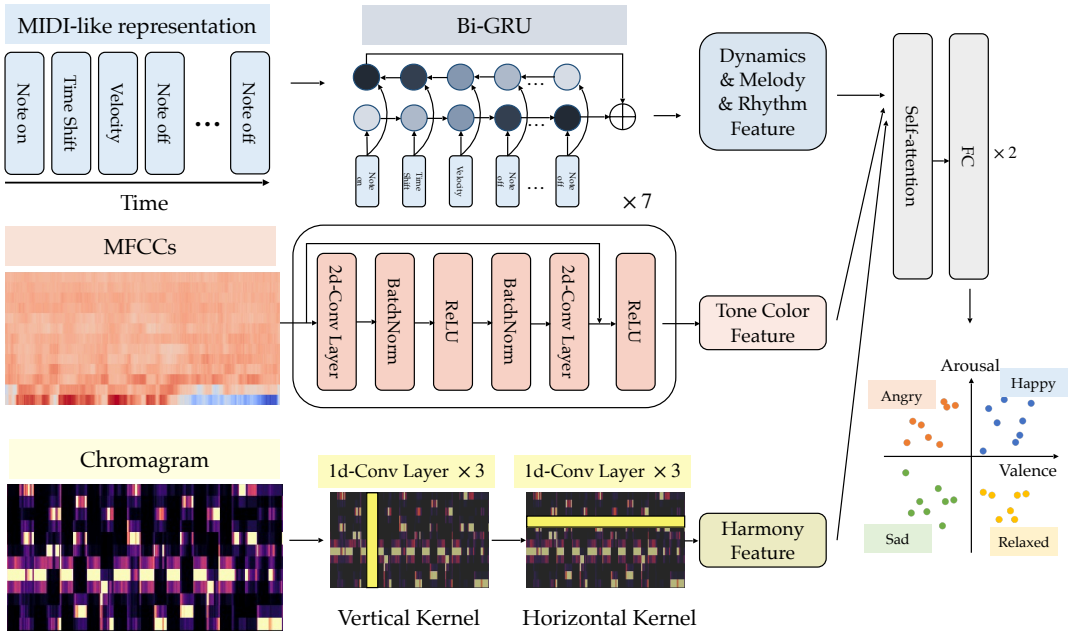

Fig. 2. The proposed network architecture consisting of symbolic and acoustic feature extraction modules and an adaptive feature fusion module with a self-attention mechanism for multimodal multifaceted music emotion recognition.

where $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$ refer to the forward and backward hidden states at time step t respectively, token_t refers to the input MIDI-like token at time step t, h_t is the output hidden state of the Bi-GRU at time step t, which is obtained by concatenating the hidden states in both directions.

After being processed by the trained Bi-GRU, the MIDI-like token sequence is encoded into symbolic domain features encompassing melody, rhythm, and dynamics information. These features can be directly fed into a fully connected classifier for emotion prediction.

B. Harmony Analysis for Chromagrams

We assume that the harmony factor can be effectively extracted from the chromagram of a music signal, which represents the time-varying distributions of twelve pitch classes ranging from C to B in one octave. The chromagram can be obtained from the short-time Fourier transform (STFT) of a music signal with librosa.

To simultaneously learn harmonic structures over frequency and their progressions over time, we use a convolutional neural network (CNN) with a stack of vertical (frequency-directional) and horizontal (time-directional) convolutions on the chromagram. More specifically, we use three Conv1D layers with a vertical convolution kernel to learn the instantaneous information (pitch combination), followed by three Conv1D layers with a horizontal convolution kernel to aggregate the temporal information. The sizes of the vertical and horizontal kernels are (12, 1) and (1, 48), respectively, in this study. Although the pitch or melody information is extracted from the chromagram as well as the harmony information, the self-attention mechanism in the feature fusion module helps this model recognize the essential part of the feature.

C. Tone Color Analysis for MFCCs

We assume that the tone color factor has a close connection to the mel frequency cepstral coefficients (MFCCs) of a music signal, inspired by many studies on various classification tasks (e.g., genre, instrument, and singer classification) including MER. The MFCCs are obtained by applying the discrete cosine transform (DCT) to a log-scale mel-spectrogram. In general, about the first twenty coefficients are used as acoustic features related to the tone color representing the characteristics of the energy distribution and spectral envelope. In this study, the music signal is resampled at 22.05 kHz and the number of mel filterbanks is set to 23, and the 25-dimensional MFCCs are extracted.

To extract the tone color features from the MFCCs, we use a CNN consisting of seven convolutional blocks as in [14]. Each block consists of two Conv2D layers, followed by a 2D batch normalization (BN) layer and a ReLU layer. The kernel size is set to (3, 3) and the stride is set to 2 for every Conv2D layer. We also use the residual connection for efficient learning.

D. Adaptive Fusion of Symbolic and Acoustic Features

We aim to fuse the symbolic and acoustic features separately exacted from the three modules. Since each feature represents only a partial aspect of music emotion, the relative weights of the three features have a large impact on the performance of MER. The basic approach to feature fusion is to design a loss function for multiple features, where the feature weights are treated as hyperparameters that should be optimized in advance based on prior knowledge or with grid search. The performance of this approach based on the fixed weights, however, is limited because the importance of each factor on the overall emotion of the piece can vary considerably.

To adaptively adjust the feature weights according to the characteristics of the musical piece, we use a multi-head self-attention (MHSA) mechanism. Let F be a concatenated feature given by

$$F = \mathrm{Concat}(F_{\mathrm{sym}}, F_{\mathrm{chroma}}, F_{\mathrm{mfcc}}), \tag{4}$$

where F_{sym}, F_{chroma}, F_{mfcc} denote the outputs of the symbolic, harmony, and tone color analysis modules, respectively. A four-headed self-attention is then computed on F to capture the intricate dependencies within F as follows:

$$\mathrm{MHSA}(F) = \mathrm{Concat}(\mathrm{head}_1, \ldots, \mathrm{head}_4)W_O, \tag{5}$$

$$\mathrm{head}_i = \mathrm{Attention}(QW_i^Q, KW_i^K, VW_i^V), \tag{6}$$

where head_i denotes an attention head i, W_O is a linear projection matrix, W_i^Q, W_i^K, and W_i^V denote projection matrices applied to Q, K, and V in the attention head i, respectively, and $\mathrm{Attention}$ is defined as

$$\mathrm{Attention}(Q, K, V) = \mathrm{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V, \tag{7}$$

where Q, K, V represent the query, key, and value matrices, respectively, and d_k represents the dimensionality of K. The output of the MHSA is flattened and fed into two fully-connected layers, followed by a sigmoid function that predicts the V/A probabilities.

IV. Evaluation

This section reports a comparative experiment conducted to evaluate the proposed and conventional MER methods.

A. Dataset and Metrics

We used a piano music dataset named EMOPIA [13] that contains 1087 piano clips from 387 songs, along with their corresponding MIDI files and emotion labels. Music recordings were collected from YouTube by their corresponding IDs with the 'youtube-dlp' package. We used the same train-validation-test split presented in [13]. Due to the unavailability of several pieces on YouTube, approximately 5% of the original data could not be included in our experiment.

The EMOPIA dataset was annotated with four-quadrant (4Q) emotion labels, where music emotions are categorized into four classes in terms of V/A levels, i.e., "happy" for high arousal and high valence, "relaxed" for low arousal and high valence, "angry" for high arousal and low valence, and "sad" for low arousal and low valence. We used the 4Q classification accuracy as the primary evaluation metric. We also focused on the binary classification accuracies in the V/A estimation. Note that these metrics indicate the performance for recognizing a single aspect of the emotion.

As MIDI-based baseline methods, we tested the symbolic linear regression model (Symbolic-LR) and the LSTM model with an attention mechanism (LSTM-Attn) [15] on the MIDI-like or REMI representation implemented in [13]. As audio-based baseline methods, we tested the acoustic linear regression model (Acoustic-LR) [13] and the short-chunk ResNet model [14]. These uni-modal methods are all lightweight models trained and evaluated only on the EMOPIA dataset.

TABLE I
COMPARISON OF THE PROPOSED AND BASELINE MER METHODS ON EMOPIA DATASET.

Method	4Q	Arousal	Valence
Ours	**0.692**	0.884	**0.869**
LSTM-Attn [15]+MIDI-like [19]	0.684	0.882	0.833
LSTM-Attn [15]+REMI [20]	0.615	0.890	0.746
Symbolic-LR [13]	0.581	0.849	0.651
Audio-LR [13]	0.523	**0.919**	0.558
Short-chunk ResNet [14], [21]	0.677	0.887	0.704

TABLE II
COMPARISON OF PRE-TRAINED MUSIC LANGUAGE MODELS ON EMOPIA DATASET.

Method	4Q Accuracy
Ours	0.692
MidiBERT [16]	0.634
MT-MidiBERT [16], [17]	0.676
QM-MidiBERT [16], [18]	**0.719**

We also tested a large-scale music language model called MidiBERT-Piano [16] and its variants called MT-MidiBERT [16], [17] and QM-MidiBERT [16], [18]. Such models were pre-trained on large-scale MIDI data. Since the V/A estimation was not evaluated on these models, we only used the 4Q metric for comparative evaluation.

B. Results and Discussions

The performances of the proposed and conventional methods are shown in Table. I and Table. II. To the best of our knowledge, our method is the first to combine acoustic and symbolic analyses on MER for piano music. We thus compared only uni-modal methods.

As shown in Table. I, the proposed method achieved the best score of 0.692 in the 4Q metric while keeping the computational cost comparable with the other methods. In arousal estimation, the proposed method performed comparably with the other methods. Since arousal is mainly attributed to low-level acoustic features (e.g., tempo and intensity), even basic audio-based models such as Audio-LR can recognize it accurately. In valence estimation, the proposed method also achieved the best score of 0.869. We found that audio- and MIDI-based methods tended to be better at arousal and valence estimations, respectively. This tendency is consistent with our hypothesis described in Section 1. Overall, by taking into account all factors, the proposed method achieved a better-balanced performance of MER. As shown in Table. II, the proposed model showed a performance comparable to the state-of-the-art large pre-trained model QM-MidiBERT [18], while keeping the computational cost small.

C. Ablation Study

To evaluate the effectiveness of the proposed multimodal multifaceted approach, we conducted an ablation study, where four ablated versions of the proposed method were made by removing two branches out of the three branches in the feature extraction stage or the MHSA mechanism in the feature fusion stage. As shown in Table. III, the full version performed best. This experimental result was consistent with our hypothesis.

TABLE III
ABLATION STUDY OF THE PROPOSED METHOD ON EMOPIA DATASET.

Method	4Q	Arousal	Valence
Full model	**0.692**	**0.884**	**0.869**
Symbolic analysis branch	0.690	0.833	0.744
Harmony analysis branch	0.514	0.726	0.685
Tone color analysis branch	0.649	0.871	0.711
Without MHSA	0.639	0.858	0.753

Since the music score includes information about rhythm, dynamics, and melody related to both valence and arousal, the symbolic analysis branch performed well in all evaluation metrics. Although harmony plays an essential role in emotional expression, it is hard to recognize the overall emotion of a piece only from its harmony information. The harmony analysis branch thus performed worst in all metrics. The tone color analysis branch showed a promising performance, especially in arousal estimation, because the energy distribution and tone color information obtained from MFCCs significantly contributes to the arousal aspect and the overall emotion. By integrating these three branches, the proposed method performed better, especially in valence estimation. We also confirmed the effectiveness of the MHSA-based adaptive feature fusion. The proposed full model outperformed its ablated version by 1.2 pts in the 4Q metric and achieved better balanced V/A estimation performance.

V. CONCLUSION

In this paper, we proposed a multimodal multifaceted MER method for piano music. Inspired by music psychology, we designed a DNN with three branches that separately analyze five main factors of music emotion, i.e., 1) rhythm, dynamics, and melody, 2) harmony, and 3) tone color, from the score, chromagram, and MFCCs of a piece, respectively. Our model fuses the extracted musically-meaningful symbolic and acoustic features with the MHSA mechanism in a data-adaptive manner. In the comparative experiment using the public dataset EMOPIA, our model achieved the state-of-the-art performance in the 4Q metric and a well-balanced performance in the V/A classification metric with a smaller computational cost. The ablation study showed the effectiveness of the multimodal multifaceted approach and that of the MHSA-based adaptive feature fusion. As a future direction, we plan to explore music embedding for MER, which can be used to design a unified MER model that can better capture multiple interdependent factors.

Abstract — **Music holds a distinct place within the realm of human artistic. Music generation is also considered as one of the highly challenging domains, demanding significant expertise and innovation artificial intelligence of in the field. In this paper, we propose a novel architecture with multi-track encoder for multi-decoder network. Furthermore, we present a novel music dataset specifically designed for string quartet compositions. Experimental results demonstrate that our architecture is capable of generating very rich musical compositions.**

I. INTRODUCTION

With the continuous development and growth of artificial intelligence, music generation is considered highly challenging and promising within the field of artificial intelligence [1] and Music Information Retrieval (MIR) tasks [2]. In the domain of music generation, there are various branches, including automatic music generation [3], jazz music composition [4], accompaniment generation and polyphonic melody generation [5]. In a broader sense, music can be seen as a form of language, both being systems that can be recorded symbolically in written form, and both having order and structure. Just as language has grammar, music also has its own set of norms and regulations.

The natural language processing (NLP) of field has achieved remarkable success when applied to MIR tasks. For instance, the application of generative adversarial networks [6] (GANs) in MIR has shown great potential. MuseGAN [7] is a GAN-based model that adopts the concept of an orchestra. It utilizes both conductor and musician architectures for music generation. There are also approaches which use conditional convolutional GANs to generate melodies following given prior chord sequences [8], either starting from scratch or conditioning on melodies from previous measures. Currently, most research directions in this domain employ generative adversarial networks for music generation.

In this paper, our goal develops a polyphonic music generator with a variational autoencoder (VAE) [9] architecture. Specifically designed for string quartet compositions. We shall refer to it as Multi-Muse variational autoencoder (MMVAE). To achieve this, we first create a music dataset for string quartets, which serves as the training data for our model. In a string quartet, the instruments are mostly divided into two parts violins, viola and cello. Inspired by the content-style disentanglement idea [10] and [11], we utilize a variational autoencoder as the main framework in this research. This architecture effectively learns the latent factors of music, such as texture. We propose a novel composite architecture that employs a multi-track encoder to a multi-layered decoder structure. By sharing parameters, the architecture enables the generation of distinctive melodic lines while maintaining their coordination.

In this paper, we have made the following primary contributions:

1) We have curated a novel MIDI dataset specifically designed for string quartets.

2) We have proposed a multi-layered variational encoder architecture for multi-track sequence generation.

II. MULTI-MUSEVAE METHOD

We have proposed a novel multi-track sequence generation model called MMVAE. In this section, we provide a detailed account of the architecture for generating string quartet music based on an encoder framework. The ultimate goal generates musical compositions specifically tailored for string quartets. This architecture primarily learns from musical compositions comprising 4 measures, totaling 16 beat in length.

Firstly, let's introduce the overall structure, with the Musical Instrument Digital Interface (MIDI) format of string quartets serving as the input format. The input MIDI files are segmented and extracted based on their tracks. The segmented tracks consist of four distinct instruments: Violin I, Violin II, Viola, and Cello. Furthermore, the four musical semantic information are extracted and compressed. By compressing the musical semantic information, the sparsity of the data is effectively

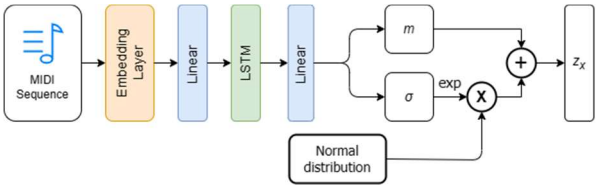

Fig. 2 The Encoder architecture of MMVAE.

reduced. After the extraction and segmentation process is completed, the data undergoes preprocessing to transform it into the desired input format for the model. Finally, the processed data is fed into the VAE architecture corresponding to each section, that it allows for separate processing and generation within each component. As VAE adheres to the structure of encoding and decoding, it enables a comparison between the generated outcomes and the original results. Furthermore, VAE can more directly generate content that closely approximates the original data.

A. Music Embedding

The MIDI files is inputted into the model, data preprocessing is required to transform the MIDI data into a suitable format. Due to the nature of MIDI files, each musical note can be viewed as a switch event. Additionally, MIDI files often represent these switch events using absolute timestamps. This can result in inconsistent durations of musical semantic information if the timing is not uniformly processed. In this paper, all MIDI files are standardized to a single tempo according to music theory and the characteristics of the music. By utilizing the library "pretty_midi" [12] to extract information from MIDI files, the beats per minute (BPM) of all MIDI files is standardized to 120 beats per minute. By standardizing the BPM to 120 beats per minute, any influence introduced by time can be eliminated during subsequent data processing.

Additionally, our proposed method enhances the model's versatility and generalizability. According to [13], we transpose all MIDI files into 11 different keys to enhance the model's versatility (A major would be transposed to G major). Indeed, this approach significantly expands the melodic possibilities. We transposing MIDI files to different keys that we obtain a broader range of musical expression and variations.

Finally, all transposed MIDI files are segmented into individual tracks based on MMVAE model architecture. Additionally, the tempo and key information are preserved during the segmentation process, we can ensure that the speed and tonality of the music are retained in the individual tracks. We obtained a rich collection of segmented MIDI tracks for string quartets, including Violin I, Violin II, Viola, and Cello.

B. Data Representation

In order to train the variational autoencoder model for polyphonic music, we convert the MIDI files into the Piano-Roll representation. The Piano-Roll representation is a binary data format that uses a matrix to record musical score information. The Piano-Roll representation can be regarded as a two-dimensional matrix. In the Piano-Roll representation, the horizontal axis corresponds to time, while the vertical axis represents pitch. The presence of notes at different time steps is represented in a two-dimensional matrix format.

The incongruity in the lengths of MIDI files within the dataset hampers the training process. According to [7], we set the temporal resolution to one beat consisting of 24-time steps and we can allow for an effective coverage of common rhythmic patterns, such as triplets and 16th notes. The size of the input tensor is hence size 4 (bar) × 96 (time steps) × 36 (range of pitches) × 4 (number of tracks).

C. Multi-MuseVAE

Inspired by MuseGAN, this study incorporates the concepts of interference and synthesis present in MuseGAN. Due to the

distinct textures exhibited by different sections, the requirements of the decoder will vary accordingly. However, the model inputs and parameters are shared among them. The overall architecture of MMVAE is depicted in the Fig. 1.

The overall model architecture follows a one-encoder to multi-decoder approach. By employing this approach, it allows the encoder to encode the latent space (z_x) with a certain degree of consistency. Based on the requirements of different decoders (D), we define four types of latent spaces generated by the encoder as follows: $z_{Violin\ I}$, $z_{Violin\ II}$, z_{Viola} and z_{Cello}.

Music is a temporal art form with inherent dependencies and contextual relationships. In previous approaches, there have been implementations of melody generation based on Recurrent Neural Network (RNN) [14]. There have also been implementations of melody generation based on Long Short-Term Memory (LSTM). Based on [15], we used LSTM as a crucial component in our proposed MMVAE model.

D. Encoder

The MIDI is transformed into the latent space through the encoder. The encoder architecture is shown in Figure 2. The model takes segmented MIDI short sequences as input. Because of the sequential nature of music, the input sequence of musical notes convert into events by the encoder. Through the encoding layer, the data is extracted and transformed into tensors representing the pitch and duration of musical notes. The encoded pitch tensor is then passed through a linear layer (Linear) to flatten it into a one-dimensional embedding tensor, which serves as the feature representation. The input size of the linear layer depends on the pitch range (typically 36 notes). The output feature size is setting to 300.

After passing through the LSTM network, the resulting tensor is further processed by a linear layer. The mean (m) and standard deviation (σ) of the variational autoencoder are obtained. The exp () operation is performed on the normal distribution with σ, and then the resulting values are combined with m. The final output of the encoder is the latent space z_x. The z_x latent space is defined in four types based on the input of the encoder: $z_{Violin\ I}$, $z_{Violin\ II}$, z_{Viola} and z_{Cello}. By adding normal distribution constraints, the encoder can learn the fuzzy structure of music data that it is helpful for generating rich music.

E. Decoder

We inspire by the content-style disentanglement idea. The decoder is required to reconstruct the data using the latent space that it is generated by the encoder. Due to the distinct characteristics of each instrument in a string quartet, the decoder needs to undergo separate training for each instrument. By utilizing different decoders to reconstruct the latent space, the goal of disentanglement and generation can be achieved. The decoder model architecture is shown in Fig. 3.

TABLE I
CORRESPONDING TO THE DECODER PARAMETER.

Decoder	*Vocabulary size*	*Pitch range*	*MIDI Pitch Number*
Violin I	*36*	*(55 , 91)*	*G3 – G6*
Violin II	*24*	*(55 , 79)*	*G3 – G5*
Viola	*36*	*(48 , 84)*	*C3 – C6*
Cello	*36*	*(36 , 72)*	*C2 – C5*

The working principle of the Multi-MuseVAE decoders is as follows. Firstly, the latent space is transformed into features that are suitable for the LSTM network through a linear layer. The LSTM network is utilized to decode the latent space at each time step. The decoded tensor is then passed through another linear layer to transform it into a latent tensor representing pitch and duration. Finally, the latent tensor representing each note and duration is reconstructed into a note sample by a SoftMax layer. Different parameters are adjusted for each instrument in a string quartet to align with the unique characteristics of each instrument. Tt is shown in Table I.

Due to the common practice in most string quartet compositions, the Violin I and Violin II parts are typically used as the melody lines. In a string quartet, the Violin I part typically encompasses a higher range of pitches compared to the Violin II part. Therefore, the pitch range of the Violin II is often limited or constrained to 24 notes to accommodate the higher range typically that it is utilized by the Violin I. They utilize a pitch range of 36 notes and spanning across 3 octaves.

Finally, we can obtain four sets of note samples by the decoder that each note sample corresponds to one instrument in the string quartet. Assign specific instruments to the four samples according to their respective tracks. MIDI post-processing is applied to the samples after they have been generated. We can obtain MIDI sequences for each of the four parts, representing the final compositions for the string quartet. Through the utilization of MIDI processing, amalgamate the acquired four musical samples into a singular MIDI file.

III. EXPERIMENTAL AND RESULT

A. Lakh MIDI Dataset

The Lakh MIDI dataset is a large collection consisting of 176,581 unique MIDI files. Among them, 115,160 MIDI files have been matched and aligned with the entries listed in the Million Song Dataset. We utilize the LPD-5 dataset according

TABLE II

INTRA-TRACK EVALUATION

(VALUES CLOSER TO THE DATASET ARE BETTER).

Part / Metric	Dataset				Generation				Ablated
	Violin I	Violin II	Viola	Cello	Violin I	Violin II	Viola	Cello	All
EB	8.9	11.3	12.9	13.9	6.8	10.1	10.3	9.1	87.3
UP	26.8	21.9	21.1	23.6	22.9	25.4	16.1	17.4	89.2
UPC	4.2	3.6	3.4	3.9	3.9	3.2	3.1	3.9	11.1
PR	57.9 – 89.4	56.4 – 82.1	50.0 – 74.3	38.1 – 66.9	57.5 – 88.42	54.6 – 76.8	48.7 – 69.2	36.4 – 63.4	10.4 – 99.6
QN	94.5	92.4	88.7	91.3	97.4	95.3	86.7	92.5	41.3

to [7]. Furthermore, we compress and merge the Lakh MIDI dataset into five common categories: Drums, piano, guitar, bass, and strings. The dataset consists of three types: LPD-5-full, LPD-5-matched, and LPD-5-cleansed. We utilize the LPD-5-cleansed dataset as our pretraining dataset. There is a total of 21,425 MIDI files.

B. String Quartet Dataset

To specifically train music generation models for string quartets, we have curated a new dataset. The String Quartet dataset consists of 110 standard classical string quartet compositions. The dataset was sourced from professional musicians and created by reproducing sheet music from renowned classical composers such as Mozart, and Bach. The sheet music was obtained from the international music score library project (IMSLP). After transposing the pieces into 12 different keys, we obtain a collection of 1,320 musical compositions. After organizing and segmenting the data, we obtained a total of 71,280 musical phrases that it consists of four measures.

C. Objective Metrics

To effectively evaluate the performance of the model, the comparison is made between the original musical phrase data and the generated melodies. This evaluation aims assess the authenticity of the melodies that are generated by the model. We randomly generated 800 musical phrases for comparison. In [7], a series of evaluation metrics is proposed, such as the number of pitch repetitions, rhythm variations, and other related evaluation metrics. To evaluate the four tracks of the string quartet, a total of five evaluation metrics is used:

1) Empty bar (EB): Proportion of empty measures, expressed as a percentage.
2) Used pitch (UP): Number of notes used.
3) Used pitch classes (UPC): Number of distinct note categories used, ranging from 0 to 12.
4) Pitch range (PR): Range of pitch used, represented by the highest and lowest notes.

TABLE III

COMPARISON WITH OTHER APPROACHES

(VALUES CLOSER TO THE DATASET ARE BETTER).

Metric / Method	EB	UP	UPC	PR	QN
Lpd5- string Dataset	8.62	27.68	3.92	50.41 – 78.23	87.42
MuseGAN [7]	6.10	30.43	4.09	47.32 – 79.67	72.12
Our	9.37	26.32	4.13	49.43 – 77.61	86.30

5) Qualified note (QN): Percentage of qualified notes, representing the proportion of notes that meet certain criteria. This metric evaluates whether the generated music by the model is too sparse.

By the aforementioned objective evaluation metrics, we can effectively analyze whether the model has learned effectively. Through this analysis, we can assess the differences between the generated samples and the training data. As training progresses, the distribution of generated samples should become increasingly closer to the distribution of the training samples.

We apply evaluation metrics to the training data to analyze various indicators of the training data. Comparing the generated results with the training data, we can effectively assess the learning performance of the model. The experiment involved splitting the training data and generated data according to the sections of the string quartet. The results are presented in Table II. From the training data, the value of EB is very low that there are very few empty measures in the dataset. From UP, we can observe that the training data exhibits a rich variety of pitch usage. From UPC, we can see that all four string section in the training data. The training data scores is higher than 3.0 that the dataset is a rich variety of chords. From PR, we observe that the pitch ranges is used in the four string sections of the training data which are generally very close to the pitch range designed for the model. This indicates

that the PR setting of the model is reasonable. From QN, we can observe that the values in the training data are very high that the training data is not overly fragmented.

To examine the results of each model's generation, we generated 800 music segments for each model based on the experimental design. According to the objective evaluation metrics, the results are shown in Table II. The values closer to the dataset are better. We found that the EB values for all four sections are very high that the model has successfully learned to generate filled melodies. In UP, the values for all four sections are very close to the dataset. It indicates that the model has successfully learned the rich musical melodies from the dataset. From the UPC, we have discovered that the four divisions have also acquired a profound understanding of harmonic variations. Furthermore, the PR values indicate that the model has adeptly grasped the tonal ranges of the individual sections within the string quartet. Lastly, with regard to the QN values, it is evident that the generated data exhibits a notable absence of fragmentation.

Furthermore, we conducted a comparison with MuseGAN, and the results are presented in Table III. It is evident that VAE's architecture exhibits superior performance in the QN category compared to GAN networks. In the PR category, the utilized pitch range is relatively close. However, in the UPC category, our proposed method slightly lags behind GAN-based approaches. In the UP category, our method aligns more closely with the dataset. Finally, in the EB category, our scores closely match those of the dataset. From these results, we discern that the VAE architecture, in contrast to the GAN framework, possesses superior reconstructive capabilities, indicating a better understanding of the foundational musical elements.

D. Subjective Evaluation

To assess our system from a user's perspective, we conduct tests involving audiences with diverse musical backgrounds and educational levels. The participants were categorized into three user groups: professional musicians, amateur musicians, and music enthusiasts.

All melodies will be rendered into music files in the same manner. The test consists of a total of 12 song segments, comprising 4 segments generated by our method, 4 segments from the original dataset, and 4 segments from the single-layer encoder architecture (ablation experiment). All participants are required to rate each of the 12 songs based on the following questions by a Likert scale ranging from 1 to 5. Users should rate the songs without knowing which ones are generated and which ones are from the original dataset.

TABLE IV
SUBJECTIVE EVALUATION
(M: Melody, R: Rhythm, MS: Musical structure, V: Variations, OR: Overall rating).

	M	R	MS	V	OR
Dataset	**4.33**	3.73	**4.23**	**3.55**	**4.19**
Generation	3.54	**3.76**	3.63	3.15	3.82
Ablated	2.26	3.28	2.36	2.96	2.30

The questions are as follows:

1) How pleasant does this melody sound?
2) How pleasant does this rhythm sound?
3) Does this melody have a clear musical structure?
4) Does this melody exhibit rich variations?
5) Overall rating.

We extended invitations to a total of 42 test participants to engage in the evaluation process. They were 24 professional musicians, 8 amateur musicians, and 10 music enthusiasts. Experimental results is presented in Table IV. Tt is evident that the compositions is generated by our proposed multi-track decoder model closely align with the ratings of the original dataset. Furthermore, the ablation experiment conducted on the single-track decoder model yielded significantly lower scores. Henceforth, it can be inferred that our proposed model has approached the realm of human artistic creation.

E. Ablation Experiment

To evaluate whether the multi-track decoder architecture has an advantage, we designed a single-track decoder as an ablation experiment. The four tracks are compressed into a single common track, and the single-track decoder needs to independently generate the four separate melodies for each section. We set the pitch range of the decoder model to the standard MIDI pitch range, which spans from C-2 to G8, comprising a total of 128 pitch values. The experimental results are presented in Table II and IV.

Due to the encoder compressing four tracks into a single track, theoretically, the decoder needs to learn more complex latent features. This can lead to suboptimal learning outcomes. From the results of ablation experiments, it is observed that in Table II, the proportion of EB is notably high. We attribute this to the scarcity of qualified notes generated, resulting in insufficient eligible notes to compose melodies for bars. Furthermore, in the UP and PR categories, the loss of decoder specificity leads to the almost comprehensive utilization of the entire tonal range. In the QN category, the notes generated by

a single encoder and decoder pair are significantly less qualified compared to others, resulting in an overly sparse generation.

IV. Conclusions

In this paper, we established a novel dataset from scratch. Furthermore, we proposed a novel music generation model. We utilize a variational encoder architecture for the generation of string quartets. By employing LSTM (Long Short-Term Memory) architecture, we implemented a model to generate multi-track sequences. Objective and subjective evaluations indicate that our proposed model demonstrates initial proficiency in generating string quartets. Although it still lags behind the creative level of human musicians in terms of music theory and human aesthetic assessment. The proposed to model already possesses certain desirable characteristics.

***Abstract*—Nowadays, road object detection has become a challenging topic and a long-standing problem. In previous algorithms, traditional convolutional neural networks (CNNs) have almost dominated computer vision and achieved considerable successes in different detection tasks. However, Transformer-based models in the past two years have shown impressive performance, and some of which even surpass CNN-based methods and become the state-of-the-art for advanced vision tasks. In this paper, we propose a detection model named SOAda-YOLOR, which uses the current mainstream Bi-FPN concept with the innovative Optimized-NMS. We also propose a novel ShuffleSimAM module to the backbone, and apply some bag-of-freebies such as SIoU loss to road object detection, and finally achieve competitive results.**

I. Introduction

Object detection is a relatively complex image processing task in computer vision related applications, such as IQA [1], [2], SIQA [3], [4], VQA [5]–[7], Superresolution [8], [9]. Traditional object detection methods are usually based on algorithms, and since current object detection algorithms are not very accurate, research and applications in this field are still innovating. As mentioned earlier, although most convolutional neural network (CNN) based methods such as YOLOv3 [10], YOLOv4 [11], YOLOv5, Scaled-YOLOv4 [12], and other different types of methods such as DINO [13] achieve excellent performance, they all have one common disadvantage. That is most close objects can be detected accurately, but far objects such as distant pedestrians, intersection signs and oncoming vehicles are hard to detect. Due to the convolutional operations required by the algorithm, the target to be detected is often compressed to less than 3 pixels. This compression impedes the model's ability to learn effectively and results in poorer quality output.

To ameliorate the issue of inadequate detection of diminutive objects, certain techniques are conventionally employed, namely: 1) enhancing the resolution of image acquisition; 2) increasing the depth of the model; 3) locating the desired image area; 4) expanding the training dataset via data augmentation; 5) learning model anchors automatically; and 6) filtering out irrelevant categories as many as possible. Of course, through these methods, a large amount of hardware resources and time investment are bound to be required. DINO is an example which is based on Swin Transformer, so the ordinary computer is not enough to train such a large model.

In addition, YOLOR [14] demonstrated models incorporating implicit knowledge can achieve impressive performance in real-time object detection. While the accuracy is slightly increased, the time required for training and detection can be greatly reduced, making it a leader in current one-stage object detection algorithms.

Overall, the principal contributions of this work can be encapsulated as follows:

- We use YOLOR [14] as our main backbone and deepen its modules and enhance the connectivity between layers. By importing the concept of Bi-FPN into the model, we create a tighter connection with the backbone layer, and use Dropout in the first layer to avoid the model learning bad features.
- We perform low-light enhancement (LLE) [15], [16] to improve the low-light problem encountered in the current road dataset.
- We propose a novel ShuffleSimAM module to the backbone.
- We propose optimized-NMS to improve our results.
- We use some bag-of-freebies (e.g., SIoU [17] loss) and apply it to our model.

By systematically integrating these components into the YOLOR framework, SOAda-YOLOR achieves improved efficiency and accuracy in small object detection for complex road scenes.

II. Related Work

The authors of YOLOR adopted Scaled-YOLOv4 as its original architecture. It demonstrated the YOLOv4 object detection neural network is based on the CSP method, which can maintain the best speed and accuracy, and can also be scaled up and down (i.e., suitable for small and large targets). This methodology can be modified not solely in terms of depth, width, and resolution, but additionally in regard to the architecture of the network. Further extending on the basis of Scaled-YOLOv4, and adding the concept of tacit knowledge, YOLOR is proposed to become a unified network that can handle multiple tasks. With the same accuracy, the inference speed of YOLOR is 88 % faster than its previous version (i.e., Scaled-YOLOv4 [12]).

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

A. Backbone Network

CSPDarknet53 [12] derives its architectural foundation from Darknet53 [11] and adopts the structure of CSPNET [12]. It is mainly composed of five CSP modules, which can reduce the computational overhead. Because of the continuous superposition of CSP modules, it makes the extraction of features by the network vulnerable to the interference of background noise. To further optimize backbone performance, modifications to the native CSP modules have been instituted by the original authors.

B. Path Aggregation Network

PANet [18] was proposed in 2018 and is still used by the public. PANet can accurately preserve spatial information, which helps to correctly locate pixels to form masks. With some minor modifications in the YOLO series, PANet usually adds adjacent layers together to use self-adapt feature pooling for mask prediction. However, when using PANet [18] in YOLOv4 [11], this approach is slightly distorted. Therefore, instead of adding adjacent layers, a concatenation operation is applied to them, improving the prediction accuracy.

C. Bidirectional Feature Pyramid Network

Bidirectional feature pyramid network (Bi-FPN) [19] was proposed as a weighted two-way feature pyramid network in EfficientDet [19], which allows simple and fast multi-scale feature fusion. The purpose of the authors is to pursue more efficient multi-scale fusion methods. In the past, feature fusion was to treat different scale features equally, and the authors introduced weights (similar to Attention) to better balance the feature information of different scales.

D. Spatial Pyramid Pooling

The CSPSPP block is formed by adding the Spatial Pyramid Pooling (SPP) [20] structure to the CSP block. SPP comes from SPPNet proposed in 2015, and fast-RCNN [21] was also proposed on its basis. At that time, the neural network contained a fully connected layer, which led to the fact that the size of the input image to the network must be a fixed size. The SPP structure was originally proposed in SPPNet to solve this problem. It can be understood as the process of generating a fixed-size input image of any scale. The SPP module consists of four max-poolings of different sizes stacked in the channel dimension. In this model, the pooling kernel sizes are set to 13×13, 9×9, 5×5, and 1×1. By incorporating the SPP architecture into YOLOv4, expansion of the receptive field is attainable, facilitating isolation of the most salient contextual elements without slowing down the detection speed.

III. Proposed Method

The proposed Small Object Adaptive-YOLOR (SOAda-YOLOR) architecture (Fig. 1) is based on the YOLOR model, and the details of each component are explained as follows:

A. CSPSE-D Block

Squeeze-and-Excitation Networks (SENet) [22] is actually a lightweight block that can be universally improved for all networks. Compared with the original network, the amount of parameters for the block is very small. In this way, the accuracy is greatly improved without additional burden, and its output is calibrated through the module. We add this module at each CSP convolution stage and include dropout in the first module to drop different neurons at each training to ensure bad information is not learned.

B. Adp-FPN

The weighted Bi-FPN[19] is the pursuit of a more efficient multi-scale fusion method. We refer to this idea and include it into our model, called Adp-FPN. Deepening between layers and connecting each other will create more features.

C. SPP

In order to obtain richer feature information, we add two additional SPP modules to our model, it can increase the most important contextual feature of accepting fields and isolation without reducing the detection speed.

D. ShuffleSimAM Attention

The attention mechanism empowers neural networks to achieve precise focus on all relevant elements of the input data, and it has gradually become an important part of improving the performance of deep neural networks. At present, there are two main attention mechanisms widely used in this field, namely spatial attention and channel attention, which are used to capture pixel-level pairwise correlations and inter-channel dependencies, respectively. Although fusing them together may achieve better performance than their respective implementations, it inevitably increases the computational overhead. We referred to the method of Shuffle Attention (SA) [23] and introduced SimAM [24] to replace the spatial attention part of SA. The resultant diagram of ShuffleSimAM is shown in Fig. 2. Although the computational overhead has increased a little, the final result is slightly improved. In order to overcome the drawbacks in the Squeeze-and-Excitation (SE) channel attention, SA adopts an optional method which first uses global average pooling (gap) to generate channel-wise data, and its formula can be expressed as:

$$s = F_{gap}(X_{k1}) = \frac{1}{H * W} \sum_{i=1}^{H} \sum_{j=1}^{W} X_{k1}(i, j), \qquad (1)$$

where X_{k1} represents the part of sub-feature X_k split into the "channel attention" branch, and s denots channel-wise statistics. The above formula means that, for X_{k1} along the dimension of the channel, the feature map of each channel is summed to get a value, and then divided by the number of pixels in this map, and use this value to replace the feature information of this channel. Then through F_c operation and

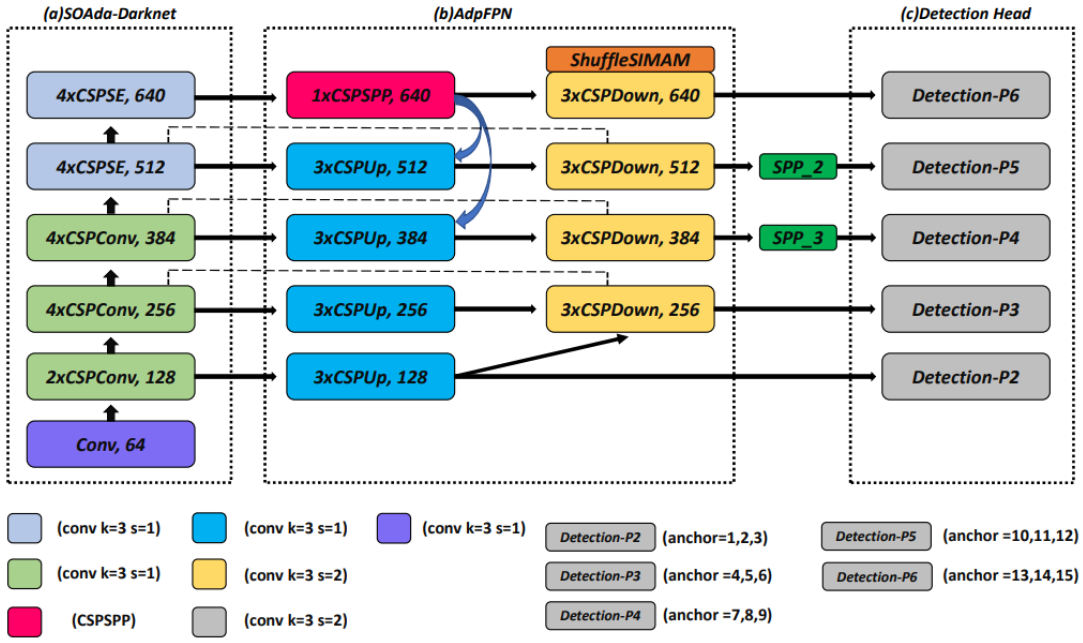

Fig. 1. The structure of SOAda-YOLOR

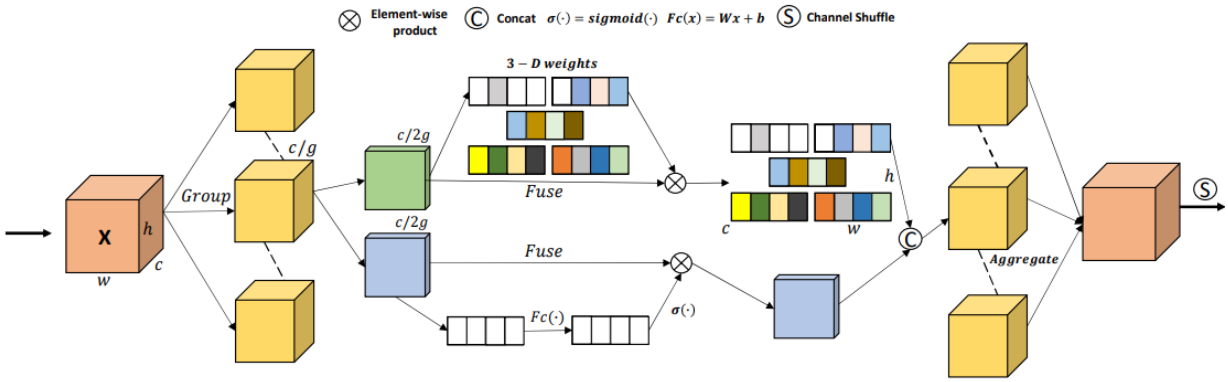

Fig. 2. The structure of ShuffleSimAM Attention.

sigmoid activation to generate the attention weight corresponding to each channel, the output of the channel attention can be obtained by

$$X'_{k1} = \sigma(F_c(s)) * X_{k1} = \sigma(W_1 s + b_1) * X_{k1}, \quad (2)$$

The F_c operation is to multiply s by a matrix $W_1 \in R^{C/2G\times1\times1}$ plus a bias $b_1 \in R^{C/2G\times1\times1}$, whose function is to scale and shift s.

Then we will mention the spatial attention part. According to the SimAM formula, the author defines the following energy function for each neuron:

$$e_t(w_t, b_t, y, x_i) = (y_t - \hat{t})^2 + \frac{1}{M-1}\sum_{i=1}^{M-1}(y_o - \hat{x}_i)^2. \quad (3)$$

Here, $\hat{t} = w_t t + b_t$ and $\hat{x}_i = w_t x_i + b_t$ are linear transforms of t and x_i, where t and x_i are the target neuron and other neurons in a single channel of the input feature $X \in R^{C\times H\times W}$. i is index over spatial dimension and $M = H \times W$ is the number of neurons on that channel. w_t and b_t are weight and bias of the transform. The Eq.(3) attains the minimal value when $\hat{t}$ equals to y_t, and all other $\hat{x}_i$ are y_o. Minimizing the above formula is equivalent to train the linear separability between the target neurons t and other neurons in the same channel. In order to simplify the presentation, the authors adopt binary labels and add a regularization term in Eq.(3). The final energy function is defined as follows:

$$e_t(w_t, b_t, y, x_i) = \frac{1}{M-1}\sum_{i=1}^{M-1}(-1 - (w_t x_i + b_t))^2 + (1 - (w_t t + b_t))^2 + \lambda w_t^2. \quad (4)$$

Therefore, the minimum energy can be obtained by the fol-

lowing formula:

$$X'_{k2} = e_t^* = \frac{4(\hat{\sigma}^2 + \lambda)}{(t - \hat{u}^2) + 2\sigma^2 + 2\lambda}, \tag{5}$$

where $\hat{\mu} = \frac{1}{M}\sum_{i=1}^{M} x_i$ and $\hat{\sigma}^2 = \frac{1}{M}\sum_{i=1}^{M}(x_i - \hat{\mu}^2)$. Next, we concatenate two features X'_{k1}, X'_{k2} and aggregate all sub-features to complete this task. Similar to ShuffleNetv2 [25], the "channel shuffle" operator is used to realize cross-group information flow along the channel dimension. The final output of SA module retains identical dimensionality to X, thereby facilitating seamless integration with contemporary architectures.

E. Non-maximum suppression (NMS) optimization

On the basis of Soft-NMS [26] and DIoU-NMS [27], the two NMS methods are fused and fine-tuned to detect small objects. When the IoU is less than the chosen threshold, the original Soft-NMS score penalty mechanism is added to the DIoU-NMS. Then the IoU value and the distance between the two boxes are modified and evaluated. The optimized NMS can be expressed as the following formula:

$$TS_i = \begin{cases} S_i, IoU - RDIoU(M, b_i) < Ni \\ S_i(1 - RDIoU(M, b_i)), IoU - RDIoU(M, b_i) \geq Ni, \end{cases} \tag{6}$$

where S_i represents the score of each box, M is the box with the highest score, b_i is one of the remaining boxes, Ni is the threshold, and $RDIoU$ is denoted as follows:

$$RDIoU = \frac{p^2(b^g, b)}{c^2}, \tag{7}$$

where b and b^g represent the center points of the two rectangular boxes, p represents the Euclidean distance between the two rectangular boxes, and c represents the diagonal distance of the closure area of the two rectangular boxes. The comparison of detection results with NMS optimization and without NMS optimization is in Fig. 3.

F. Data Augmentation

For data augmentation [28]–[30], initial conditions delineated in Table I were established, with 500 images excerpted from the validation set for image enhancement via low-light enhancement (LLE) [31], [32]. Detection outcomes post-LLE are visualized in Fig. 4. Furthermore, adhering to small object augmentation methodology, labeling software was utilized for cropping small target labels and duplicating generation, with insertion into 4,000 images from the validation set, comprising 2,000 daytime and 2,000 nighttime images selected by the same criteria in TableI. This subset of 4,000 images was exclusively for small object label augmentation, independent of the previous 500 images augmented via LLE. Additionally, only the following 4 categories were chosen: 1) Traffic signs; 2) Traffic lights; 3) Pedestrians; 4) Cars, with small target labels in each category copied twice, thereby introducing 8 small target labels per image to enrich small object diversity and mitigate original target label imbalance.

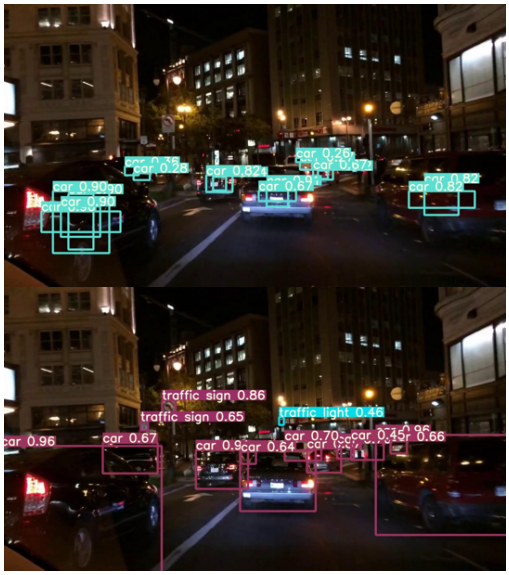

Fig. 3. Top) Detection results without NMS optimization. Bottom) Detection results with NMS optimization.

TABLE I
SELECTION CRITERIA FOR THE AUGMENTATION DATASET

Condition (1).	After the height and width are multiplied, it is less than 10 to 20 pixels
Condition (2).	The photo was taken at night or rainy day
Condition (3).	The category focus on traffic lights, traffic signs, cars, pedestrians
Condition (4).	In a single photo, there are more than or equal to 3 targets that meet the criteria of condition (1)

G. Bag of freebies

The variation of activation functions is a part of the Bag of freebies. For distinct models and task modalities, different activation function imports can lead to remarkable improvements. Accordingly, we conducted comparative analyses of different activation functions, scrutinizing their traits and limitations, and finally chose to import the Cyclemoid activation function into the model. Although it will bring a little calculation, the final result shows that Cyclemoid has its advantages, where the Cyclemoid activation function can be defined as:

$$Cyclemoid = tanh(\pi x) * tanh(\pi x^2 - 0.95)^2 * cos(-3 \leq x \leq 3)^2. \tag{8}$$

Regarding loss functions, SIoU loss [17] was appended to the native loss function. This can take into account the vector angle between the required regressions and redefine the penalty index. Thus, there can be slight improvements in training performance.

IV. EXPERIMENTS

For experimentation, we use YOLOR [14] as the baseline, and combine the methods described in Section III, called SOAda-YOLOR. Training and evaluation were conducted on the BDD100k dataset [33], one of the largest and most diverse

autonomous driving datasets to date, released by UC Berkeley. After adding the augmentation data to the existing training set, the final number of training set is 74,500 (70000+4000+500), the number of validation set is 15,500 (20000-4000-500), and the number of test set is 10,000. The training epoch number is set to 100, the number of anchors is increased from 9 to 12, and the input image resolution is 1280×1280 pixels. The time to complete the training is 51 hours.

KITTI [34] is another dataset that covers most categories for autonomous driving detection. In Table II, we compared the precision, recall, mean Average Precision (mAP), and Time results with other SOTA methods, including YOLOR [14], YOLOv3 [10], YOLOv4 [11], YOLOv5, Scaled-YOLOv4 [12], YOLOv7 [35], and Tph-YOLOv5[36]. We can see our proposed model has the highest or the 2nd highest mAP among all models in both BDD100k [33] abd KITTI [34]. Also, the Time, parameters, and FLOPs of our approach are smaller than Scaled-YOLOv4 and YOLOv7. To prove the effectiveness of each component in Section III, we perform the ablation study in Table III. We can conclude the performance will be the best when using SOAda-I model (i.e., using all the components). As evident in Fig. 5, we can see that our model can detect more small objects, and increase more confidence for other objects in the road images at night. It proves that our model can have high accuracy in this environment. In addition, we compare the test results of AP_S, AP_M, and AP_L for each model in BDD100k. The experimental results can be found in Table IV.

Fig. 5. Detection results from SOAda-YOLOR in BDD100k dataset.

V. Conclusions

In this paper, we propose a model tailored for small object detection in the context of road driving. First, We optimize the original CSP module to become CSPSE-D Block. Secondly, we take YOLOR as our backbone and deepen its modules and enhance the connectivity between layers by proposing a new model similar to Bi-FPN, and use Dropout in the first layer to avoid the model learning bad features. Thirdly, we propose a novel ShuffleSimAM module for the backbone, and improve the problem of poor detection for small targets. Moreover, the traditional NMS [37] is optimized, so that it can detect objects and reduce redundant detection frames as many as possible. Then for data augmentation, we propose a solution targeting the imbalance between large and small object labels. Through the LLE and small object label augmentation, the final trained model has achieved performance improvements in detection results. Finally, we apply some bag-of-freebies to our model to further improve the detection performance.

***Abstract* —In sports games, quick sensory processing and attention are crucial for athletes to win. Therefore, players need to strengthen their perceptual response and movement coordination through iterative training to increase their chances of winning. However, conventional badminton training is limited by the availability of training venues and coaches. Additionally, training materials are imprecise and unstable due to human factors, and players cannot effectively analyze their strengths and weaknesses from training results.**

This study proposes a virtual reality badminton self-training system to solve these training problems, including the lack of training venues and coaches, imprecise training materials, and ineffective analysis of strengths and weaknesses. As a result, the proposed system provides players with an effective evaluation of their training performance under stable and precise training processes. Players can identify their shortcomings and receive constructive suggestions for improvement.

I. INTRODUCTION

Virtual Reality (VR) applies 3D computer rendering to construct a virtual environment that resembles the actual world. Users can directly interact with virtual objects through user interfaces or sensing devices such as helmets and controls in an immersive environment [1, 2]. VR can simulate interactive effects between objects, like those in the physical environment, making it widely applicable in several domains, such as training, education, and entertainment [3, 4].

The advantages of VR for educational training include:

i. 3D visualization can present complex, abstract problems in a visual interface to facilitate observation and interpretation.

ii. Learners can attempt to solve problems differently without operating restrictions.

iii. First-hand hypotheses and test results can be acquired through the user's direct interaction with virtual objects.

iv. The VR environment can enable learners to acquire knowledge more efficiently through repeated practice [5, 6].

II. VR AND BADMINTON

Recently, VR has been adopted in badminton training systems. This includes watching detailed movements closely via VR helmet [7], using motion capture equipment to perform full-body badminton combat training [8, 9], recording eye tracking and smash actions to verify hand-eye coordination between beginners and experienced players [10], and using Kinect and an inertial measurement unit (IMU) to capture hand tracks and evaluate the effectiveness of badminton players' movements [11, 12].

Badminton Kings VR and Space Badminton are two 3D VR games on the Steam VR website. Players can challenge virtual opponents and judge effectiveness based on their scores. However, these games still focus on entertainment and lack further analysis to identify weaknesses in player training.

During the training process, objective information collected through information technology can more effectively assist athletes in understanding their own shortcomings [13-16]. These shortcomings may include the lack of coordination in certain body parts or insufficient proficiency in certain movements. Furthermore, this information can help coaches better understand athletes' performances and provide more personalized advice. For example, when coaches understand that athletes are performing poorly in certain areas, they can focus on specialized training in those areas. In addition, by collecting and analyzing information technology, coaches can better evaluate athletes' progress and adjust training plans for better results.

In summary, badminton training studies mainly focus on learner operation and battle practice but lack the ability to analyze learner problems during training processes effectively. We also plan to incorporate machine learning or deep learning

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

methods to help training process such as facial age estimation [17, 18], facial expression recognition [19], clothing retrieval [20, 21], segmentation of remote sensing image [22], and visual quality assessment [23]. This study aims to address this issue by building a VR badminton self-training system that provides players with precise and stable training materials during badminton training. The system will also provide players with practical analysis and suggestions to help them identify their own shortcomings more effectively.

III. VR Badminton Self-training

The badminton self-training system uses HTC VIVE devices to perform badminton training settings and actions. A virtual badminton court is modeled in 3D (see Fig. 1). The system has four functions: posture demonstration, serve practice, hitting practice, and effectiveness analysis (see Fig. 2).

A. Posture Demonstration

On the left side of the court (Fig. 3), badminton swing, forehand serve and backhand serve are demonstrated via teaching animations. Players can imitate and adjust their posture in accordance with demonstration contents.

B. Serve Practice

In this stage, the focal point is to improve the precision of the serve. Players can set the target position through the setting panel on the right side of the court as shown in Fig. 4. Then players must hit the target accurately by manipulating their own serve. All hitting data will be recorded and analyzed in the effectiveness analysis.

C. Hitting Practice

In Fig. 4, players set the serve point, landing point, height, and speed of the serve machine according to their distinct needs. Players can overcome their difficulties of specified hitting positions by means of iterative practices in this stage. These hitting data will also be recorded and analyzed in the effectiveness analysis.

D. Effectiveness Analysis

Players can turn on/off the traveling track to observe badminton trajectories during the training process. The analyzed results from serve and hitting records are presented in the effectiveness analysis panel. They show hit rate, hitting deviation, strength, and speed to assist players in effectively understanding the strengths and weaknesses of the training.

Fig. 3 Posture demonstration (backhand serve).

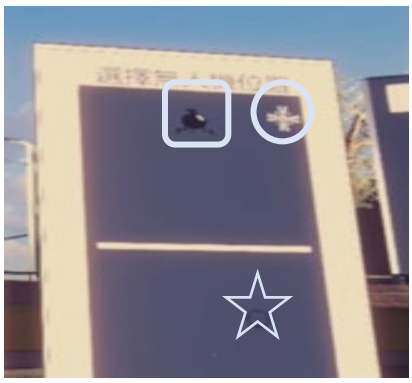

Fig. 4 Serve and hitting practice settings(circle, rectangle and star denote the target position, serve point and landing point, respectively).

Fig. 5 Effectiveness analysis panel.

IV. Training Suggestion

During badminton training, analyzing the results of serving and hitting for the player's reactions is one of the important issues for understanding and improving the player's weaknesses. With the assistance of artificial intelligence algorithms, the historical records of the player's training process can be analyzed, and individual analysis can be carried out for the serving and hitting status.

For example, when serving, whether the player has a blind spot on the landing point and cannot let the ball fall in a scoring position. In the process of hitting, whether the player has a high turnover rate in a specific position, the contact position between the ball and the racket face, the acceleration force, and the information about the landing position after hitting are analyzed.

The training system finds the focus that needs to be strengthened during training by analyzing the player's problems. For example, when the distance between the two landing points of the hit ball is too large and the player cannot react to the hit in time, the player's movement speed can be strengthened, or other hitting methods can be used to improve the problem of the distance between the landing points being too large.

The virtual coach in the system can give players suggestions on ball route patterns based on training analysis results, including improving the player's movement training method and hitting method, which can help players overcome their weaknesses in subsequent practices. In the future, artificial intelligence may be integrated to correct the target position of the badminton serve and the hitting trajectory of the serve.

For example, if the player has specific routes that they are not good at, the number of serves and hitting trajectories can be increased for individual weaknesses to enhance the training intensity of individual players' serving and hitting weaknesses. This can lead to a better understanding of the player's strengths and weaknesses, as well as the potential adjustments that can be made to improve their overall performance.

Moreover, the analysis of serving and hitting can also help players to understand the importance of positioning and timing, which are crucial factors in badminton. By analyzing the player's movement and reaction time, the system can provide targeted training suggestions to help players improve their positioning and timing, which in turn can improve their overall performance.

V. Conclusion

In conventional badminton training, players are restricted by the availability of a venue and coach. This badminton self-training system overcomes these limitations by constructing a realistic 3D VR environment. Players can practice as much as they need according to their individual requirements without being limited by time, space, or the availability of a coach.

This system provides stable and precise training materials without human intervention. Players can set various training conditions based on their own weaknesses. Finally, the training results are analyzed and presented in the effectiveness analysis panel. The analysis of serving and hitting in badminton training is a crucial aspect of understanding and improving a player's weaknesses, and the use of artificial intelligence algorithms can greatly enhance this process. By providing targeted training suggestions and automatic corrections, the system can help players to overcome their weaknesses and improve their overall performance effectively through the proposed system.

***Abstract*—Robust watermarking methods are necessary to resist attacks. With conventional watermarking methods, watermarks are extracted and their errors are corrected regardless of the type of attack. For example, error-correcting codes and spread spectrum are used to correct watermark errors. To reduce watermark errors, embedding methods in the frequency domain, such as DCT and DFT, and the use of scale invariant feature transform have been proposed. These methods are effective for non-geometric attacks such as additive noise and distortion. However, they do not work well against geometric attacks due to the lack of synchronization. It is necessary to perform optimal synchronization for geometric attacks such as scaling, rotation, cropping, etc. We focus on the rotation attack and propose a method of estimating the rotation angle using a grid-shaped pilot signal. While suppressing the original image-derived slant, the slant of the pilot signal can be emphasized and detected. Thus, the rotation angle of a stego-image can be accurately estimated.**

I. Introduction

Watermarking is a technique for embedding secret information in digital content such as still images. The embedded information is called a watermark, and the image into which the watermark is embedded is called a stego-image. Image-watermarking methods can be used to manage digital content and prevent unauthorized use of images. For example, by embedding an invisible signature as a watermark in an image, the author can claim their copyright when the image is illegally used. However, many of the images that are misused in social media are processed by scaling, rotating, cropping, and so on. The processed images are also always compressed when they are saved. That is, published images may be vulnerable to different types of attacks. Attacks on these images may cause loss of the watermark. Therefore, robust watermarking methods are necessary against various attacks.

The simplest method is to embed the watermark directly into the pixel values. However, it is easy to detect the position of the watermark, and the watermark can be easily removed by an attacker. To make watermarks imperceptible, they are embedded in the frequency domain by using discrete cosine transforms (DCT), discrete Fourier transforms (DFT), discrete wavelet transforms (DWT), and so on [1], [2], [3]. The watermark in the frequency domain also tends to be insensitive to errors even if the image is degraded by compression or other processing.

Watermark errors are caused by degradation of the image due to attacks. There are two main types of attacks: geometric and non-geometric. Non-geometric attacks are those that change pixel values, such as JPEG compression and noise addition. While they degrade the watermark, its coordinates remain unchanged. Therefore, conventional error-correcting methods can be applied to the watermark. These methods include using error-correcting codes [4] and spread-spectrum methods [5], [6]. However, if the watermark was not extracted, no error correction is conducted. Geometric attacks are those that change the positions of pixels due to scaling, rotation, or clipping of the image. Since geometric attacks change the positions of the watermark, error-correcting methods cannot be applied without synchronization. With watermarking methods using scale invariant feature transform (SIFT) features [7], synchronization can be achieved at SIFT feature points. Watermarks are embedded around the feature points, allowing the watermark to resist geometrical attacks [8], [9], [10].

With many conventional watermarking methods, the redundancy of the watermark is used to recover the watermark even if it is distorted by an attack. However, if the type and strength of the attack could be estimated, it would be possible to extract the watermark more accurately. Therefore, we focused on reducing errors by estimating the type and strength of attacks on the basis of the framework of communication-channel models in which a message degraded through the channel is received. Hyper-parameters, such as noise strength of the channel, are estimated by a signal called a pilot signal, which is distinct from the message. Therefore, the pilot signal is introduced into a watermarking method to estimate an attack. If the embedding position of the watermark can be estimated correctly, watermarking errors would be reduced. Assuming that an attack can be estimated, the embedding strength of the watermark would be reduced, resulting in improved image quality.

Su *et al.* [11] proposed a watermarking method using pilot signals. With this method, SIFT feature points are first detected, then pilot signals around the points are detected to discover the embedding positions of watermarks. The embedding regions are rotated so that the gradient direction of the SIFT feature is the reference angle. In other words, the image quality and watermarks degrade due to the rotation of the image during the embedding process. Note that both the watermark and pilot signal are embedded in the same domain. This method doesn't use a pilot signal for estimation of the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

attack parameters.

A novel approach is required to estimate the type and strength of attacks. The optimal shape of the pilot signal for each attack may be different, and its embedding technique may also be different. It is difficult to determine a type of attack due to there being many types. Therefore, we fix the type of attack and focus on estimating the strength of the attack. In our previous study, we estimated the magnification ratio of the image using a grid-shaped pilot signal [12]. Therefore, in this paper, we propose a method of estimating the rotation angle using the pilot signal.

This paper is organized as follows. In Section II, we present the proposed method for estimating the rotation angle using the pilot signal. In Section III, we present the results from computer simulations conducted to verify the proposed method. We conclude our study in Section IV.

II. Estimation of Rotation Angle Using Pilot Signal

The proposed method estimates the rotation angle of a stego-image using the pilot signal. The advantage of this method is that the estimated rotation angle can be used to synchronize the embedding regions, potentially reducing watermarking errors. Eventually, watermarks will be able to be extracted with smaller embedding strengths, improving the quality of stego-images.

Similar to our previous study on magnification-ratio estimation [12], we focused on the embedding of a grid-shaped pilot signal. When the stego-image is rotated, orthogonal lines corresponding to the rotation angle appear in the DFT coefficients. Therefore, the rotation angle can be estimated by calculating the slant of the orthogonal lines.

A. embedding method

The original color image is decomposed into its YUV components, and the watermark is embedded in the Y component, the luminance value. To avoid affecting the watermark, the pilot signal is embedded in the V or U component. In the following explanation, the U component is used. The size of the image is $L_w \times L_h$ pixels, and the pixel value at coordinate (x, y) is denoted as $U(x, y)$.

A grid-shaped pilot signal is embedded into $U(x, y)$ by using quantization index modulation (QIM) [13]. Figure 1 shows the shape of the pilot signal. The grid interval γ and grid width β shown in Fig. 1 are $\gamma = 50$ and β pixels, respectively. The pilot signal takes the value 0 or 1. The yellow area is embedded with the value 0, and the blue area with the value 1. The green regions, which are the intersections of the two types of grids, are embedded with alternating values of 0 and 1. Other non-colored regions are left unchanged.

With QIM [13], the pilot signal is embedded by quantizing the original value with a step size Δ_r. The pilot signal $p \in \{0, 1\}$ is embedded in $U(x, y)$ by using QIM, and the embedded pixel value $U'(x, y)$ is obtained by

$$U'(x,y) = 2\Delta_r \left(\left\lfloor \frac{U(x,y)}{2\Delta_r} - \frac{p}{2} + 0.5 \right\rfloor + \frac{p}{2} \right). \quad (1)$$

In this study, Δ_r of QIM was set to 10.

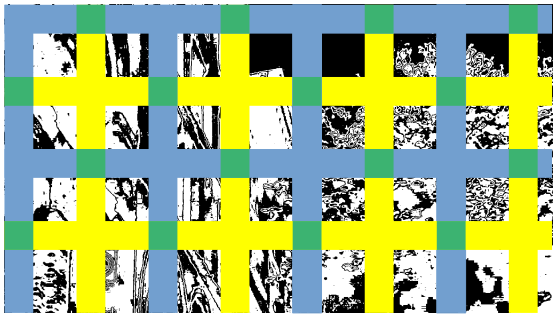

Fig. 1. Shape of pilot signal. Pilot signal is embedded in colored regions by using QIM. Non-colored regions are left unchanged.

B. Detection of rotation angle

We describe the procedure for estimating the rotation angle on the basis of the pilot signal. We assume that the stego-image has been rotated by an angle of $-180 \leq \theta < 180$ degrees. Since the pilot signal has a grid shape, slant components appear as orthogonal lines in the DFT coefficients when the stego-image is rotated. Therefore, the rotation angle can be estimated by measuring the slant of these lines.

Figure 2 shows the procedure for estimating the rotation angle. Each processing step is described below.

1) Color-space separation: An image is decomposed into its YUV components, then the U-component image is divided into N_s blocks of $L_r \times L_r$ pixels. We set the length of one side of the block to $L_r = 300$ pixels. If the block size is too small, the period of the pilot signal cannot be detected. The block size L_r should be several times larger than the grid interval γ.

2) Extraction of embedded information: Binary embedded information $\hat{p}^l(x, y)$ is extracted from the l-th block $U^l(x, y)$ by using QIM. Embedded information can be obtained by

$$\hat{p}^l(x,y) = \left\lfloor \frac{U^l(x,y)}{\Delta_r} + 0.5 \right\rfloor \bmod 2. \quad (2)$$

The pilot signal or original image-derived information is extracted as $\hat{p}^l(x, y)$.

3) Amplitude-spectrum calculation: When each block is transformed by DFT, the DFT coefficients are given by

$$F^l(k_1,k_2) = \frac{1}{L_r} \sum_{x=0}^{L_r-1} \sum_{y=0}^{L_r-1} \hat{p}^l(x,y) e^{-2\pi j \left(\frac{k_1 x}{L_r} + \frac{k_2 y}{L_r} \right)}, \quad (3)$$

where j is an imaginary unit. The amplitude spectrum $|F^l|$ is calculated from the DFT coefficients $F^l(k_1, k_2)$. Denoting the real and imaginary parts of the DFT coefficients as $\mathrm{Re}\ F^l(k_1, k_2)$ and $\mathrm{Im}\ F^l(k_1, k_2)$, respectively, the amplitude spectrum is given by

$$|F^l(k_1,k_2)| = \sqrt{(\mathrm{Re}\ F^l(k_1,k_2))^2 + (\mathrm{Im}\ F^l(k_1,k_2))^2}. \quad (4)$$

As mentioned above, when the stego-image is rotated, the slants due to the pilot signal appear as orthogonal lines in the

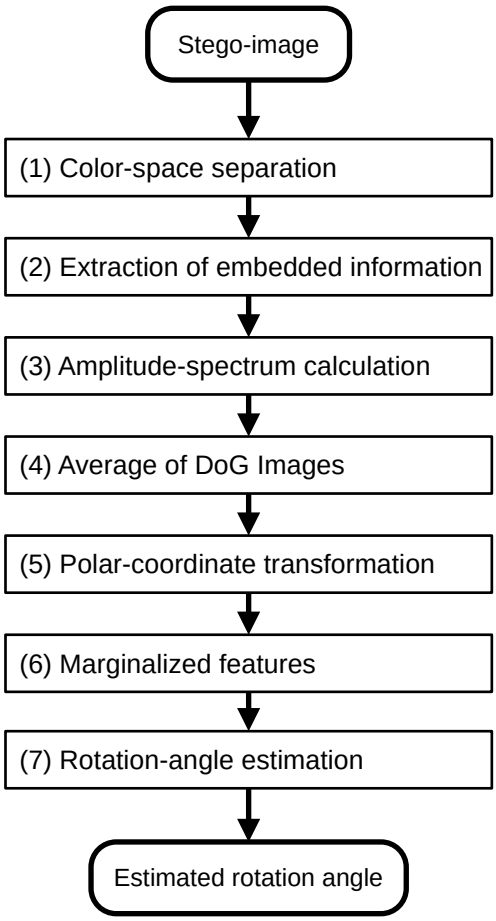

Fig. 2. Procedure for estimating rotation angle

amplitude-spectrum $|F^l|$. In addition, horizontal and vertical lines through the center point appear in a few cases. Figure 3 is the amplitude spectrum when the image is rotated 30 degrees. We can find that orthogonal lines appear through the center point corresponding to the rotation angle.

4) Average of DoG Images: The orthogonal lines may be difficult to see depending on the content of the images. To improve line detection, the Difference of Gaussian (DoG) filter [7] is applied to $|F^l|$. Let $\mathrm{DoG}^l(k_1, k_2)$ be the l-th DoG image generated by the filter. The average DoG image $\overline{\mathrm{DoG}}(k_1, k_2)$ over N_s blocks is computed by

$$\overline{\mathrm{DoG}}(k_1, k_2) \quad = \quad \frac{1}{N_s} \sum_{l=1}^{N_s} \mathrm{DoG}^l(k_1, k_2). \tag{5}$$

By dividing the image into blocks and averaging the DoG images of the blocks, the components derived from the original image are averaged out, and the components derived from the pilot signal can be emphasized.

5) Polar-coordinate transformation: To extract the slant, $\overline{\mathrm{DoG}}(k_1, k_2)$ is converted to polar coordinates. The coefficients converted to polar coordinates are defined as feature $G(\theta, \rho)$. The range of the radius ρ is $0 \leq \rho \leq \sqrt{2}L_r/2$. The radius ρ and angle θ are quantized to integers. Note that the

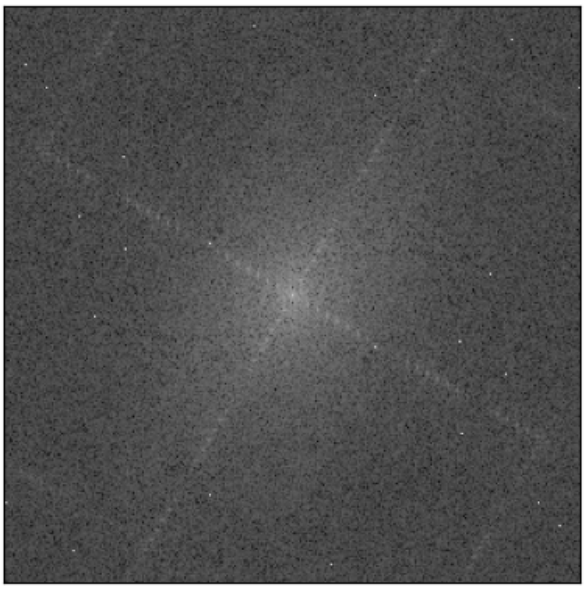

Fig. 3. Amplitude spectrum at 30-degree rotation. Slanted orthogonal lines appear.

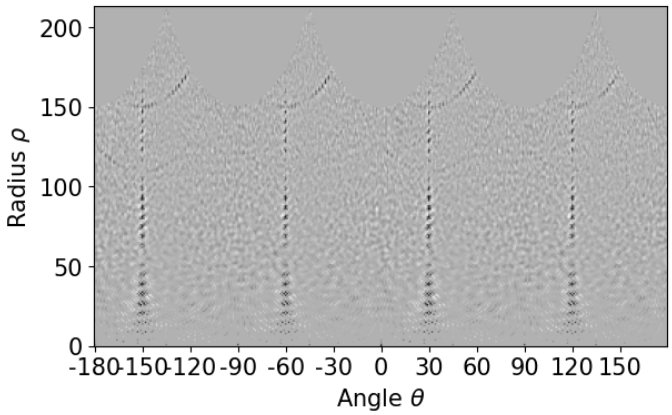

Fig. 4. Feature space. Minima appear at position of rotation angle.

components of the feature corresponding to the regions outside the square block are assumed to be $G(\theta, \rho) = 0$.

Figure 4 shows $G(\theta, \rho)$ when the stego-image is rotated 30 degrees. The horizontal axis represents θ, and the vertical axis represents ρ. We can see that minima appear at $30 + 90n, n = -2, -1, 0, 1$ degrees.

6) Marginalized features: The features are marginalized for the radial direction to determine the rotation angle. The marginal distribution $S(\theta)$ of the features can be given by

$$S(\theta) \quad = \quad \sum_{\rho=0}^{\sqrt{2}L_r/2} G(\theta, \rho). \tag{6}$$

The distribution $S(\theta)$ is also normalized so that it has mean 0 and variance 1. Letting the mean of $S(\theta)$ be μ_S and the standard deviation be σ_S, the Normalized feature intensity

$z(\theta)$ is given by

$$z(\theta) \quad = \quad \frac{S(\theta) - \mu_S}{\sigma_S}. \tag{7}$$

Figure 5 (a) shows the normalized feature intensity for Fig. 4. The peaks appear at $30 + 90n$ degrees. Angles that coincide by rotating $90n$ degrees are defined as one angle group. For example, if $(30 + 90n)$-degrees angles appear, they are called a 30-degree group.

7) Rotation-angle estimation: The rotation angle is estimated from the peak of $z(\theta)$. The angles with peaks below the threshold Θ are detected. When the rotation angle is θ, four angles $\theta+90n, n = -2, -1, 0, 1$ of the θ-degree group are detected. Angles of $-180, -90, 0, 90$ degrees may be detected regardless of the rotation angle. Thus, four or eight peaks will be detected. Figure 5 (b) shows $z(\theta)$ when the image is rotated 25 degrees. In this case, eight peaks of $25 + 90n$ and $0 + 90n, n = -2, -1, 0, 1$ degrees appear. When eight peaks are detected, a non-zero-degree group angle is chosen as the estimated rotation angle. Therefore, 25 degrees is chosen as the estimated rotation angle. In summary, the proposed method can determine the estimated rotation angle from the amplitude spectrum, excluding the $90n$-degree differences. At most four extraction processes are required to extract the correct watermark. One property of DFT is that the DFT coefficients and their point symmetries are complex conjugate. Hence, the conjugate-amplitude spectrum satisfies

$$|F(k_1, k_2)| \quad = \quad |F(-k_1, -k_2)|. \tag{8}$$

Thus, if the image is rotated 180 degrees, the rotated amplitude spectrum $|F(-k_1, -k_2)|$ is equal to the original spectrum before rotation, $|F(k_1, k_2)|$. If watermarks are embedded in the amplitude-spectrum, they must also be embedded in the conjugate amplitude-spectrum, so that the same watermarks can be extracted even if the stego image is rotated 180 degrees. Therefore, if the watermarks are extracted after the rotation angle is estimated in advance using this method, the number of extraction processes can be reduced to a maximum of two, since the 180-degree rotation need not be taken into account.

III. COMPUTER SIMULATION

We evaluated the proposed method in terms of the percentage of successful detections of the rotation angle.

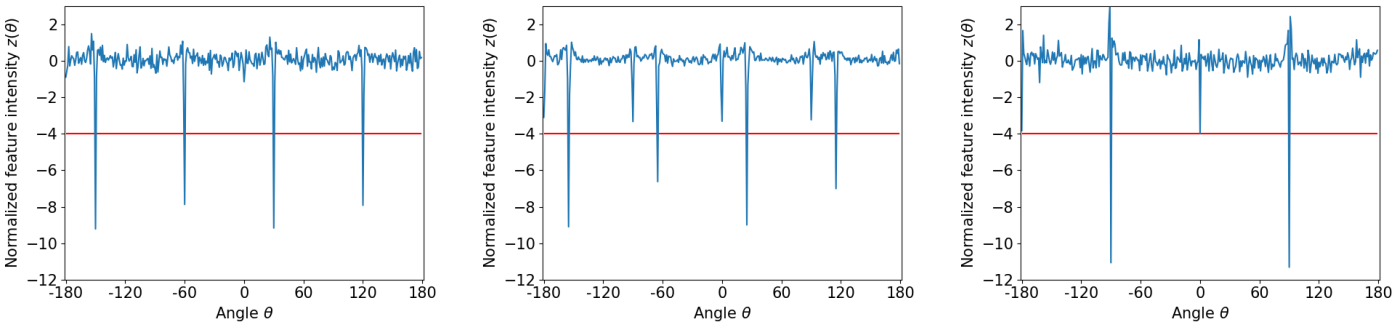
A. experimental conditions

The images used for evaluation were six IHC (Information Hiding and its Criteria for evaluation) standard images (4608×3456 pixels) [14]. The pilot signal is embedded in the U component of the image. A rotation attack on the stego-image is conducted with the rotation-angle range $\theta \in [-90, 90]$. After scaling each stego-image, four HDTV-sized (1920×1080 pixels) images are cropped out, centered at the coordinates $(x \pm 700, y \pm 500)$. The watermark is then estimated from the total $24 = 6 \times 4$ cropped images.

The length of one side of the block is set to $L_r = 300$ pixels, and the U-component image is divided into $N_s = 18$ blocks. The threshold for detecting peaks from the normalized feature intensity $z(\theta)$ is set to $\Theta = -4$.

B. Percentage of successful detections of rotation angle

Although this method can determine the rotation-angle group, it cannot uniquely determine the estimated rotation angle. Therefore, if the rotation-angle group is correct, we assume that the detection was successful. Figure 6 shows the successful-detection rate of rotation angles. The horizontal and vertical axes represent the rotation angle of θ and success rate, respectively. For rotation angles other than 0 degrees, the detection was 100% successful. We examined the 0-degree case with several detection failures. Figure 5 (c) shows the intensity $z(\theta)$ for the detection failures. The red line represents the threshold $\Theta = -4$. Less than four peaks below the threshold were detected. Since four peaks must be detected when detecting the rotation angle, detection failed.



C. Validity of averaging process

If the original image contains slant, the binary embedded information may include the slant derived from the original image, resulting in false detection of the slant. Figure 7 shows the stego-image rotated -90 degrees. If the angle is estimated without averaging ($N_s = 1$), only the solid red block is used to estimate the rotation angle. This block obviously contains the original image-derived slant. Figure 8 (a) show the intensity $z(\theta)$ obtained without averaging ($N_s = 1$). The peaks appear at $\theta = -180, -167, -90, 0, 90$ degrees. Here, the peak at $\theta = -167$ degrees is not a pilot signal but a slant derived from the original image. If the angle is estimated with the average of five blocks ($N_s = 5$), the rotation angle is estimated from the average of the five blocks consisting of the red square and the four yellow squares in Fig. 7. Figure 8 (b) shows the intensity $z(\theta)$ averaged over $N_s = 5$ blocks. The averaging process reduces the original image-derived slant and emphasizes the pilot signal peaks, thus detecting very clear peaks. Figure 9 shows the detection rate when the number of blocks is $N_s = 1, 5$. The average detection rate for $N_s = 1$ was about 89% and for $N_s = 5$ about 99%. We found that the detection rate was not good without averaging, but averaging over at least five blocks resulted in almost 100%.

IV. CONCLUSIONS

To extract a watermark from a rotated stego-image, it is necessary to synchronize the position of the watermark with respect to the geometric transformation. Therefore, watermarks have been embedded using invariants such as SIFT feature points. With conventional watermarking methods using SIFT feature points [11], the watermark is embedded on the basis of the SIFT feature points, and the correct embedding position can be detected. However, even if the position can be estimated, a slanted embedding region is detected. Hence, the rotation angle must be searched by brute force to extract the watermark.

With the proposed method, the pilot signal is used as the synchronization. As in our previous study [12], we introduced

(a) $\theta = 30$ degrees (b) $\theta = 25$ degrees (c) $\theta = 0$ degrees

Fig. 5. Normalized feature intensity $z(\theta)$ at rotation angle of θ

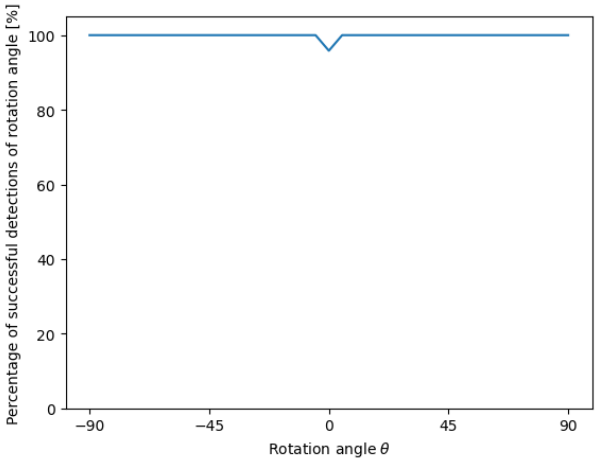


Fig. 6. Successful-detection rate of rotation angle

a grid-shaped pilot signal. The rotation angle is estimated by detecting the pilot signal in a rotated stego-image. From computer simulations, we verified that the rotation angle can be accurately detected. If the rotation angle can be estimated, the embedding strength of the watermark will be reduced, which is expected to improve image quality. For future work, the embedding strength will be optimized and the bit error rate of the watermark will be evaluated. As future work, we will examine methods for estimating combination attacks. Also, the embedding strength will be optimized and the bit error rate of the watermark will be evaluated.

***Abstract*—We developed an application that can generate a screenshot image of a website and redisplay the website with the URL extracted from the image. Since URLs contain multibyte characters and have variable length, they are converted using Base64 and QR code. The QR code allows error correction. The converted bit sequence is then embedded as a watermark. Unlike natural images, screenshot images are artificial. In many screenshot images, luminance values tend to be distributed around 0 or 255. When embedding, many watermarks are dropped due to overflow. Therefore, we also propose a method of shrinking the luminance distribution for screenshot images. Compared with the case in which the luminance distribution was left unchanged, the proposed method had a smaller bit error rate and was able to redisplay websites with the URLs extracted from the screenshot images.**

I. Introduction

Smartphones now have a screenshot function that allows users to save information displayed on the screen as an image. The screenshot is very useful since a user can always refer back the information viewed in the browser. However, there are often cases in which the information one wants to see is outside the scope of the screenshot image. In this case, the user needs to search the website again. To mitigate this inconvenience, we developed an application that enables re-access to a website from a screenshot image and applies watermarking.

Watermarking is a technique of secretly embedding in or extracting information from content, such as still images, video, and audio [1]. For example, watermarking is used to detect and track unauthorized use of content and prevent tampering. Information embedded into an image is called a watermark, and the embedded image is called a stego-image. Typical watermarking methods include additive embedding [2] and quantization index modulation (QIM) [3] to embed the watermark into the content. Since screenshot images may be shared or transferred between devices, QIM is used as a robust embedding method [3]. Processing to the content, such as compression and cropping, causes errors in the watermark. Therefore, error-correcting codes [4] and spread-spectrum technique [5] are used to correct these errors.

We developed an application that can generate a screenshot image of a website and redisplay the website with the URL extracted from the image The images used in our application are screenshots of websites displayed in a browser; thus, smartphone-application screenshots are out of the scope of this study. Screenshot images are artificial and most of their luminance values tend to be close to 0 or 255. Hence, unlike natural images, conventional watermarking methods often fail to embed watermarks in screenshot images correctly. Therefore, we propose a method for shrinking the luminance distribution for screenshot images.

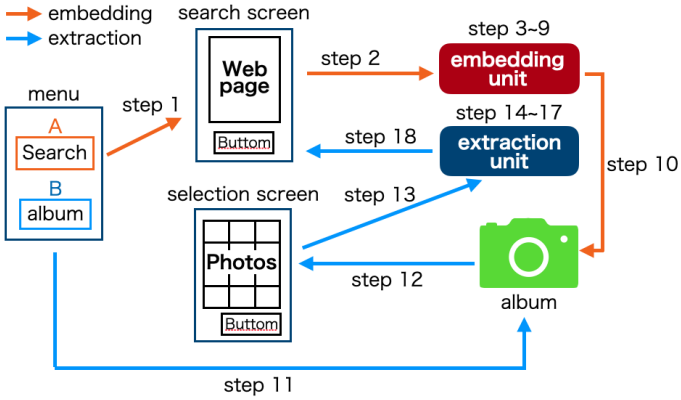

Fig. 1: Overview of application

This paper is organized as follows. In Section II, we present our developed application and proposed method. In Section III, we discuss the evaluation of the proposed application on extracting URLs. We conclude the paper in Section IV.

II. Developed application and proposed method

We describe the overall concept of our application and method suitable for screenshots. Since our study is aimed at developing applications for the iPhone, the following sample codes are written in Swift.

A. Process flow of application

The main functions of the application are to save a screenshot image with a URL and display the website with the URL extracted from the stego-image in a browser. Figure 1 shows an overview of the application, which includes embedding and extraction procedures.

1) Embedding Procedure: Steps 1–10 (steps 1, 2 and 10 in Fig. 1 and steps 3–9 in Fig. 2) are those involved in the embedding procedure.

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

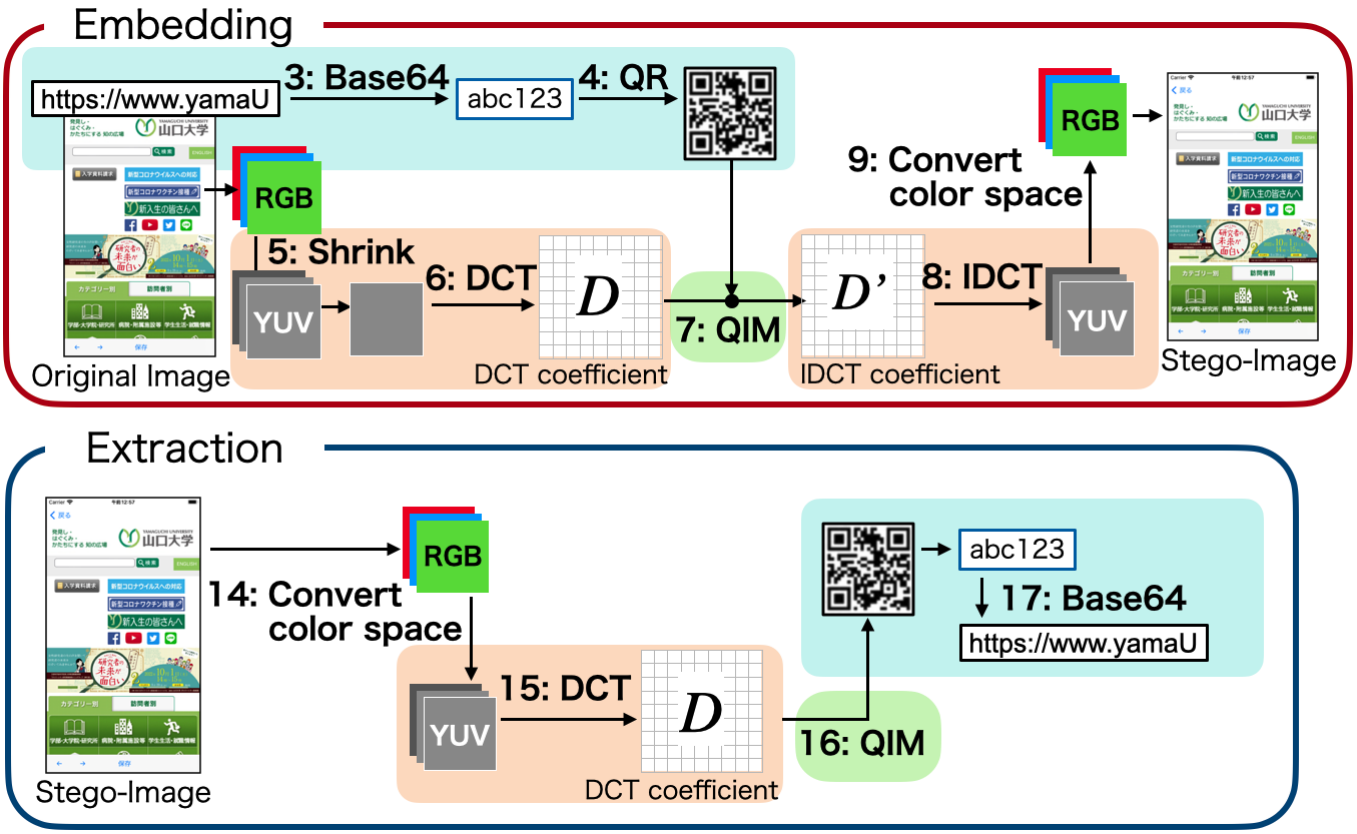

Fig. 2: Processing in the embedding unit and extraction unit. The light blue area shows the conversion process between URL and QR Code, the orange area the DCT process, and the green area the QIM process.

step 1: When the user presses the ”search” button on the menu, the screen changes to the search screen, as shown in Fig. 3 (b).

step 2: When the user presses the ”screenshot” button at the bottom of the screen shown in Fig. 3 (b), both the URL as a watermark and screenshot image as an original image are sent to the embedding unit.

step 3: In the embedding unit, the URL is encoded using Base64 since multibyte characters, such as Japanese, are often included in the URL. Hereafter, an encoded string is referred to as a Base64-encoded URL. The number of letters in a Base64-encoded URL should be a constant length.

step 4: The Base64-encoded URL is converted into a QR code. The bit sequence binarized from the black-and-white pixels of the generated QR code is called a watermark.

step 5: The original image is converted from the RGBA color space to YUV color space. The distribution of luminance values is shrunk.

step 6: Luminance values are converted to the frequency domain by the two-dimensional (2D) discrete cosine transform (DCT).

step 7: The watermark is embedded in the DCT coefficients by QIM.

step 8: The Y component of the stego-image is generated by the inverse DCT.

step 9: The generated Y component is combined with the U and V components of the original image and converted to the RGBA color space to generate a stego-image.

step 10: The generated stego-image is saved to the photo folder in the device.

2) Extraction Procedure: Steps 11–18 (step 11-13 and 18 in Fig. 1 and steps 14–18 in Fig. 2) are involved in the extraction procedure.

step 11: When the ”album” button on the menu screen shown in Fig. 3 (a) is pressed, the album of the device is displayed, as shown in (c).

step 12: When a user selects an image from the album, the selected image is displayed, as shown in (d).

step 13: When the ”Extract URL” button in the lower right corner of the screen is pressed, the selected stego-image is sent to the extraction unit.

step 14: A stego-image is converted from the RGBA color space to the YUV color space.

step 15: The Y component of the stego-image is transformed to the frequency domain by 2D DCT.

step 16: Watermark, which is a binarized QR code, is extracted from the DCT coefficients by using QIM.

step 17: The extracted watermark is converted to a black-and-white image and decoded into a string by using the

(a) menu (b) search screen

(c) album (d) selection screen

Fig. 3: Application screen on simulator

QR-code-reader function. Since this string is a Base64-encoded URL, it is further decoded using Base64.

step 18: The decoded string is converted to a URL by removing the nil character at the end of the decoded string. The website with the URL is then displayed.

B. QR Code and Base64

When embedding a watermark, the watermark should be of fixed length to simplify the algorithm. A fixed length is often assumed with conventional watermarking methods. Watermarks must also be robust against errors. Our application converts a variable-length URL into a QR code, making the watermark fixed-length and providing error-correction capability.

A fixed-length QR code can be generated if the version can be specified. However, the QR-code-generation method `QRCodeGenerater` [6] in the Swift standard library cannot specify the version. Therefore, the length of the QR code varies depending on the length of the URL. In addition, alphanumeric characters, special symbols, and multibyte characters in URLs are assigned different bit lengths in the QR code, so the length of the QR code may differ even for the same number of letters. Therefore, it is necessary to encode multibyte characters into alphanumeric characters only. A method `base64EncodedString` [7] in the Swift standard library was used for encoding. It is a method that returns a Base64-encoded string when binary data are given. The sample code for `base64EncodedString` is shown in Fig. 4. Since the URL is string type, it is converted to data type. As the argument `data` is given to `base64EncodedString`, the encoded string is returned. As a result, the URL can be converted to an alphanumeric-only Base64-encoded URL.

The terminating character in Base64 is ”=” and can be decoded even if there are two or more ”=”s at the end. In other words, it is possible to make the length of a string constant by adding an ”=” at the end. A sample code for adjusting the length of a string is shown in Fig. 5. The argument `length` is the desired number of letters. The variable `url_ad` is assigned the string `url`, and ”=” is added until its length becomes the target number of letters. Thus, an encoded fixed-length URL is generated.

Watermarks must be robust against errors. In our application, QR codes are used for error correction. To convert a Base64-encoded URL to a QR code, it is necessary to specify `"CIQRCodeGenerater"` [6] to `CIFilter` in the Swift standard library. This method generates a QR code when a string and error-correction level are given as arguments. A sample code of `QRCodeGenerater` is shown in Fig. 6. The encoded URL and error-correction level ”H” (high) are given. Accordingly, the generated QR code is returned. Since the returned QR code is an image, the pixel values are scanned and converted to binary values. That is, white pixels are converted to 1 and black pixels are converted to 0. This binarized code is used as a watermark.

C. Histogram Shrinkage

In our application, the original image in which the URL is embedded is a screenshot image of a website. Figure 7 shows histograms of luminance values, where (a) and (b) represent histograms of luminance values of a screenshot image and natural image, respectively. This indicates that, unlike natural images, screenshot images have a sparse luminance distribution. The screenshot image is an artificial image, and many of the background colors of websites take luminance values close to 0 or 255. Therefore, embedding the watermark causes an overflow of luminance values, and the watermark is lost due to the rounding process. In other words, embedding watermarks in screenshot images often fails. Therefore, our proposed method shrinks the luminance distribution.

The luminance components are separated from the original image. Let $Y(i,j)$ be the luminance value at coordinate (i,j). If there is a pixel of luminance value $Y(i,j) < 14$ or $Y(i,j) > 241$, the distribution is shrunk. Let $Y'(i,j)$ be the luminance

```
//Encode URLs in Base64
func Enc64(url: String)->String{
    let data = url.data(using: .utf8)
    let EncStr: String! = data?.base64EncodedString()

    return (EncStr)
}
```

Fig. 4: Sample code of base64EncodedString

```
//Adjust the number of characters
func adjust(length: Int, url: String)->String{
    var url_ad: String = url
    //Add "=" to adjust the number of characters to the variable length
    for _ in 0...length-url.count-1{
        url_ad += "="
    }

    return (url_ad)
}
```

Fig. 5: Sample code for adjusting length of string

```
//Generate QR Code
func generateQR(url: String)->(uiQR:UIImage, cgQR:CGImage){
    let url = url

    //Convert url from String type to Data type
    let data = url.data(using: .utf8)!
    //inputCorrectionLevel specifies the level of error correction
    let qr = CIFilter(name: "CIQRCodeGenerator", parameters: ["inputMessage":data,
        "inputCorrectionLevel": "H"])!
    //put a white border
    let sizeTransform = CGAffineTransform(scaleX: 1, y: 1)

    //Convert QR code to CIImage type
    let ciQR = qr.outputImage!.transformed(by: sizeTransform)

    //CI to (UI & CG)
    let uiQR = UIImage(ciImage: ciQR)
    let OpCG = context.createCGImage(ciQR, from: ciQR.extent)
    let cgQR = OpCG!

    return (uiQR,cgQR)
}
```

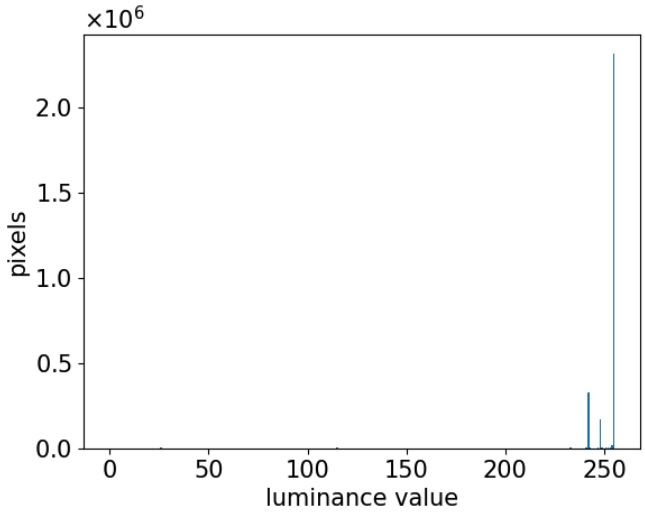
Fig. 6: Generation of QR code

value after shrinkage, which is given by

$$Y'(i,j) \quad = \quad rY(i,j) + (1-r)m, \tag{1}$$

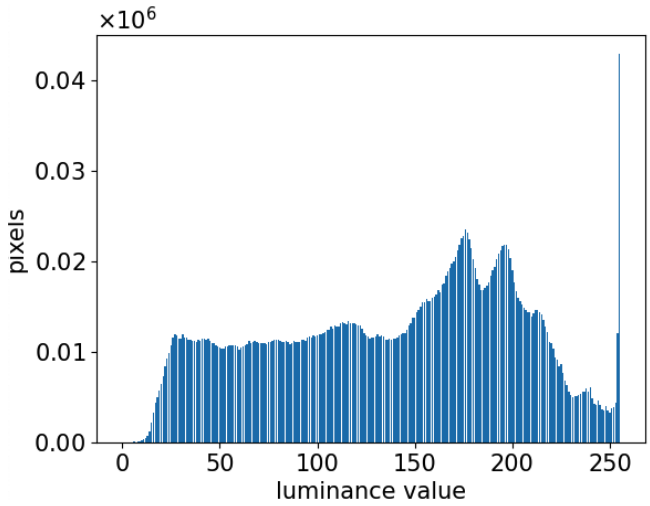
where $m = 255/2 = 127.5$, and $r \leq 1.0$ is the magnification rate.

The embedding domain is the frequency domain of the DCT. Thus, the 2D DCT is used on $Y'(i,j)$. When using the DCT in Swift, the DCT class of the vDSP framework is used. However, this DCT class implements only the 1D DCT. Therefore, we implemented the 2D DCT by using the 1D DCT twice.



D. Embedding and Extraction with QIM

There are two types of watermark embedding and extraction methods: non-blind that requires the original image for extraction and blind that does not require the original image. Our application uses a blind method, i.e., QIM [3]. First, we explain the embedding process by QIM. Let a K-bit watermark be $\boldsymbol{m} = (m_1, m_2, ..., m_K)^\top, m_i \in \{0,1\}$. The watermark m_i is embedded into the DCT coefficients D_i by using QIM. The embedded DCT coefficient D'_i is given by



$$D'_i \quad = \quad 2\Delta \left(\left\lfloor \frac{D_i}{2\Delta} - \frac{m_i}{2} + 0.5 \right\rfloor + \frac{m_i}{2} \right), \tag{2}$$

where Δ is a quantization step size [3] and $\lfloor x \rfloor$ represents the floor function.

We next explain the extraction process by QIM. The watermark $\hat{m}_i$ is extracted from D'_i. The extracted watermark

(a) Histograms for screenshot image (No. 2 in Table I)

(b) Histograms for natural image

Fig. 7: Histograms of luminance values

$\hat{\boldsymbol{m}} = (\hat{m}_1, \hat{m}_2, ..., \hat{m}_K)^\top$ is given by

$$\hat{m}_i \quad = \quad \left\lfloor \frac{|\hat{D}_i|}{\Delta} + 0.5 \right\rfloor \bmod 2. \tag{3}$$

III. Evaluation

We describe the evaluation method of this application and present the results.

A. Bit Error Rate

We evaluated whether URLs were correctly extracted from the screenshot images. The evaluation was based on the bit error rate (BER) for the watermark. Note that a watermark is a binary bit sequence of a QR code containing a Base64-encoded URL. The BER is defined as

$$\text{BER} \quad = \quad \frac{1}{K} \sum_{i=1}^{K} m_i \oplus \hat{m}_i, \tag{4}$$

where $\oplus$ is an exclusive OR.

B. Simulation Conditions

We ran our application on the iPhone SE (3rd generation) simulator on Xcode. The screen size of the iPhone SE is 750×1334 pixels. The method that leaves the luminance distribution unchanged is called an original embedding, in contrast to the proposed method. Screenshots were taken at the 15 different websites shown in Table I. For the screenshot image of each site, the same URL was embedded with both the proposed method and the original embedding. The error-correction level of the QR code is set to "H". The desired number of letters in the Base64-encoded URL was set to 1000. The magnification rate r of the luminance distribution was set to $r = 0.95$. The step size of QIM was set to $\Delta = 5000$.

C. Evaluation Results

The results of the computer simulation are listed in Table I, where the URLs were the addresses of 15 different websites, including the number of letters of the URLs. The table shows whether the websites could be displayed again by using the extracted URLs with the proposed method and the original embedding, and the BERs of the watermark. Figure 8 shows the BERs. In the original embedding, only Nos. 4, 6, and 10 could be redisplayed. For all other websites, the QR codes were not decoded. A zero-length string representing decoding failure was returned. Figure 8 shows that the BERs with the original embedding were larger than 0.14, except for website Nos. 4, 6, and 10. This is considered due to overflow of luminance values and loss of the watermark.

As shown in Table I, all websites could be redisplayed by using the proposed method. The table also shows that BER< 0.015 for all websites. To confirm that no overflow occurred, the shrunken luminance distribution is shown in Fig. 9. Compared with Fig. 7 (a), the luminance values were distributed inward, mostly within the range $[0 : 255]$. In other words, the shrinkage of the luminance distribution was effective for embedding into the screenshot images.

IV. Summary

We developed an application that can embed the URL of a website into a screenshot image, then redisplay the website from the image. Since many background colors have luminance values close to 0 or 255, embedding a watermark in a screenshot image will cause an overflow of such values. To solve this problem, we also proposed a method of shrinking the luminance distribution.

From computer simulations involving our application, we confirmed that it can be operated from the user's viewpoint without crashes or other problems. As a result of URL extraction using the proposed method and the original embedding,

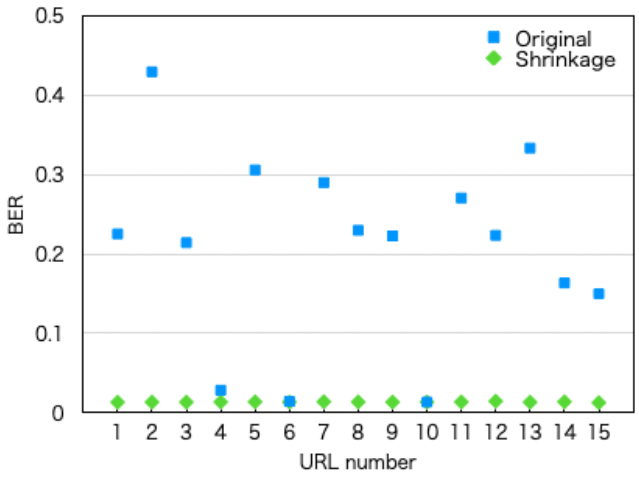

Fig. 8: BERs of watermarks from extracted QR code. Blue and green points represent BERs of original embedding and proposed method, respectively.

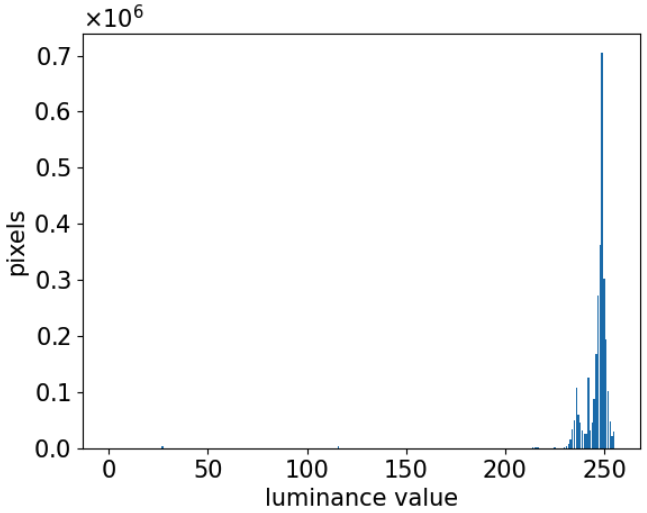

Fig. 9: Histogram of luminance values after embedding into screenshot image with proposed method. (No. 2 in Table I)

the original embedding had large BERs and failed to redisplay in 12 out of 15 cases. The proposed method had small BERs and was able to redisplay all websites. Therefore, shrinking the luminance distribution is effective for embedding a watermark in a screenshot image.

The current proposed application does not re-access dynamic pages or web pages that use cookies for session management. It also does not support screenshots in other applications that cannot capture URLs. This application only provides the function to retrieve a URL.

***Abstract*—In recent years, deep neural networks (DNNs) trained with transformed data have been applied to various applications such as privacy-preserving learning, access control, and adversarial defenses. However, the use of transformed data decreases the performance of models. Accordingly, in this paper, we propose a novel method for fine-tuning models with transformed images under the use of the vision transformer (ViT). The proposed domain adaptation method does not cause the accuracy degradation of models, and it is carried out on the basis of the embedding structure of ViT. In experiments, we confirmed that the proposed method prevents accuracy degradation even when using encrypted images with the CIFAR-10 and CIFAR-100 datasets.**

I. Introduction

Deep neural networks (DNNs) have been deployed in many applications including security-critical ones such as biometric authentication and medical image analysis. In addition, training a deep learning model requires a huge amount of data and fast computing resources, so cloud environments are increasingly used in various applications of DNN models. However, since cloud providers are not always reliable in general, privacy-preserving deep learning has become an urgent problem [1], [2].

One of the privacy-preserving solutions for DNNs is to use encrypted images to protect visual information on images for training models and testing. In this approach, images are transformed by using a learnable encryption method, and encrypted images are used as training and testing data. The use of models trained with encrypted images enables us to use state-of-the-art learning algorithms without any modification. However, all conventional learnable encryption methods [3]–[8] have the problem that is the performance degradation of encrypted models compared to models without encryption.

Traditional cryptographic methods such as homomorphic encryption [9], [10] are one of the other privacy-preserving approaches, but the computation and memory costs are expensive, and it is not easy to apply these methods to state-of-the-art DNNs directly. Federated learning [11] allows users to train a global model without centralizing the training data on one machine, but it cannot protect privacy during inference for test data when a model is deployed in an untrusted cloud server.

Accordingly, we focus on the problem of degraded model performance when models are trained with encrypted images. In this paper, we consider reducing the performance degradation of encrypted models when using encrypted images in the vision transformer (ViT) [12] which has high performance in image classification, and we propose a domain adaptation method to reduce the influence of encryption. In experiments, the proposed method is demonstrated to maintain almost the same performance as models trained with plain images in terms of image classification accuracy even when using encrypted images.

A. Image Encryption for Deep Learning

Various image transformation methods with a secret key, often referred to as perceptual image encryption or image cryptography, have been studied so far for many applications [1]. In this paper, we focus on learnable images transformed with a secret key, which have been studied for deep learning. Learnable encryption enables us to directly apply encrypted data to a model as training and testing data. Encrypted images have no visual information on plain images in general, so privacy-preserving learning can be carried out by using visually protected images. In addition, the use of a secret key allows us to embed unique features controlled with the key into images. Adversarial defenses [13] and access control [14] are carried out with encrypted data using unique features.

Tanaka first introduced a block-wise learnable image encryption method (LE) with an adaptation layer [3], which is used prior to a classifier to reduce the influence of image encryption. Another encryption method is a pixel-wise encryption (PE) method in which negative-positive transformation (NP) and color component shuffling are applied without using any adaptation layer [4]. However, both encryption methods are not robust enough against ciphertext-only attacks, as reported in [15], [16]. To enhance the security of encryption, LE was extended to ELE by adding a block scrambling step and a pixel encryption operation with multiple keys [5]. However, ELE still has an inferior accuracy compared with using plain images, although an additional adaptation network (denoted as ELE-AdaptNet hereinafter) is applied to reduce the influence of the encryption. Moreover, images large in size cannot be applied to ELE because of the high computation cost of ELE-AdaptNet.

Recently, some methods have been proposed to use these block-wise encryptions combined with isotropic networks such as ViT to prevent performance degradation [6], [7], but this problem has not been completely solved. Another encryption method, a neural network-based image encryption method called NeuraCrypt [17], has been proposed, but it has problems

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

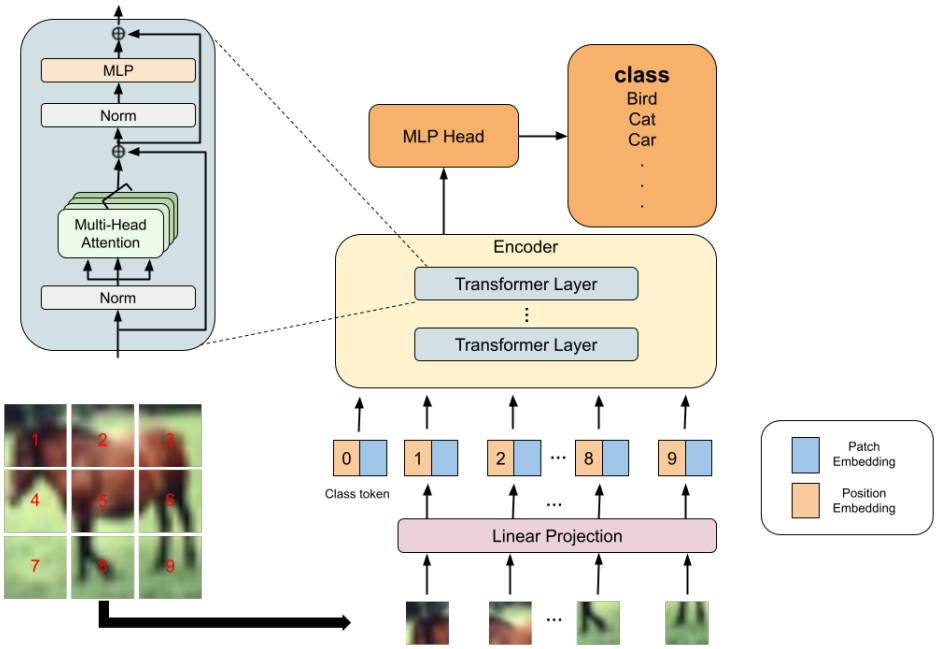

Fig. 1: Architecture of Vision Transformer

such as difficulty in using it for color images and difficulty with existing models because the input is not an image. To solve the problem, Color-NeuraCrypt [8], which is an extension of NeuraCrypt, was proposed, but this method also has the same performance degradation problem as conventional block-wise encryption methods.

Accordingly, we focus on the performance degradation problem when combining block-wise encryption and an isotropic network, and we propose a domain adaptation method to solve the problem.

B. Vision Transformer

The Vision Transformer (ViT) [12] is commonly used in image classification tasks and is known to provide a high classification performance. As shown in Fig. 1, in ViT, an input image is divided into patches, and each patch is transformed into a one-dimensional trainable vector. Afterward, they are input into the transformer encoder. The encoder outputs only the class token, which is a vector of condensed information about the entire image, and it is used for classification. Also, the architecture of ViT has two types of embedding: positional embedding, which stores the location information of cropped patches in an image, and patch embedding, which transforms each patch into a trainable vector.

Previous studies have indicated that when DNN models are trained with encrypted images, the performance of the models is degraded compared to models trained with plain images. In contrast, it has been pointed out that block-wise encryption has a high affinity with models that have embedding structures such as ViT [6], [18]. Accordingly, we focus on the affinity between block-wise image encryption and the embedding structure of ViT to reduce the influence of image encryption even when encrypted images are used for training models.

III. Proposed Method

A. Overview

Figure 2 shows the procedure for fine-tuning ViT models with encrypted images and the proposed domain adaptation. Since the pre-trained model as in [12] was prepared in advance, the area surrounded by a red box is discussed in this paper.

In ViT, an input image $x \in \mathbb{R}^{h \times w \times c}$ is divided into N patches with a size of $p \times p$, where h, w and c are the height, width, and number of channels of the image. Also, N is given as hw/p^2. Afterward, each patch is flattened into $x_p^i = [x_p^i(1), x_p^i(2), \ldots, x_p^i(L)]$. Finally, a sequence of embedded patches is given as

$$z_0 = [x_{class}; x_p^1\mathbf{E}; x_p^2\mathbf{E}; \ldots x_p^i\mathbf{E}; \ldots x_p^N\mathbf{E}] + \mathbf{E_{pos}}, \quad (1)$$

where

$$\mathbf{E_{pos}} = ((e_{pos}^0)^\top (e_{pos}^1)^\top \ldots (e_{pos}^i)^\top \ldots (e_{pos}^N)^\top)^\top,$$
$$L = p^2 c, x_{class} \in \mathbb{R}^D,\ x_p^i \in \mathbb{R}^L,\ e_{pos}^i \in \mathbb{R}^D,$$
$$\mathbf{E} \in \mathbb{R}^{L \times D},\ \mathbf{E_{pos}} \in \mathbb{R}^{(N+1) \times D}.$$

x_{class} is a class token, $\mathbf{E}$ is an embedding (patch embedding) to linearly map each patch to dimensions D, $\mathbf{E_{pos}}$ is an embedding (position embedding) that gives position information to patches in the image, e_{pos}^0 is position information of a class token, e_{pos}^i is position information of each patch, and z_0 is a sequence of embedded patches.

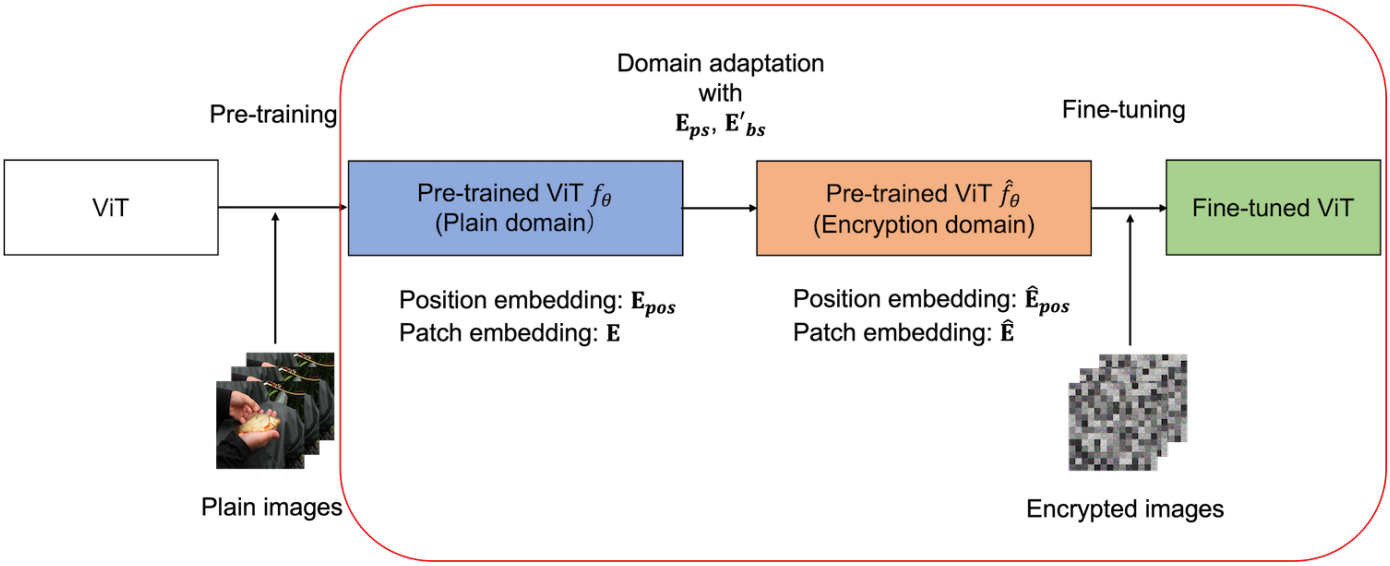

Fig. 2: Fine-tuning procedure using image encryption and domain adaptation

In this paper, we use block scrambling and pixel shuffling used in ELE for image encryption [5], where two keys are commonly applied to all images and blocks, respectively. In block scrambling, since an image is divided into non-overlapped blocks (patches) and the divided blocks are randomly permutated with a key, position embedding $\mathbf{E_{pos}}$ is affected by the position scrambling in general. In contrast, since pixel shuffling randomly permutates the position of pixels in each block, patch embedding $\mathbf{E}$ is affected by the pixel shuffling. As a result, models fine-tuned with encrypted images have a lower performance than models fine-tuned with plain images due to the influence of encryption. In other words, since pre-training a model is carried out by using plain images, the domain of fine-tuned models is different from that of pre-trained ones.

Accordingly, to reduce the influence of encryption, we propose a domain adaptation method, which is carried out on the basis of the embedding structure of ViT, for efficiently fine-tuning models.

B. Image Encryption

Encrypted images are used to fine-tune a ViT model f_θ as shown in Fig. 2. Figure 3 illustrates the encryption procedure used in this paper. This procedure can be expressed as follows.

(a) Divide an image $x \in \mathbb{R}^{h \times w \times c}$ into non-overlapped blocks with a size of $p \times p$ such that $B = \{B_1, \ldots, B_N\}$.

(b) Permutate blocks with secret key k_1 such as

$$\hat{B} = \mathbf{E_{bs}} B^\top, \ \hat{B} \in \mathbb{R}^N, \tag{2}$$

where $\mathbf{E_{bs}}$ is generated using the key k_1 as follows.

1) Using key k_1, generate a random integer vector with a length of N as

$$l_e = [l_e(1), l_e(2), \ldots, l_e(i) \ , \ldots, l_e(N)] \ , \tag{3}$$

where

$$l_e(i) \in \{1, 2, ..., N\} \, ,$$
$$l_e(i) \neq l_e(j) \text{ if } i \neq j$$
$$i, j \in \{1, \ldots, N\} \, .$$

2) Given $k_{(i,j)}$ as

$$k_{(i,j)} = \begin{cases} 0 & (j \neq l_e(i)) \\ 1 & (j = l_e(i)) \end{cases} . \tag{4}$$

3) Define $\mathbf{E_{bs}}$ as

$$\mathbf{E_{bs}} = \begin{bmatrix} k_{(1,1)} & k_{(1,2)} & \cdots & k_{(1,N)} \\ k_{(2,1)} & k_{(2,2)} & \cdots & k_{(2,N)} \\ \vdots & \vdots & \ddots & \vdots \\ k_{(N,1)} & k_{(N,2)} & \cdots & k_{(N,N)} \end{bmatrix}, \tag{5}$$

$$\mathbf{E_{bs}} \in \mathbb{R}^{N \times N}.$$

(c) Flatten each block $\hat{B}_i$ into a vector $\hat{b}_i$ such that

$$\hat{b}_i = [\hat{b}_i(1), \ldots, \hat{b}_i(L)]. \tag{6}$$

where $\hat{b}_i$ is the same as x_p^i in Eq. (1).

(d) Shuffle pixels in $\hat{b}_i$ with secret key k_2 such as

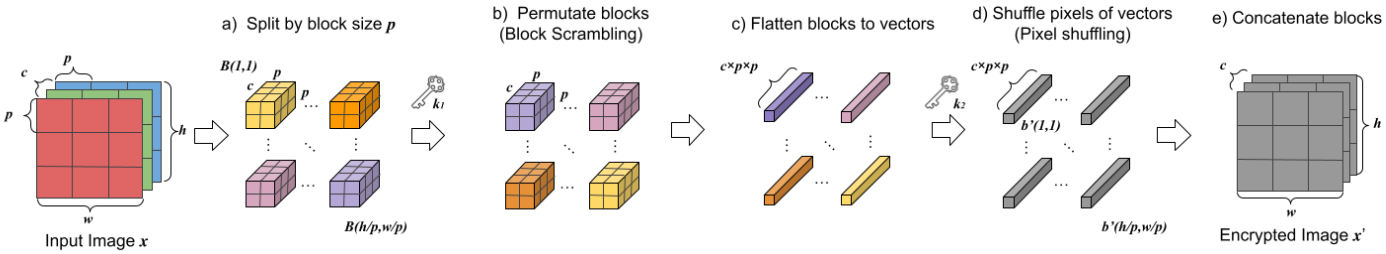
$$b'_i = \mathbf{E}_{ps} \hat{b}_i^\top, \ b'_i \in \mathbb{R}^L, \tag{7}$$

where $\mathbf{E_{ps}}$ is a matrix generated by the same procedure as $\mathbf{E_{bs}}$ (N is replaced with L).
Also, Eq. (7) is expressed as

$$b'_i = \mathbf{E}_{ps} \hat{b}_i^\top = \mathbf{E}_{ps} x_p^i \top = x_p^{'i}. \tag{8}$$

(e) Concatenate the encrypted vectors $b'_i (i \in 1, \ldots, N)$ into an encrypted image x'.

Figure 4 shows an example of images encrypted with this procedure, where block size p was 16.



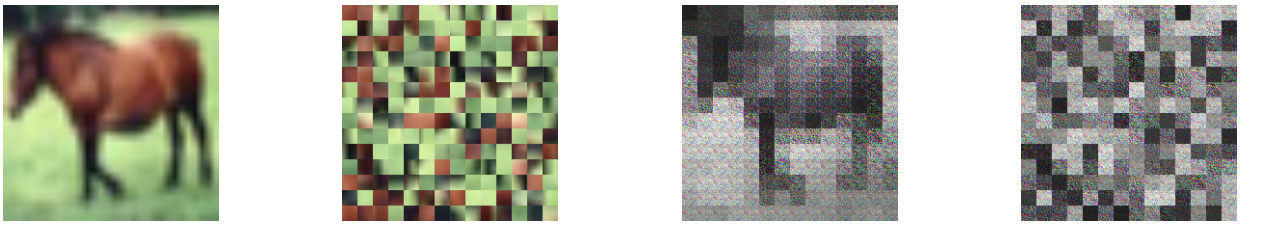


Fig. 3: Procedure of image encryption

(a) Original ($224 \times 224 \times 3$)
(b) Block scrambling (block size = 16)
(c) Pixel shuffling (block size = 16)
(d) Block scrambling + Pixel shuffling (block size = 16)

Fig. 4: Example of encrypted images

C. Domain Adaptation

As shown in Fig. 2, a model f_θ pre-trained in the plain domain is transformed into a model $\hat{f}_\theta$ to reduce the influence of encryption prior to the fine-tuning of the pre-trained model by using a novel domain adaptation method. The procedure of the proposed adaptation is summarized here.

The domain adaptation is carried out in accordance with the embedding structure of ViT. $\mathbf{E_{bs}}$ in Eq. 5 is used to permutate blocks in an image, so it has a close relationship with position embedding $\mathbf{E_{pos}}$. $\mathbf{E_{pos}}$ includes the position information of a class token x_{class}. In contrast, $\mathbf{E_{bs}}$ does not consider the information of x_{class}. To fill the gap, $\mathbf{E_{bs}}$ is extended as

$$\mathbf{E'_{bs}} = \begin{bmatrix} 1 & 0 & 0 & \dots & 0 \\ 0 & k_{(1,1)} & k_{(1,2)} & \dots & k_{(1,N)} \\ 0 & k_{(2,1)} & k_{(2,2)} & \dots & k_{(2,N)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & k_{(N,1)} & k_{(N,2)} & \dots & k_{(N,N)} \end{bmatrix}, \tag{9}$$

$$\mathbf{E'_{bs}} \in \mathbb{R}^{(N+1)\times(N+1)}.$$

In the domain adaptation, $\mathbf{E_{pos}}$ is transformed as in

$$\hat{\mathbf{E}}_{\mathbf{pos}} = \mathbf{E'_{bs}}\mathbf{E_{pos}}. \tag{10}$$

By using the adaptation, the position embedding of the pre-trained model can be adapted to the position information permutated by the block scrambling of images. Similarly, patch embedding $\mathbf{E}$ is transformed to adapt the position information of every pixel randomly replaced by pixel shuffling, as in

$$\hat{\mathbf{E}} = \mathbf{E_{ps}}\mathbf{E}. \tag{11}$$

TABLE I: Classification accuracy (%) with and without proposed method (CIFAR-10)

	Domain Adaptation	
Encryption	Yes	No
Pixel shuffling	**99.05**	97.78
Block scrambling	**98.93**	94.25
Pixel shuffling + Block scrambling	**98.98**	72.86
Plain	99.00	

From Eqs. 2, 8, 10, and 11, under the use of image encryption and domain adaptation, an adapted sequence of embedded patches is given by

$$\begin{aligned} \hat{z}_0 =& \mathbf{E'_{bs}}[x_{class}; \mathbf{E_{ps}}x_p^1\mathbf{E_{ps}}\mathbf{E}; \dots \mathbf{E_{ps}}x_p^N\mathbf{E_{ps}}\mathbf{E}]^\top + \mathbf{E'_{bs}}\mathbf{E_{pos}} \\ =& \mathbf{E'_{bs}}[x_{class}; \hat{x}_p^1\hat{\mathbf{E}}; \dots \hat{x}_p^N\hat{\mathbf{E}}]^\top + \mathbf{E'_{bs}}\mathbf{E_{pos}}. \end{aligned} \tag{12}$$

Finally, fine-tuning with encrypted images is applied to the pre-trained model corrected with the proposed adaptation.

IV. Experiments

A. Setup

We conducted image classification experiments on the CIFAR-10 [19] and CIFAR-100 datasets [19]. CIFAR-10 consists of 60000 images with 10 classes (6000 images for each class), and CIFAR-100 consists of 60000 images with 100 classes (600 images for each class), where 50000 images were used for training and 10000 images were used for testing. Also, we fine-tuned a ViT-B_16 model pre-trained with the ImageNet21k dataset, so we resized the image size from $32 \times 32 \times 3$ to $224 \times 224 \times 3$. Training parameters were a batch size of 32, a learning rate of 0.001, a momentum of 0.9, and

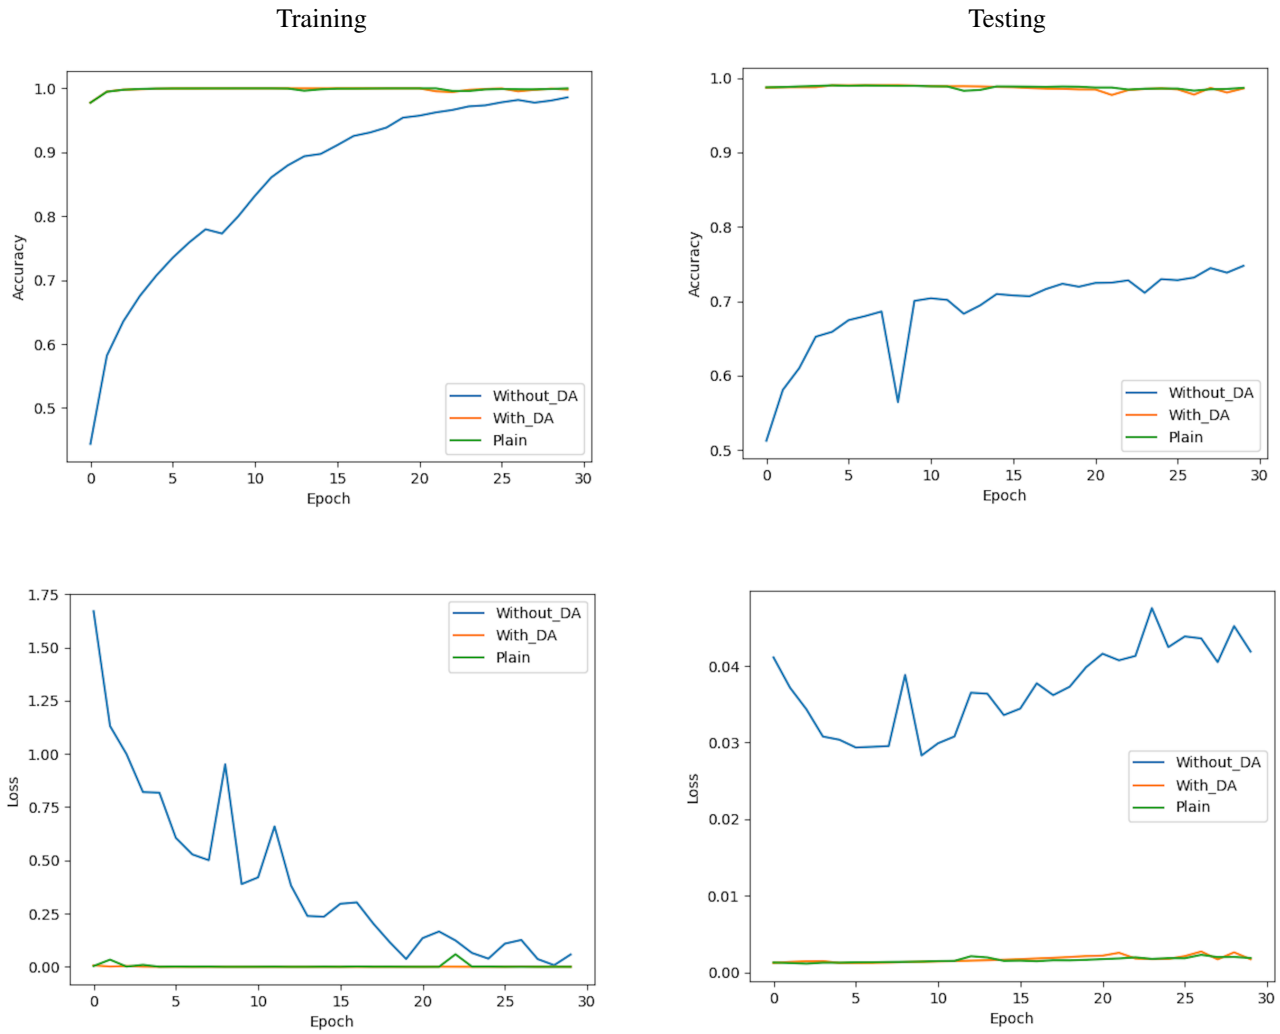

Fig. 5: Efficiency of model training
(Top: classification accuracy per epoch, Bottom: loss value per epoch)

a weight decay of 0.0005 on the stochastic gradient descent (SGD) for 15 epochs. A cross-entropy loss function was used as the loss function. The block size of the encryption was set to 16 to match the ViT patch size.

B. Effects of Domain Adaptation

1) Classification Performance: Table I shows the classification accuracy of models trained with encrypted images. When training models without the proposed domain adaptation, the accuracy decreased compared with that of using plain images. In particular, when applying the combined use of pixel shuffling and block scrambling, the classification accuracy decreased significantly. In contrast, when training models with the domain adaptation, the accuracy was almost the same as that of using plain images. Accordingly, we confirmed that the proposed domain adaptation was effective in fine-tuning pre-trained models with encrypted images.

2) Training Efficiency: Figure 5 shows the classification accuracy and loss value per epoch during training and testing where the number of epochs was increased to 30.

For training, when using the domain adaptation during training, models fine-tuned with encrypted images (with_DA) achieved almost the same training efficiency as those trained with plain images. In contrast, models fine-tuned without the domain adaptation (without_DA) needed the larger number of epochs to achieve the same performance as plain models. For testing, models with the domain adaptation also achieved the same performance as those with plain images, but models without the domain adaptation were overtrained.

Accordingly, the domain adaptation allows us not only to train a high-performance model without increasing training time even when using encrypted images, but to also avoid overtraining during test time.

C. Comparison with Conventional Methods

In Table II, the proposed method is compared with the state-of-the-art methods for privacy preserving image classification with encrypted images such as LE [3], PE [4], and ELE [5]. From the table, the proposed method not only has the lowest performance degradation on both CIFAR-10 and CIFAR-100

TABLE II: Comparison with existing methods

Encryption	Model	Accuracy (%)	
		CIFAR-10	CIFAR-100
LE [3]	AdaptNet + Shakedrop	94.49	75.48
ELE [5]	AdaptNet + Shakedrop	83.06	62.97
PE [4]	ResNet-18	92.03	-
EtC [6]	ViT-B_16	87.89	-
	ConvMixer-256/8	92.72	-
Color-NeuraCrypt [8]	ViT-B_16	96.20	-
Block scrambling + Pixel position shuffling [7]	ViT-B_16	96.64	84.42
Block scrambling + Pixel shuffling + Domain adaptation (Proposed)	ViT-B_16	**98.98**	**92.58**
Plain	ShakeDrop	96.70	83.59

Plain	ViT-B_16	99.00	92.60
Plain	ConvMixer-256/8	96.07	-

datasets but also outperforms all existing methods in terms of the accuracy of image classification.

V. Conclusion

In this paper, we proposed a domain adaptation method to reduce the influence of image encryption for ViT models. The method is applied to a model pre-trained in the plain domain prior to the fine-tuning of the pre-trained model. In experiments, the proposed adaptation was demonstrated not only to reduce the performance degradation of models but to also achieve the highest classification accuracy in conventional methods on the CIFAR-10 and CIFAR-100 datasets.

***Abstract*—With the development of deep learning technology, artificially created images and videos, known as deepfakes, have become a problem. It is very difficult for human visual and auditory senses to distinguish them from real ones. Therefore, there is a growing risk of them being used for crimes such as bullying, defamation, extortion, and fraud on social media. StyleGAN is one of the generators for such fake content and is known for its ability to generate high-quality images with a great degree of realism. This study aims to distinguish between real and fake images generated by StyleGAN. We introduce effective image processing techniques into the detector which is CNN model designed by fine-tuning the XceptionNet. We examined two methods: one that extracts color attributes from the image and the other that distinguishes based on landmarks. We evaluated the accuracy of distinguishing between real and fake images by computer simulation.**

I. Introduction

Using deep learning-based editing techniques in multimedia content, it has become easier to create scenes with potential risks or high production costs. These techniques are widely utilized in various fields such as television programs, film production, medical applications, and educational media materials. However, the advancement of such sophisticated content editing techniques has also brought about new challenges, such as the emergence of fake content which is artificially created by using a deep neural network. One prominent example of fake content is deepfakes, a term combining ”deep learning” and ”fake”. Deepfakes refer to a type of synthesized photos or videos created using deep learning techniques, characterized by their high quality, making it difficult to distinguish them from genuine content at first glance. This pose concerns as it enables the production of artificially created videos or images featuring influential individuals, such as leaders of nations or political parties, which could be used for manipulating public perception and damaging trust. Additionally, there are issues concerning the abuse of deepfakes for cyberbullying, defamation, threats, fraud, and other criminal activities on social media.

One of the techniques used to create such fake content is Generative Adversarial Networks (GANs) [1], which can generate entirely sysnthesized content by learning features from given datasets. Currently, various GAN derivatives, such as DCGAN [2], BigGAN [3], and PGGAN [4], have been developed. StyleGAN [5], capable of generating high-resolution images, can produce highly realistic fake images to the extent that it has been said, ”The era when photographs can serve as evidence is over”.

To address these fake content challenges, several countermeasures have been developed, including tools like Microsoft Video Authenticator[1] and initiatives like the DeepFake Detection Challenge[2] [6]. Microsoft Video Authenticator, released by Microsoft in September 2020, is a deepfake detection tool that analyzes images and videos to identify any anomalies and provides a confidence score indicating the likelihood of the content being a deepfake. The DeepFake Detection Challenge, launched in September 2019 by major companies and research institutions, is a contest aimed at developing technologies for detecting deepfake videos. While the detection rate for the provided deepfake videos exceeded 80%, the detection rate for different deepfake videos was around 65%, highlighting the challenge of detecting unknown data.

A problem in conventional study is that the performance of a detector significantly decreases when it is trained on images generated by one version of StyleGAN and tested on images generated by a different version. Our objective in this study is to achieve a universal detector that is not affected by the differences in the generator. We begin with a basic detector by designing a fine-tuning model of XceptionNet [7], which is customized for a binary classifier to distinguish between real and fake images. Since StyleGAN artificially combines characteristics from multiple training images to create its output, we propose a method for classifying local regions. In order to extract the features that reflect the characteristics of artificially generated images, we conducted to evaluate the classification accuracy based on different color spaces as a preliminary experiment. The results showed that the classification based on images represented in the HSV color space was effective. Therefore, we developed a method to classify the hue component, saturation component, and value component, which are the color attributes of the target images in the HSV color representation system. We evaluate the

identification accuracy of real and fake images using these methods and an effective combination of them.

II. Related Study

In this section, we describe the technologies related to our study.

A. Generative Adversarial Networks (GANs)

GANs are a type of generative model that can learn features from data and generate new data or transform existing data along learned feature directions. GANs have attracted attention as an unsupervised learning method that can learn features without the need for labeled data.

GANs consist of two neural networks: a Generator and a Discriminator. The Generator generates data by adding features to random noise inputs and transforming them into data such as images. The Discriminator receives both the fake data generated by the Generator and the real data, and estimate the probability that a sample comes from the Generator. The Generator attempts to create fake samples, while the Discriminator attempts to determine which samples are fake and which are real. If the two models are allowed to compete for a long time, they will ultimately improve.

B. StyleGAN

StyleGAN is one type of generative adversarial network that can generate high-resolution images. It has been continuously improved and extended, including StyleGAN [5], StyleGAN2 [8], StyleGAN2-ADA [9], and StyleGAN3 [10]. Fig. 1 shows the architecture of StyleGAN, where the left side represents GAN, and the right side represents StyleGAN. StyleGAN consists of two networks: the Mapping network and the Synthesis network. Unlike conventional GANs, StyleGAN generates images from a fixed $4 \times 4 \times 512$ tensor instead of directly from the latent variable z. The Mapping network performs a non-linear transformation of the latent variable z into the latent space w using 8 fully connected layers. This transforms a sequence of random numbers (latent variable z) that has no semantic meaning at input time into a multidimensional space representing style information such as age, gender, and expression, which is used as style information in the Synthesis network. The Synthesis network performs image upsampling, merges style and noise information, and performs various manipulations such as adjusting the overall color and facial expressions by inserting style information at each upsampling step. AdaIN merges the latent space w obtained from the Mapping network as style information for each resolution. Noise introduces stochastic variation in fine visual details such as hair flow, beard, and freckles. If the noise is removed, the image will have a featureless, painting-like appearance.

StyleGAN2 addressed the problem of distortion on droplets, which was an issue in StyleGAN image generation, by modifying the method of applying style to each resolution. StyleGAN2-ADA applies a data augmentation technique called data augmentation to the Discriminator to prevent overfitting. StyleGAN3 resolved issues such as the teeth position, hair, and hair patterns being unnaturally fixed in absolute coordinates.

C. Synthetic Media Recognition

To analyze the slight unnatural signals present in GAN-generated images, identification methods using convolutional neural networks (CNNs) have been studied. When training CNN models from scratch, a huge dataset and computational resources are required, so fine-tuning of pre-trained models for image recognition is mainly studied [11]–[13]. Xuan et al. [14] use Gaussian filters in preprocessing to extract stable components that exclude unstable distorted signals and obtain stable identification accuracy. McCloskey et al. [15] consider a method that extracts feature components by weighting the color space based on the ratio of red to green in the RGB color space and identifies them using a support vector machine (SVM). Wang et al. [16] achieve high-accuracy identification by augmenting the data through techniques such as blurring and compression, thereby enhancing generalization and robustness.Methods using co-occurrence matrices [17] and analysis techniques using forensics [18], [19] have also been studied.

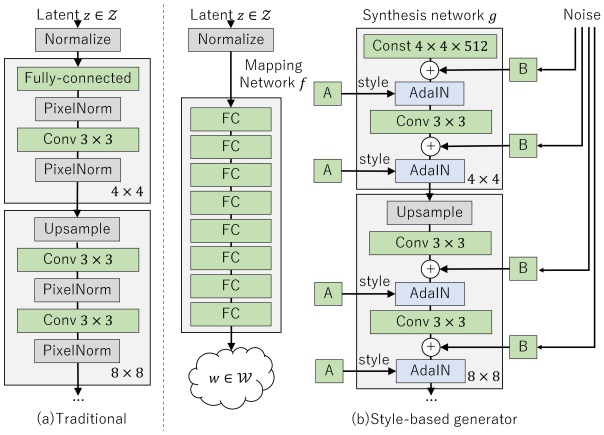

Fig. 1. Architecture of StyleGAN

D. Fine-Tuning Model

Fine-tuning is a technique where the fully connected layers of a pre-trained model are replaced, and the last part of the convolutional layers is retrained along with them. By using this technique, the pre-trained model is trained as a different model, allowing it to be utilized as a feature extractor. Fine-tuning offers several advantages, such as the ability to create high-accuracy models even with limited datasets and significant reduction in training time. As a result, it has become an essential technique in the development of CNN systems.

In this study, we employ fine-tuning on the pre-trained model, XceptionNet, to create a binary classifier capable of distinguishing between real and fake images. For training, we use the SGD gradient-based optimization scheme with a learning rate of 0.001, a batch size of 64, and momentum of 0.9. The network is trained until the loss, evaluated on the validation data, does not improve for 5 consecutive epochs.

III. PROPOSED METHOD

In this study, we propose a method that combines two preprocessing methods with the basic approach of fine-tuning the XceptionNet [7] model for identifying images generated by StyleGAN. The first method involves identifying segmented image blocks corresponding to local regions, namely the nose, right mouth corner, left mouth corner, right eye, and left eye (referred to as landmarks). The second method involves identifying images based on their color attributes (hue, saturation, and brightness).

A. Basic Detector

The basic detector is a binary classifier that fine-tunes the XceptionNet to distinguish between real and fake images. Without loss of generality, a target image is a RGB color image of $M \times N$ pixels, and it is divided into non-overlapping blocks B_i of $s \times s$ pixels for $1 \leq i \leq n$, where $n = \lfloor M/s \rfloor \times \lfloor N/s \rfloor$. To determine if the target image is a fake, each block B_i is checked by the detector, and the confidence level is calculated as the probability p_i that the block is fake. The final decision for the target image is determined by the decision rule given by the following equation:

$$P_b = \frac{1}{n} \sum_{i=1}^{n} (2p_i - 1) \tag{1}$$

- If $P_b \geq 0$, the image is classified as fake.
- Otherwise the image is classified as real.

As the input size of XceptionNet is 299×299 pixels, we use $s = 299$ as the input to the basic detector in this study.

B. Local Regions

When using StyleGAN to generate fake images, the characteristics of multiple training images are mixed to create artificially synthesized images. Since each local region has different characteristics, it is suitable to customize the detector to account for these differences. Therefore, we focus on five landmarks in a face and cut out five blocks that take into account the overlap of these blocks. We then use these landmark-specific blocks to train five fine-tuning models of the same architecture. Table I presents the five binary classifiers corresponding to each landmark. The final classification is determined by majority voting based on the results of these five blocks.

The MTCNN [20] is used to detect the five landmarks: nose, right mouth corner, left mouth corner, right eye, and left eye.

the coordinate points of each landmark are denoted as (x_ℓ, y_ℓ), $\ell \in \mathcal{L}$, where $\mathcal{L} = \{N : nose, MR : mouth_right, ML : mouth_left, RE : right_eye, LE : left_eye\}$. To determine if the target image is a fake, each block B_ℓ is checked by the detector, and the confidence level is calculated as the probability p_ℓ that the block is fake. The final decision for the target image is determined by the decision rule given by the following equation:

$$P_f = \frac{1}{5} \sum_{\ell \in \mathcal{L}} (2p_{\ell-1}) \tag{2}$$

TABLE I
BINARY CLASSIFIERS CORRESPONDING TO EACH LANDMARK

Binary classifier	landmark
model N	nose area
model MR	mouth_right area
model ML	mouth_left area
model RE	right_eye area
model LE	left_eye area

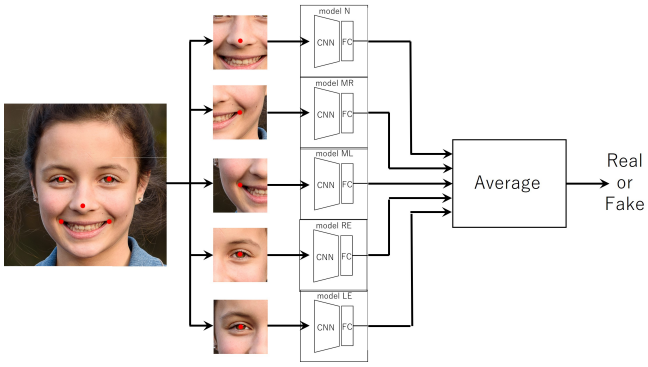

Fig. 2. Local regions processing flow

- If $P_f \geq 0$, the image is classified as fake.
- Otherwise the image is classified as real.

The processing flow of this method is as shown in Fig. 2.

C. Color Attributes

In order to extract the features that reflect the characteristics of artificially generated images, we conducted a preliminary experiment to evaluate the classification accuracy based on the differences in color spaces. Among the four color spaces tested, namely RGB, HSV, Lab, and YCbCr, it was found that the images represented in the HSV color space showed effective classification results. Fig. 3 illustrates real images and fake images generated by StyleGAN2-ADA in the RGB color space, HSV color space, and the Hue component. In the RGB color space, when the brightness of a certain color varies, the detectable range of that color may also change. However, in the HSV color space, the hue of a color remains consistent even when the brightness changes, allowing for the detection of the same color regardless of its brightness. This is a characteristic of the HSV color space. In convolutional processes like CNN, spatial features such as shape and position can be captured. However, these processes are unable to capture features resulting from differences in color spaces. Therefore, techniques such as color space conversion and extraction of color attributes are necessary to handle such differences in color spaces.

We aim to investigate the effective color attributes among the hue, saturation, and value components. Hue represents the type of color and is represented within a range of 0 to 360 degrees. Saturation refers to the intensity or vividness of a color and is represented within a range of 0 to 100%. Value represents the brightness of a color and is also expressed within a range of 0 to 100%. To convert from the RGB color space to the HSV

Fig. 3. The differences in color representation between real images and fake images vary depending on the color space used: the top images represent real images, while the bottom images represent fake images generated by StyleGAN2-ada. From left to right, the images correspond to the RGB color space, HSV color space, and the hue component.

color space, you can follow the steps below. However, note that among the three values R, G, and B, the maximum value should be denoted as MAX, and the minimum value should be denoted as MIN:

$$H = \begin{cases} \lfloor 60 \times ((G-B)/(MAX-MIN)) \rfloor & \text{if } R = MAX, \\ \lfloor 60 \times ((B-R)/(MAX-MIN)) + 120 \rfloor & \text{if } G = MAX \\ \lfloor 60 \times ((R-G)/(MAX-MIN)) + 240 \rfloor & \text{if } B = MAX \\ 0 & \text{if } MIN = MAX \end{cases}$$

$$S = \lfloor (MAX - MIN)/MAX \rfloor$$

$$V = MAX$$

We use blocks from the hue component to train fine-tuning model in this method, and the classification approach is the same as the basic detector.

IV. SIMULATION

In this section, we describe the simulation environment, evaluation metrics, and experimental results.

A. Simulation Environment

We used various datasets and set hyperparameters for the identifier in this study. We conducted the study under four different conditions, using a training dataset and a testing dataset. The breakdown of these cases is summarized in Table II.

The dataset used with StyleGAN2-ADA consists of two types of images: real images used to train StyleGAN2-ADA, taken from the FFHQ dataset, and fake images generated by StyleGAN2-ADA. The same applies to the dataset used with StyleGAN3. The original image size is 1024×1024 pixels, while the block size after division is set to 299×299 pixels. In the "Local Region" approach, 10,000 blocks each of fake and real images are used per landmark. In the "Basic Detector" and "Color Attributes" approaches, the image is divided into 9 segments, resulting in a total of 90,000 blocks (10,000 blocks per block for fake and real images).

TABLE II
BREAKDOWN OF DATASET

	Train dataset	Test dataset

TABLE III
HYPERPARAMETERS IN FINE-TUNING MODEL

Batch size	64		
Epoch	50		
Input size	299×299		
Fully connected layer	Dense	Nodes	256
		Activation function	relu
	Dropout	Node ratio	0.5
	Dense	Nodes	1
		Activation function	sigmoid
Optimizer	SGD(learning rate = 1e-3,momentum=0.9)		
Loss function	binary_crossentropy		

Additionally, we summarize the hyperparameters set for the detector used in this study in Table III.

B. Evaluation Metrics

In this study, as it involves binary classification of fake and real images, there are four possible outcomes for correctness assessment: True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN). Let's explain each of them:

TP Represents the number of true (positive) items correctly identified as positive. In this study, it refers to the number of correctly identified real images as real.

TN Represents the number of false (negative) items correctly identified as negative. In this study, it refers to the number of correctly identified fake images as fake.

FP Represents the number of false (negative) items incorrectly identified as positive. In this study, it refers to the number of fake images mistakenly identified as real.

FN Represents the number of true (positive) items incorrectly identified as negative. In this study, it refers to the number of real images mistakenly identified as fake.

Accuracy
It is the ratio of the correctly identified images to the total number of images. This metric indicates how accurate the predictions are. The formula for accuracy is:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (3)$$

Precision
It is the ratio of the number of images correctly identified as real to the total number of images identified as real. This metric indicates the level of

misidentification. The formula for precision is:

$$Precision = \frac{TP}{TP + FP} \tag{4}$$

Recall

It is the ratio of the number of real images correctly identified as real to the total number of actual real. This metric indicates the level of under-detection. The formula for recall is:

$$Recall = \frac{TP}{TP + FN} \tag{5}$$

C. Difference of Local Regions

We compared the classification accuracy of the basic detector with the classification accuracy of each local region to examine the effect of local regions.

First, We present the comparison results of the classification accuracy for the five detectors trained on local regions in a Table IV. Each detector was trained using blocks that consider the overlapping landmarks. Specifically, if a single block contains multiple landmarks (e.g. nose, right_eye, left_eye), that block is used for training multiple detectors (model N, model RE, and model LE). However, images that failed to detect any of the five landmarks are excluded from the training data.

Next, we present the total result of the majority voting based on the five detectors in the Table V.

According to Table IV, when the training and testing datasets differ, the landmark-specific classifiers showed approximately 10-20% improvement in Accuracy and Precision compared to the basic detector. There was no significant difference in performance among the classifiers based on landmarks. Similarly, according to Table V, the overall results also showed approximately 10-20% improvement in Accuracy and Precision compared to the basic detector.

D. Difference of Color Attribute

To examine the effect of color attributes, we compared the classification accuracy of the classification accuracy of images where the Hue (H), Saturation (S), and Value (V) components were extracted separately. The experimental results are shown in the Table VI.

The results showed that both Accuracy and Precision were highest for the H component, with approximately 13-45% improvements compared to the basic detector. The S and V components showed similar accuracy to the basic detector. Recall was high for all cases.

E. Combination Approach

Based on the results of the proposed methods so far, an effective combination approach was performed by conducting local region-based classification on the Hue component of the target image. The comparison results of the classification accuracy for the five detectors are shown in Table VII, and the results of majority voting for the five detectors are shown in Table VIII.

TABLE IV
COMPARISON OF ACCURACY BETWEEN THE BASIC DETECTOR AND THE FIVE DETECTORS IN IDENTIFYING THE TARGET IMAGE IN THE RGB COLOR SPACE

(A) Accuracy

dataset		Accuracy					
train	test	basic	N	MR	ML	RE	LE
2-ADA	2-ADA	1.000	0.996	0.993	0.994	0.992	0.992
2-ADA	3	0.502	0.636	0.641	0.659	0.724	0.655
3	2-ADA	0.512	0.736	0.672	0.711	0.721	0.738
3	3	1.000	0.999	0.999	0.998	0.989	0.998

(B) Precision

dataset		Precision					
train	test	basic	N	MR	ML	RE	LE
2-ADA	2-ADA	1.000	0.994	0.989	0.991	0.989	0.988
2-ADA	3	0.501	0.579	0.582	0.594	0.645	0.592
3	2-ADA	0.506	0.655	0.604	0.634	0.642	0.657
3	3	1.000	1.000	0.999	1.000	0.999	1.000

(C) Recall

dataset		Recall					
train	test	basic	N	MR	ML	RE	LE
2-ADA	2-ADA	1.000	0.999	0.998	0.998	0.996	0.997
2-ADA	3	1.000	0.998	0.998	0.998	0.996	0.997
3	2-ADA	1.000	0.998	0.998	0.997	0.997	0.995
3	3	1.000	0.998	0.998	0.997	0.997	0.995

TABLE V
TOTAL RESULT OF FIVE DETECTORS BASED ON THE TARGET IMAGE IN THE RGB COLOR SPACE

dataset		Accuracy	Precision	Recall
train	test			
2-ADA	2-ADA	0.999	0.999	1.000
2-ADA	3	0.638	0.580	1.000
3	2-ADA	0.712	0.635	0.999
3	3	1.000	1.000	0.999

Based on the results, as shown in Table VII, the detectors for MR and ML exhibited higher Accuracy and Precision compared to the detectors for other landmarks. When comparing Table VIII and Table VII, it can be observed that the overall results of the five detectors did not show any improvement in accuracy compared to their individual results. One possible reason for this is that when classifying fake images, if one out of the five landmarks is determined to be real with high probability while the others are determined to be fake with subtle probabilities, the final result may be erroneously classified as real due to being influenced by the result of that one landmark.

F. Dependency on generator

According to Table IX, the detector trained with the older version of StyleGAN exhibited higher accuracy in image classification compared to the detector trained with the newer version of StyleGAN. Therefore, it was hypothesized that detectors trained with relatively newer versions of StyleGAN would show a decrease in classification accuracy. To test this hypothesis, an experiment was conducted.

The detector used in this experiment was trained on the Hue component of the target images, as mentioned in the previous

TABLE VI
COMPARISON OF ACCURACY BETWEEN RGB COLOR SPACE IMAGES AND IMAGES WITH HUE, SATURATION, AND VALUE COMPONENT USING THE BASIC DETECTOR

section on "Color Attribute Effects". The test dataset consisted of real images and fake images generated from both StyleGAN and StyleGAN2. The original image size was 1024×1024 pixels, and the block size after division was set to 299×299 pixels. Since there were 9 divisions, a total of 400 images $\times$ 9 divisions = 3600 blocks were used.

The experimental results are shown in Table IX. The results show that the discriminator that used StyleGAN3 during training had lower Accuracy and Precision when using StyleGAN than when using StyleGAN2 during testing. In addition, discriminators that used StyleGAN2-ADA during training had lower Accuracy and Precision when using StyleGAN than when using StyleGAN3 during testing (refer to the previous section on "Color Attribute Effects"). This indicates that performance tended to be higher when using images generated with a lower version of StyleGAN than when training with images generated with a newer version of StyleGAN.

V. CONCLUSIONS

In this study, we evaluated the classification accuracy of two methods: one that identifies images based on local regions and another that extracts the color attributes of the images. We also proposed an effective combination of these methods. The method of using the basic detector to identify the Hue component of the target image was the most effective. The proposed method achieved the highest accuracy of approximately 95% when distinguishing between fake images trained with a different GAN. This demonstrates the effectiveness of our approach. In the future, we plan to further investigate the classification of other GANs, ensemble learning through bagging to determine the majority vote of the five classifiers, and delve into the impact of generator differences.

***Abstract*—High-dynamic range (HDR) images are circulated rapidly over the internet with risks of being exploited for unauthorized usage. To protect these images, some HDR image-based watermarking methods were put forward. However, they inherited the same problem faced by the conventional IW methods for standard dynamic range images, where only trade-offs among conflicting requirements are managed instead of simultaneous improvement. In this paper, a novel saliency (eye-catching object) detection based trade-off independent HDR-IW is proposed, to simultaneously improve robustness, imperceptibility and payload. First, the host image goes through our proposed salient object detection model to produce a saliency map, which is, in turn, exploited to segment the foreground and background of the host image. Therefore, a convolutional deep learning model is trained with various datasets containing multiple salient objects. Next, the binary watermark is partitioned into the foregrounds and backgrounds using the same mask and scrambled using a random permutation algorithm. Finally, the watermark segments are embedded into the selected bit-plane of the corresponding host segments using quantized indexed modulation. Experimental results suggest that the proposed work outperforms state-of-the-art methods in terms of concurrently improving the aforementioned conflicting requirements.**

I. Introduction

High dynamic range (HDR) imaging allows for better image quality and visual perception because it can represent a wider range of illumination in comparison to standard dynamic range (SDR) imaging [1]. Consequently, HDRI is deployed for various applications, including computer graphics, computer vision, broadcasting, surveillance, to name a few [2]. Often these images are of commercial, political, educational, or sentimental value. Hence they must be secured from unauthorized usage or illegal copying during transmission or in storage. Image watermarking (IW) is an art and science that injects copyright data into an image (host) to guard the host image. The inserted data can be retrieved later from the potentially modified image for copyright claim, authentication, tampering detection, etc. [3]–[5].

In the case of HDR-IW, various non-blind and blind state-of-the-art (SOTA) IW methods are proposed, but often only a trade-off among capacity, quality, and robustness (especially against the tone-mapping operations (TMOs)) is achieved. Huang et al. [6] designed a zero-bit IW method to protect the HDR image using dual-tree complex wavelet transform (DCWT) and Quaternion Fast Fourier transform (QFFT). First, DCWT and QFFT are sequentially applied to each color channel. Next, singular value decomposition (SVD) is applied to each LL subband, and finally, the watermark is embedded into the diagonal of the S matrices. Perez et al. [7] presented an HDR-IW method using Luma Variation Tolerance. Specifically, the scrambled watermark is embedded into the selected HDRI regions with less luma variation, to maintain the image quality. Maiorana et al. [8], [9] and Shiju et al. [10] designed an HDR-IW system primarily based on Guerrini et al.'s method [4]. However, the watermarked image quality is better due to the utilization of the radon-DCT. Autrusseau et al. [11] proposed an HDR-IW to improve the robustness feature. First, RGB channels are extracted from the HDRI using the normalization process. Fianlly, DWT is applied to each color channel to obtain the LH sub-band for the watermark embedding using α-blending.

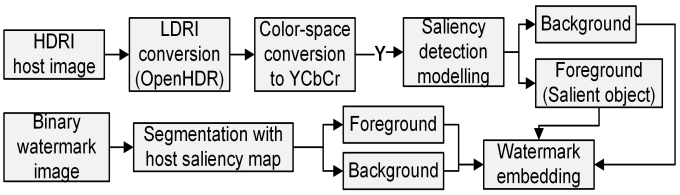

Fig. 1: Proposed framework of HDR-IW method based on salient object detection. Detailed flow-diagrams of the proposed saliency detection model and the watermark embedding procedure are shown in Fig. 3 and 2, respectively.

In analyzing the aforementioned methods, it is evident that capacity is sacrificed in an attempt to improve the other two aspects of quality and robustness [6], [8]–[19]. To simultaneously achieve high embedding capacity, image quality, and robustness, one approach is to leverage on different saliency regions of an image for a watermarking process [12], [20]. This can be achieved by using salient object detection (SoD) to extract the salient regions of an image to embed the watermark. With this approach, the critical regions of an image are used to embed the watermark without compromising the apparent visual quality. While subjectively reducing any observed visual distortions by the human eye, the IW can be made more resilient against different attacks. Motivated by this approach, we propose a novel framework for a reliable and invisible HDR-IW using SoD (see Fig 1 and Fig 3). The proposed method ensures that the quality of the watermarked image remains intact while protecting the watermark (i.e., by providing an extra layer of security).

details the proposed method, SoD-Net, watermark encryption, embedding methods. Experimental results are discussed in Section III, followed by the conclusion in Section IV.

II. Methodology

First, the host HDR image is tone-mapped to an SDR image H. From H, the foreground H_f and background H_b are determined using our proposed SoD-Net method (see Fig 3). Based on the features of H, the watermark W is then divided into two partitions W_f and W_b such that the $W = W_f \bigcup W_b$, and both W_f and W_b are shuffled before being embedded into the H (see Fig. 1). Details are provided in the following subsections.

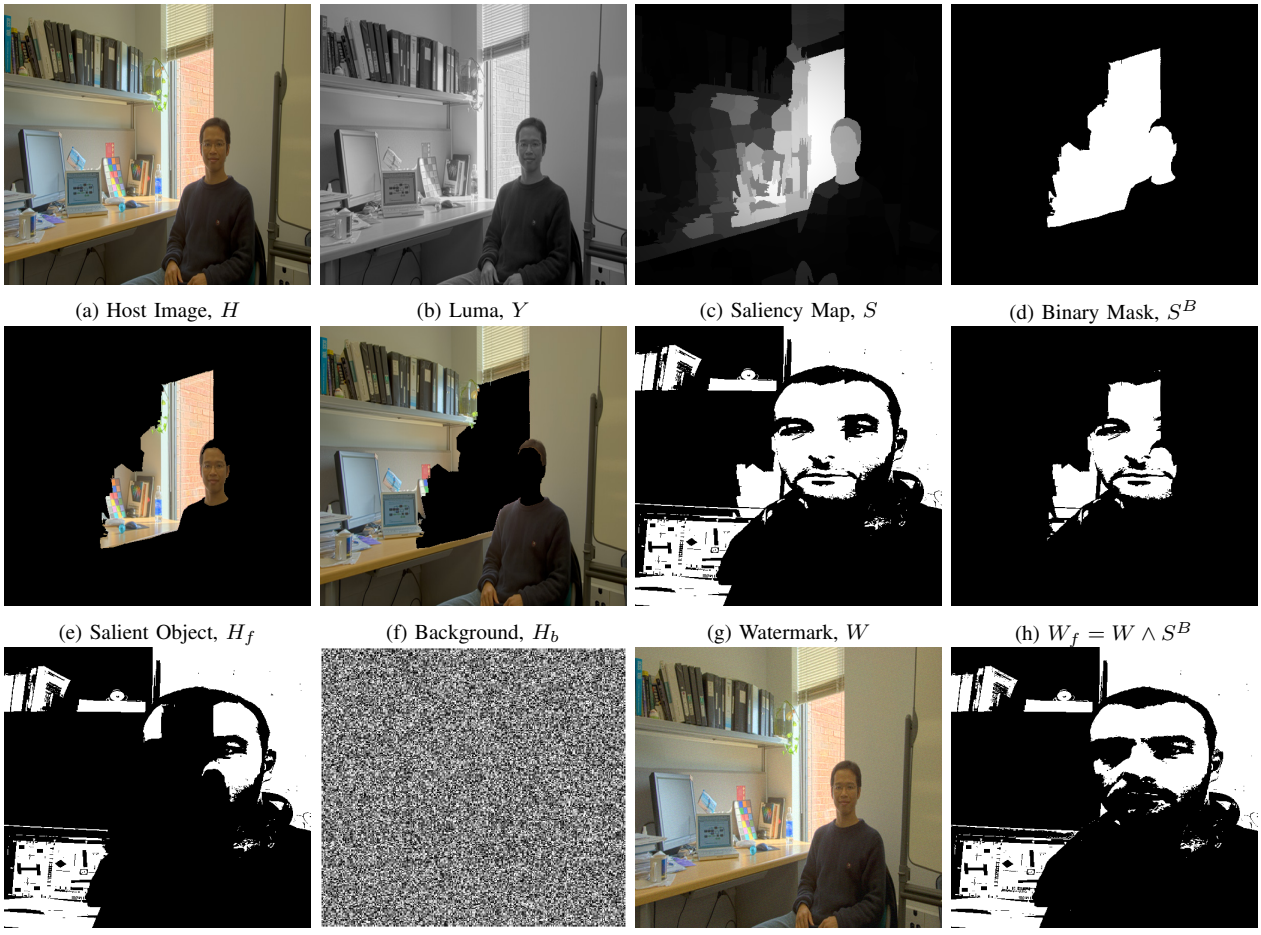
A. Res2Net based Salient Object Detection

SoD-Net aims to detect salient objects in H (see Fig. 3). First, HDR to SDR conversion is performed using normalized tone-mapping operation

$$\tau = \lceil \log_2[\max(c) + 128] \rceil \tag{1}$$

to get

$$H'_c = \lfloor \frac{c \cdot 256}{2^{(\tau - 128)}} \rfloor \tag{2}$$



and

$$H''_c = \lfloor \frac{H'_c + 0.5 + 2^{(\tau - 128)}}{256} \rfloor \tag{3}$$

where $c \in \{R, G, B\}$. Here, $\{H''_c, H'_c\}$ are the corresponding color channels c in SDR and HDR, respectively. Next, the color and edge features are extracted from H' using Res2Net [21].

In SoD-Net, to verify that the output of Res2Net is an image, we eliminate all the completely linked layers. We remove the initial max pooling layer and, we set CONVs stride to 1 (instead of 2) to avoid excessive down-sampling ($\downarrow$). As a result, sparse feature loss is avoided, while retaining the saliency details. Res2Net offers four outputs through the $\downarrow$ phases, namely, low-level features extracted at Layer 1, middle-level features at Layers 2 and 3, and sparse features at Layer 4, which we receive at $\downarrow$ phase. One crucial use of 1×1 CONVs is as a dimension reduction module to eliminate computational constraints that would restrict the size of SoD-Net. It expands our networks' depth and width without suffering performance degradations. The number of channels is then reduced to 1/8 of the original number using four 1×1 CONVs. The downsizing is performed because the original data is large in size, hence consuming more time for the training and testing phase.

Similarly, to create the depth saliency map, we erase the first max pooling layers, set the CONVs stride to 1, and utilize 3×3 CONVs. The depth error in non-salient objects causes the disparity map's nearest objects to have either the lowest or highest intensities. These objects have the potential to deceive neural networks (NN) when NN models seek for salient objects in depth maps. As a result, a single-modal saliency map that simply includes depth information is flawed. By building a hybrid saliency map using the additive RGB and depth information, we can get rid of depth inaccuracy.

Fig. 4: Intermediate images produced by proposed image watermarking method

Specifically, the weighted saliency map created by combining the RGB and depth modes contains the likelihood information of each pixel to be part of a certain object. We design a decoder network that consists of 3×3 CONVs and up-sampling ($\uparrow$) to produce the cumulative saliency map. We concatenate the lower-level and current features following each $\uparrow$. The decoder block D^n is as follows

$$S = \bigcup D^n = \sum_{i=1}^{k} \uparrow (CONV(D_i^{n-1} \bigoplus d_i^n.\Theta)), \quad (4)$$

where i refers to the i^{th} feature channel, $CONV$ is the convolution with value Θ, and $\bigoplus$ is the *concatenation* operator. The binary mask S^B is produced by thresholding S [12]. The loss function is $L(S, g) = \sum\sum(S \log g) + (1 - S) \log(1 - g)$, where g is the ground truth. Finally, H_b is obtained by $H_b = H' \wedge (1 - S^B)$. Likewise, H_f is obtained by $H_f = H' \wedge S$. Subsequently, W_f and W_b are calculated (see Fig. 4).

B. QIM based Watermark Embedding

We embed the divided watermark $\{W_f, W_b\}$ correspondingly into $\{H_f, H_b\}$ after shuffling them according to a secret key (see Fig. 2). Details are provided in the following steps.

Step 1: First, $\{H_f, H_b\}$ are resized (cubic interpolation) to 512×512, followed by the YC_bC_r conversion. Next, lifting wavelet transform (LWT) using *Daubechies cdf2.2-kernel* is applied to H_f of Y to produce the sub-bands $[LL, HL, LH, HH]_{\downarrow}$. Similarly, LWT using *Haar-kernel* is applied to H_b of Y. Note that we apply the same method for both $\{H_f, H_b\}$ to embed $\{W_f, W_b\}^e$, which is of size $H/2$.

Step 2: Subsequently, the shuffled binary $\{W_f, W_b\}^e$ is generated by applying random permutation to $\{W_f, W_b\}$. Next, a binary image $B^n_{\kappa,(i,j)} \in \{0, 1\}$ is constructed from the n-th bit plane of $\kappa \in \{HL, LH, HH\}$ sub-band. In order to generate the sampled host signal $\varphi_{(i,j)}$, a random sampling operation is applied to $B^n_{\kappa,(i,j)}$ according to a secret key.

Step 3: The quantization modulation operation is applied to embed $W^e_{(i,j)}$, which is the (i, j)-th element of $\{W_f, W_b\}^e$, in $\varphi_{(i,j)}$. The watermarked signal $\varphi^W_{(i,j)}$ is computed as:

$$\begin{aligned} \varphi^W_{(i,j)} &= \text{QIM}(\varphi_{(i,j)}, W^e_{(i,j)}, \Delta) \\ &= \begin{cases} \Delta \cdot \tilde{\varphi}_{(i,j)} & \text{if } W^e_{(i,j)} = \tilde{\varphi}_{(i,j)} \pmod 2; \\ \Delta \cdot \tilde{\varphi}_{(i,j)} + 1 & \text{otherwise,} \end{cases} \end{aligned} \quad (5)$$

where Δ is the quantization step within the range of [0.01,

(a) Exploratorium (b) BMW 507 (c) Frontier

Fig. 5: Additional host images for experiments

1.00], and $\tilde{\varphi}_{(i,j)} = \lfloor \frac{\varphi_{(i,j)}}{\Delta} \rfloor$. Next, τ is embedded into LL (Eq. 5) for synchronized robust TMO.

Step 4: The binary form of $\varphi^{W}_{(i,j)}$ is produced in order to combine it with the binary $B^{n}_{\kappa(i,j)}$ to perform the smooth inverse operation. Finally, inverse LWT followed by YC_bC_r to *RGB* conversion are computed to achieve H'^{W}. Finally, inverse-TMO is applied to H'^{W} to produce the HDR watermarked H^{W}. Intermediate results are shown in Fig. 4.

C. Watermark Extraction

It is noteworthy that the watermark can be extracted as W' by reversing the embedding steps. Note that the SoD-Net process is independent of the QIM based watermark embedding. Specifically, SoD-Net builds a model of the saliency maps information of the earlier used host images. On a later stage, at the time the watermark extraction, the same saliency maps are used to segment the foreground and background of the host images. That means, the host images are not going to pass through the SoD-Net model again to evaluate the saliency maps. Therefore, SoD-Net is completely stable with the QIM based watermark embedding. Next, inverse QIM is applied to extract the watermark images.

In addition, the watermark is extracted in the SDR domain, and hence robustness against tone-mapping is important and is of our interest. Intermediate results are shown in Fig. 4.

III. Experiments and Results

Our SoD-Net HDR-IW method is implemented in Matlab 2020 (Windows 10) running on a PC with an AMD Ryzen 5 3500U, Radeon Vega Gfx, and 16GB-RAM. For experiment and comparison purposes, we used the RIT-MCSL [22] and MSRA datasets[1] [24]. Additionally, we set the $\Delta = 0.50$, background to be slightly hazy ($\beta = 0.04$) and salient object to be entirely invisible ($\alpha = 0.02$). Visual results are shown in Fig. 4. The PSNR and SSIM of H^{W} are evaluated [19]. Results suggest that H^{W} produced by our method is of high quality, i.e., $>$ 59dB in terms of PSNR, and it is consistently higher in comparison to SOTA methods (see Table I). The SSIM values also indicate that our watermarked images are of high quality, which agrees with the PSNR value.

Next the normalized correlation (NC) [6] $NC \in [0, 1]$ and bit error rate (BER), is considered to assess the quality of W'.

[1]For each SDR image, we produce 6 images each of different exposure, which are then combined using Durand's inverse TMO method [23].

TABLE I: Analyzing quality of W and H^{W} for our and SOTA methods

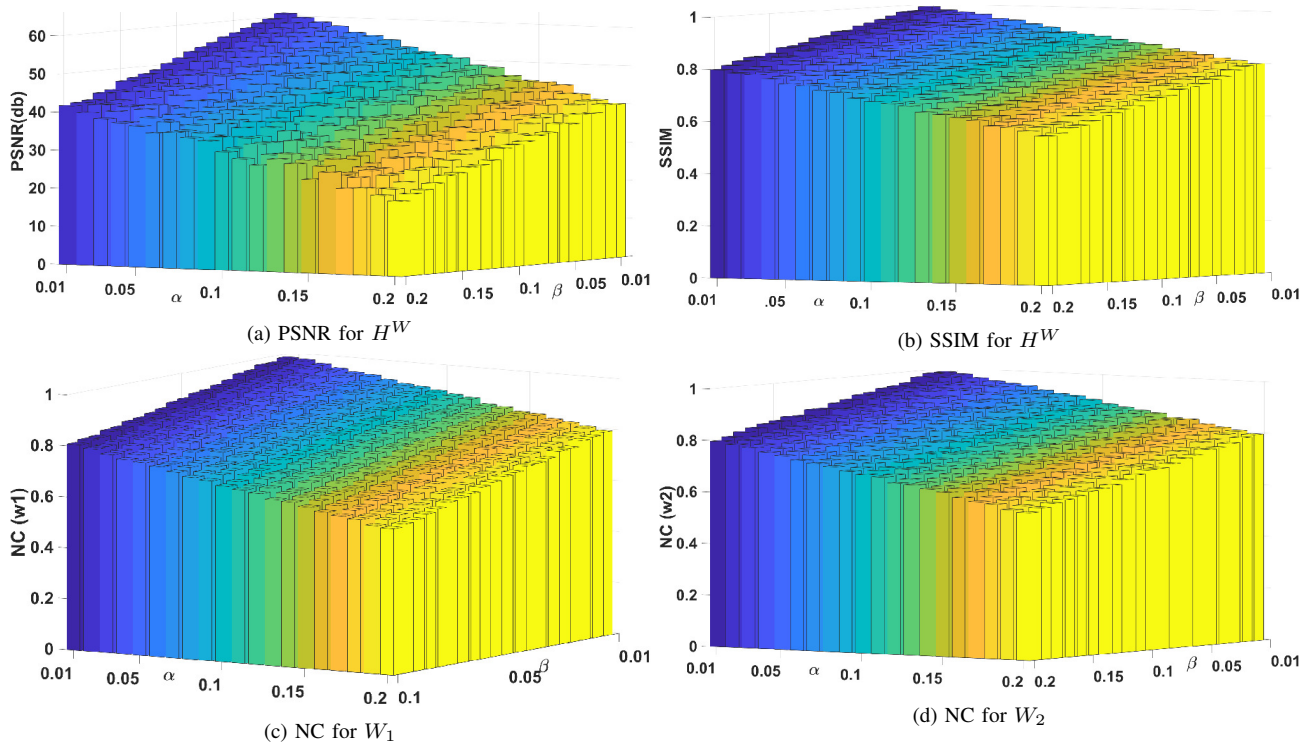
TABLE II: Results NC after applying watermark attack

Attack	NC_{W_1}	NC_{W_2}	[25]	[22]	[23]	[18]	[6]
Mean-filter	0.9861	0.9699	**0.9872**	0.9718	0.9748	-	0.9710
Median-filter	0.9848	0.9683	**0.9911**	-	-	0.9840	-
Shearing	**0.9864**	0.9675	-	-	0.9513	0.9658	-
Noise	**0.9920**	0.9792	0.8931	0.9680	0.9905	0.9850	0.9178
Rotation	**0.9791**	0.9518	0.9090	0.9055	0.6335	0.9498	0.8799
Cropping	**0.9893**	0.9681	-	0.9552	0.9602	-	0.9685
JPEG-Comp	0.9672	0.9446	-	**0.9688**	0.9559	-	0.9220

Mathematically,



$$NC = \frac{\sum_{(i,j)}(W_{(i,j)} - \mu_W)(W'_{(i,j)} - \mu_{W'})}{\sqrt{\sum_{(i,j)}(W_{(i,j)} - \mu_W)^2}\sqrt{\sum_{(i,j)}(W'_{(i,j)} - \mu_{W'})^2}} \tag{6}$$

and

$$BER = \frac{\sum_x \sum_y |W'_{(i,j)} - W_{(i,j)}|}{512 \times 512}, \tag{7}$$

where, μ_W is average value of the W. As expected, for the case of not undergoing any attack, the NC value is high as reported in Table I (see row NC for W'). The results here are collected using Durand's TMO.

To evaluate robustness, H^{W} is subjected to the mean and median filterings, affine shearing $[1, 0, 0; 0.5, 1, 0; 0, 0, 1]$, additive noise (0.01), rotation of 45^o, cropping with $[75 : 424, 68 : 424]$, and JPEG compression to assess the robustness of our HDR-IW method. Here, all attacks take place in the tone-mapped SDR images produced by using Durand's TMO. The results are recorded in Table II. Note that two cases are considered here, namely, using the proposed SoD-Net approach (NC_{W_1}) and embedding equally throughout the host image (NC_{W_2}). First, results show that the $NC_{W_1} > NC_{W_2}$ for all of the mentioned attacks in Table II. This outcome suggest that embedding W into salient regions of the host image leads to better robustness against attacks. It is because $\{W'_f, W'_b\}$ are embedded (spreaded) into different regions (details) of the H by using different embedding methods. Besides robustness, the SoD based embedding also ensures the imperceptibility feature. Hence, this leads to the concurrent improvement in watermarking conflicting requirement. On the other hand, when embedding W evenly throughout the image

(a) PSNR for H^W

(b) SSIM for H^W

(c) NC for W_1

(d) NC for W_2

Fig. 6: The graphs of image quality and NC for various α and β values. The NC value shown is the average NC for the 7 attacks mentioned in Table II.

H (without SoD), H^W may undergo the attacks evenly and hence attaining the low robustness.

When compared to the SOTA methods, the proposed SoD-Net HDR-IW method achieves the high robustness for four out of seven attacks. It should be noted that, although our method does not achieve the highest NC value for the Mean-filter, Median-filter, and JPEG-Comp attacks, our NC values are only marginally below the best performing methods (i.e., [22], [25], respectively). Note that the BER values are calculated for all attacks mentioned in the Table II, that is 0.09 on average which is significantly better then the SOTA methods [6], [18], [22], [23]. Our HDR-IW performs better against noise attack. This result may have resulted from W being shuffled before embedding into H, which spreads W, as opposed to the typical SOTA approaches that do not encrypt the W prior to embedding. In addition, for the same H, the SOTA methods can embed less than 1 bit/pixel (bpp) (e.g., [18], [25] can only embed 128×128 and 32×32 bits, respectively), while our method can diffuse 256×256, which means 1 bit of W into 1 pixel of H, i.e., 1 bpp.

Interestingly, despite embedding significantly more data, our method produces H^W of the highest quality when compared to the SOTA approaches. Furthermore, we also analyzed the quality of watermarked H^W and the extracted watermark W' with different (α, β) values as shown in Fig. 6. Results suggest that the increment in (α, β) values produces lower quality H^W, which eventually generates low quality (less robust) W', and vice versa. However, for security purposes, we set $\alpha \neq \beta$.

All in all, we conclude that our HDR-IW method outperforms the conventional HDR-IW methods in terms of imperceptibility, robustness, and payload capability, hence achieving simultaneous improvement, viz., trade-off independence.

IV. Conclusion & Future Work

In this study, a novel trade-off independent HDR image watermarking based on saliency detection is proposed, which simultaneously achieves higher robustness, image quality and payload. First, the HDR image is tone-mapped to an SDR image, which is then segmented into the background and foreground regions based on a mask produced by the proposed neural-network based SoD method called SoD-Net. Prior to embedding, bit-plane of the watermark are partitioned into foregrounds and backgrounds using the same mask derived from the host and scrambled using the pseudo-random permutation algorithm. Next, the watermark segments are embedded into the chosen bit-planes of the host image segments using the quantized indexed modulation. Results suggest that our method is resilient to the non-malicious attacks (TMOs) and outperforms SOTA IW methods in terms of image quality, robustness, and payload.

In future, we analyze the effect of different wavelets and decomposition levels on proposed HDR-IW method and investigate the robustness for the different tone mapping operators.

***Abstract*—This study presents an innovative approach for concealing textual content within Versatile Video Coding (VVC), H.266 by utilising the Quantisation Parameter (QP) and modifying the QP index within the existing quantisation framework. The primary objective is to seamlessly integrate concealed textual content into video streams while minimising any noticeable impact on visual fidelity and compression efficiency. Additionally, the study investigates the capability of the proposed method to embed Quick Response (QR) code into the video to enhance interactivity and provide viewers with quick access to supplementary information. The proposed method focuses on the encoder aspect, precisely adjusting the QP index to incorporate the concealed data. By strategically manipulating the index values, the encoded video frames maintain their visual fidelity while accommodating the concealed textual content. The embedding process seamlessly integrates into the pre-existing quantisation framework, providing an effective and efficient solution for hiding information in video streams.**

I. Introduction

In today's modern culture, videos have become an integral part of daily life, serving as a powerful means of communication and information dissemination across various platforms, such as social media, education, and entertainment industries [1]. The power of videos lies in their ability to captivate audiences and present information engagingly, thus encouraging participation and enhancing knowledge transfer. With the widespread accessibility of high-speed internet and mobile devices, videos have become an increasingly effective medium for spreading awareness, educating on critical topics, promoting products and services, and fostering customer loyalty and interaction.

As digital communication advances, the importance of information security has reached unprecedented levels [2]. Within this context, the utilisation of QR code has gained significant prominence. QR code serve as a versatile tool with diverse applications in our daily lives. They enable contactless payments, provide quick access to product information and promotions, facilitate ticketing and boarding processes, enhance authentication and security measures, and empower digital marketing campaigns [1]. The ability to store and convey information in a compact and machine-readable format makes QR code indispensable to our modern society.

Meanwhile, embedding information within videos has emerged as a critical method for delivering various video services, including authentication, copyright protection, and the concealment of sensitive data [3], [4]. By seamlessly integrating QR code into videos, new opportunities arise for utilising these codes to enhance interactivity and engagement. The integrated framework for encryption and decryption of digital data, including 21 x 21 QR code and text, is depicted in Figure 1. During the embedding process, it may be necessary to assign a secret key to ensure that only authorised recipients can access the concealed data. All digital data is transformed into binary form to facilitate the encryption process. QR code embedded in videos can provide viewers instantaneous access to additional content, resources, or promotions, enriching the video experience and facilitating knowledge dissemination.

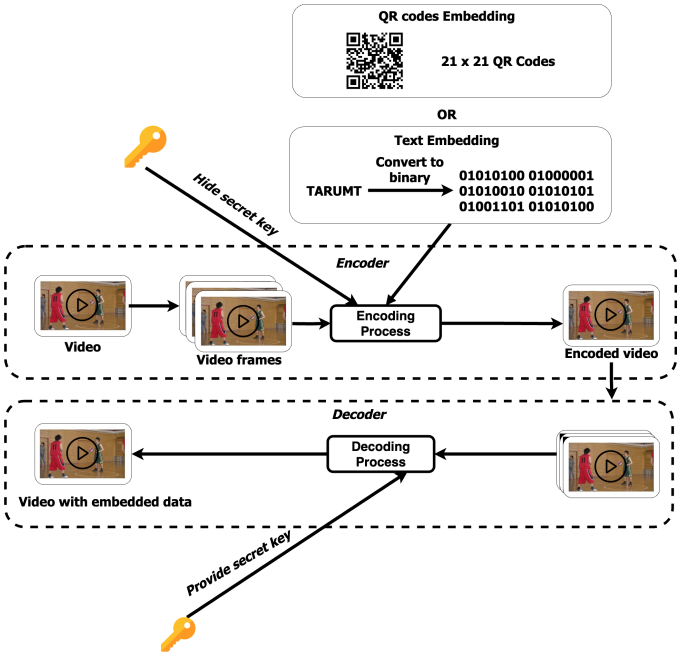

Fig. 1. An integrated framework for encryption and decryption of digital data

However, alongside the advancements in video technology, ensuring the integrity and authenticity of video content has become increasingly paramount. The rise of deepfake technology [5], [6] has underscored the importance of secure and responsible video content manipulation. has underscored the importance of secure and responsible video content ma-

nipulation. Deepfakes, which employ sophisticated machine learning algorithms to replace or superimpose one person's likeness onto another's in video or audio, have raised concerns regarding the potential misuse of such technology for deceptive or malicious purposes. While our primary focus in this research is on concealing textual content and the potential to hide QR code within videos using QP manipulation, we recognise the broader context of deepfake-related challenges. By developing techniques for information hiding within video streams, our work aligns with the broader objective of ensuring the integrity and authenticity of multimedia content in an era where deepfakes pose significant threats to trust and credibility. Therefore, the ability to hide and reveal information within videos, such as through QR code, becomes a valuable means of securing the trustworthiness of video content.

The embedding of QR code within videos brings forth a range of usability benefits [7], [8], [9], enhancing user engagement and interaction. QR code offer an interactive element, allowing viewers to access additional information or resources by scanning the embedded QR code. This seamless integration ensures that the QR code does not detract from the video content but enriches it by providing supplementary information or functionalities. Viewers can easily access detailed product information, relevant web pages, or social media profiles by scanning the QR code, facilitating efficient information retrieval. Moreover, embedded QR code are a powerful marketing tool, enabling businesses to promote products, services, or special offers, fostering customer engagement and driving conversions. By monitoring QR code scans and engagements, content creators and marketers can gather valuable analytics data, gaining insights into viewer preferences and campaign effectiveness.

Furthermore, QR code provide contextual information within videos, enhancing the viewing experience by offering translations, definitions, or supplementary resources. Additionally, incorporating QR code in videos allows for gamified experiences, where viewers can scan codes to unlock rewards, access hidden content, or participate in interactive challenges. Overall, the usability of QR code embedded in videos extends beyond their conventional applications, offering enhanced interactivity, easy access to information, marketing opportunities, tracking capabilities, contextual information, and gamified experiences. Leveraging the power of QR code in videos elevates the viewer experience, drives engagement, and unlocks new dimensions of user interaction and involvement.

Within the realm of VVC, this paper introduces a novel technique for embedding QR code into video using QP Manipulation. The proposed method modifies the QP index within the quantisation layer, specifically in the quantisation framework. The primary objective is to seamlessly integrate hidden QR code into video frames while minimising any perceptible impact on visual quality and compression efficiency. By addressing the demand for efficient and imperceptible QR code embedding in VVC, this research significantly contributes to the advancement of video coding and information security.

Here is an outline of the paper's structure: Section II offers an exhaustive review of pertinent literature in video coding and information hiding. It delves into the fundamental concepts and techniques that form the foundation of our approach, with a particular focus on manipulating the QP index and its seamless integration into the existing quantisation framework. Section III presents a comprehensive exposition of our proposed compressed video information hiding algorithm. Section IV presents our experimental results, which vividly demonstrate the effectiveness of our approach concerning both visual fidelity and compression efficiency. In conclusion, we summarise our findings and discuss the broader implications of our work, highlighting its significance in interactive video content and information dissemination, and suggest avenues for future research.

II. VVC Video Encoder Architecture and Functionality

VVC, also known as H.266 [10], [11], is the latest international video coding standard introduced by the Joint Video Experts Team (JVET). Building upon its predecessor, High-Efficiency Video Coding (HEVC) [12], VVC aims to improve video compression efficiency, enabling higher resolutions significantly, enhanced visual quality, and improved streaming capabilities. During the general compression process, before moving on to the first stage of the video encoder, the input video is often pre-processed to reduce noise and artefacts and to improve the video quality. Following that, each video frame is split up into several coding units (CUs) [13], which are blocks of varying sizes and shapes that depend on the complexity and spatial properties of the image. The next step is to do intra [14] and inter-prediction [15], in which each CU's pixels are predicted based on those of its neighbours. The prediction error (or residual), which would otherwise be redundant, is then encoded using a transform [16], [17] (such as the Discrete Cosine Transform (DCT) or Discrete Sine Transform (DST)).

Additionally, motion estimation and compensation may lower the prediction error for frames with a strong temporal association with their preceding frames. The motion vector and residual are then encoded due to the encoder's search for the best match between the current block and a block in the reference frame [18]. Each block will go through transformation and quantisation [19], where the transform coefficients are reduced in bit depth and enhanced for compression. Depending on the frame's content, the quantisation step size may be changed to achieve the desired trade-off between bit rate and video quality. The quantised coefficients and other syntactic components (such as motion vectors and intra/inter coding modes) are further reduced using context-adaptive binary arithmetic coding (CABAC) to exploit their statistical properties.

A. Quantisation

Quantisation [20], [21] is a fundamental process that determines the level of compression and quality achieved in

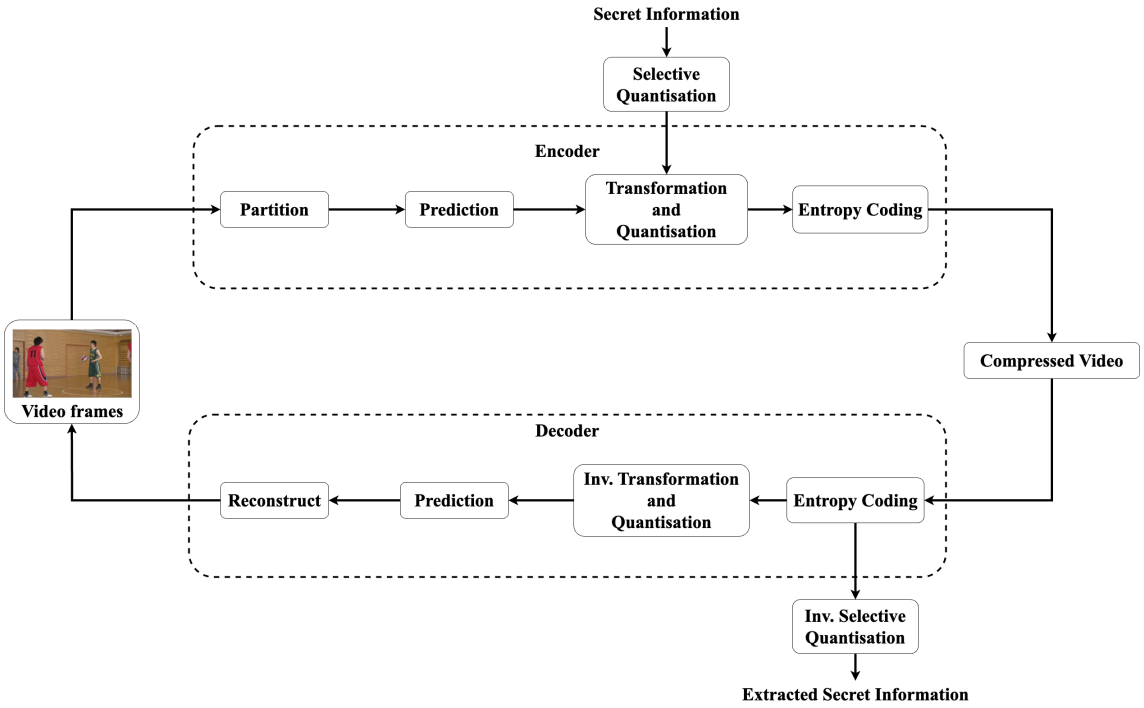

Fig. 2. Selective Quantisation-based Information Hiding Technique in Versatile Video Coding.

the encoded video. The goal of quantisation is to reduce the precision of video data, allowing for more efficient storage and transmission. VVC employs a flexible and adaptive quantisation scheme to improve compression efficiency and video quality compared to previous video coding standards. The quantisation process in VVC involves the following steps:

1) Transform Coding [17]
   First, the input video frame is divided into blocks or transform units (TUs), such as square blocks of 4x4, 8x8, or 16x16 pixels. Transform coding is applied to these TUs to convert them from the spatial domain to the frequency domain using mathematical transformations like the DCT or the Integer Transform.
2) Quantisation [22], [19]
   After the transformation, quantisation is performed on the transformed coefficients. The quantisation process reduces the precision of these coefficients by dividing them by a quantisation step size. The quantisation step size is determined by a QP specified for each TU.
3) Adaptive Quantisation [23]
   VVC introduces adaptive quantisation, where the quantisation step size can vary within a frame or a TU. Adaptive quantisation allows for more precise control over the level of quantisation applied to different parts of the video, enabling better quality preservation in essential regions and more significant compression in less critical areas.
4) Rate Distortion Optimization (RDO) [24]
   A RDO technique is employed during the quantisation process to find the optimal QP for each TU. RDO considers the trade-off between the compression efficiency (bitrate) and the encoded video's visual quality (distortion). It searches for the best QP that minimises the distortion while achieving the desired bitrate.
5) In-loop Filtering [25]
   After quantisation, in-loop filtering techniques are applied to the quantised coefficients to refine the quality further and reduce artefacts caused by quantisation. These filtering operations can alleviate blocking artefacts and enhance the visual quality of the reconstructed video.

VVC allows for a flexible balance between compression efficiency and video quality by controlling the quantisation process. The QP is a critical parameter that determines the strength of quantisation applied to the video, and its adaptive usage in VVC contributes to improved compression efficiency and enhanced video coding performance.

III. Proposed Information Hiding Technique

In the proposed information hiding framework depicted in Figure 2, a selective quantisation-based approach is adopted to conceal data within video frames during encoding. This process occurs precisely during the transformation and quantisation stages, making it an integral part of the video processing pipeline. During the selective quantisation, the algorithm focuses on modifying the QP values of video slices based on the assigned information at the beginning of the information-hiding process. By switching between odd and even QP values according to the detected program bits, the algorithm enables embedding secret information into video frames. The

variations in QP values are utilised to distinguish the embedded data within the video frames. This algorithm presents a robust approach for concealing information while preserving video quality.

A. Quantisation-Based Text Concealment Algorithm

This algorithm 1 aims to integrate concealed text into a video stream while ensuring minimal impact on the visual fidelity. The steps of the algorithm are as follows:

1) If the **enable hide text** (h) flag is true, proceed with the hiding process.
2) Check if the **index** (i) is within the valid range of **length of the binary text** (γ).
3) If the current **binary digit** (β_i) is '1':
   - Make sure the slice's **QP** (α_i) is even. Otherwise, increment it by 1 to ensure it becomes even.
   - Increment the i to move to the next binary digit.
4) If β_i is '0':
   - Make sure the α_i is odd. Otherwise, increment it by 1 to make it odd.
   - Increment the i to move to the next binary digit.
5) If the hiding process reaches the maximum γ:
   - Set the α_i of the video slice to its current α_i.
   - Set the h flag to false to indicate that no text is being hidden.

This approach focuses on modifying the video slice's QP depending on the binary text that has to be concealed. The program ensures the hidden text is merged while preserving visual accuracy by carefully altering the QP values.

B. Quantisation Parameter Analysis Algorithm for Concealed Text Extraction

Algorithm 2 provided above focuses on extracting hidden information from the video. The steps of the algorithm are as follows:

1) If the last eight elements of β_i do not match the **end of the text** (e) condition and the h flag is set to true, the algorithm proceeds with the extraction process.
2) In this process, the algorithm examines the parity of the α_i. If α_i is an even value, it implies that the hidden binary digit appended to β_i is '1'.
3) Conversely, if α_i is an odd value, it signifies that the hidden binary digit appended to β_i is '0'.
4) If the conditions are not met, indicating the completion of the extraction process, the algorithm updates the h flag to false, signifying the termination of any further information extraction.

By analysing the parity of the QP, the algorithm selectively extracts hidden information from β_i while adhering to specific conditions. This approach ensures accurate retrieval of concealed data in a professional and controlled manner.

Both the information concealing and information extraction procedures include a reset mechanism at the end of each separate operation to guarantee adherence to accepted norms.

Algorithm 1 Quantisation-Based Text Concealment Algorithm

```
Initialise x, h
Assign n = x + e
Convert n to β, where γ is the length of β
if h is true then
    if i < γ then
        if β_i = 1, where i ∈ {0, 1, ..., γ − 1} then
            if α_i mod 2 ≠ 0 then
                α_i += 1
                i++
            end if
        else if β_i = 0, where i ∈ {0, 1, ..., γ − 1} then
            if α_i mod 2 = 0 then
                α_i += 1
                i++
            end if
        end if
    end if
else
    α_i = α_i
    h = false
end if
```

Algorithm 2 QP Analysis Algorithm for Concealed Text Extraction

```
Initialise h
if β_[−8:] ≠ e and h is true then
    if α_i%2 == 0, where i ∈ {0, 1, ..., γ − 1} then
        β_i+ = 1
    else if α_i%2 ≠ 0, where i ∈ {0, 1, ..., γ − 1} then
        β_i+ = 0
    end if
else
    h = false
end if
Insert β_i to arr_i
Convert arr to s
Display s
```

This technique works to stop any tweaks or modifications that are unnecessary or without a valid reason. The algorithms guarantee a regulated and dependable execution, safeguarding the integrity of the data while respecting professional standards by reverting to the usual standard procedure after completion.

IV. Performance Evaluation

Video compression techniques play a pivotal role in optimising the storage and transmission of video data by achieving high compression ratios without compromising visual quality. This study evaluates a proposed technique's compression efficiency and performance within VTM 18.1, employing a range of video sequences.

The assessment encompasses two fundamental aspects: compression efficiency and visual fidelity. Compression efficiency is measured through Rate-Distortion (RD) curves, which depict the trade-off between bitrate (in kilobits per second) and Peak Signal-to-Noise Ratio (PSNR) in decibels (dB). Higher PSNR values indicate superior visual quality. Visual fidelity is evaluated using Bjontegaard Delta-Peak Signal-to-Noise Ratio (BD-PSNR) and Bjontegaard Delta-Rate (BD-BR) metrics. The proposed technique is compared against three scenarios: embed words within specific frames (M_1), embed bit '0' in all frames (M_2), and embed bit '1' in all frames (M_3).

The video sequences selected for evaluation include BasketballPass (BP), BasketballDrill (BD), FourPeople (FP), and ParkScene (PS), ensuring a diverse range of content for a comprehensive analysis of the proposed technique's performance across different scenarios. By examining the PSNR values and bitrates, we can assess the effectiveness of the proposed technique in enhancing compression efficiency while preserving visual quality.

The RD curves presented in Figure 3 depict the relationship between PSNR and bitrate for the original video sequences and the proposed technique across various scenarios. These curves illustrate the impact of the proposed technique on compression efficiency and its ability to maintain visual fidelity. Notably, PSNR values across various video sequences and resolutions at each bitrate are similar for the original and proposed technique's video. This can be attributed to the proposed technique's utilisation of a modified QP value, minimising the impact on video quality. The RD curves demonstrate a consistent trend between the original and proposed video when encoded using identical video sequences in different scenarios. The maximum degradation observed between the two versions is less than or equal to 0.05 dB in terms of PSNR, indicating minimal impact on visual quality. The minimum degradation observed among the four encoded videos under different scenarios is less than 0.05 dB.

Table I comprehensively evaluate the PSNR performance, comparing the original VVC standard with the proposed technique implemented in VTM 18.1. The assessment encompasses various bitrates and three distinct scenarios. The analysis of PSNR values allows for an accurate assessment of the proposed technique's effectiveness in enhancing video quality compared to the original standard.

For the BP sequence, at a bitrate of 100 kbps, the proposed technique achieves a higher PSNR of 32.3890 dB than the original standard's PSNR of 32.3793 dB. This trend continues at higher bitrates, demonstrating improved PSNR values for the proposed technique. Specifically, the average PSNR difference amounts to 0.0496 dB in M_1. When considering the M_2, the average PSNR difference is 0.0137 dB, and for the M_3, the average PSNR difference is 0.0161 dB.

Likewise, for the BD sequence, at a bitrate of 100 kbps, the proposed technique achieves a PSNR of 28.9460 dB, while the original standard yields a lower PSNR of 28.8720 dB. The average PSNR difference is 0.0149 dB in M_1. When considering the M_2, the average PSNR difference is 0.0058 dB, and for the M_3, the average PSNR difference is 0.0388 dB.

As we go on to the FP sequence, the video with the proposed technique exhibits the highest quality at 500 kbps in M_2 compared to the original video out of all the scenarios with a difference of 0.0454 dB. However, the maximum degradation of the FP video sequences under all the scenarios is 0.5747 dB, which occurs in M_3 at 100 kbps.

In addition, for the PS video sequence, the PSNR is improved by a maximum of 0.011 dB at 2000 kbps in the M_1 condition, and the maximum degradation of this video from the original video is 0.1742 dB at 100 kbps in the M_2 condition.

The table II showcases the BD-BR and BD-PSNR values obtained for all video sequences, indicating the quality gains and bitrate savings achieved by the proposed video compared to the original video. BD-PSNR quantifies the quality improvement achieved by the proposed video at equivalent bitrates. At the same time, BD-BR reflects the bitrate savings required to maintain the same quality level, as denoted by the BD-Rate value.

For the BP video sequence, the BD-PSNR values indicate the quality improvement achieved by the proposed technique in scenarios M_1, M_2, and M_3. In scenario M_1, the proposed technique yields a BD-PSNR improvement of 0.0414 dB, demonstrating enhanced visual quality. However, it is essential to note that the BD-BR value is negative (-0.7661%), indicating that the proposed technique's video needs fewer bits to achieve the original video quality. In contrast, in scenario M_2, the BD-PSNR improvement is smaller (0.0020 dB), with a negligible BD-BR change (0.0961%). Scenario M_3 exhibits a decrease in visual quality (-0.0485 dB) with a moderate BD-BR reduction (0.5906%). When employing the proposed technique, these results highlight the trade-off between visual quality and bitrate reduction.

For the BD video sequence, similar trends are observed. In scenario M_1, the proposed technique achieves a BD-PSNR improvement of 0.0287 dB, albeit with a slight increase in bitrate (-0.6779%). Scenario M_2 shows a BD-PSNR improvement of 0.0309 dB, accompanied by a BD-BR reduction of -0.7192%. In scenario M_3, the proposed technique demonstrates the highest BD-PSNR improvement of 0.0399 dB, with a notable BD-BR reduction of -0.9439%. These findings emphasise that scenario M_3 provides the best trade-off between visual quality improvement and bitrate reduction for the BD video sequence.

Moving on to the FP video sequence, scenario M_1 shows a marginal decrease in visual quality (-0.0129 dB) with a small BD-BR increase (0.8474%). In scenario M_2, the BD-PSNR change is minimal (0.0020 dB) with a BD-BR reduction of -1.0316%, indicating a balance between quality and bitrate. Scenario M_3 yields a slight BD-PSNR improvement (-0.0094 dB) with a BD-BR increase of 1.6120%. These results suggest that scenario M_2 strikes a reasonable compromise between visual quality and bitrate reduction for the FP video sequence.

Moreover, scenario M_1 exhibits a slight BD-PSNR decrease (-0.0040 dB) with a minor BD-BR increase (0.1489%) for the PS video sequence. In scenario M_2, the BD-PSNR change is -0.0089 dB, and the BD-BR increase is 0.2642%. Scenario M_3 shows a similar BD-PSNR decrease (-0.0088 dB) with a BD-BR increase of 0.2745%. These findings indicate that all three scenarios have a relatively small impact on visual quality and bitrate for the PS video sequence.

Furthermore, the BD-BR values range from -1.0316% to 1.6120%, while the BD-PSNR values span from -0.0485 dB to 0.0399 dB. Notably, a BD-BR value of -1.0316% indicates that the original video requires 1.0316% more bits than the

TABLE I
COMPARISON OF PSNR PERFORMANCE IN VVC: ORIGINAL STANDARD VS. PROPOSED TECHNIQUE IN VTM 18.1

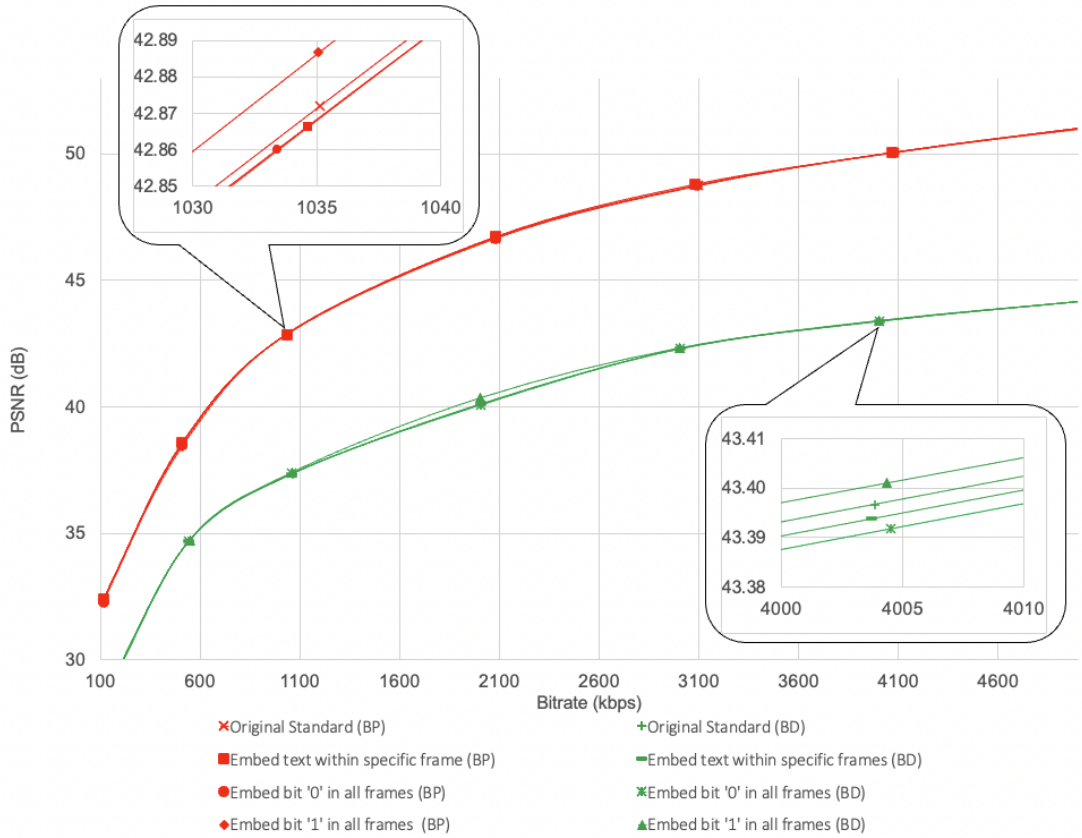
proposed video to achieve an equivalent quality level. Additionally, the proposed video showcases a maximum quality improvement of 0.0399 dB compared to the original video at equivalent bitrates.

Overall, the experimental results demonstrated the proposed technique's effectiveness in achieving high compression efficiency while maintaining acceptable visual quality. The RD curves illustrated the trade-off between bitrate and PSNR, indicating the impact of the proposed technique on compression efficiency and its ability to preserve visual fidelity. Comparing the proposed technique to the original video, the average differences in PSNR were relatively small, indicating that the proposed technique minimised the impact on video quality. Moreover, the evaluation of BD-PSNR and BD-BR values further emphasised the improvements achieved by the proposed video in terms of both quality gains and bitrate savings compared to the original video. Across different video sequences and scenarios, the proposed technique consistently outperformed the original standard, yielding higher PSNR values at equivalent bitrates. The experimental results showcased the potential of the proposed technique in enhancing video quality and compression efficiency across a range of content.

The experimental findings affirm the efficacy of the proposed techniques for concealing QR codes within video se-



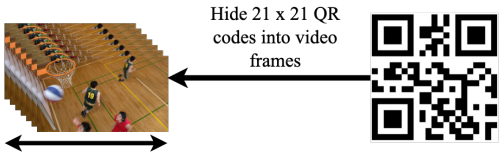


Fig. 3. RD Analysis for BP and BD Video Sequence: Original vs. Proposed Technique in Various Scenarios

TABLE III
QR DATA PAYLOAD FOR DIFFERENT QR VERSIONS AND ERROR CORRECTION LEVELS [26]

QR Version	Number of QR data (bit/modules)			
	L	M	Q	H
1	152	128	104	72
5	864	688	496	368
10	2,192	1,728	1,232	976

40	23,648	18,672	13,328	10,208

quences. Among the various versions of QR code as shown in Table III, the embedding process primarily focuses on QR Code Version 1, which features a matrix grid size of 21 x 21 modules comprising black and white squares. This version boasts a data capacity ranging from 72 (with a high Error Correction (ECC) Level) to 152 (with a low ECC level) bits. In Figure 4, a 21 x 21 QR code is embedded within 68 video frames, each running at 24 frames per second (fps). The content, 'TARUMTMYKL', is stored in the QR code with 68 bits. High-level error correction has been employed, allowing

Content	TARUMTMYKL
Error Correction Level	30%
Version	1
Size	21 x 21
Data Bits	68 bits

Fig. 4. Procedure for Integrating QR code into Video Frames using VVC

recovery of up to 30% of data in the event of errors. According to the proposed techniques present in this paper, we can store the bits in the video depending on how many video frames are in the sequences. Therefore, it can be concluded that, to hide a 21 x 21 QR code with a high ECC level (72 bits), 72 frames of video sequences are sufficient.

The evaluation of compression efficiency and visual fidelity, including the analysis of RD curves and BD-PSNR/BD-BR values, serves as a basis for assessing the feasibility of embedding QR codes in video. The results obtained from this study demonstrate that the proposed technique effectively maintains video quality while achieving high compression

efficiency. This indicates that the technique can be adapted to seamlessly embed QR codes within video frames, allowing for their hidden presence without compromising visual quality. In summary, the concepts and techniques presented in this study hold promise for integrating QR codes within video sequences, thereby offering new avenues for information dissemination, interactive media experiences, and enhanced video content.

V. Conclusion

In conclusion, this study evaluated the compression efficiency and visual fidelity of a proposed video compression technique implemented in VTM 18.1 in VVC. The experimental results demonstrated that the proposed method achieved successful information hiding and showed the capability to embed QR code with minimal impact on video quality. However, it is essential to acknowledge a limitation of the proposed technique. It is currently limited in its ability to hide information, with the total number of bits hidden dependent on the video frames. To address this limitation and further enhance the technique's versatility, future work should explore more sophisticated approaches and further investigate the security of the information hiding technique proposed. This could involve investigating the feasibility of embedding more complex QR code with larger data payloads. This direction of research aims to overcome the current constraint and unlock new possibilities for information hiding within video sequences.

***Abstract*—Lossy image coding standards such as JPEG and MPEG have successfully achieved high compression rates for human consumption of multimedia data. However, with the increasing prevalence of IoT devices, drones, and self-driving cars, machines rather than humans are processing a greater portion of captured visual content. Consequently, it is crucial to pursue an efficient compressed representation that caters not only to human vision but also to image processing and machine vision tasks. Drawing inspiration from the efficient coding hypothesis in biological systems and the modeling of the sensory cortex in neural science, we repurpose the compressed latent representation to prioritize semantic relevance while preserving perceptual distance. Our proposed method, Compressed Perceptual Image Patch Similarity (CPIPS), can be derived at a minimal cost from a learned neural codec and computed significantly faster than DNN-based perceptual metrics such as LPIPS and DISTS.**

***Index Terms*—End-to-end learned compression, image quality assessment, perceptual distance, coding for machines.**

I. Introduction

The concept of *efficient coding* [1], [2] in early biological sensory processing systems hypothesized that the internal representation of images in the human visual system is optimized to encode the visual information it processes efficiently. In other words, the brain effectively compresses visual information.

The field of neural science has made discoveries regarding modeling neural single-unit and population responses in higher visual cortical areas using goal-driven hierarchical convolutional neural networks (HCNNs) [3]. The sensory cortex's fundamental framework models the visual system through encoding, the process by which stimuli are transformed into patterns of neural activity, and decoding, the process by which neural activity generates behavior. In their work [3], HCNNs have successfully described the mapping of stimuli to measured neural responses in the brain.

In recent years, the rapid advancement of deep neural network techniques has significantly improved computer vision tasks [4]–[6] and image processing tasks [7]–[9]. Neural compression [10], an end-to-end learned image compression method [11]–[17], has also gained significant attention and has been shown to outperform traditional expert-designed image codecs. Traditionally, most image processing algorithms cannot be directly applied to hand-crafted image codecs like JPEG [18]. As a result, the first step before further image processing or analysis is typically decompressing the image into raw pixels. With the evolution of neural compression, there is a growing trend to apply CNN-based methods directly to the compressed latent space [19]–[22], leveraging the advantages of joint compression-accuracy optimization [21] and eliminating the need for decompression. Consequently, international standards such as JPEG AI [23] and MPEG VCM (Video Coding for Machines) [24] have been initiated to bridge data compression and computer vision, catering to both human and machine vision needs.

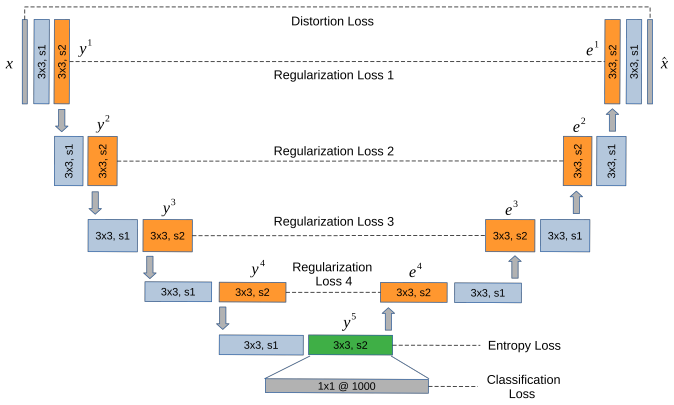

Fig. 1. The architecture we proposed for conducting perceptual distance preserving image compression. The innermost green convolution output y^5 represents the compressed latents to be further entropy-coded. The orange layer outputs y^l and e^l, trained with the image classification task, contain semantic features that preserve perceptual differences in human vision.

Drawing inspiration from sensory cortex modeling [3] and the efficient coding hypothesis employed in information-theoretic perceptual quality metrics [25], we aim to develop an end-to-end learned image compression method jointly trained with the ImageNet classification task as the goal-driven HCNN. Fig. 1 illustrates our proposed architecture, which resembles a UNet network. The compressed latent representations and the intermediate decoder output layers are mapped to a semantic space that preserves the perceptual distance between two different images. We name our method the *Compressed* Perceptual Image Patch Similarity (CPIPS), which utilizes the entropy-coded bitstream and intermediate decoder output to measure the perceptual distance between

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

images. In the context of Coding for Machines, the compressed image bitstream transmitted by IoT devices can be readily utilized by machines to assess perceptual distortions resulting from image operations.

Our contributions can be summarized as follows:

- We demonstrate the utilization of a goal-driven HCNN as an auxiliary task to map the latent space of the end-to-end learned image compression method to a space with semantic meaning.
- We provide guidance and insights on designing the network architecture when a high-level computer vision task is jointly trained with a variational autoencoder network.
- The proposed perceptual metric, CPIPS, is lightweight compared to other CNN-based perceptual metrics, such as LPIPS [26] and DISTS [27]. Computing CPIPS is significantly faster than LPIPS, with an acceleration of approximately 50 times.

II. Related Works

A. Learned Image Compression

The field of learned image compression has witnessed significant advancements with the introduction of convolutional neural networks. Several approaches have been proposed in the literature, starting with Ballé et al. [12] that surpassed traditional codecs like JPEG [18] and JPEG 2000 [28] in terms of PSNR and SSIM metrics. Minnen et al. [13] further improved coding efficiency by employing a joint autoregressive and hierarchical prior model, surpassing the performance of the HEVC [29] codec. More recently, Cheng et al. [15] developed techniques that achieved comparable performance to the latest coding standard VVC [30]. Several comprehensive survey and introduction papers [10], [31], [32] have summarized these advancements in end-to-end learned compression.

Currently, there are two remaining challenges [33] in this field: computational complexity and subjective image quality. The neural compressor employs high-capacity networks to end-to-end model data dependency in exchange for better bitrate-distortion (BD) efficiency. The channel-conditional method proposed by Minnen et al. [14] achieves performance close to VVC but at the cost of high computational complexity (600K FLOPS/pixel). Regarding image quality, Valenzise et al. [34] conducted subjective tests on DNN-based methods and observed that these methods produce artifacts that are difficult to evaluate using traditional metrics like PSNR. They concluded that PSNR is inadequate for evaluating DNN-based methods. Upenik et al. [35] benchmarked a set of DNN-based image codecs using a crowdsourcing-based subjective quality evaluation procedure with Differential Mean Opinion Scores (DMOS). Their results demonstrate that learning-based approaches can achieve promising bitrate-DMOS performance compared to HEVC. However, despite their superior subjective scores, these DNN-based image codecs are optimized with pixel difference-based distortion functions.

B. Perceptual Quality Metrics

The evaluation of image codec quality traditionally relies on full-reference image quality assessment (FR-IQA) metrics, which measure the similarity between the reconstructed image and the original image as perceived by human observers. In addition, to mean square error (MSE) or PSNR, various FR-IQA metrics, such as SSIM variants [36], [37], PIM [25], and DISTS [27], have been proposed to predict subjective image quality judgments. Johnson et al. [38] proposed using the feature vector distance from the VGG network [39] as a perceptual loss for image transformation tasks based on the hypothesis that the same image features used for image classification are also helpful for other tasks.

Zhang et al. [26] introduced the BAPPS dataset, which includes a large-scale collection of human judgments on image pairs, and trained the Learned Perceptual Image Patch Similarity (LPIPS) metric. LPIPS was found to be more aligned with human judgments than traditional quality metrics such as L2, PSNR, and SSIM. Ding et al. [40] conducted an interesting study to evaluate whether DNN-based quality metrics can be used as objectives for optimizing image processing algorithms. Developing effective perceptual quality metrics for image tasks remains a challenging problem.

C. Coding for Machines

Lossy image coding standards such as JPEG and MPEG have primarily focused on achieving high compression rates for human consumption of multimedia data. However, with the rise of IoT devices, drones, and self-driving cars, there is a growing need for efficient compressed representations that cater not only to human vision but also to image processing and machine vision tasks. Techniques such as image data hiding [19], image denoising [20], and image super-resolution [41] have been developed to operate directly on neural compressed latent spaces.

Le et al. [21] proposed an inference-time content-adaptive fine-tuning scheme that optimizes the latent representation to improve compression efficiency for machine consumption. Duan et al. [22] employed transfer learning to perform semantic inference directly from quantized latent features in the deep compressed domain without pixel reconstruction. Choi et al. [42] introduced scalable image coding frameworks based on well-developed neural compressors, achieving up to 80% bitrate savings for machine vision tasks.

III. Proposed Methods

To enable joint training of the image compression network and an image classification task, one has to design a suitable network architecture that can be shared between a variational encoder network $\mathcal{G}_e$ and a DNN feature extraction network $\mathcal{F}$. We leverage the successful UNet [5] and VGG [39] networks and propose a Left-UNet. Our Left-UNet consists of $L = 5$ downsampling convolution layers, each with two convolution blocks. As shown in Fig. 1, the first orange block from the top-left represents the intermediate encoder output feature y^1 from the second convolution block of the first layer, denoted

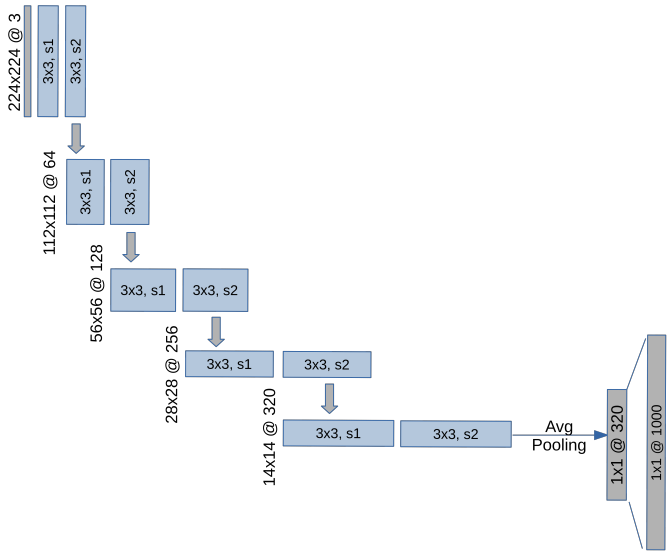

Fig. 2. The Left-UNet feature extraction network $\mathcal{F}$ and the classifier we proposed for the image classification task.

as **conv_1_2**. In Fig. 1, the innermost latent vector y^5, colored green, is outputted from **conv_5_2**. This vector is subject to quantization, resulting in an approximation $\hat{y}^5 = \mathsf{Q}(y^5)$, which is then entropy-coded.

A. Image Classification

We illustrate the Left-UNet architecture in Fig. 2 and provide details in Table I. The feature extraction network $\mathcal{F}$ for the image classification task uses the parameterized ReLU as the activation function for all layers, while the encoder network $\mathcal{G}_e$ employs Generalized Divisive Normalization (GDN) at the end of each downsampling layer. GDN, proposed by Ballé et al. [43], is inspired by modeling neurons in biological visual systems and has been proven effective in Gaussianizing image densities for a superior rate-distortion trade-off.

The extracted image features are then average pooled and connected to a linear layer with 1,000 neurons to optimize the classification loss $\mathcal{L}_C$ using cross-entropy:

$$\mathcal{L}_C = -\sum_i t_i \log(\mathcal{F}(x)_i) \tag{1}$$

It is known that a high-capacity neural network trained for a high-level vision task implicitly learns to reason about relevant semantics [38]. Our goal is not to solve the classification problem directly. Instead, we aim to design a moderately-sized network that can learn semantic features without significantly increasing the encoder-decoder complexity.

B. Image Compression Network

A typical learned neural codec consists of an encoder-decoder pair, a quantization module, and an entropy coder. Given an input image $x \in \mathcal{X}$, the neural encoder $\mathcal{G}_e$ transforms x into a latent representation $y = \mathcal{G}_e(x)$, which is later quantized to a discrete-valued vector $\hat{y}$. The discrete probability distribution $P_{\hat{y}}$ is estimated using a neural network and then encoded into a bitstream using an entropy coder. The *rate* of this discrete code, R, is lower-bounded by the entropy of the discrete probability distribution $H(P_{\hat{y}})$. On the decoder side, we decode $\hat{y}$ from the bitstream and reconstruct the image $\hat{x} = \mathcal{G}_d(\hat{y})$ using the neural decoder. The *distortion*, D, is measured by a perceptual metric $d(x, \hat{x})$. Overall, we optimize the network parameters for a weighted sum of the rate and distortion, $\mathsf{R} + \lambda\mathsf{D}$, over a set of images.

Table II illustrates the decoder network $\mathcal{G}_d$, which is designed to complement the encoder. In the generic neural codec concept, the innermost latent vector $\hat{y}^5$ is equivalent to the discrete-valued vector $\hat{y}$. During image reconstruction, the intermediate output vectors e^l from each upsampling layer **conv_l_2** play a crucial role because they represent learned multi-scale semantic layers, which are equivalent to the feature layers of a VGG-16 network.

TABLE I
LEFT-UNET ARCHITECTURE FOR $\mathcal{G}_e$ AND $\mathcal{F}$

GDN					e^1
deconv_1_1	3	2	32	32	
PReLU					
conv_1_2	3	1	32	3	$\hat{x}$

Like [12], we employ kernel density estimation with a neural network to obtain the probability distribution $P_{\hat{y}}$. The rate loss R is computed as follows:

$$\mathsf{R} = -\mathbb{E}[\log_2 P_{\hat{y}}] \tag{2}$$

In our experiments, we utilize the MSE as the distortion function. However, alternative quality metrics such as SSIM variants [36], [37] can be employed to fit perceptual quality better. The distortion loss D is defined as:

$$\mathsf{D} = \mathbb{E}[d(x, \hat{x})] = \mathbb{E}||x - \hat{x}||_2^2 \tag{3}$$

C. Joint Compression-Classification Learning

Although the intermediate convolution output features are seldom used in most machine learning tasks, these features, which are tuned to be predictive of essential structures, exhibit a high correlation with human perceptual similarity [26]. However, storing intermediate latent features in the context of data compression becomes impractical if the final bottleneck layer contains sufficient information for the decoder to reconstruct the image. Another approach to mitigate storage waste is to reduce the number of downsampling layers. However, modeling the sensory cortex in the visual system [3] requires at least five layers of feature extraction to generate neural responses, a finding that our experiments validate as well. Consequently, we utilize the intermediate output e^l from the decoder as a proxy for multi-scale semantic features and apply a regularizer to constrain the decoder. Specifically, we employ the l_1 distance to define our regularization loss:

$$\mathcal{L}_R = \sum_{l=1}^{4} ||e^l - y^l||_1 \tag{4}$$

To initialize the Left-UNet encoder $\mathcal{G}_e$ and an auxiliary classifier, we utilize pre-trained semantic features from the image classification task mentioned in Section III-A. Subsequently, we train an end-to-end image compression network using the overall loss function:

$$\mathcal{L} = \mathsf{R} + \lambda \mathsf{D} + \alpha \mathcal{L}_C + \beta \mathcal{L}_R \tag{5}$$

The hyper-parameter λ represents the rate-distortion trade-off, which can be adjusted according to the desired image quality factor Q. We set $\alpha = 0.3$ and $\beta = 1.0$ for our experiments.

Through joint compression-classification training, the weights of the Left-UNet encoder are initially initialized with pre-trained semantic features. Subsequently, the gradient descent optimizer updates the encoder-decoder weights to analyze and synthesize the image while improving classification accuracy.

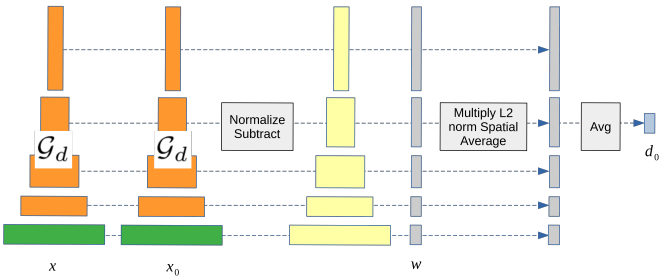

Fig. 3. Computing Euclidean distances from feature outputs e^l and $\hat{y}^5$ between images x and x_0.

D. Compressed Perceptual Image Patch Similarity

To obtain the distance between two images, denoted as x and x_0, we follow the same procedure as LPIPS [26] by learning a linear layer w on the BAPPS dataset. This linear layer assigns weights to the compressed latents and intermediate decoder outputs. Fig. 3 illustrates the process of obtaining the distance using entropy-decoded $\hat{y}^5$ and feature outputs e^l from our decoder network $\mathcal{G}_d$. We extract feature maps $\hat{y}^5, e^l \in \mathbb{R}^{C_l \times H_l \times W_l}$ for all layers l and normalize them in the channel dimension. The activations are then scaled channel-wise using the vector $w^l \in \mathbb{R}^{C_l}$, and the l_2 distance is computed. Finally, we average across the spatial dimensions and all layers to obtain the following:

$$d(f^l) = \frac{1}{H_l W_l} \sum_{h,w} ||w_l \odot (f^l_{hw} - f^l_{0hw})||_2^2 \tag{6}$$

Eq. (7) calculates the final distance between image x and x_0, that is:

$$d_0 = \sum_{l=1}^{4} d(e^l) + d(\hat{y}^5) \tag{7}$$

Furthermore, we train another smaller network, denoted as $\mathcal{D}$, to predict perceptual judgments h from the distance pair (d_0, d_1) on the BAPPS 151k patches 2AFC (two alternative forced choice) dataset.

IV. Experimental Results

A. Experimental Settings

To implement our CPIPS, we utilize the CompressAI[1] [44] implementation of the hyperprior neural compressor [12] and the official release[2] of LPIPS. We pre-train the image classification task on the ImageNet dataset, which consists of 1.2 million images. The training is performed using the PyTorch Adam optimizer with a learning rate 0.0001 for 120 epochs. Following that, we jointly train the compression-classification task with the pre-trained weights for 150 epochs, employing the Adam optimizer with a learning rate of 0.0001.

[1]https://github.com/InterDigitalInc/CompressAI
[2]https://github.com/richzhang/PerceptualSimilarity

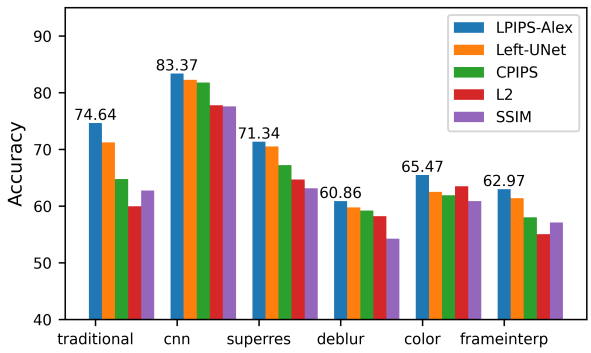

Fig. 4. Comparison of 2AFC accuracy against human ratings on the BAPPS dataset.

Regarding CPIPS weights w and the judgment network $\mathcal{D}$, we train them for ten epochs using the BAPPS 2AFC dataset, as mentioned in the original LPIPS paper.

B. Left-UNet Image Classification

Table III displays our top-1 and top-5 accuracy compared to high-capacity deep networks such as VGG-16. The achieved top-1 accuracy of 60.11% is considered favorable, indicating that the pre-trained weights can serve as a suitable initialization for the Left-UNet encoder $\mathcal{G}_e$.

TABLE III
IMAGENET CLASSIFICATION ACCURACY

Network	**Top-1 Acc.**	**Top-5 Acc.**
AlexNet	56.52%	79.06%
Left-UNet	60.11%	81.95%
ResNet18	69.36%	89.03%
VGG-16	71.51%	93.38%

C. Human Judgment Accuracy

We compare our method with LPIPS and traditional L2 and SSIM metrics, in terms of the accuracy of image judgments against human ratings on the BAPPS dataset. Table IV and Fig. 4 present the results.

TABLE IV
2AFC JUDGMENT ACCURACY

Method	Trad.	CNN	S.Res	DeBlur	Color	F.Interp
LPIPS-Alex	74.64	83.37	71.34	60.86	65.47	62.97
Left-UNet	71.23	82.27	70.51	59.74	62.50	61.39
CPIPS	64.77	81.77	67.21	59.20	61.91	58.00
L2	59.94	77.76	64.67	58.19	63.50	55.02
SSIM	62.73	77.59	63.13	54.23	60.88	57.10

Evidently, the metrics incorporating learned semantic features, such as LPIPS, Left-UNet, and CPIPS, exhibit a higher correlation with human judgments compared to L2 and SSIM. While Left-UNet does not achieve the same level of accuracy as LPIPS, it serves as an upper bound for our proposed CPIPS since they share the same feature extraction convolution layers. Our CPIPS achieves similar accuracy to Left-UNet in the CNN, DeBlur, and Color subsets but experiences a more considerable drop in accuracy in the Traditional, Super-Res, and Frame-Interp subsets. We attribute this drop to two factors: 1) the rate-distortion optimization process influencing the semantic properties of the latent vectors, thereby affecting the perceptual representation, and 2) the multi-scale feature maps e^l serving as proxies for the feature extraction vectors y^l reconstructed in the decoding stages through the regularization loss. Investigating and improving upon these factors are left as future work.

Qualitatively, we select some sample image patches from the BAPPS dataset and present their different judgments in Fig. 5. We can see that the L2 and SSIM cannot reflect human perceptual preferences. At the same time, the CPIPS and LPIPS align with the ground truth better. The second image pair in Fig. 5 demonstrates that the SSIM has a strong bias with structures and tends to be impacted by additive noises.

D. Computational Complexity

We assessed the computation time of the metrics on an Intel i7-9700K workstation with an Nvidia GTX 3090 GPU. To compare our CPIPS metric with LPIPS and DISTS[3], we used the Kodak dataset [45] and calculated the average time cost, as shown in Table V. Due to utilizing of a less complex neural network that only requires decoding the bitstream and intermediate features, our CPIPS method is approximately 50 times faster.

TABLE V
METRIC COMPUTATION TIME ON KODAK

Method	Avg. Time (secs.)
CPIPS	**0.0205**
LPIPS-Alex	1.0681
DISTS	1.0373

V. CONCLUSIONS

In this work, we have introduced an end-to-end learned approach for image compression that aims to preserve perceptual distances. By leveraging pre-training on an image classification task and joint compression-classification training, we initialize the parameters of a learned image coding model with semantic features and guide the gradient descent process to emphasize semantic relevance. We have proposed a UNet-inspired network architecture Left-UNet, shared between the image classifier and the image encoder. Our approach calculates the difference in feature vectors between rate-distortion optimized compressed latents and intermediate decode outputs of two images, providing a perceptual distance preserving metric. We refer to this metric as CPIPS, derived from a learned image codec bitstream at no additional cost. Our experimental results demonstrate that CPIPS aligns more with human subjective judgments than traditional distortion metrics such as L2 and SSIM.

***Abstract*—This study explores the optimization effect of task-specific pruning in object detection models. Object detection models are designed to handle classification and regression tasks, which are fundamentally distinct. However, the relationship between these two tasks, particularly regarding loss calculation, remains an unresolved issue in both model training and pruning. To address this, we propose a task-specific pruning method that combines the advantages of pruning-during-training with established sparsity learning techniques. Through our experiments, we demonstrate that task-specific pruning is the most effective approach for reducing parameter count while maintaining high accuracy in multi-task deep neural networks, across different configurations. Specifically, when applied to the Scaled-Yolov4-p5 model using the MS COCO 2017 dataset, our approach achieves a target sparsity of 90% with only a marginal 1% drop in mAP.**

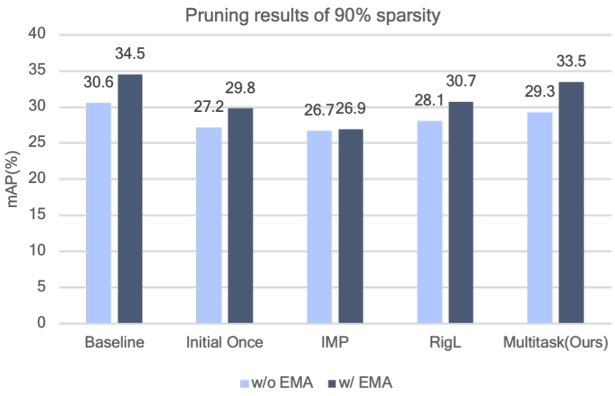

Fig. 1. Our experimental results show that the multi-task(Ours) setting produces the most promising results on the Scaled-Yolov4-p5 object detection model. It achieves a target sparsity of 90% with only a 1% drop in mAP on the MS COCO 2017 dataset. EMA (Exponential Moving Average) is a method of calculating an average that assigns higher weights to recent parameters. This technique can improve training performance. The experimental results indicate that both with and without EMA, the pruning method exhibits the same trend in accuracy after pruning.

I. Introduction

In recent years, there has been a significant increase in the number of edge devices. To achieve faster computation, deep neural networks are often installed directly on the edge device instead of transmitting the computation information over the network. However, these edge devices have limited storage and less computational capabilities compared to general computers. Therefore, techniques such as model compression and multi-task learning have become increasingly important in order to make these models more efficient for practical applications.

A current mainstream approach is to use a multi-task model architecture to implement multi-task learning. For example, DeepLab [8], originally designed for semantic segmentation, can be modified with some output structure adjustments to simultaneously handle tasks such as key-point detection and depth prediction. These types of model architectures have the characteristic of sharing task information within a single model, which results in savings in storage space and faster computational speed compared to using multiple single-task models. The architecture can be divided into two parts: shared layers, which store generic information shared by all tasks, and task-specific layers, which handle the specific information required by each task. To prevent conflicts between task-specific information, model designers often design multiple task-specific heads to differentiate between different tasks.

Object detection models, which are widely used in computer vision, can also be classified as multi-task models as they handle different tasks such as classification and bounding box regression within a single model. However, the inherent differences between these two tasks, with one focused on differentiating between object classes and the other focused on the distribution trend of object positions, have always posed a challenge in loss calculation during model training [14] [15].

Among various model compression approaches, pruning is an efficient and practical technique that compresses models by determining the importance of model parameters and removing unnecessary ones. The mainstream pruning methods can be categorized based on their timing relative to training into three types: train-prune-finetune, prune-at-initial, and prune-during-training. Another approach involves repeatedly pruning during training to optimize sparse models. Sparse learning [5] methods enable models to learn how to prune themselves during

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

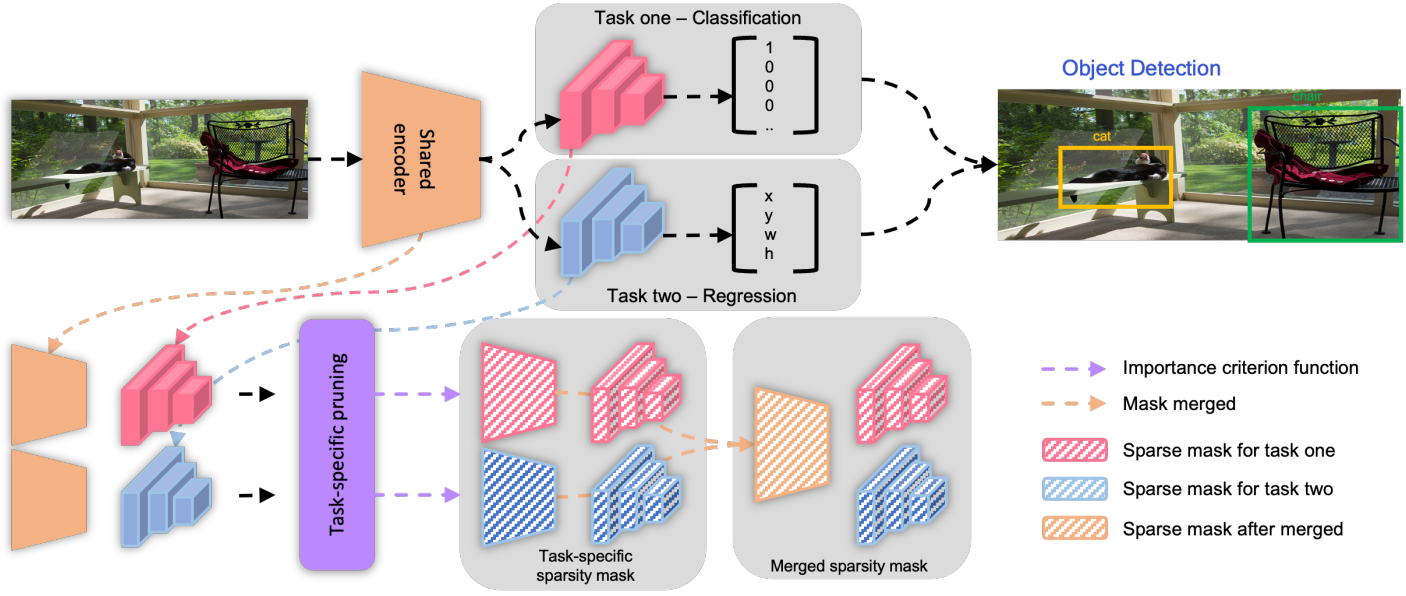

Fig. 2. Our proposed multi-task pruning for object detection.

training, which helps the models acquire additional knowledge that normal training processes may not capture, such as the importance of weights or gradients within individual layers. Prune-during-training [10] attempts to find the optimal trade-off between train-prune-finetune and prune-at-initial methods by determining the stability of the model during training and selecting the best timing for pruning.

In general, multi-task models often handle multiple closely related tasks to improve accuracy and memory efficiency, such as object classification, object detection and segmentation, joint scene geometry, and key point detection. However, applying pruning techniques commonly used for classification tasks to these models may not yield the best results. The DiSparse [7] method introduces a multi-task pruning technique that can be applied to multiple tasks, such as semantic segmentation and depth prediction. This technique allows for pruning across multiple tasks simultaneously. On the other hand, the MTP [9] method addresses the implicit multi-task learning problem in semantic segmentation models by combining the tasks of classification and segmentation for pruning. By leveraging the relationship between these two tasks, these method improves the performance of semantic segmentation models.

Inspired by such pruning methods, our work categorizes object detection models, which traditionally handle a single object detection task, as a type of multi-task model (Fig. 2). We apply the same concept to help the model learn how to differentiate shared and task-specific information. By evaluating the model with the loss functions specific to classification and regression tasks, we obtain task-specific gradients as the basis for pruning importance. However, calculating these task-specific gradients consumes a significant amount of computation time, which increases with each iteration. Therefore, we combine the advantages of sparse learning and prune-during-training methods to determine the optimal timing for pruning. This approach allows us to save considerable computation time while learning to distinguish tasks.

II. Related Works

A. Network Pruning

Currently, network pruning methods can be classified into two categories based on their approach to processing the model architecture: unstructured pruning and structured pruning. Unstructured pruning [5], [13], [19] removes unimportant parameters or neuron connections to achieve computational resource savings, while structured pruning directly removes neurons, channels, filters, or other structured parts of the network to achieve model size reduction and computational resource savings. Unstructured pruning is more precise and intuitive in pruning strategy, but due to its unstructured nature, it usually requires special hardware or software support. Structured pruning [10], [16], [17], on the other hand, presents a greater challenge as it requires careful consideration of pruning positions to mitigate potential accuracy degradation. This is due to the dependencies among the pruned elements, making it more complex to implement.

There are two commonly used methods for determining the importance of network elements for pruning: magnitude-based [16], [17] and gradient-based [18]–[20] methods. Magnitude-based methods typically involve ranking network parameters according to their absolute values, while gradient-based methods compute the gradient of the loss function with respect to each parameter and use this information to rank them. It should be noted that implementing the pruning method mentioned above requires additional computational resources. Therefore, the timing and duration of performing pruning are factors that need to be considered when designing pruning algorithms. The Prune-during-Training [10]–[12] method is suitable for such adjustments, and it is also the method we have

adopted. By finding the optimal timing and duration, a trade-off between saving computational resources and achieving the best accuracy can be achieved.

B. Object detection tasks

Object detection can be widely used in various applications, such as security monitoring, autonomous driving, and crowd recognition. It is mainly used to identify objects in images or videos and label their positions and types. Modern object detection technology is mainly based on Convolutional Neural Networks (CNN) [21], [23], [24] and Transformer [25]–[28] models. The model processes the image multiple times to obtain different features. These features are then used to detect objects in the image through two tasks, object localization and object classification. Object localization generates a bounding box for each object, indicating its position and size, while object classification classifies the detected objects and labels them with their respective types.

Among CNN-based object detection models, there are two types based on their detection method: two-stage and one-stage. Two-stage methods first identify potential object locations as proposals and then perform feature recognition and classification on those proposals, such as the RCNN [4], [29], [30] family, including Mask R-CNN [4]. One-stage methods, on the other hand, simultaneously process both bounding box regression and object classification to identify the object's position. While the accuracy of one-stage methods is not as high as two-stage methods, they are faster. One-stage models can further be divided into coupled-head [1], [2], [21] and decoupled-head [22], [24] based on how they handle the two tasks in the model architecture. Decoupled-head is a commonly seen model structure in Multi-task-learning. It will perform classification and bounding box regression separately in two model heads for final calculation and output. Coupled-head is a more commonly used architecture in one-stage models today, where both tasks are combined and calculated in the same head to achieve smaller model size.

III. Method

A. Decouple the tasks

To begin with, we decompose the original coupled loss function ℓ into task-specific loss functions ℓ_k, depending on the task k we wish to address. We calculate the task-specific loss L_k for each task separately using the current N sets of predictions x_i and targets y_i.

In addition, we define task-specific loss functions ℓ_1 and ℓ_2 for the classification and bounding-box regression tasks, respectively. These loss functions will be used to compute the importance criteria $\mathbb{I}_k$ for multi-task pruning.

$$L_k = \frac{1}{N}\sum_{i=1}^{N} \ell_k(y_i, f_p(x_i)). \tag{1}$$

$$\ell = \ell_{cls} + \ell_{obj} + \ell_{box}. \tag{2}$$

$$\ell_1 = \ell_{cls} + \ell_{obj}. \tag{3}$$

$$\ell_2 = \ell_{box} + \ell_{obj}. \tag{4}$$

Algorithm 1 Task-specific-Pruning During Training

Input: $Loss\ Functions\ of\ each\ Task\ \ell_k$,
$Sparsity\ Distribution: \mathbb{S} = \{s^1, ..., s^L\}$
$Schedule: T_i, T_e, \Delta T$
$Untrained\ Network\ f_w$,
$Parameter\ Sets\ of\ each\ Layer\ W_l\ in\ f_w$
$W_l \leftarrow Random\ sparsify\ W_l\ using\ \mathbb{S}$
while $T_i \leq epoch\ t \leq T_e$ **do**
  if epoch t $(\mathrm{mod}\ \Delta T) == 0$ **then**
    $copy\ network\ f_p \leftarrow W_l\ of\ pruning\ target\ f_w$
    for `each task k` **do**
      $L_k = \frac{1}{N}\sum_{i=1}^{N} \ell_k(y_i, f_p(x_i))$
      $\mathbb{I}_k = ArgTopK(-|\nabla_{W_l} L_k|, s^l)$
      if k == 0 **then**
        $\mathbb{I}_{prune} \leftarrow \mathbb{I}_k$
      else
        $\mathbb{I}_{prune} \leftarrow \mathbb{I}_{prune} \cap \mathbb{I}_k$
      end if
    end for
    $W_l \leftarrow Update\ connections\ W_l\ using\ \mathbb{I}_{prune}$
  end if
end while

Before completing the pruning process, we create a copy of the target model f_w's weights and optimizer in a new model f_p. We then pass the task-specific loss L_k to this copy model to obtain the task-specific gradient magnitudes. These gradient magnitudes are used to determine the importance $\mathbb{I}_k$ of each parameter for pruning. Finally, we prune the top s^l smallest unimportant parameters in the dictionary $\mathbb{I}_{prune}$ for each layer l such that $1 \leq l \leq L$, to achieve the desired sparsity distribution $\mathbb{S}$ for each layer. We use RigL [5]'s Erk distribution as the sparsity calculation metric for both CNN and linear layers. The sparsity distribution $\mathbb{S}$ represents the ratio of zero parameters to the total parameter count in each layer, resulting in an overall model sparsity of S.

$$\mathbb{S} = \{s^1, ..., s^L\} \tag{5}$$

$$S = \frac{1}{L}\sum_{l=1}^{L} s^l. \tag{6}$$

$$\mathbb{I}_k = ArgTopK(-|\nabla_{W_l} L_k|, s^l). \tag{7}$$

B. Prune a stable model

After training the model for a period, it will reach a state of stability where pruning can be viewed as beneficial noise

in the training process. Various metrics, such as the number of remaining neurons after pruning [10], flatness [6], and Stochastic Gradient Descent(SGD) noise [13], are employed by different studies to assess stability. However, a common observation is that the model tends to become more stable after a certain number of training epochs, making it conducive for pruning. Pruning a stable model can lead to better results, where stability refers to the point in time where the pruned model structures, obtained from evaluating the model using the same importance criteria over several consecutive training epochs, exhibit little variation.

To prune a stable model, we use a schedule that defines T_i as the epoch when the first pruning begins, ΔT as the required number of training epochs for the model to reach stability, and T_e as the latest possible time for pruning. We utilize a grid-search approach to identify the optimal pruning start time T_i with a slight delay, ensuring that the model reaches stability before initiating the pruning process. Additionally, we adjust the end epoch T_e for pruning to reduce the computational overhead associated with the pruning process.

IV. Experiment

A. Experiment settings

In this section, we present a comprehensive experiment on model pruning for object detectors. Considering the practical application ability, we choose the object detector from the YOLO series [1]–[3], which has a better trade-off between inference time and detection performance. In this experiment, we use Scaled-YOLOv4-p5 [1] as our base detector. If there are no other mentions, all object detectors are trained in one Nvidia 2080ti GPU for 300 epochs from scratch. Because of the limitation of the hardware resources, we use a lower input image size(256) and lower batch size(32) in our training process. We adopt the SGD optimizer with the parameters as the original Scaled-YOLOv4 settings: a momentum of 0.937, an initial learning rate of 0.01, and a weight decay of 0.0005. At last, we evaluate our model on the most general and challenging object detection dataset, the MS COCO dataset. The following experiments show our proposed method can achieve a competitive performance with other state-of-the-art pruning methods.

We utilize "mean average precision (mAP)" as the performance evaluation metric. It is calculated by averaging the precision scores across all 80 categories in the MS COCO dataset, considering 10 Intersection over Union (IoU) thresholds ranging from .50 to .95 with an increment of .05. Averaging over IoUs rewards detectors with better localization, making mAP a comprehensive measure of both detection accuracy and localization performance.

B. Performance

Main result. To present a fair comparison, we re-implement our baseline, IMP [13] and RigL [5] with the same settings as our training process. Tab. I reports the performance of our pruning method for object detection and other baselines for the MS COCO dataset. Initial once means the model will be randomly pruned at the beginning of the training process. In IMP, model weight magnitudes are used for importance evaluation during the pruning interval. In RigL, an additional metric based on model gradient magnitudes is incorporated following the weight magnitude importance evaluation. In the multi-task settings, we calculate the losses of the two tasks separately for task-specific gradient calculation, and we utilize their intersection as the final evaluation metric for pruning. This represents the primary distinction between the multitask method and RigL.

As the results shown in Tab. I, our method surpasses all the other methods and loses only 1.0 mAP (-3%) with 90% sparsity while other methods get a performance loss of at least 3.8 mAP (-11%). This excellent result validates our perspective that the important weights have some nuances between the regression task and classification task, which can be addressed through the multi-task settings (ours).

Pruning with different pruning intervals. RigL [5] suggests pruning the first three-quarters of all training epochs, using an

TABLE I
Detection accuracy comparisons in terms of mAP on MS COCO 2017 Dataset

Pruning method	mAP(%)	Input size	Batch size	Sparsity(%)
Baseline	34.5	256×256	32	0
Initial Once	29.8 (-4.7)	256×256	32	90
IMP [13]	26.9 (-7.6)	256×256	32	90
RigL [5]	30.7 (-3.8)	256×256	32	90
multi-task(Ours)	**33.5 (-1.0)**	256×256	32	90

TABLE II
Results with varying pruning interval

IMP [13]	26.9	1	0 - 225	90
IMP	29.6	1	10 - 20	90
IMP	28.6	1	100 - 110	90
multi-task	**33.5**	1	10 - 20	90
multi-task	31.3	1	100 - 110	90

TABLE III
Results with different pruning settings

Pruning Method	mAP(%)	ΔT	T_i - T_e	Sparsity(%)
None(baseline)	34.5	-	-	0
Initial Once	29.8	-	-	90
IMP [13]	26.9	1	0 - 225	90
RigL [5]	30.7	1	0 - 225	90
IMP	29.6	1	10 - 20	90
multi-task (head only)	30.7	1	10 - 20	90
multi-task (backbone + head)	**33.5**	1	10 - 20	90

update interval of 100 iterations and an initial drop fraction of 0.5 for the best results. We follow the settings mentioned above, as well as the dynamic pruning method of DiSparse [7]. However, we found that continuously pruning from the beginning until 3/4 of training epochs is inefficient and unnecessary. Instead, we reduced the pruning epochs from 225 to 10, with an update interval of $\Delta T = 1$ epoch.

Referring to Tab. II, our experimental results show that pruning only at these 10 epochs can still yield good or even better pruning results. When to Prune [10] states that pruning slightly after the start of training, when the model becomes more stable, can lead to better pruning results. We set the pruning start epoch T_i as epoch 10 out of the total 300 training epochs. Furthermore, we conducted pruning at different intervals during epochs 10-20 and epochs 100-110 separately within the same total 300 training epochs. The results showed that pruning during the interval 10-20 produced better outcomes. This suggests that pruning after a short initial training phase is more effective and provides additional epochs for fine-tuning after pruning the target model.

Task-specific pruning for the partial model. To validate the need for task-specific pruning in coupled-head models, our method assumes that performing task-specific pruning on the target model will lead to better performance of the pruned model. In our experiments, we explore multi-task processing by separately applying task-specific pruning to the backbone + head and head-only configurations of the model. Among them, the backbone + head configuration shows the best performance, indicating that for a coupled-head model, performing multi-task processing on all layers except the input and output layers yields the best results. This approach effectively addresses the conflict between the two tasks in the coupled head.

V. Conclusions and Future Work

In this work, we applied task-specific pruning to address the challenges of pruning in the object detection task. By adjusting the timing of the pruning start and interval, we achieved improved results compared to other methods that require more effort. Our findings highlight the importance of considering the two tasks of the object detection model separately and ensuring model stability during the initiation of the pruning process.

The concept of this work is model-agnostic, which means it can be applied to various object detection models. In the future, we plan to validate this by applying the proposed method to other models such as transformers and two-stage object detection models.

Transformer-based Image Compression with Variable Image Quality Objectives

Chia-Hao Kao*, Yi-Hsin Chen*, Cheng Chien, Wei-Chen Chiu, and Wen-Hsiao Peng
National Yang Ming Chiao Tung University, Taiwan

***Abstract*—This paper presents a Transformer-based image compression system that allows for a variable image quality objective according to the user's preference. Optimizing a learned codec for different quality objectives leads to reconstructed images with varying visual characteristics. Our method provides the user with the flexibility to choose a trade-off between two image quality objectives using a single, shared model. Motivated by the success of prompt-tuning techniques, we introduce prompt tokens to condition our Transformer-based autoencoder. These prompt tokens are generated adaptively based on the user's preference and input image through learning a prompt generation network. Extensive experiments on commonly used quality metrics demonstrate the effectiveness of our method in adapting the encoding and/or decoding processes to a variable quality objective. While offering the additional flexibility, our proposed method performs comparably to the single-objective methods in terms of rate-distortion performance.**

I. Introduction

Compared to traditional image codecs, learned image codecs can be easily adapted to any differentiable quality metrics. When a learned image codec is trained separately with different quality metrics, the decoded images may exhibit distinctive visual characteristics. For instance, involving mean squared error (MSE) in the training objective usually leads to blurry reconstructed images, particularly at low bitrates. On the other hand, when trained to minimize the Learned Perceptual Image Patch Similarity (LPIPS) [1], the codec typically yields visually pleasing images, but may sometimes introduce undesirable artificial patterns [2]. By supporting multiple quality objectives, a compression system can cater to a wide range of application requirements and user preferences. It enables the user to adapt the quality objective to their needs, whether it is to maximize the perceptual quality or reconstruction fidelity of the decoded image, or a weighted combination of these objectives. Therefore, developing a flexible compression system that can support multiple quality objectives is of importance in meeting the diverse demands of different image compression applications.

Although end-to-end learned image compression has made significant progress [3], [4], [5], most existing methods have to train separate models for different quality objectives. Normally, each model is optimized for one specific quality metric, which can be MSE, multi-scale structural similarity (MS-SSIM), or a weighted combination of these metrics. However, this approach is impractical in terms of computational resources and storage requirements.

*Equal contribution.

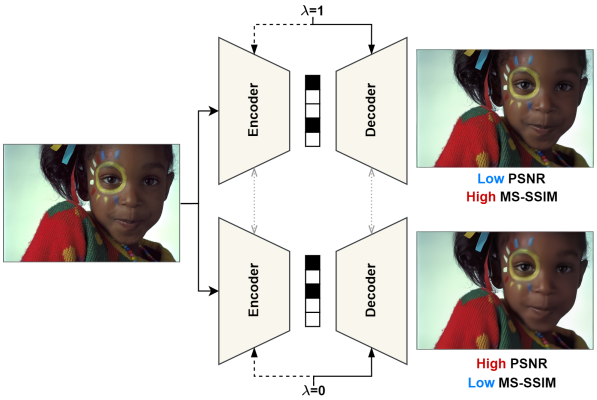

Fig. 1. Illustration of our proposed framework. By adjusting the condition parameter λ, the reconstructed images exhibit distinct characteristics, enabling customizable quality balance based on specific preferences.

Recently, Agustsson *et al.* [6] propose a compression system with a conditional decoder for adaptive reconstruction of images to trade off high fidelity (i.e. low MSE) for realism. From the same bitstream, it is able to decode an image with variable quality objectives. However, they [6] only address the trade-off between realism and MSE, disregarding other metrics. Furthermore, their conditioning mechanism is performed on the decoder side only, without exploring the potential benefits of incorporating it into both the encoder and decoder.

In this work, we propose a Transformer-based learned image codec that is able to trade off one image quality objective for another (e.g. Peak-Signal-to-Noise-Ratio versus MS-SSIM). Transformer-based image compression systems [7], [5], [8] have attracted lots of attention recently for their comparable or even superior coding efficiency to CNN-based methods. Fig. 1 illustrates the main idea of our framework, which is designed to adapt the encoding and/or decoding processes to optimize the decoded image quality according to a given trade-off between two selected quality objectives. Motivated by the recent success of prompt tuning techniques [9], [10], we propose a prompt generation network to adapt the coding process according to the specified quality objective. Specifically, we explore two variations. The first applies prompt tuning to both encoder and decoder, specializing the bitstream for a specific quality objective. In comparison, the second adapts only the decoder, allowing a single bitstream to be decoded into images that meet variable quality objectives.

The contributions of this paper are as follows:

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

- We introduce a Transformer-based image compression framework that is able to adapt the decoded image quality to a variable objective.
- To our best knowledge, this is the first work that leverages prompt-tuning techniques to trade off one image quality objective for another. Additionally, we explore two variants of the proposed method for different application scenarios.
- Extensive experiments confirm the effectiveness of our proposed method. Specifically, when both encoder and decoder are adapted, our method is able to trade off one quality objective for another effectively while achieving similar rate-distortion performance to the case when the codec is optimized solely for one of the two objectives.

II. Related Works

A. Learned Image Compression

End-to-end learned image compression methods [11], [12], [3], [4] have made significant amount of progress over the past few years, even outperforming traditional codecs, such as intra coding in HEVC [13] and VVC [14]. While most of the existing literature in this field adopt CNN-based autoencoder as their foundation, Transformer-based compression systems [5], [7] have emerged as promising alternatives, particularly for their low computational complexity and outstanding coding efficiency. Zhu *et al.* [5] adopt Swin-Transformer [15] architecture for image compression, showing comparable performance to its CNN-based counterparts with significantly reduced decoder-side kMACs (multiply-accumulate-operations). Similarly, Lu *et al.* [7] utilize Swin-Transformer blocks but substitute the patch merging/splitting operations with more general convolution and transposed convolution layers. More recently, Liu *et al.* [8] propose a mixed Transformer-CNN image compression system that further improves the coding efficiency.

B. Conditional Compression Systems

Conditional compression systems designs are commonly adopted for variable rate coding, enabling a single compression model to encode input images at various bit-rates based on the given trade-off of rate and distortion. In this line of works, the condition is often applied through altering the distribution of the feature maps. Cui *et al.* [16] introduce gain units that perform channel-wise scaling on the image latents for continuous rate adaptation. Song *et al.* [17] use spatial feature transform (SFT) layers [18] to perform element-wise affine transformation on the intermediate feature maps of the autoencoder, achieving both variable rate and ROI coding simultaneously. In a similar vein, Wang *et al.* [19] target Transformer-based models and perform channel-wise scaling on value matrices in all self-attention layers for variable rate control. Recently, Agustsson *et al.* [6] extend the idea to trade off realism for fidelity (i.e. MSE) of reconstructed images, introducing a conditional decoder that performs channel-wise shifting on the intermediate feature maps inside each residual blocks. The condition is applied to adapt the decoder for different levels of realism and produce the reconstructed images accordingly. However, this method only addresses the trade-off between realism and fidelity, and limits the adoption of conditioning mechanism on the decoder side alone.

C. Prompt Tuning

Prompting techniques [9], [20], [21] were first introduced in natural language processing (NLP) field for efficiently adapting large pre-trained Transformer models to various downstream tasks. The main idea is to keep the entire large pre-trained Transformer frozen, and introduce additional input tokens, known as prompts, for adaptation. These tokens are involved in the self-attention and act as a guidance for the current task. Recently, Jia *et al.* [10] extend the idea to Vision Transformers [22] and computer vision tasks. They prepend learnable prompts to the image tokens at each Transformer blocks, achieving comparable or even superior performance than fine-tuning the entire model on downstream task while only learning less than 1% of the total parameters.

III. Proposed Method

A. Preliminary

Most of the learning-based image compression models [11], [12], [3], [4] share a similar coding architecture, consisting of a main autoencoder and a hyperprior autoencoder [11]. As illustrated in Fig. 2, our framework also adopts this design. Specifically, given an input image $x \in \mathbb{R}^{3\times H\times W}$ of height H and width W, a learned non-linear analysis transform N_{enc} encodes the image into its latent representation $y \in \mathbb{R}^{192\times \frac{H}{16}\times \frac{W}{16}}$. To efficiently transmit y, it is first uniformly quantized into $\hat{y}$, which is then entropy coded using a learned prior distribution $p(\hat{y})$. This prior distribution is modeled using the hyperprior autoencoder in a content-adaptive manner [12]. As shown, the hyper-analysis transform H_{enc} converts the quantized latent $\hat{y}$ into the side information $\hat{z} \in \mathbb{R}^{128\times \frac{H}{64}\times \frac{W}{64}}$ and the quantized $\hat{z}$ is transmitted for generating the learned prior distribution for entropy coding $\hat{y}$. Lastly, the synthesis transform N_{dec} decodes $\hat{y}$ from the bitstream to obtain the reconstructed image $\hat{x} \in \mathbb{R}^{3\times H\times W}$.

B. System Overview

Our work proposes an image compression system capable of producing reconstructed images that reflect variable image quality objectives. Specifically, given two selected quality objectives, the coding process is adapted to trade off one objective for the other. Fig. 2 illustrates the overall framework of our proposed method, which is built upon TIC [7], a Transformer-based image compression system. For the analysis transform N_{enc}, synthesis transform N_{dec}, and hyper-autoencoder H_{enc}, H_{dec} of TIC, the commonly-seen CNN-based design is replaced with interleaving convolutional layers and Swin-Transformer blocks (STB). Note that we discard the context model in favor of a simpler Gaussian prior for entropy coding. To achieve variable image quality objectives, our system incorporates an additional input, a uniform lambda

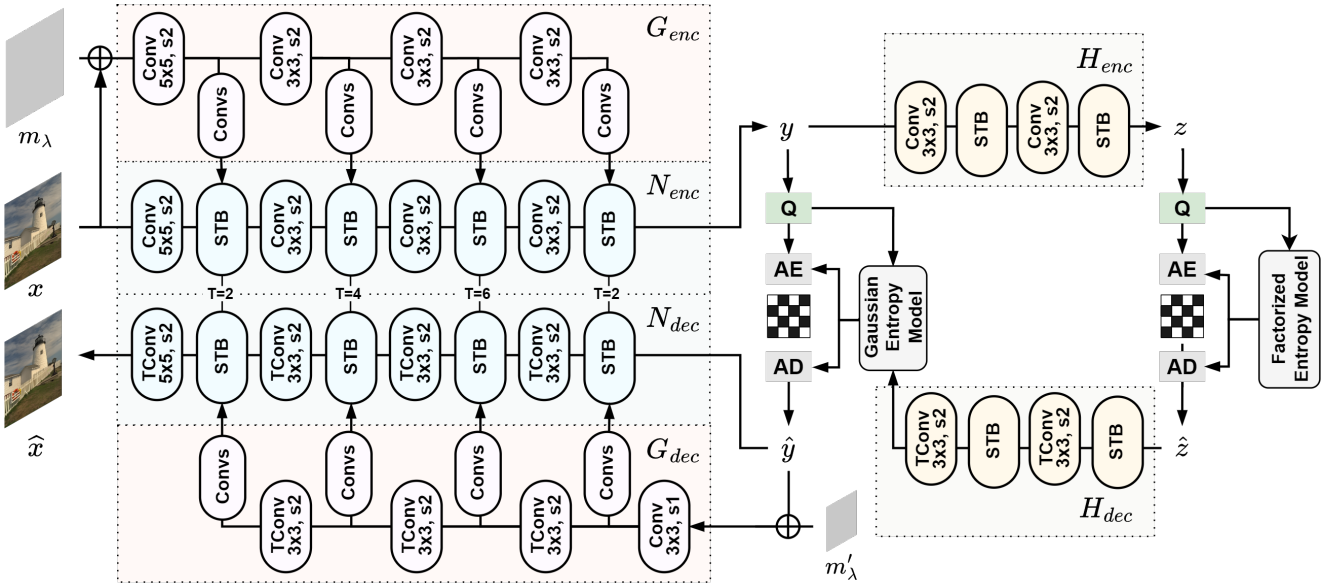

Fig. 2. Overall architecture of our proposed method. We introduce prompt generation networks G_{enc}, G_{dec} to generate prompt tokens as additional input for adapting to variable image quality objectives.

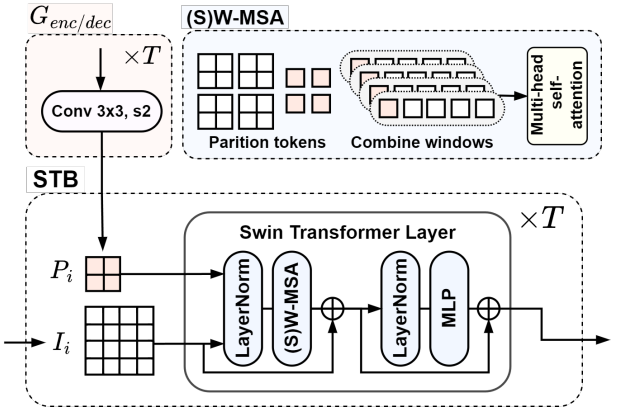
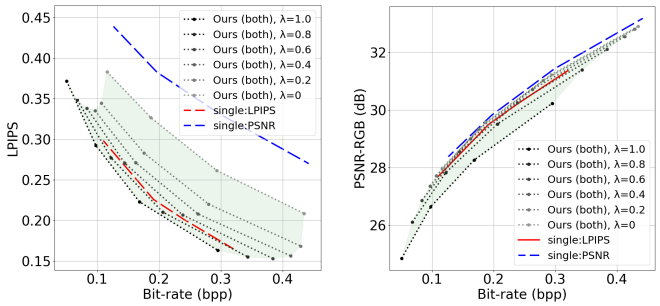
map $m_\lambda \in \mathbb{R}^{1\times H\times W}$ of the same resolution as the input image on the encoder side, and a smaller-scale uniform lambda map $m'_\lambda \in \mathbb{R}^{1\times \frac{H}{16}\times \frac{W}{16}}$ on the decoder side. Both m_λ and m'_λ are populated with the same parameter $\lambda \in [0, 1]$. By adjusting the value of $\lambda \in [0, 1]$, users can specify their desired trade-off between the two quality objectives. At the two extreme ends, where $\lambda = 0$ or $\lambda = 1$, the system reduces to simply optimizing for one specific quality objective. Inspired by the success of prompt tuning [10], we leverage the idea of prompting to condition our Swin-Transformer based codec for adaptation. In this work, we explore two variants of our conditioning method for two different application scenarios. The first variant incorporates the conditioning mechanism into both the encode and decoder, specializing the resulting bitstream for a specific quality objective. The other variant adopts only the decoder-side adaptation, enabling a single compressed bitstream to be decoded into images with variable quality objectives. The details of these variants are presented in the last paragraph of Section III-C.

C. Prompt-based Conditioning

Drawing inspiration from prompt tuning methods [10], we employ additional learnable tokens, termed prompts, to condition our Transformer-based compression model for variable image quality objectives. We introduce prompt generation networks G_{enc} and G_{dec} as add-on modules on top of our main autoencoder. As shown in Fig. 2, G_{enc}, which consists of several convolutional layers, is introduced to the encoder. It takes as input the concatenation of the input image x and lambda map m_λ to generate prompt tokens for each STB in N_{enc}. Similarly, the decoder incorporates G_{dec}, which shares the same architecture as G_{enc} but replaces convolutions with transposed convolutions for upsampling. The input to G_{dec} is the concatenation of the quantized latent $\hat{y}$ and a smaller-resolution lambda map m'_λ. What sets our method apart from [10], in which prompts are directly learned parameters, is the introduction of prompt generation networks for generating prompt tokens adaptively according to the given λs and the input image or latent.





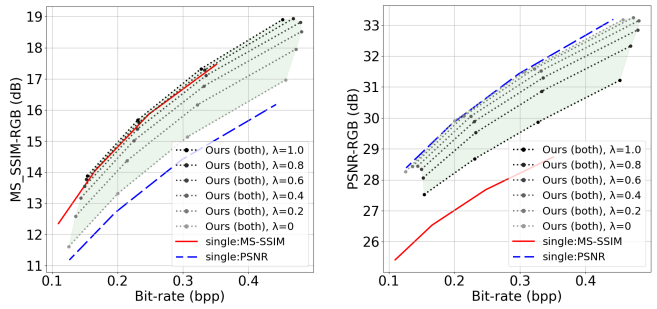


Fig. 3. Detailed architecture of Swin-Transformer Block (STB).

Fig. 3 illustrates the structure of STB and how we incorporate prompt tokens. A regular STB is comprised of multiple Swin-Transformer layers, with T denoting the number of layers and the image tokens I_i being the input to the i^{th} layer. Each Swin-Transformer layer consists of layer normalization, window-based multi-head self-attention (W-MSA), and a MLP layer to aggregate neighboring information. Note that the window for W-MSA is shifted every other layer for tokens across windows to exchange information. To perform prompting, the input to i^{th} Swin-Transformer layer additionally includes a set of prompt tokens P_i obtained through the prompt generation network. In our design, the number of tokens for P_i is only a quarter of that of I_i for reducing computational complexity.

Fig. 6. Rate-distortion performance under (LPIPS, PSNR) pair with decoder-side only prompts. Green shaded area indicates the adaptive range of our method.

(a) MS-SSIM (b) PSNR

Fig. 7. Rate-distortion performance under (MS-SSIM, PSNR) pair with decoder-side only prompts. Green shaded area indicates the adaptive range of our method.

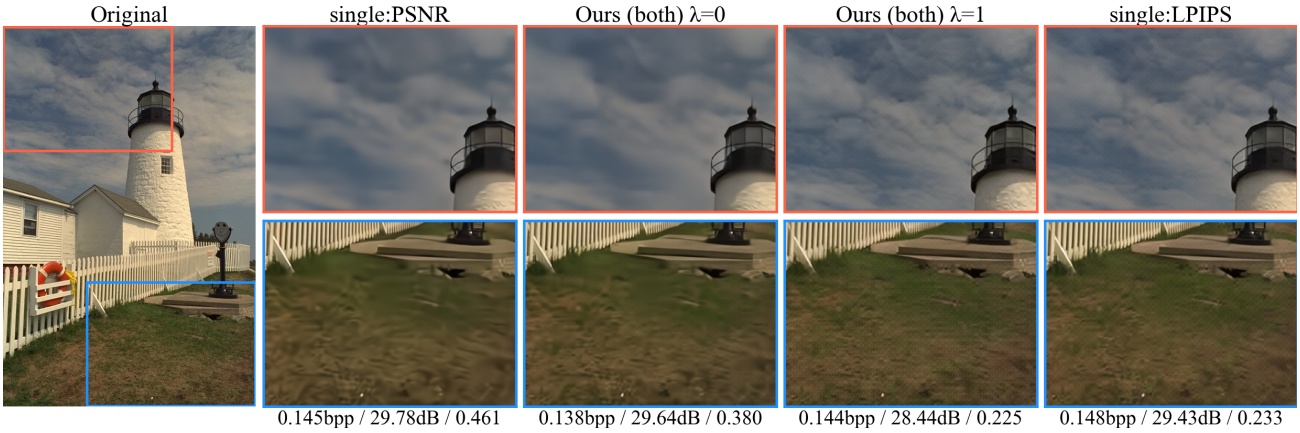
As depicted in Fig. 3, in W-MSA or SW-MSA, both I_i and P_i are arranged into windows of tokens, and the collocated windows are combined in the first step of the (S)W-MSA. Specifically, both the prompt and image tokens are involved in formulating the key and value matrices, whereas the query matrix is derived solely from the image tokens only. The query matrix remains unchanged since only the output of image tokens is propagated and not that of prompt tokens. In symbols, we have

$$\begin{aligned} Q &= I\mathbf{W}_Q \\ K &= [P, I]\mathbf{W}_K \\ V &= [P, I]\mathbf{W}_V, \end{aligned} \tag{1}$$

where P, I collectively refer to the prompt and image tokens in the windows, and $[\cdot, \cdot]$ denotes concatenation along the token dimension. $\mathbf{W}_Q, \mathbf{W}_K, \mathbf{W}_V \in \mathbb{R}^{d\times d}$ are learnable weights projecting the input into query $Q \in \mathbb{R}^{N\times d}$, key $K \in \mathbb{R}^{M\times d}$, and value matrices $V \in \mathbb{R}^{M\times d}$, where d is the number of channels of each token, N is the number of query tokens, and $M = N + \frac{N}{4}$ is the number of key (or value) tokens. Then we perform canonical self-attention as follows:

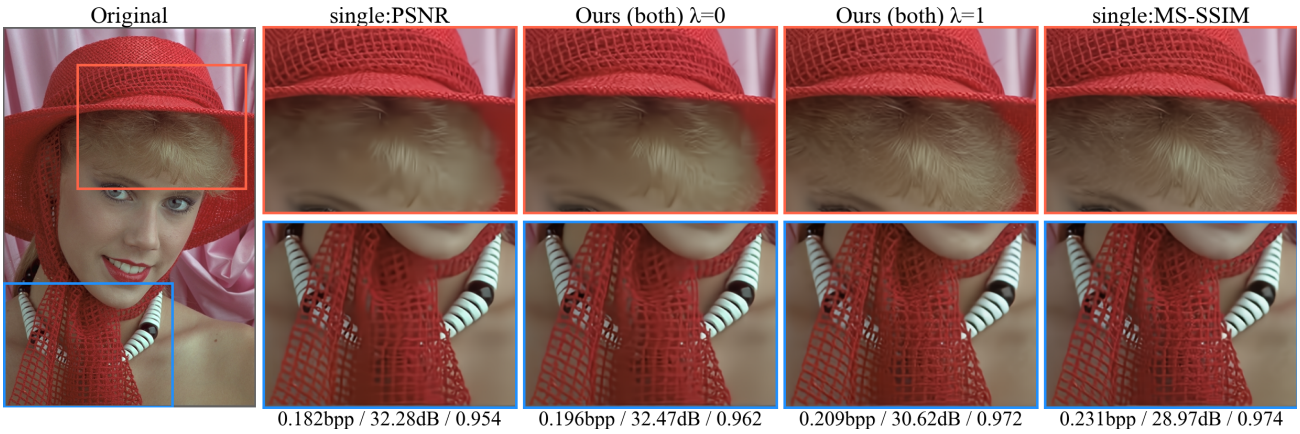
$$\text{Attention}(Q, K, V) = \text{Softmax}(QK^\top/\sqrt{d} + B)V, \tag{2}$$

where B is the learned relative positional bias matrix.



In this work, we explore two variants of the prompt-based conditioning methods for different application scenarios. The first one, both-side prompts, applies prompting to both the analysis and synthesis transforms by introducing G_{enc} and G_{dec}. In this way, the latent y is specialized for one specific trade-off λ. Although the λ needs to be specified before encoding, this approach achieves better rate-distortion performance because of the fully-customized bitstream. The other variant conditions only the decoder, i.e. no G_{enc}, resulting in a shared latent y that can be decoded with different λs. However, it has certain limitations, including showing inferior rate-distortion performance or not being able to adapt on certain cases, which are discussed and compared with both-side conditioning in Section IV.

D. Training Objective



We follow the conventional training objective of learning-based image compression, which involves minimizing a rate-distortion cost, to train our model. In order to adapt between two selected quality objectives, we formulate the loss function $\mathcal{L}$ as

$$\mathcal{L} = R_\lambda \underbrace{(-\log p(\hat{z}) - \log p(\hat{y}|\hat{z}))}_{Rate} + \underbrace{\lambda d_A + (1-\lambda) d_B}_{Distortion}, \tag{3}$$

where d_A, d_B denote the distortion terms corresponding to two selected quality objectives, respectively, and R_λ controls the trade-off between distortion and rate. When λ is set to one, the distortion d_A of the quality objective A dominates the distortion term, resulting in the optimization for the quality objective A only, and vice versa. During training, λ is uniformly sampled

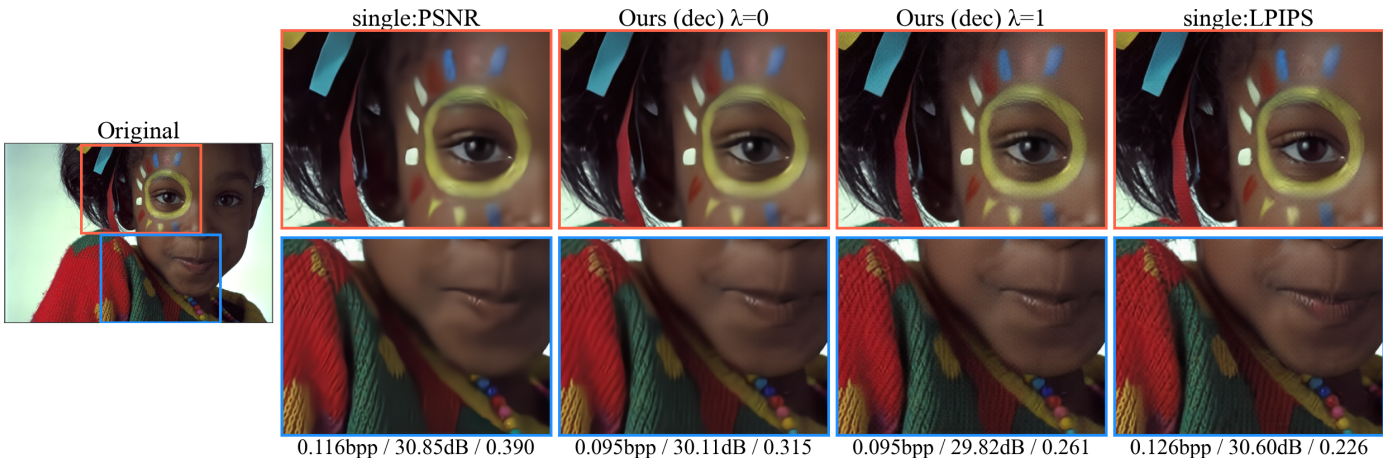
Fig. 8. Subjective quality comparison of single-metric methods and our method with both-side prompts on two pairs of quality objectives. Zoom in for better visualization.

so that the model is able to adapt the coding process to variable image quality objectives.

IV. Experiments

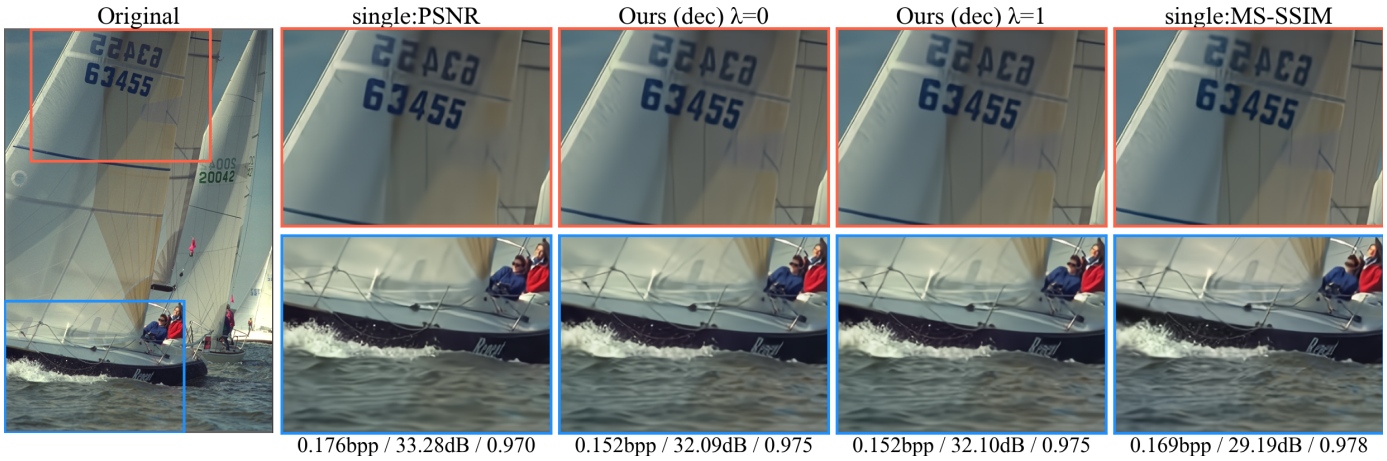
A. Settings

Quality Objectives. In this paper, the two quality objectives selected for adaptation are commonly-used image quality metrics. Specifically, we demonstrate the effectiveness and generalization of our proposed method on two selected quality objective pairs, (LPIPS, PSNR) and (MS-SSIM, PSNR). Note that the two objectives in either pair exhibit distinct differences from each other. Optimizing for PSNR, which is simply minimizing the mean squared error between the reconstructed and original images, leads to blurry decoded images. On the other hand, MS-SSIM considers luminance, contrast, and structure distortions all at once, and LPIPS utilizes a pre-trained VGG network [23] to measure the image distortion in the feature domain. Both MS-SSIM and LPIPS tend to produce subjectively more pleasing results than PSNR. Each quality metric has its own distortion function d, as defined below:



$$\begin{aligned} d_{\text{PSNR}}(x,\hat{x}) &= 0.01 \times \text{MSE}(x,\hat{x}), \\ d_{\text{MS-SSIM}}(x,\hat{x}) &= 25 \times (1 - \text{MS-SSIM}(x,\hat{x})), \\ d_{\text{LPIPS}}(x,\hat{x}) &= 2.5 \times \text{LPIPS}(x,\hat{x}). \end{aligned} \tag{4}$$

By plugging these distortion functions into Eq. (3) as d_A and d_B, we obtain the final training loss function for each objective pair.



Training. For both objective pairs, we first pre-train the base codec (i.e. $N_{enc}, N_{dec}, H_{enc}, H_{dec}$) by optimizing it only for PSNR following [7] on Flicker2W dataset [24]. The resulting PSNR model is then combined with the prompt generation networks G_{enc} and G_{dec} for the next training stage, which jointly trains the entire model end-to-end using the loss function in Eq. (3) and Eq. (4). During training, we choose $R_\lambda = \{5.556, 2.857, 1.493, 0.769\}$, which is the reciprocal of the Lagrange multiplier used in [7] times 0.01. Note that R_λ is associated with the rate term. The trade-off λ is uniformly sampled between 0 and 1.

Evaluation. We evaluate the performance of our proposed method on Kodak dataset [25], which consists of 24 uncompressed images with resolution 512x768 or 768x512. The evaluation is done for both pairs of quality metrics (i.e. PSNR versus LPIPS, and PSNR versus MS-SSIM). When testing our proposed method, we choose $\lambda = \{0, 0.2, 0.4, 0.6, 0.8, 1\}$ to evaluate the capability of the proposed method in fulfilling various quality objectives.

Baselines. We compare the performance of our proposed

(a) (LPIPS, PSNR), the text below each image indicates its BPP/PSNR/LPIPS

(b) (MS-SSIM, PSNR), the text below each image indicates its BPP/PSNR/MS-SSIM

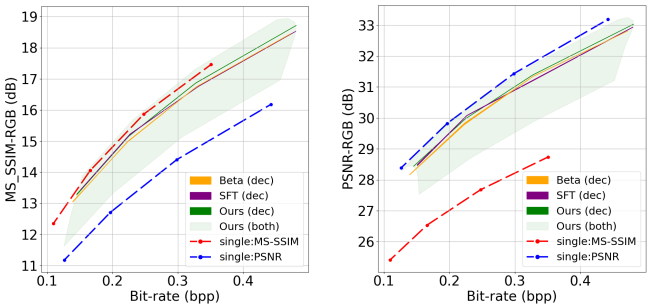


Fig. 9. Subjective quality comparison of single-metric methods and our method with decoder-side prompts on two pairs of quality objectives. Zoom in for better visualization.

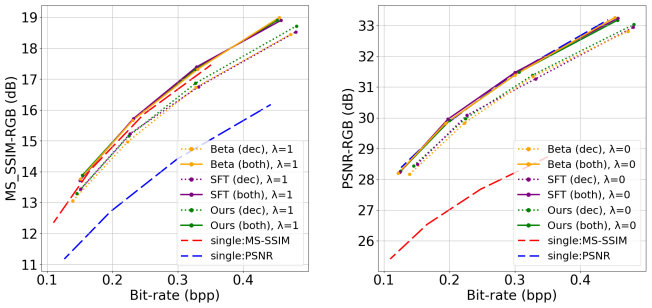
method with various baselines. Firstly, we train our base codec (i.e. $N_{enc}, N_{dec}, H_{enc}, H_{dec}$) by optimizing for a single quality metric, which is denoted as *single:*$\{$*metric*$\}$ (e.g. *single:PSNR*). Note that for *single:LPIPS*, we also include a MSE term during training to prevent instability when solely optimizing for LPIPS. In addition, we compare our prompt-based conditioning method with the existing methods: **SFT** [17] and **beta conditioning** [6]. For a fair comparison, both conditioning methods are implemented on our Swin-Transformer base codec and trained following the same procedure as ours. In the case of SFT [17], we adopt the conditioning networks from [17] and apply affine transformation to the output feature maps of every STB in both the encoder and decoder following [17]. As for the beta conditioning [6], we employ the mapping function and projection to perform channel-wise shifting on the output feature maps of every Swin-Transformer layer in the decoder following [6]. In order to compare with our both-side and decoder-side conditioning methods, we construct a variant of SFT with only the decoder-side condition. Likewise, we develop a variant of the beta conditioning method by applying it to both the encoder and decoder.

B. Performance Comparison for Both-side Prompts



We first examine the compression performance of our proposed method with both-side prompts, where both G_{enc} and G_{dec} are utilized. For the (LPIPS, PSNR) objective pair, Fig. 4 compares the rate-distortion performance of our method with that of the single-metric methods. By adopting different λ values, our method is able to adapt to a wide range of quality objectives (see the green shaded area). When $\lambda = 0$, which translates to optimizing solely for PSNR, our method is able to reach the same performance as the single-metric method *single:PSNR*. Notably, when $\lambda = 1$, our method even outperforms marginally *single:LPIPS*, which is due in part to the increased model capacity. These results suggest that our proposed method has the capability of fulfilling a wide range of image quality objectives with a single model, while performing comparably to or even better than the single-metric methods at the two extreme λs.

Similarly, Fig. 5 shows that our method is capable of effectively trading off MS-SSIM for PSNR. Similar to (LPIPS, PSNR), our method performs comparably or superior to *single:PSNR* on PSNR with $\lambda = 0$ and *single:MS-SSIM* on

(a) MS-SSIM (b) PSNR

Fig. 10. Adaptive range comparison under (MS-SSIM, PSNR) pair with various conditioning methods.

(a) MS-SSIM (b) PSNR

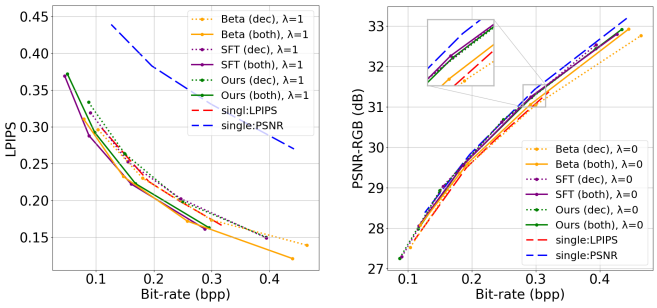


Fig. 11. Rate-distortion performance comparison under (MS-SSIM, PSNR) pair with various conditioning methods at $\lambda = 1$ or $\lambda = 0$.

MS-SSIM with $\lambda = 1$. This demonstrates the versatility of our proposed method, which is able to handle various quality objective pairs with ease and achieve consistently good performance.

Fig. 8 visualizes the decoded images produced by our method and the single-metric methods for both pairs. The variable quality objectives are also reflected on the reconstructed images. For LPIPS and PSNR (Fig. 8(a)), the two methods with higher PSNR (*single:PSNR*, Ours $\lambda = 0$) have smoother images with fewer details, while the other two with low LPIPS (*single:LPIPS*, Ours $\lambda = 1$) shows clearer edges and more refined structures. However, the latter two, when examined closely, have some artificial patterns. This may be attributed to the characteristics of the LPIPS metric. With our proposed method, the undesirable patterns can be reduced through adjusting λ to strike a balance between the two quality objectives, while the single-metric methods have to re-train the entire codec for different objectives. With MS-SSIM and PSNR (Fig. 8(b)), the results are similar. It is observed that ours with $\lambda = 0$ produces blurry reconstructed images with less distinct edges and details. In contrast, ours with $\lambda = 1$ and *single:MS-SSIM* both exhibit sharper and more visually pleasing reconstructed images despite their lower PSNR.

C. Performance Comparison for Decoder-side Prompts

Next, we analyze the compression performance of our method with decoder-side prompts alone, where only G_{dec} is utilized. Fig. 6 presents the rate-distortion results of the

(a) LPIPS (b) PSNR

Fig. 12. Rate-distortion performance comparison under (LPIPS, PSNR) pair with various conditioning methods at $\lambda = 1$ or $\lambda = 0$.

(LPIPS, PSNR) objective pair. While our method is still able to adjust the reconstructed quality with different λ values, the range of adaptation is relatively smaller in comparison with the both-side results shown in Fig. 4. At the two extreme λ values, the adapted results barely match the rate-distortion performance of the single-metric methods. This observation may be attributed to the removal of G_{enc}, thereby producing a single bitstream that needs to be decoded at different λ values.

Fig. 7 presents the rate-distortion results on the (MS-SSIM, PSNR) objective pair. Contrary to the previous results with both-side prompts, the rate-distortion performance remains somewhat fixed regardless of the given λ, with all six curves coinciding with each other. This indicates that when relying only on the decoder for adaptation, our method is unable to trade off PSNR for MS-SSIM. This result suggests that there exist some metric pairs where the metrics involved are incompatible with each other in the sense that when a single bitstream is used, the decoder-side only adaptation is not able to fulfill variable quality objectives. We further verify this through experiments with the other conditioning methods in the next section.

Fig. 9 presents the subjective quality comparison of decoded images obtained through the single-metric methods and our method on both pairs of metrics. For LPIPS and PSNR, our method with $\lambda = 1$, which corresponds to optimizing for LPIPS, displays richer details but also exhibits more prominent artificial patterns, the result of which is similar to *single:LPIPS* (Fig. 9(a)). In contrast, $\lambda = 0$ and $\lambda = 1$ produce nearly identical images on MS-SSIM and PSNR (Fig. 9(b)).

D. Comparison with Competing Methods

In this section, we compare our proposed method with the other conditioning methods, namely SFT [17] and beta conditioning [6]. First, we focus on the failure case with decoder-side prompts on MS-SSIM and PSNR, and test both baselines under the same setting of decoder-side only conditioning. Fig. 10 illustrates the effective range of adaptation. It is apparent that all methods using decoder-side only conditioning are unable to display any substantial adaptation range, which is a direct contrast to our variant with both-side prompts. This further indicates that the failure to adapt between MS-SSIM and PSNR lies in the combination of these objectives rather

than the proposed conditioning method.

Fig. 11 and Fig. 12 further compare the rate-distortion performance of all the methods at $\lambda = 1$ and $\lambda = 0$ under the both-side and decoder-side settings. For the (MS-SSIM, PSNR) objective pair, Fig. 11 shows that while all three methods with the both-side conditioning show similar performance on both metrics, our proposed prompt-based method outperforms SFT [17] and the beta conditioning [6] when using the decoder-side only conditioning. This suggests that prompting offers a better means to condition Swin-Transformer-based models. As for the (LPIPS, PSNR) metric pair, Fig. 12 shows that the beta conditioning performs the best in terms of LPIPS; however, it exhibits a significant drop in PSNR under the both-side and decoder-side settings. On the other hand, although SFT achieves a slight gain over our method in terms of LPIPS with the both-side prompts, we note that SFT introduces considerably higher complexity than our method, adding nearly 15 million model parameters as opposed to 6 million with our scheme. Overall, our proposed method strikes a better balance among the adaptation capability, rate-distortion performance, and complexity.

V. Conclusions

In this paper, we propose a practical yet efficient solution for adapting to variable quality objectives in image compression, which is achieved through inserting model-generated prompts into the Swin-Transformer based codec. It offers superior performance compared to existing methods and demonstrates consistent results across different quality objective pairs. We additionally explore two variants of our proposed method and compare them in terms of performance and applications. The ability to trade off one quality objective for another using a single model, without the need for retraining, makes our method highly versatile and applicable to a wide range of scenarios.

***Abstract*—One of the major challenges in developing deep learning models for automatic retail stores is the availability of diverse and accurate data. Achieving high accuracy requires a large amount of data that is specifically collected and labeled for the task at hand. However, this process is time-consuming and prone to potential errors during labeling, which can affect model training. To mitigate this challenge, data augmentation methods have been widely adopted to train models when data is limited. However, the effectiveness of data augmentation is not always guaranteed, as it still relies on the original data. To address this limitation, a new approach has been developed that utilizes synthetic data generated through 3D scanning of objects. However, the challenge lies in ensuring that this synthetic data accurately represents real-world data to maintain model accuracy. In this paper, we propose an approach that integrates adversarial learning into the YOLOv8 model and trains it using synthetic data. We then apply this method to automatic retail stores to demonstrate its efficacy in real-life scenarios. Experimental results on the AIC-22 dataset reveal significant improvements compared to the original YOLOv8 version. The proposed approach achieves around 6.7% increase in precision, a 7.1% improvement in recall, and a 10.3% enhancement in mAP while maintaining the same inference speed of 127 fps on the RTX 3090Ti.**

Index Terms—object detection, domain adaptation, automatic retail stores

I. Introduction

Currently, traditional methods such as bar-code or QR-code scanning are still widely used at payment counters, but they are not highly efficient or fast. This is evident from the long queues of customers waiting at supermarkets and convenience stores. To address this issue, various studies have been conducted, including the use of image processing to recognize products within enclosed chambers [1]. However, this method is not fast as it can only identify one product at a time, as depicted in Figure. 1. Moreover, it does not provide a user-friendly experience when implemented at payment counters, resulting in its limited popularity.

Another approach involves leveraging deep learning models and cameras to identify products while customers are still holding them. This solution focuses on developing the model and dataset rather than requiring complex hardware setups. However, deep learning models rely on large and accurate datasets, which can be time-consuming and labor-intensive to create. As an alternative, synthetic data [2] has been considered, as it can be automatically generated and is independent of the original data. Synthetic data enables the creation of a sufficiently diverse and minimally erroneous dataset. However, effectively utilizing synthetic data poses a challenge due to the differences between synthetic and real-world images, particularly in terms of domain dissimilarity, which affects accuracy.

Fig. 1. The isolated condition (left) and the real-life condition (right)

To overcome this limitation, a novel approach is proposed in this paper, which incorporates domain adaptation techniques. The proposed method combines the GAN idea [3] with the YOLOv8 framework [4] during the training process to enhance object detection accuracy using synthetic data. The key idea is to identify the shared domain, which represents the common features between synthetic and real data, and enable the model to extract real features within the synthetic domain. In this approach, GAN is responsible for determining these domains, which subsequently guides YOLOv8 to learn from the identified shared feature domain. As a result, the model is trained solely on synthetic data but performs effectively on real-life data through unsupervised domain adaptation for object detection.

By utilizing synthetic data, the need for a large labeled dataset is eliminated, reducing the time and cost associated with data collection and labeling. The combination of GAN

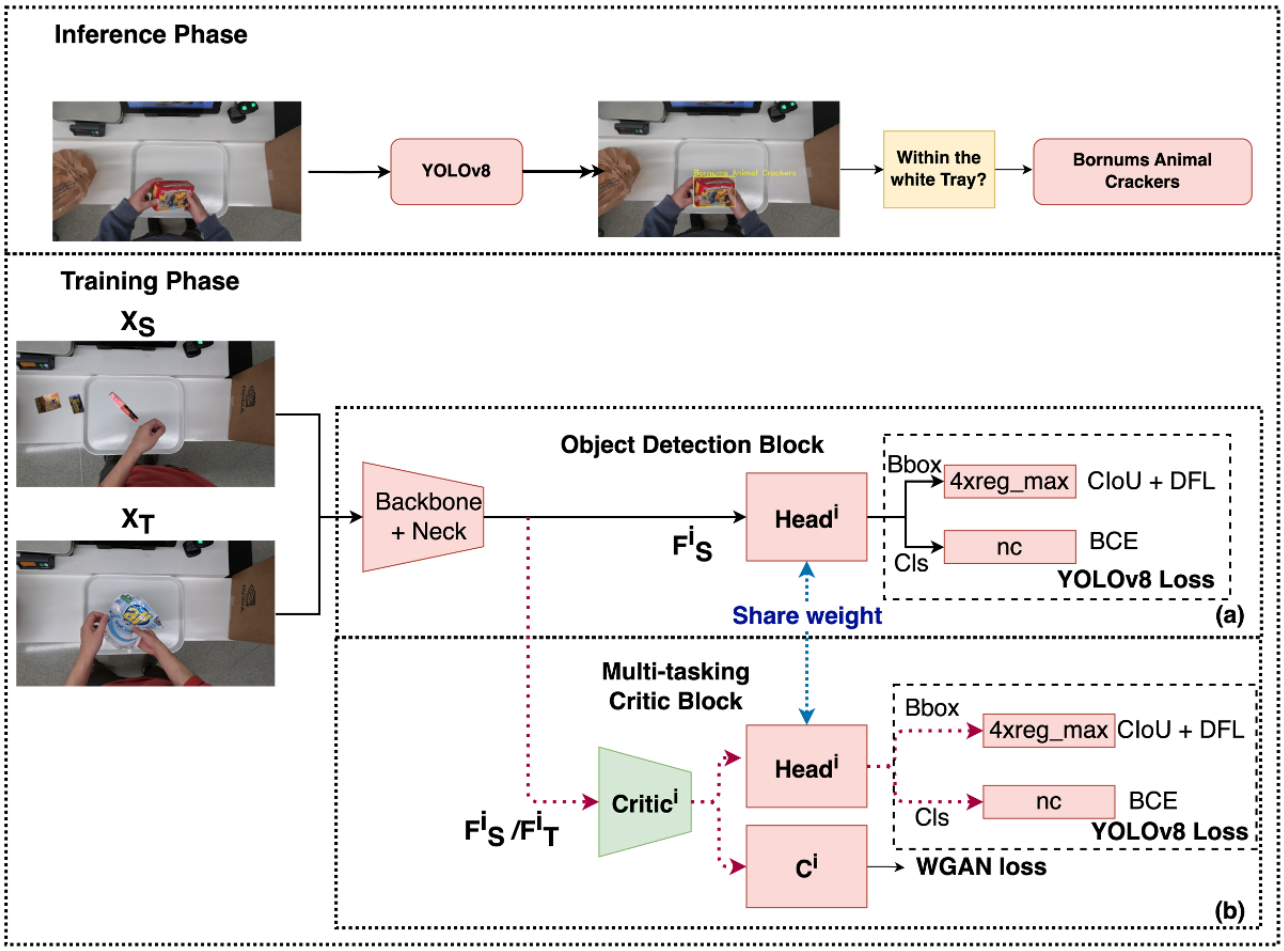

Fig. 2. The overall system

and YOLOv8 during training enhances the accuracy of object detection, thereby improving the reliability of the system. Additionally, the use of unsupervised domain adaptation ensures that the model performs well on real-life data, further enhancing its efficiency in a retail environment. In summary, our contributions can be summarized as follows: (1) integrated adversarial learning into YOLOv8 framework for automatic retail system; (2) proposed multi-critic framework to embed the idea of WGAN into existing multi-head detection networks; (3) Proposed a multi-tasking Critic structure to solve the problem of domain adaptation in object detection and recognition applications.

II. Proposed Method

As shown in Fig. 2, our proposed system utilizes the YOLOv8-based Detection model, which is then enhanced through the application of a domain adaptation technique. Due to the inherent differences between the synthetic and real feature domains, if the detection model is only trained on the synthetic domain, it cannot perform well on the real domain. Domain adaptation allows for the transfer of knowledge from a well-trained source domain to a related target domain. To achieve this, we employ an adversarial learning strategy inspired by generative adversarial networks (GANs) to minimize the domain discrepancy. This strategy aims to generate source and target feature distributions that are indistinguishable from a well-trained domain discriminator. By incorporating these techniques, our method not only improves the performance of the YOLOv8 model during training with synthetic data but also maintains the inference speed. It is important to note that the training phase and the inference phase have different architectures. In order to simplify the process, the region of interest (ROI) is fixed. During inference, if any product is detected by YOLOv8 within the ROI, the system generates an output containing the product name. In the following sections, we will provide a detailed explanation of each block in the system design.

A. Object Detection Block with Multi-Critic based Adversarial Learning

As mentioned previously, during the training phase, only the synthetic dataset is utilized. To address the domain discrepancy between real and synthetic images, an adversarial learning technique, specifically WGAN [5] [6], is employed. This tech-

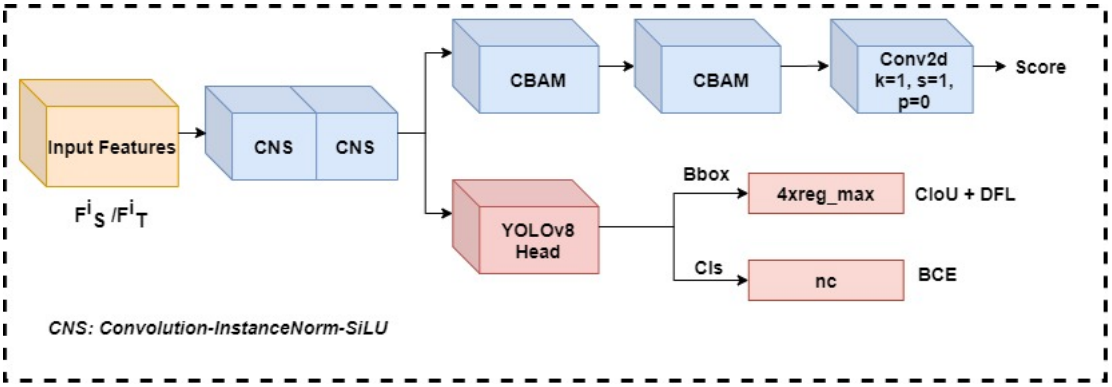

Fig. 3. The Multi-tasking Critic architecture

nique aims to minimize the feature domain differences between the real and synthetic images during training. The training architecture is illustrated in Fig. 2. In the architecture, X_T and X_S represent real images (target domain) and synthetic images (source domain), respectively. F_T^i and F_S^i correspond to the features extracted from the Backbone and Neck of YOLOv8 for the real and synthetic images. The variable i denotes the serial number of YOLOv8's Head. In this paper, in order to both minimize the difference on feature domains with different scales and have a framework suitable for multi-head detection system, we apply adversarial learning on all Heads of YOLOv8. Therefore, each Head will have a corresponding Critic module. The structure of these Critic modules is the same as shown in Fig. 3, so for the sake of simplicity, we only present one Critic module and one YOLOv8's Head in Fig. 2. With the incorporation of the WGAN technique, the total losses of YOLOv8 are transformed as shown in (1). YOLOv8 network will be trained to minimize this Loss function in order to both solve the detection and recognition problem, and to be able to extract common features between the two domains of synthetic and real images.

$$Det_{Loss} = YOLOv8_{losses} + \gamma_1 * Adv_{loss}, \quad (1)$$

where, $YOLOv8_{losses}$ is the original loss of YOLOv8 [4] as in (2), it is used to help the model still work on the detection task. Adv_{loss} is the loss of WGAN as calculated in (3) to make sure features extracted by YOLOv8 from real and synthetic images are not so different, γ_1 is the balance factor between $YOLOv8_{losses}$ and Adv_{losses}.

$$YOLOv8_{losses} = L_{CIOU} + \alpha_1 * L_{DLF} + \alpha_2 * L_{BCE}, \quad (2)$$

where, L_{CIOU} [7] is used to guide the predicted bounding box towards the ground truth, while L_{DLF} [8] is introduced to encourage the network to build a general distribution for that bounding box. This means introducing uncertainty about the boundaries of the object in the dataset into the learning process. L_{BCE} is the binary cross-entropy loss classification loss proposed in [9] to establish information connection between the classification task and the object detection task during training. α_1 and α_2 are the balance weights.

$$Adv_{loss} = \frac{1}{3}\sum_{i=1}^{3}[\mathbb{E}_{F_S^i} C^i(F_S^i) - \mathbb{E}_{F_T^i} C^i(F_T^i)]. \quad (3)$$

In (3), $C^i(F_S^i)$ and $C^i(F_T^i)$ are the scores, evaluated by i^{th} Critic model, assigned to synthetic and real features extracted from the i^{th} YOLOv8's Head, respectively. YOLOv8 has 3 Heads corresponding to 3 different scales, so our network architecture will also have 3 Critics and we will average the scores evaluated from these critics.

B. Multi-tasking Critic Block

The Critic will work opposite of YOLOv8, it will take the features from YOLOv8 and try to evaluate whether the feature is from real or synthetic images. Therefore, the objective of Critic will be opposite of YOLOv8 as shown in (4), the plus sign in formula (1) is replaced by a minus sign to maximize the difference between real and synthetic features. Thus, if the YOLOv8 can extract features that fool the Critic, those features will be able to represent both image domains, and when the YOLOv8 performed well on synthetic data, it will also work well on real data. The Critic model is designed to be compatible with the speed and learning capabilities of YOLOv8 as shown in Fig. 3, which include 2 blocks CNS (Convolution - InstanceNorm - SiLU) for extract features, then those features are fed into 2 branches for two different tasks. Therefore, we have named our Critic model as the multi-tasking Critic to reflect its ability to perform multiple tasks simultaneously. The first one consists of 2 CBAM Block [10] (Convolution Block Attention Module) and a final Convolution layer with a kernel size of 1, stride of 1 and no padding. The second brand is copied directly from YOLOv8's Head. Our design is quite different from the traditional Critic design, which has only a first branch, because the nature of our problem is different from the traditional problem. In the traditional problem, the feature of the whole image is taken into account when trying to minimize the difference between the two regions. But in our problem, the synthetic image is created by stitching the synthetic objects into the real background. Therefore, to orient the Critic to focus only on evaluating features extracted from

objects, a second branch is added. This results in the Loss Function for the multi-tasking Critic still consisting of two components as shown in (4). With a small network capacity as shown in Fig. 3, in order to perform well on both tasks in the loss function (4), the multi-tasking Critic is forced to focus solely on extracting and evaluating object features without considering the presence of the background.

$$Critic_{Loss} = YOLOv8_{losses} - \gamma_2 * Adv_{loss}, \quad (4)$$

C. Inference

During the training, the Critic will be added to the system to train the YOLOv8 on synthetic data. However, during inference, the Critic is removed from the system, and only the detection block is retained, as shown in Fig. 2. This ensures that the system maintains the fast inference speed of the original YOLOv8 while also improving performance. During testing, a real image is input into the system, and after passing through YOLOv8, the object's location is obtained. If the object falls within the fixed ROI, the system outputs the object's name.

III. Experiment Results

A. Dataset details

The training data used in this study was provided by NVIDIA as part of the AIC22 Track 4 dataset [2] [11]. This dataset consists of 116,000 images, each accompanied by its corresponding mask. Each image represents a single object and is classified into one of 116 classes. These images are generated from 3D scanned models of objects, as illustrated in Fig. 4. The dataset covers a wide range of conditions, including variations in brightness, resolution, orientation, and environmental noise.

However, the provided synthetic data is not directly suitable for training an object detection model since the objects are presented separately. To address this, preprocessing steps were performed to generate a dataset suitable for object detection. First, product images and their corresponding masks were randomly selected and merged onto backgrounds obtained from video clips that did not contain any products. This integration process resulted in a final dataset image, as shown in Fig. 4. Additionally, histogram equalization was applied to address brightness variations, ensuring consistent lighting conditions across the images.

To address class imbalance, the number of occurrences for each class was limited to 100. This approach prevents certain classes from dominating the training data and helps maintain class distribution balance. As a result, the training dataset consists of approximately 7,500 images, with each image containing 3 to 5 products. The validation set followed the same approach and consists of around 2,000 images.

In contrast, during the testing phase, a real-world dataset extracted from video clips of payment scenes is utilized. This dataset, also provided by NVIDIA, encompasses over 100 different types of products. In the video clips, the camera is positioned above the checkout counter, facing downwards, while a customer mimics the checkout process by naturally "scanning" objects placed in front of the counter. To represent the testing area for the AI model, a white tray is placed beneath the camera. Each video clip captures one or more complete scanning actions involving multiple items. For the testing set, frames were extracted from the video clips and manually labeled. This process ensures that each image in the testing set is annotated with the corresponding groundtruth labels. The testing set consists of approximately 1,500 images.

Fig. 4. The provided dataset (left) and the dataset for detection (right)

B. Implementation details

The outstanding dedication of the Ultralytics [4] team has played a significant role in achieving the impressive performance of the YOLOv8 model. Therefore, the author has selected this model as the target for improvement in terms of accuracy and as the baseline for modifying the training architecture to align with the proposed method.

To enhance the training process, several techniques are employed with the Critic model. These include the use of the RMSprop optimizer with an initial learning rate of 1e-3, an alpha value of 0.99, and weight sharing between the Head of YOLOv8 and the Head of Critic. Besides, the proposed loss is balanced by assigning specific balance weights: γ_1 is given a weight of 10, γ_2 a weight of 100, α_1 a weight of 0.2, and α_2 a weight of 0.06. The training procedure of the proposed network is followed as in [5].

C. Results

The final results are shown in Table I, which used Precision, Recall, and mAP50-95 for evaluation. The term 'Source only' refers to the model training without adversarial learning, the symbol w means that the weight between YOLOv8's Head and the critic's Head is shared, m means that the mixup augmentation method is implemented to augment the training data. It is easy to see that training with adversarial learning greatly enhances precision and mAP. However, it is important to note that the system starts to focus more on minimizing the difference between the features of the objects, instead of the background, only when the head weights of YOLOv8 and Critic are shared and the data is augmented. This leads to a significant increase in the Recall rate. Overall, the proposed system achieves an increase of approximately 6.7% in precision, a 7.1% improvement in recall, and a 10.3% enhancement in mAP compared to the baseline model with the same settings, this demonstrates the effectiveness of our approach in improving object detection accuracy. Moreover,

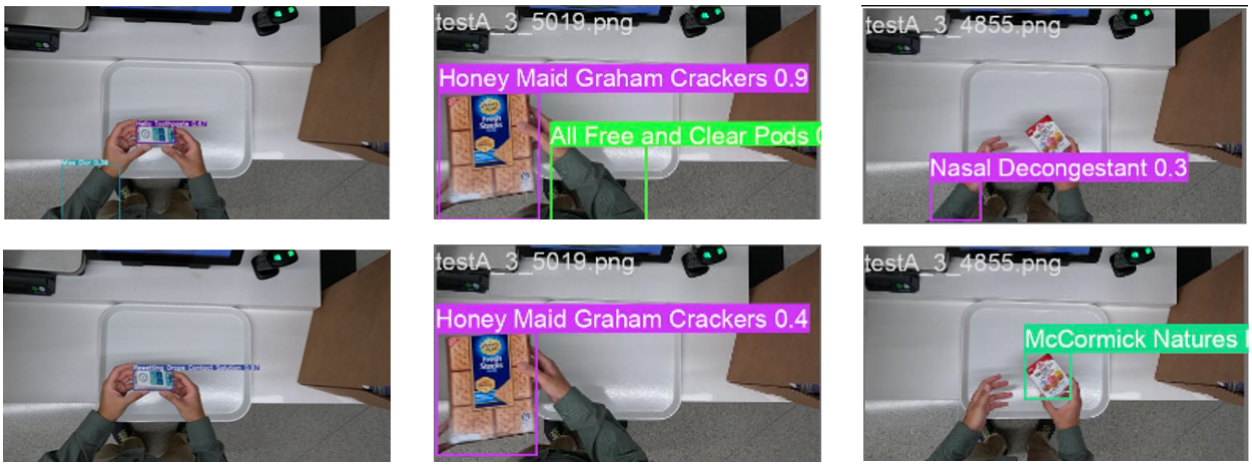

Fig. 5. Compare results between original YOLOv8 (first row) and Our method (second row)

our system is fully trainable as semi-supervised learning by adding some labeled real data to the training dataset. Table II demonstrated that by adding only 10% of the real labeled data, the system performance was increased dramatically. This proves a problem that, the proposed method helps to build the automatic retail stores system more effectively, we can completely pre-train the system with sythetic data, then it only takes a very small amount of effort to label the real data and we can have a system with very high accuracy.

TABLE I
COMPARISON OF PROPOSED METHOD WITH BASELINES USING UNSUPERVISED TRAINING

Method	Learning style	Precision	Recall	mAP50-95
YOLOv8	Source only	0.660	0.496	0.409
YOLOv8^{m}	Source only	0.708	0.578	0.470
Our	Unsupervised	0.723	0.501	0.451
Our^{w}	Unsupervised	0.762	0.539	0.495
Our$^{w\ m}$	Unsupervised	**0.775**	**0.649**	**0.573**

TABLE II
COMPARISON OF PROPOSED METHOD WITH BASELINE USING SEMI-SUPERVISED LEARNING

Method	Learning style	Precision	Recall	mAP50-95
YOLOv8^{m}	10% labeled real data	0.924	0.826	0.784
Our$^{w\ m}$	10% labeled real data	**0.935**	**0.887**	**0.831**

For an intuitive look, the results of the visual comparison between the proposed method and the baseline are shown in Fig. 5. It is easy to see that, when adversarial learning is not integrated, the baseline often confuses the objects to be detected with the human hand. This is understandable, because the baseline is only learned with synthetic data, and it is possible that the human hand in the test image is quite similar to the characteristics of a certain object in the synthetic data. By using adversarial learning, the proposed system tries to find the most common features between real and synthetic objects, thereby excluding these cases. However, our system still has some cases of mis-classification and mis-detection as shown in Fig. 6. In the image on the top, the shopper's hand accidentally came close to the shoes, resembling the act of holding an object, and the shape of the shoes now bears a striking resemblance to Advil Liquid Gel, leading to a false detection by our system. However, this problem can be completely eliminated at the post-processing stage, since the detected object is outside the ROI (white tray) area. In the image on the bottom, the shopper's right hand covers most of the object when passing it from one hand to the other, resulting in the system not being able to detect the object. And this can also be solved because in the next few frames, the shopper has to show the object to the camera.

Fig. 6. Some failure cases

IV. Conclusion

In conclusion, this paper addresses the challenge of limited data for training deep learning models by proposing a novel approach that integrates Adversarial Learning into the YOLOv8 model. The approach utilizes synthetic data generated through 3D scanning of objects, aiming to overcome the limitations of traditional data augmentation methods. The study demonstrates the effectiveness of the proposed method in improving model accuracy and performance. Experimental results on the AIC-22 data-set showcase a 6.7% increase in precision, a 7.1% improvement in recall, and a 10.3% enhancement in mAP compared to the original YOLOv8 version. Importantly, these improvements are achieved without sacrificing inference speed, with the model reaching an impressive 127 fps on the RTX 3090Ti. The practical application of this method in automatic retail stores further validates its real-life efficacy. By leveraging synthetic data and integrating Adversarial Learning, this approach presents a promising solution to the data limitations faced by deep learning models, paving the way for enhanced accuracy and performance in various applications.

Abstract — **Owing to the rapid growth of the e-commerce industry, image-based virtual try-on has emerged as a popular research topic in recent years. Despite the introduction of multiple approaches to achieve this concept, there remains ample scope for research and improvement. In this regard, Generative Adversarial Networks (GANs) demonstrate a framework possessing immense potential for subsequent development. Nonetheless, the generated images reported in the literature often manifest blurred edges between semantic regions, thereby diminishing the credibility of results. Furthermore, the generation of try-on images may retain the original shape of the upper body clothing on the model mistakenly, such as the length and tightness of the torso, rather than adapting to the shape of the target clothing. In this paper, we propose a more comprehensive architecture to overcome the limitations of GAN-based approaches, which includes the following contributions. First, we introduce a new parsing and context generator that takes into account the warped binary mask of the geometric matching image of the target clothing. The outputs of this generator incorporate the generation of human parsing images that correspond to the generated try-on images. Moreover, we have designed a novel discriminator group that is specifically focused on judging whether the generated image is a reasonable representation of the specific clothing being worn. According to the experimental results, our method effectively exhibits better synthesis quality and remedies the common challenges encountered while using GANs for virtual try-on.**

I. INTRODUCTION

In the passage of recent years, the e-commerce industry has shown a swift and pronounced expansion, characterized by a growing number of individuals migrating towards online outlets for their routine acquisitions, including apparel [1]. Yet, online clothing purchases harbors a glaring disadvantage when compared with conventional retail experiences: the lack of physical interaction with prospective purchases. This absence of tangible evaluation escalates the likelihood of consumers seeking refunds upon realizing that their ordered garments fail to fulfill their initial visualized expectations. Such circumstances incited the inception of "Virtual Fitting Rooms," a concept offering the potential for online consumers to visualize their appearance in a selected item whilst navigating digital catalogues.

Image-based virtual try-on techniques have emerged as an exceptionally viable alternative [2], outshining methods like 3D modeling [3, 4, 5], owing to their non-reliance on costly hardware and graphics rendering equipment. These methodologies predominantly aim to fabricate try-on images by utilizing two inputs: an image of the potential wearer and another of the selected attire, endeavoring for maximal authenticity. The assessment of a virtually generated try-on image's efficacy fundamentally revolves around three cornerstones: 1) the ability of the image to retain the target individual's identity adequately, 2) the faithfulness of the texture or patterns of the synthesized garment to the target item, and 3) the degree to which the shape of the generated clothing aligns with the target item. Overlooking any of these critical elements would substantially jeopardize the integrity of the resulting images.

Particularly, C-VTON [6] demonstrates proficiency in preserving garment textures and patterns, achieved through the incorporation of an image warping phase within its proposed architecture, and context aware normalization—a technique that empowers the generator in the GAN [7] structure to utilize image context and furnish it with essential contextual insights. Nonetheless, the clothing shapes in its outcomes frequently fall short of authenticity as they tend to echo the shapes of the garments worn in the target person image, demonstrating less

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

sensitivity to distinct shape attributes such as fit, length, and neckline.

In response to these challenges, this paper introduces the Parsing and Context Driven Virtual Try-On Network (PC-VTON), an architectural innovation inspired by C-VTON. This model encompasses an advanced parsing and context generator that factors in the warped binary mask of the geometric matching image of the target attire. The outputs of this generator facilitate the creation of human parsing images that synchronize with the generated try-on images. Additionally, we have proposed an unprecedented group of discriminators, purposefully dedicated to determining whether the generated image accurately mirrors the specific attire depicted. As affirmed by our experimental findings, our methodology exhibits superior synthesis quality, effectively counteracting the commonplace obstacles faced when leveraging GANs for virtual try-on applications.

II. Related Work

This section provides an overview of significant contributions in the field, classifying them into three categories: techniques involving a garment warping stage, methods utilizing latent space interpolations, and approaches employing separate encoding of distinct features. By analyzing these categories, we aim to recognize both the strengths and weaknesses that define existing methodologies, setting the stage for the introduction of our novel approach.

A. Techniques Involving a Garment Warping Stage

SwapNet [8] embodies a two-tier process. Initially, a warping network is employed to align the garments with the pose of the potential wearer. Subsequently, a U-net architecture is deployed to generate the virtual try-on image. Although it manages to spawn a variety of poses, the system is constrained to a coarse generation of clothing content, compromising the precise replication of patterns or designs.

ACGPN [9] enhances the performance of the generator network by comparing network-generated garments with their warped counterparts, utilizing pixel-to-pixel L1 loss as a better reference. This, coupled with perceptual losses such as VGG loss, results in improved outputs. The dataset requires both pose information and product images of the garments. The technique manages to faithfully recreate clothes with text or patterns, but its effectiveness decreases in other domains, such as the replication of body parts and clothing shapes.

CP-VTON [10] incorporates a fully learnable Thin-Plate-Spline transformation [11] in its geometric matching stage. This approach demonstrates better alignment with the target body pose, especially when compared to prior works that often relied on hand-crafted keypoint-based shape matching. However, in its try-on module, which employs a U-Net architecture, the system does not directly produce an image of the target person wearing the desired clothing. Instead, it pastes the try-on clothing onto the target person using a generated clothing mask.

C-VTON [6] leverages a two-tier generative adversarial network structure to enable virtual try-on functionality. The first stage involves a Body-Part Geometric Matcher (BPGM) mapping product images of clothes onto a given human pose via an unconventional geometric method. The subsequent stage's generator utilizes the output of BPGM, densepose information of the human pose, and the original image (with the upper garment region excised) to generate a virtual try-on image. While this technique succeeds in accurately reproducing patterns and texture of the try-on items, its performance is less than satisfactory in terms of shape restoration (e.g., fit and length).

B. Methods Utilizing Latent Space Interpolations

VOGUE [12] constructs try-on images by interpolating and generating images in latent space of a StyleGAN [14] network with the assistance of produced human parsing images, based on the images of the individual and the clothing being tried on. Despite its potential, this approach could lead to an amalgamation of the target clothing with the attire originally worn by the model, thereby inducing inaccuracies in texture and pattern details.

FashionTex [13] seeks to condition virtual try-on image synthesis using both text and texture. By harnessing the generative capabilities of a pretrained StyleGAN [14], it maps input images into the model's latent space using an e4e encoder [15]. The system further introduces a latent code editor conditioned by text and texture embeddings. While it can generate fashion images influenced by text and texture, its omission of clothing product images as a synthesis constraint prevents it from serving as a comprehensive virtual try-on solution.

C. Approach Employing Separate Encoding of Distinct Features

ADGAN [16] segments and concatenates the encoded style codes of diverse parts from the human parsing. Upon applying

these codes to a particular human pose via an AdaIN layer, it spawns images of the person adopting the specified posture. By swapping the encoded part of the upper garment in the style code, the effect of changing clothes is enabled. However, it can only roughly replicate the shape and pattern of the attire.

III. The Proposed Methods

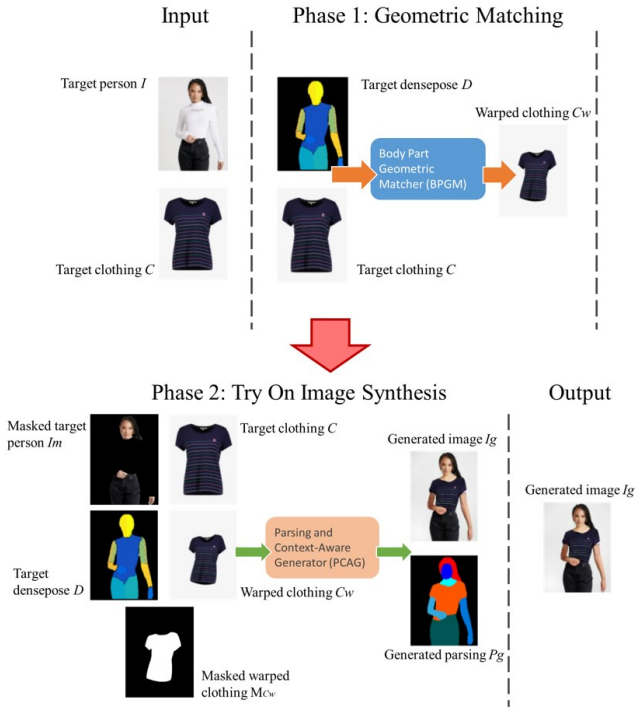

Fig. 1 Overview of the proposed PC-VTON architecture.

This research introduces the Parsing and Context Driven Virtual Try-On Network (PC-VTON), a dual-phase virtual fitting framework, consisting of Phase 1: Clothing Image Warping and Phase 2: Virtual Try-On Generation. The process flow is depicted in Fig. 1. In Phase 1, the targeted attire's image is warped to align with the densepose representation of the prospective wearer's body posture. Subsequently, the warped garment image, obtained from Phase 1, is processed through a generator, accompanied by auxiliary information, including a masked RGB image of the target person, a densepose image of the target person, an unwarped frontal image of the clothing item, and the binary mask image of the warped clothing item, in Phase 2. Ultimately, the generator produces a virtual try-on image showcasing the subject wearing the targeted attire.

A. Phase 1: Clothing Image Warping

The proposed PC-VTON architecture employs the BPGM [6] for the first phase. The BPGM, shown in Fig. 2, processes a densepose image and a frontal view clothing item image, encoding them with two dedicated encoders, E_1 and E_2, into feature representations $\psi_{E_1} \in \mathbb{R}^{d_f \times w_f \times h_f}$ and $\psi_{E_2} \in \mathbb{R}^{d_f \times w_f \times h_f}$, where w_f and h_f represent the spatial dimensions of the feature representations, and d_f signifies the number of output channels. The feature representations are subsequently normalized channel-wise into a unit L2 norm, spatially flattened, and restructured into a matrix $\psi_{\{E_1,E_2\}} \in \mathbb{R}^{d_f \times w_f h_f}$, serving as the basis for computing the correlation *Corr* between the two feature representations.

$$Corr = \psi_{E_1}^T \psi_{E_2} \in \mathbb{R}^{(w_f h_f) \times (w_f h_f)} \quad (1)$$

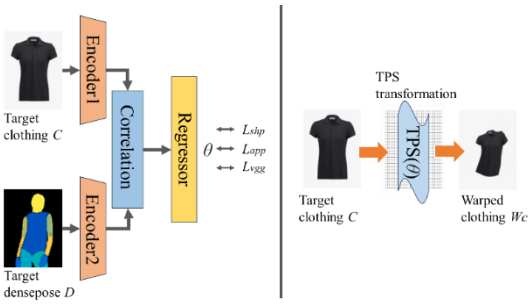

Fig. 2 Workflow of the Body-Part Geometric Matcher.

The correlation matrix is then processed through a regressor that predicts the Thin-Plate-Spline (TPS) transformation [11] parameters θ, a $2n^2$ dimensional vector accounting for the x and y offsets of an $n \times n$ grid, symbolizing how the frontal view clothing item image should be warped to conform to the provided densepose image. The BPGM's parameters are trained according to the following metrics:

- The shape loss L_{shp} calculates the L1 loss between the mask image of the warped frontal view clothing item and the clothing region's mask of the source person image I, i.e.:

  $$\mathcal{L}_{shp} = \|M_w - M_c\|_1 = \|T_\theta(M_f) - M_c\|_1 \quad (2)$$

  where M_c is the mask of the clothing item region in I; M_w is the mask of the warped frontal view of the clothing item; M_f is the mask of the frontal view of the clothing item and T_θ is the TPS transformation with parameters θ.

- The appearance loss L_{app} compares the image content of the torso area in the warped clothing item image C_w and the source person image I, i.e.:

  $$\mathcal{L}_{app} = \|C_w \odot M_t - I \odot M_t\|_1 \quad (3)$$

  where M_t is the binary mask of the torso, and $\odot$ is the Hadamard product operation.

- The perceptual loss L_{vgg} compares the high-level differences, such as image content, between the warped

clothing item image C_w and the source person image I, i.e.:

$$\mathcal{L}_{vgg} = \sum_i^m \lambda_i \|\Phi_i(C_w \odot M_t) - \Phi_i(I \odot M_t)\|_1 \quad (4)$$

where Φ_i is a feature map generated before each max-pooling layer (before $m = 5$) of a pretrained VGG19 model, and λ_i is its corresponding weight.

Thus, the BPGM is optimized to minimize the following joint loss function:

$$\mathcal{L}_{BPGM} = \lambda_{shp}\mathcal{L}_{shp} + \lambda_{app}\mathcal{L}_{app} + \lambda_{vgg}\mathcal{L}_{vgg} \quad (5)$$

where λ_{shp}, λ_{app}, λ_{vgg} represent the respective weights of the three loss functions in order.

B. Phase 2: Virtual Try-On Generation

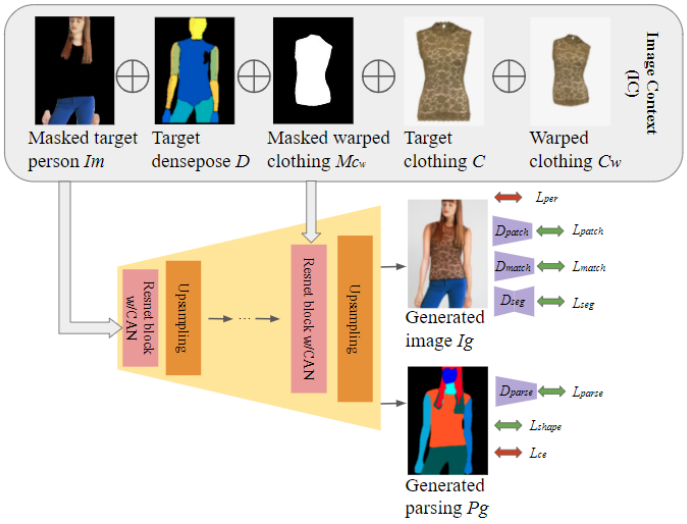

Fig. 3 Overview of the proposed PCAG in phase 2.

Phase 2, the proposed try-on image synthesis phase, adopts a GAN structure comprising a single generator, the Parsing and Context Aware Generator (PCAG), and four discriminators, which forms a discriminator group: the segmentation discriminator (D_{seg}), the match discriminator (D_{match}), the patch discriminator (D_{patch}), and the human parsing discriminator (D_{parse}).

PCAG design. The proposed PCAG, shown in Fig. 3, takes as input an RGB image of the target person where the upper body and background are masked, a corresponding densepose image, a frontal image of the targeted attire, a warped image of the same (output of Phase 1), and an additional binary mask of the transformed garment. It then produces a virtual try-on image of the target person adorned in the target attire along with a corresponding 16-channel human parsing image. The proposed PCAG incorporates context aware normalization (CAN) layers, introduced in [6], within a series of modified ResNet blocks and 2× upsampling layers allows the generator to integrate essential contextual information from the input images through normalization at various resolutions. Each ResNet block repeats the processes of batch normalization and CAN operations twice. The concept of generating human parsing images alongside RGB try-on images draws inspiration from [12], which demonstrates how the application of losses—based on human parsing images that are generated simultaneously and serve in an auxiliary capacity—can enhance the performance of try-on image generation, particularly in aspects related to semantic regions and context.

Training of the PCAG. The PCAG training involves losses that can be categorized into two groups:

- **Losses that do not involve discriminators:**

1. The perceptual loss L_{per} compares the high-level differences, such as image content, between the generated try-on image and its corresponding ground truth image, i.e.:

$$\mathcal{L}_{per} = \sum_i^m \lambda_i \|\Phi_i(I_g) - \Phi_i(I)\|_1 \quad (6)$$

where Φ_i denotes a feature map, generated before each max-pooling layer (before $m = 5$) of a pre-trained VGG19 model. λ_i is the corresponding weight. I_g and I symbolize the synthesized image and the ground truth image, respectively. This loss is calculated solely in instances where the ground truth is extant, which applies to the generation of virtual try-on images that depict the original attire worn by the target individual.

2. The shape loss L_{shape} quantifies the L2 loss between the upper body clothing region in the generated parsing image and its counterpart in the image warped via BPGM, i.e.:

$$\mathcal{L}_{shape} = \|M_{gc} - M_w\|_2 \quad (7)$$

where M_{gc} designates the region encompassing the upper-body attire within the generated parsing image, while M_w signifies the analogous segment in the BPGM-warped clothing item image. Through our experimental results, we determined that applying L2 loss yields better outcomes compared to L1 loss. The latter appears to overly constrain the generation of garment parsing by adhering too strictly to the input BPGM-warped mask, often neglecting the nuances of the human body pose.

3. The cross-entropy loss, L_{ce}, evaluates the dissimilarity between the probability distributions of the generated human parsing image and the corresponding ground truth. Formally, it is articulated as:

$$\mathcal{L}_{ce} = -\sum_k^d \sum_i^p log\left(\frac{\exp\left(P_g^{(k,i)}\right)}{\sum_h^d \exp\left(P_g^{(h,i)}\right)} P^{(k,i)}\right) \quad (8)$$

Herein, d represents the number of labels, while p denotes pixels in the image. P_g corresponds to the predicted human parsing, and P is the ground truth human parsing. This loss is computed when ground truth is available, which is when virtual try-on images that depict the original attire worn by the target individual are generated.

- **Adversarial losses based on a respective discriminator:**

1. The segmentation discriminator, denoted as D_{seg}, derived from [6], examines whether an image is real by predicting per-pixel segmentation maps S and their origin. Given an authentic image I, or a synthesized image I_g, the discriminator predicts a tensor of dimensions $w \times h \times (d+1)$, where the initial d channels encompass information about the segmentation of bodily regions, while the terminal channel signifies the authenticity of each pixel (i.e., whether the pixel is genuine or fabricated). The loss function for the discriminator is formulated as:

$$\mathcal{L}_{D_{seg}} = -\mathrm{E}_{(I,S)}\left[\sum_{k=1}^d a_k\left(S_k \odot logD_{seg}(I)_k\right)\right] \quad (9)$$
$$-\mathrm{E}_{I_g}\left[logD_{seg}\left(I_g\right)_{d+1}\right]$$

, where a_k symbolizes the balancing weight associated with each term. Subsequently, the loss function for the generator, specifically in the context of the Parsing and Context-Aware Generator (PCAG), is articulated as:

$$\mathcal{L}_{seg} = -\mathrm{E}_{(I_g,S)}\left[\sum_{k=1}^d a_k\left(S_k \odot logD_{seg}\left(I_g\right)_k\right)\right] \quad (10)$$

2. The patch discriminator, symbolized as D_{patch}, aims to ensure the verisimilitude of body-part generation. It accomplishes this by focusing its attention on body-part patches P, defined for 5 distinct body parts, such as the torso, as well as the left and right upper arms and forearms. The main objective of this discriminator is to identify whether a body part is generated or real. The loss function for this discriminator is as follows.

$$\mathcal{L}_{D_{patch}} = -\mathrm{E}_{P_{real}}\left[logD_{patch}(P_{real})\right] \quad (11)$$
$$-\mathrm{E}_{P_{fake}}\left[log\left(1 - D_{patch}\left(P_{fake}\right)\right)\right]$$

where P_{real} and P_{fake} represent the patches extracted from authentic and synthesized images, respectively. The corresponding loss function for the generator is formulated as:

$$\mathcal{L}_{patch} = -\mathrm{E}_{P_{fake}}\left[logD_{patch}\left(P_{fake}\right)\right] \quad (12)$$

3. The match discriminator, denoted as D_{match}, is engineered to impel the proposed PCAG to synthesize output images wherein the fidelity of the attire adorning the subject is in close approximation to the target clothing item, symbolized as C. This discriminator is calibrated using authentic (I) and synthesized (I_g) images. The loss function for D_{match} is expressed as:

$$\mathcal{L}_{D_{match}} = -\mathrm{E}_{(I,C)}[logD_{match}(I,C)] \quad (13)$$
$$-\mathrm{E}_{(I_g,C)}\left[log\left(1 - D_{match}(I_g,C)\right)\right]$$

, while the generator loss it provides to the PCAG is designed as the following:

$$\mathcal{L}_{match} = -\mathrm{E}_{(I_g,C)}\left[logD_{match}\left(I_g,C\right)\right] \quad (14)$$

4. The parsing discriminator, denoted as D_{parse}, is entrusted with the discerning task of evaluating the verisimilitude of a human parsing image in aptly representing a specified attire donned by a particular individual. The goal of this discriminator is to encourage the PCAG to generate human parsing images that scrupulously preserve the morphological characteristics of the target clothing item, denoted as C, as well as the posture information in the densepose. The loss function attributed to this discriminator is as follows.

$$\mathcal{L}_{D_{parse}} = -\mathrm{E}_{(H,M_c,Dp)}\left[logD_{parse}(H,M_c,Dp)\right] \quad (15)$$
$$-\mathrm{E}_{(H_g,M_c,Dp_g)}\left[log\left(1 - D_{parse}\left(H_g,M_c,Dp_g\right)\right)\right]$$

, where H_g and H represent the synthesized and authentic human parsing images of C in wear respectively; M_c, symbolizing the binary mask of C; and Dp_g and Dp, representing the densepose images upon which H_g and H are based on. That leads us to the following generator loss for the PCAG:

$$\mathcal{L}_{parse} = -\mathrm{E}_{(H_g,M_c,Dp_g)}\left[logD_{parse}\left(H_g,M_c,Dp_g\right)\right] \quad (16)$$

In summary, the joint training objective for the PCAG can be denoted as:

$$\mathcal{L}_{PCAG} = \lambda_{per}\mathcal{L}_{per} + \lambda_{shape}\mathcal{L}_{shape} + \lambda_{ce}\mathcal{L}_{ce} + \lambda_{seg}\mathcal{L}_{seg} \quad (17)$$
$$+\lambda_{patch}\mathcal{L}_{patch} + \lambda_{match}\mathcal{L}_{match} + \lambda_{parse}\mathcal{L}_{parse}$$

where the lambda terms are the coefficients of the respective generator losses.

IV. Experimental Results

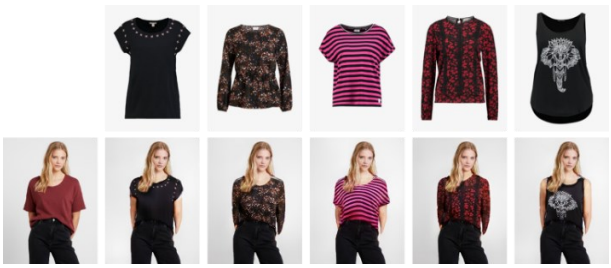

Fig. 4 Exemplar demonstrations of garment adaptability across diverse styles using the proposed method.

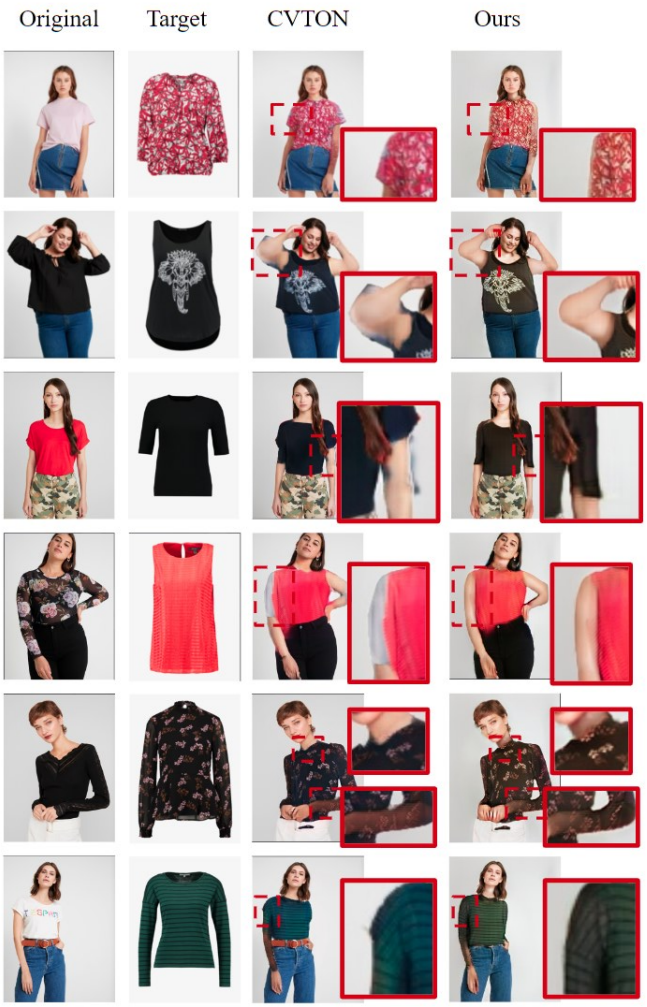

Fig. 5 Comparison of the results utilizing the VITON-HD dataset. A discernible enhancement in image quality is observed with our approach, particularly in areas that have been emphasized through highlighting.

Training was rigorously conducted by harnessing the computational prowess of an Nvidia A100 GPU, graciously provisioned by Google Colab. To facilitate periodic monitoring and potential recovery from unintended interruptions, the models were checkpointed at intervals of 2,000 iterations. Subsequent to each training session, we employed an adaptive approach to parameter tuning; we fine-tuned the hyperparameters such as the learning rate in accordance with the emergent patterns in the convergence profiles of the various loss functions. The models were subjected to intensive training on the VITON-HD dataset [17], endowed with images having a resolution of 256×192 pixels.

In Figure 4, we unveil the capabilities of our method in orchestrating a virtual try-on of an assortment of garments on an identical individual. The outcomes conspicuously illustrate that our model is adept at gracefully navigating scenarios characterized by drastic shape changes.

Figure 5 presents a comparison of images engendered by our model vis-à-vis those generated by the C-VTON model. A meticulous examination reveals that the images produced by C-VTON exhibit a predilection for maintaining the morphological integrity of the original attire mistakenly. For instance, when simulating the try-on of a long-sleeved garment, vestiges of the original short-sleeved cuff remain discernible, with the model exhibiting palpable difficulties in accommodating variations in sleeve length. On the other hand, our proposed model evinces a superlative acuity in accurately reproducing the salient features of the try-on attire, including but not limited to sleeve length, cuff, and collar.

V. Conclusions

In this research, we have unveiled PC-VTON, a dual-phase virtual try-on image generation architecture, which is bolstered by a Generative Adversarial Network (GAN) paradigm and targets the harmonious fusion of clothing morphology and contextual preservation. This architecture is complemented by an array of purpose-crafted loss functions and an innovative discriminator group design. Our work has addressed the weakness often observed in extant virtual try-on methodologies –the incapacity to faithfully render the shapes of clothing during image synthesis. Our empirical evidence compellingly attests to the prowess of the proposed framework, which not only retains the laudable capacity for the precise depiction of textures and patterns, reminiscent of its predecessor, the CVTON framework, but also excels in the reproduction of structural attributes of clothing with remarkable finesse. The cornerstone of this marked enhancement is the incorporation of human parsing generation into our schema, which is further augmented by the proposed loss functions and discriminators.

***Abstract*—The large amount of data of point cloud poses challenges for efficient storage and transmission. To address this problem, various learning-based techniques, in addition to rule-based solutions, have been developed for point cloud compression. While many previous works employed the variational autoencoder (VAE) structure, they have failed to achieve promising performance at high bitrates. In this paper, we propose a novel point cloud attribute compression technique based on the Augmented Normalizing Flow (ANF) model, which incorporates sparse convolutions where a sparse tensor is used to represent the point cloud attribute. The invertibility of the NF model provides better reconstruction compared to VAE-based coding schemes. ANF provides a more flexible way to model the input distribution by introducing additional conditioning variables into the flow. Not only comparable to G-PCC, the experimental results demonstrate the effectiveness and superiority of the proposed method over several learning-based point cloud attribute compression techniques, even without requiring sophisticated context modeling.**

I. INTRODUCTION

In recent decades, point clouds have garnered significant attention in the field of computer vision, particularly in human-machine collaboration. They have found wide-ranging applications in areas such as autonomous driving, augmented reality, and robotics. Unlike images, point cloud is a set embedded in a continuous space. It comprises the 3D coordinates and corresponding attributes such as color, normal and reflectiveness. Due to the unordered and non-uniform distribution of points in the point cloud, processing them poses significant challenges.

Efficient point cloud compression has recently gained considerable attention and the MPEG has developed two point cloud coding standards: Video-based Point Cloud Compression (V-PCC) [1] and Geometry-based Point Cloud Compression (G-PCC) [2]. In V-PCC, 3D patches are formed by grouping points with similar normals. The geometry and the attribute are then projected and packed into 2D images, and an occupancy map is built to guide the patch packing. The geometry, attribute and occupancy map are encoded by conventional video codecs. In G-PCC, point cloud geometry and attribute are separately compressed. The geometry is encoded first, followed by attribute compression which relies on the decoded geometry.

Graph Fourier Transform (GFT) has been utilized in numerous studies for point cloud attribute compression [3, 4]. Besides, sparse representation is typically leveraged to model point clouds [5, 6]. While popular transform, such as DCT, DFT and GFT are commonly used, [7] performs multi-scale structured dictionary learning to more effectively represent the sparsity of point clouds. In [8], geometry-guided sparse representation was proposed for compressing the voxelized point cloud attribute. This method uses a virtual adaptive sampling technique to model irregular point clouds.

In G-PCC, geometric information is expressed using octree representation, which recursively divides point cloud into eight sub-cubes based on root cube occupancy. Attributes are compressed using three coding methods: Region-Adaptive Hierarchical Transform (RAHT) [9], Prediction Transform and Lifting Transform. RAHT is a variant of the Haar wavelet transform that converts attributes into frequency domain coefficients. The upsampled transform domain prediction further improves coding efficiency by using decoded RAHT coefficients in lower resolution to predict coefficients in higher resolution. The Prediction Transform first constructs level of details (LOD) by arranging the points into a set of refinements levels, followed by distance-based prediction. The Lifting transform is built on top of the Prediction Transform to further improve coding efficiency, employing an update operator and adaptive quantization in additional to the prediction operation. The G-PCC encoding platform, TMC13, demonstrates state-of-the-art performance in point cloud attribute compression.

Learning-based techniques have been successful in point cloud geometry compression and can be classified into point-based and voxel-based methods. Point-based methods, such as those presented in [10] and [11], use PointNet as the encoder backbone. A fully-connected network is used in the decoder in [10] while a graph neural sampling module is incorporated to gather neighborhood features in [11]. Voxel-based methods first partition the point cloud into non-overlapping 3D cubes and employ 3D convolutional neural networks (CNNs) to

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

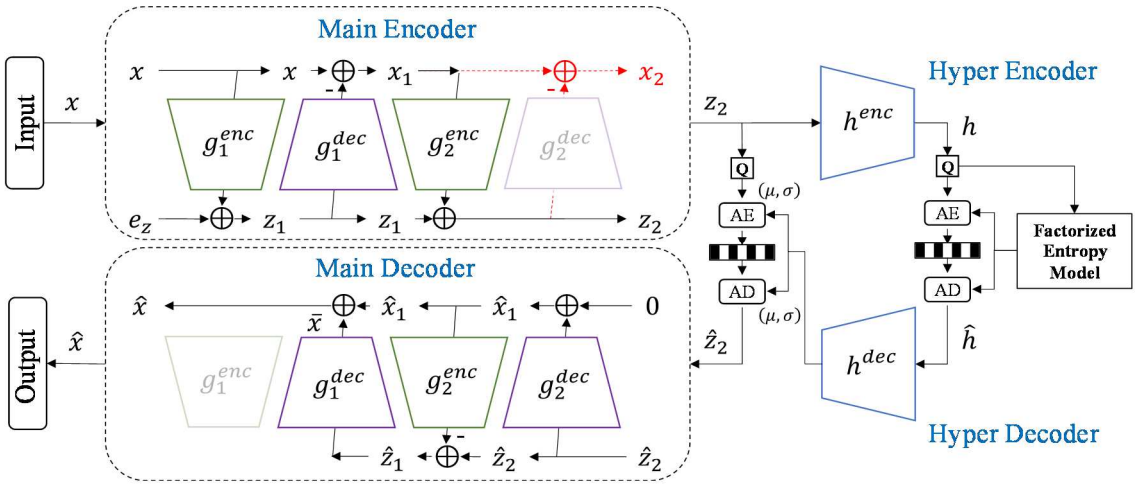

Fig. 1. The network architecture of our proposed ANF-PCAC. The red lines indicate the paths used during the training phase.

compress the geometry [12]. In CNN-based methods, the input data is transformed into a lower dimensional latent space. For the voxel-based approach, the geometry reconstruction is represented as a binary classification. In [13], a VAE structure with hyperprior is proposed. Later, sparse convolution on a multi-scale structure is presented in [14] to further improve coding efficiency. This architecture processes the downsampled latent in a lossy manner, while preserving the coarse geometry in a lossless manner. A hierarchical reconstruction is then conducted from low resolution to high resolution.

The network architectures used for point cloud geometry coding can be also applied to point cloud attribute coding. Many works have adopted VAE-based architectures, such as Deep-PCAC [15], which is the first end-to-end learned point cloud attribute compression using multilayer perceptrons (MLPs). In addition, sparse convolutions have been used in [16-17] to decrease computation cost. These methods apply an adaptive entropy model with the joint utilization of a hyper prior and autoregressive neighbors [18] to better estimate the bit rate. In [19], point cloud attributes are represented with volumetric functions modeled by local coordinate-based networks. They adopt a hierarchical structure of latent codes, which are represented by RAHT. In [20], folding-based image compression is proposed. The method parameterizes a point cloud as a 2D manifold and folds the geometry into 2D grids. Then, an image is formed by projecting the associated attribute in the grid, followed by conventional image compression.

Flow-based models have emerged as a promising alternative to VAE-based models for compression task due to their ability to ensure perfect reconstruction with quantization [21-22]. Affine coupling layers are typically used to establish a bijective mapping between the input and its latent features. In [23], a point cloud attribute compression method using normalizing flow (NF) was proposed, which included a 3D voxel squeeze layer to process irregular point clouds as regular 3D data. However, this method had a large number of model parameters.

In [24], an augmented normalizing flow (ANF) was used for point cloud geometry compression (ANFPCGC), focusing on voxelized point cloud geometry and leveraging 3D CNNs to extract the latent features. Built on top of the flow model, an independent noise input is coupled in ANF to enable improved transformation capability [25]. ANFPCGC comprises a stack of 2 VAEs and superior coding performance over several VAE-based designs [13-14] are demonstrated.

In this paper, we present ANF-PCAC, an ANF-based point cloud attribute coding scheme that utilizes a sparse tensor architecture with sparse convolution instead of 3D CNN, which distinguishes it from ANFPCGC. The main contributions of this paper are as follow:

- We introduce ANF-PCAC, a learning-based framework for compressing point cloud attributes. ANF-PCAC utilizes the ANF structure and incorporates sparse convolution.
- Experimental results provide validation for the effectiveness of the proposed technique, showcasing competitive performance with G-PCC.
- Our method surpasses several learning-based solutions, even when no context model is applied.

II. Proposed Method

The sparse convolution takes into account sparsity in CNNs by only computing outputs on predefined voxels and storing them as compact sparse tensors. It is efficient for irregular point clouds and can significantly reduce computation and memory costs. In our proposed network, we use sparse convolution as the basic operation. The sparse tensor $\{\vec{C}, \vec{F}\}$ is represented by a set of coordinates $\vec{C} = \{(x_i, y_i, z_i) \mid i \in [0, N-1]\}$ of the point cloud and the corresponding features $\vec{F} = \{(R_i, G_i, B_i) \mid i \in [0, N-1]\}$, where N is the total number of occupied points. We assume that the point cloud geometry is available and can be losslessly coded, which is consistent with other learning-based point cloud attribute compression methods. In the following, we introduce our ANF model and the internal VAE structure in detail, as well as our training strategy.

A. ANF-PCAC

Following the design in ANFPCGC, we proposed ANF-based point cloud attribute compression. Fig. 1 shows the network architecture of the proposed ANF-PCAC, which is built upon SparsePCAC [16] while discarding the context model. ANF-PCAC consists of two parts: the main encoder/decoder and the hyper encoder/decoder. We employ two layers of autoencoding transform in the main encoder/decoder, resulting in a two-step ANF that balances model capacity and complexity. The two autoencoding transforms have the same design with g_1^{enc} and g_2^{enc} sharing the same structure, and so do g_1^{dec} and g_2^{dec}. The detail of the autoencoding transforms are shown in Fig. 2. Similar to [16], we increase the channel size from 3 to 128 and perform three-time downsampling in g_1^{enc} and g_2^{enc} to make the features smaller and more compact. In g_2^{dec} and g_1^{dec}, we perform the reverse operation to reconstruct the point cloud attributes.

During encoding, we input the point cloud attribute and an augmented noise e_z, which follows a Gaussian distribution with zero mean. In the experiments, e_z is set to zero. During the training, we obtain an additive coupling output z_1 by feeding the input to the first encoding transform g_1^{enc}. Then we get the difference between x and the reconstructed one, denoted as x_1, after performing the first decoding transform g_1^{dec}. In the next step, x_1 and z_1 are served as inputs to the second autoencoder, and we get x_2 and z_2 as the final output of the main encoder, as shown in (1) and (2):

$$(x_1, z_1) = (x - g_1^{dec}(z_1), g_1^{enc}(x) + e_z) \quad (1)$$

$$(x_2, z_2) = (x_1 - g_2^{dec}(z_2), g_2^{enc}(x_1) + z_1) \quad (2)$$

As indicated in (2), x_2 is the difference between the original x_1 and the reconstructed one and is expected to be close to zero if the encoding and decoding are well matched to each other. It implies that the input information x is expected to be completely transferred to the latent z_2. It this way, we can save bits if x_2 is not transmitted. In inference, g_2^{dec} is not executed during encoding.

After quantization, we perform decoding by reversing the operation of encoding. Following the design in ANFPCGC, we do not transmit x_2 and the main decoder performs reconstruction by setting x_2 to zero. To reduce the mismatch between the true value of x_2 and zero. We encourage x_2 to be close to zero by including a loss term. We obtain $\hat{x}_1$ by feeding the quantized $\hat{z}_2$ to g_2^{dec}. Then we input $\hat{x}_1$ and $\hat{z}_2$ to the bottom autoencoder in a reverse direction, and we obtain the final output $\hat{x}$, as shown in (3)(4):

$$(\hat{x}_1, \hat{z}_1) = (g_2^{dec}(\hat{z}_2), \hat{z}_2 - g_2^{enc}(\hat{x}_1)) \quad (3)$$

$$\hat{x} = \hat{x}_1 + g_1^{dec}(\hat{z}_1) = \hat{x}_1 + \bar{x} \quad (4)$$

To further reduce bit consumption, we use a conditional entropy model based on hyperpriors [18]. The hyper encoder learns the probability distribution of the latent z_2 and

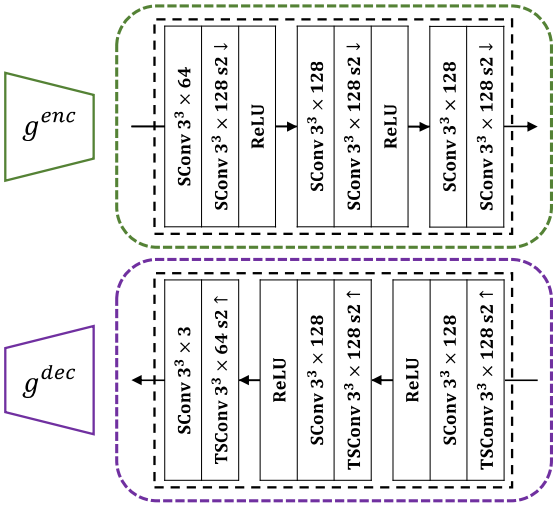

Fig. 2. Encoding transform and decoding transform of the ANF-PCAC transform architecture.

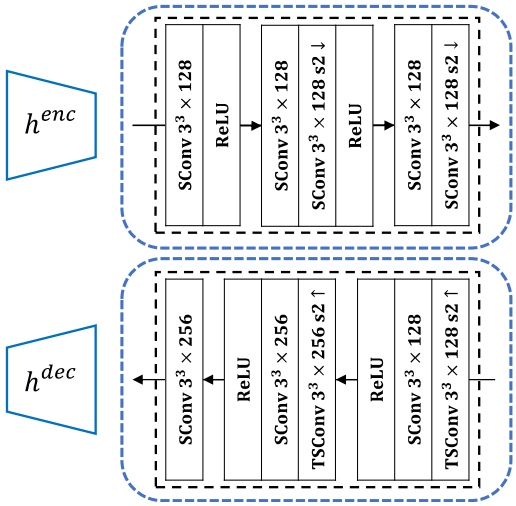

Fig. 3: The hyperprior transform

generates a hyper prior h, which is then quantized as $\hat{h}$ and described by a factorized entropy model. Then $\hat{h}$ passes through the hyper decoder to generate the mean and variance (μ, σ) which are used to describe the distribution of the latent z_2. With this conditional Gaussian distribution, the bits consumption of the latent z_2 can be estimated. The detail of the hyper encoder/decoder can be seen in Fig. 3.

B. Training strategy

To train the proposed ANF-PCAC, we use Lagrangain loss, as shown in (5). For the rate, there are two terms, denoted as $R_{\hat{z}_2}$ and $R_{\hat{h}}$, presenting the rate of the latent $\hat{z}_2$ and the hyperprior $\hat{h}$, respectively. Three terms are involved in the computation of the distortion. The first term $d(x, \hat{x})$ computes the mean squared error (MSE) between the input x and the reconstructed signal. The second term $d(x, \bar{x})$ measures the MSE between the input x and $\bar{x}$ with the aim of enabling better reconstruction for the autoencoding. As mentioned earlier, x_2 represents the residual information that is expected to be

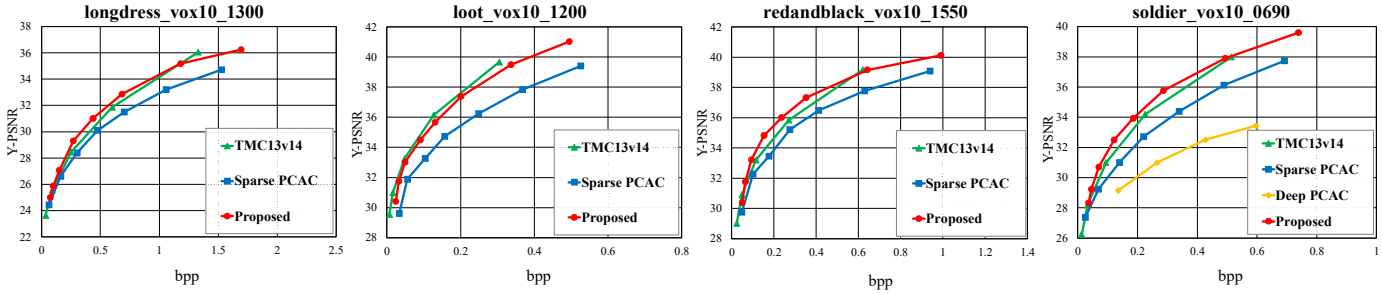

Fig. 6: R-D curves for longdress, loot, redandblack, and soilder.

approximated by zero. This task can be accomplished by including the third term.

$$J = R_{\hat{z}_2} + R_{\hat{h}} + \lambda \cdot \left(\left(d(x, \hat{x}) + d(x, \bar{x}) \right) + \gamma \cdot (x_2 - 0)^2 \right) \quad (5)$$

III. Experimental Results

In this section, we will provide the information of our training and testing datasets, as well as the anchor schemes. We will also describe our training details, followed by the presentation of quantitative and qualitative comparisons to demonstrate the superiority of our proposed method.

A. Dataset and Anchor

For our training dataset, we utilize the ScanNet [26] dataset, which is a large open-source dataset of indoor scenes. The dataset contains both high-quality and low-quality reconstructed meshes, and we used the high-quality version, as shown in Fig. 4. We converted the mesh into point cloud and scaled the geometry to 10 bits, followed by cube division with size $64 \times 64 \times 64$. We randomly selected 50,000 cubes and used them for training. To make a fair comparison, the test dataset utilized in SparsePCAC [16] has been assessed. Four point clouds in the 8i Voxelized Full Body(8iVFB) [27] are used, as shown in Fig. 5. Notably, our training and testing datasets are entirely different, enabling us to demonstrate the generalization ability of our proposed scheme. We compared our approach with three methods, including two learning-based methods: Deep PCAC [15] and SparsePCAC [16], and a traditional point cloud compression standard G-PCC (TMC13v14).

Table 1: BD-Rate (%) and BD-PSNR (dB) with respect to abchors

Point Cloud	TMC13 v14		SparsePCAC		Deep PCAC	
	BD-Rate (%)	BD-PSNR(Y) (dB)	BD-Rate (%)	BD-PSNR(Y) (dB)	BD-Rate (%)	BD-PSNR(Y) (dB)
longdress	-6.42	0.28	-26.92	1.09	-	-
loot	23.78	-0.56	-39.75	1.73	-	-
redandblack	-10.99	0.42	-33.65	1.28	-	-
soldier	-11.58	0.46	-37.63	1.64	-70.52	4.45
Average	-1.30	0.15	-34.49	1.44	-70.52	4.45

B. Training details

We set λ to 0.05, 0.025, 0.01, 0.005, 0.0025, 0.001, 0.0005 and 0.00025 to obtain models with different bitrates. γ is set as 0.01 to balance the distortion. We trained our models for 500 epochs, and all models use the initial learning rate 1×10^{-4} which gradually decreases to 1×10^{-6}. We use Nvidia GeForce RTX 2080 Ti for training and testing.

C. Objective Quality Comparison

We present the R-D (rate-distortion) performance in Fig.6, in which the bitrate is measured in bits per point (bpp) and the distortion is measured by the Peak Signal-to-Noise Ratio (PSNR) of the Y channel. Deep-PCAC evaluates only the sequence of soldiers in the 8iVFB dataset, while it is trained with others sequence in the same dataset. Fig. 6 shows that our proposed scheme outperforms Deep-PCAC and SparsePCAC. Additionally, our method is comparable with TMC13v14. To assess the average R-D performance, we used the Bjøntegaard

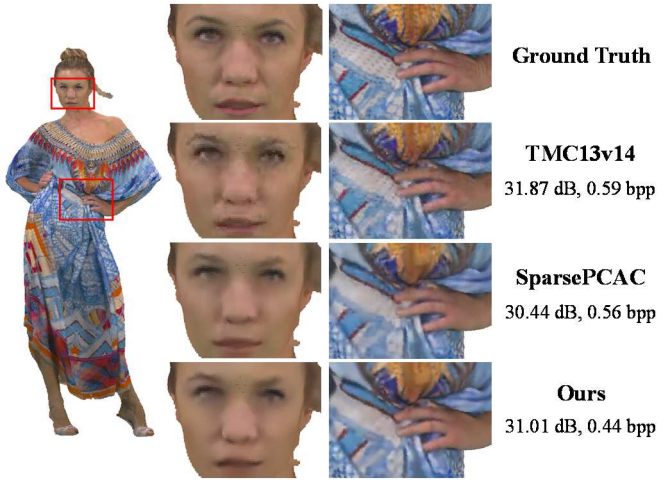

Fig. 7: Qualitative comparison of longdress.

Table 2: Average runtime for 8iVFB dataset

	TMC13v14	SparsePCAC	Ours
Enc (s)	1.17	122.92	0.45
Dec (s)	0.84	835.63	0.29

metric, including BD-PSNR and BD-Rate, which is summarized in Table 1. The results indicate that our method achieves, on average 70.52%, 34.49% and 1.3% rate reduction when compared to Deep PCAC, SparsePCAC and TMC13v14, respectively.

D. Subjective Quality Comparison

For quality visualization, we compare our method with TMC13v14 and SparsePCAC in Fig. 7. The reconstruction by TMC13v14 has noticeable blurs and noise, while our method generally delivers a more visually pleasing result with smoother textures.

E. Runtime Comparison

To specifically demonstrate the efficiency of our method where only a hyperprior is used to build the entropy model of the latent, we compare our method with SparsePCAC and TMC13v14. Since SparsePCAC relies on both autoregressive prior and hyperprior, it requires a more expensive inference time, as shown in Table 2.

IV. Conclusions

In this paper, we propose a learning based point cloud attribute compression using ANF. We use sparse convolutional layers as our basic layer in the two-step VAE network. Our proposed method outperforms Deep PCAC, SparsePCAC and TMC13v14 with 70.52%, 34.49% and 1.3% rate reduction, respectively, and shows competitive qualitative performance compared to state-of-the-art TMC13v14. For the runtime of inference, our method saves significant time consumption compared to SparsePCAC, as our method works well even without an autoregressive context model.

Toward Leveraging Pre-Trained Self-Supervised Frontends for Automatic Singing Voice Understanding Tasks: Three Case Studies

Yuya Yamamoto
University of Tsukuba, Tsukuba, Japan
E-mail:s2130507@u.tsukuba.ac.jp

***Abstract*—Automatic singing voice understanding tasks, such as singer identification, singing voice transcription, and singing technique classification, benefit from data-driven approaches that utilize deep learning techniques. These approaches work well even under the rich diversity of vocal and noisy samples owing to their representation ability. However, the limited availability of labeled data remains a significant obstacle to achieving satisfactory performance. In recent years, self-supervised learning models (SSL models) have been trained using large amounts of unlabeled data in the field of speech processing and music classification. By fine-tuning these models for the target tasks, comparable performance to conventional supervised learning can be achieved with limited training data. Therefore, in this paper, we investigate the effectiveness of SSL models for various singing voice recognition tasks. We report the results of experiments comparing SSL models for three different tasks (i.e., singer identification, singing voice transcription, and singing technique classification) as initial exploration and aim to discuss these findings. Experimental results show that each SSL model achieves comparable performance and sometimes outperforms compared to state-of-the-art methods on each task. We also conducted a layer-wise analysis to further understand the behavior of the SSL models.**

I. Introduction

The singing voice plays an important role in the music. It provides emotional expressions for us through its melody and lyrics. Computational understanding tasks of singing voices, such as singer identification, singing voice transcription, and singing expression identification, are beneficial for many applications such as music discovery [1], pedagogy [2], musicological analysis [3], etc. Processing the singing voices is a long-running challenge in the music information retrieval (MIR) field [4] due to its wide variation. Recently, the methods based on deep learning outperformed the conventional methods based on the hand-crafted manner in many singing voice understanding tasks thanks to its intense expressiveness [5], [6], [7], [8]. However, deep learning approaches typically necessitate extensive datasets comprising sung tracks with high-quality labels, entailing substantial costs for both data collection and annotation.

Transfer learning is one of the techniques to alleviate the requirements of large-scale datasets for the low-resource situation. It is based on the transfer of the knowledge derived from high-resource upstream pre-training tasks to target downstream tasks. In the audio domain, there are many works on audio classification tasks that utilize transfer learning of PANNs [9] and VGGish [10], which are pre-trained on a large-scale audio dataset. Notably, transfer learning of the model that is pre-trained by self-supervised learning (SSL) fashion is rapidly emerging. SSL models are leveraging a vast amount of unlabeled data, several notable models have been developed in both the speech and music domains. In the speech domain, these models include Wav2Vec2.0 [11], HuBERT [12], and WavLM [13]. Meanwhile, in the music domain, models such as MERT [14], and MapMusic2Vec [15] have been introduced.

Singing voice encompasses characteristics of both speech and music, and researchers have explored leveraging pre-trained SSL models in singing voice understanding tasks [16], [17], [18], [19] for each. The transfer learning of pre-trained SSL models from the speech or music domains to the singing domain holds potential. However, there is still ample room for investigating the utility of each pre-trained SSL model. This includes investigating which domains can contribute to singing voice understanding tasks, how the model extracts valuable features for the target tasks, and how to fully utilize the potential of the SSL models, and so on.

In this study, our objective is to examine the usefulness of SSL models pre-trained on the speech or music domains for singing voice understanding tasks. To achieve this, we employ pre-trained SSL models as a front-end to our voice identification model and evaluate their performance through fine-tuning.

We present the following contributions in this study:

1) Comparative analysis of SSL models: We compare multiple SSL models across three distinct three tasks: singer identification, singing voice transcription, and singing technique classification, corresponding to ”Who sings?”, ”What song?”, and ”How to sing?”, respectively.
2) Comparison with SoTA models: We also compared the SSL models with state-of-the-art (SoTA) models. Through fine-tuning the pre-trained SSL models, we demonstrate that they achieve performance comparable to that of current state-of-the-art methods in several singing voice understanding tasks.
3) Investigation of layer-wise behavior: Additionally, we delve deeper into the behavior of the model’s layers and analyze their characteristics across different tasks,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

by utilizing learnable weight for each layer.

II. Related Works

Various machine learning approaches have been explored for low-resource problems in the singing voice understanding tasks. Semi-supervised learning [20], [21], data augmentation [22], [23], and self-supervised learning on singing voices [24], [25], leveraging speech data [26], [27] etc. have been proposed to mitigate the drawbacks of supervised-learning fashion.

More recent, pre-trained self-supervised models are used for singing understanding tasks. Ou et al. leveraged Wav2Vec 2.0 [11] model that is pre-trained using Librispeech corpus [28] and fine-tuned automatic speech recognition for lyric transcription. They achieved comparable performance with the state-of-the-art performance of lyric transcription methods [29], [30], which are learned from over 150 hours of data, by using its 10% of amount (i.e., 15 hours) [16]. Gu et al. leveraged Wav2Vec2.0 for singing voice transcription and outperformed conventional works [18]. Heydari et al. tackled singing beat tracking, which is a beat tracking method when the input is only a singing voice. They leverage WavLM [13] and DistilHuBERT [31] for the frontend of the model, and they outperformed the model that adapts only the spectrogram for the frontend feature. Donahue et al. proposed melody transcription from the musical mixture utilizing codified music representation [32] derived from the hidden representation of JukeBox [33], which is originally proposed for musical audio generation.

III. Methods

We compare four SSL models: 1) Wav2Vec2.0 [11], 2) WavLM [13], 3) MERT [14], and 4) MapMusic2Vec [15]. Each model takes a raw waveform as input and employs convolutional layers for feature extraction along with 12 Transformer encoder layers. The output of each model consists of a 768-dimensional vector per frame. We utilized these models as the frontend for each singing voice understanding task.

A. SSL models

1) Wav2Vec2.0: Wav2Vec2.0 [11] is the model that has convolutional and Transformer Encoder layers and acquired speech representation through contrastive learning and masking. It takes raw speech waveforms as input, and the initial convolutional layers produce latent representations denoted as z. To facilitate contrastive learning, the quantization module is applied to convert z into discrete representations denoted as Q. Simultaneously, z is fed into the Transformer layers after applying random masking to several frames. The output feature C is then derived from the Transformer layers. Finally, contrast learning is performed masked time step in C and Q. Here, the same time steps are considered as positive examples and different time steps are considered as negative examples. Wav2Vec2.0 has shown its effectiveness in several downstream speech tasks by fine-tuning [34], [35], [36]. We used the Wav2Vec2.0 Base model[1].

[1]https://huggingface.co/facebook/wav2vec2-base-960h

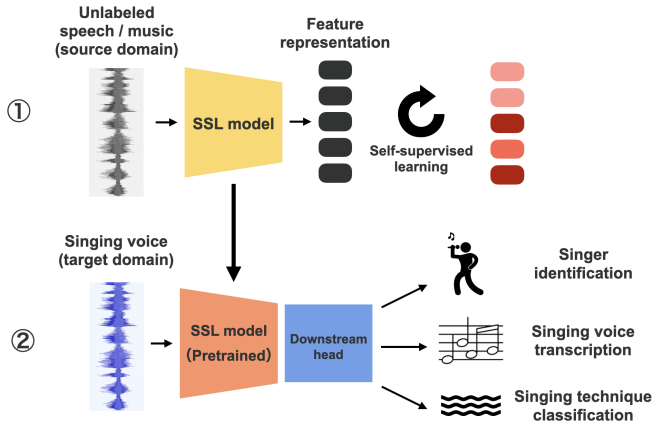

Fig. 1. The concept of this paper. 1) Pre-training on upstream task: Utilizing a vast amount of unlabeled data (either speech or music) and pre-training the model in a self-supervised fashion. 2) Transfer learning for downstream task: Leveraging pre-trained model and solving the target task (i.e., singing voice understanding tasks).

2) WavLM: WavLM [13] is a large-scale pre-trained model with 94k hours of speech data as input that can treat full-stack speech processing. It adopts masked prediction of hidden units like HuBERT [12] and denoising of the input speech as self-supervised pretraining. The diversity of the pre-trained corpus of WavLM is wider than that of Wav2Vec2.0; Gigaspeech [37], a collection of audiobooks, podcasts, and YouTube and VoxPopli[38], a collection of European Parliament, in addition to Librispeech. We used the WavLM Base plus model, which demonstrates better performance than the Base model[2].

3) MERT: MERT [14] is a large-scale pre-trained model using unlabeled music data. It is also inspired by masked prediction of hidden units as WavLM while it uses CQT spectrogram as its target in addition to quantized acoustic features with the purpose of enhancing the pitch representative power. It can achieve the parameter efficiency compared to the JukeMIR [32], the musical audio representation derived from JukeBox. We used the public-v0 model[3], which is only trained on a public music dataset.

4) MapMusic2Vec: MapMusic2Vec[4] [15] is a model that is pre-trained using BYOL [39] with 1k hours of music data. It relies on two neural networks that have the same structure as each other, reffed to the teacher model and the student model. The parameters of the teacher model are updated according to the exponential moving average (EMA) of the student model. The student model takes partially masked audio raw waveform as input while the teacher model takes unmasked one and outputs the prediction of hidden outputs from the last K layers of the teacher model.

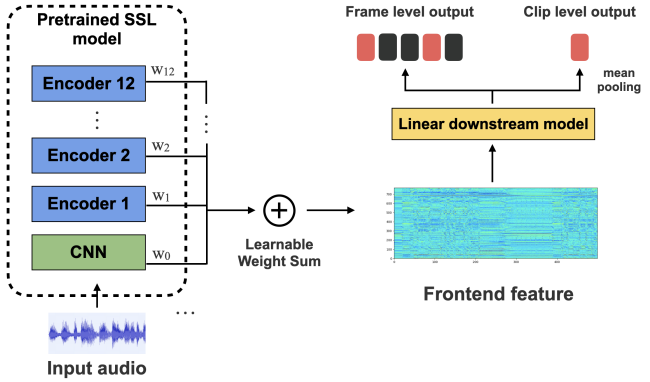

Fig. 2. The overview of the whole model to solve the target tasks.

B. Downstream model

We describe the overview of how to use the SSL model and the downstream models in Figure 2.

1) Weighted sum: We employed a weighted sum of the outputs from each Transformer encoder layer, including the input of the first layer, as the input for the downstream model. This approach was motivated by previous works (e.g.,[40], [41], [42], [43]) that have demonstrated different aspects of the input being captured by early, intermediate, and late layers of Transformer models. By using a weighted sum, we aimed to fully leverage the potential of SSL models. We set 13 learnable weight values, each corresponding to the weight value assigned to the output of each layer.

2) Classifier: Given the aforementioned features, we use a linear downstream model to predict each. The way of deriving the output of the target is depending on the tasks; For singing voice transcription, we directly used the frame-wise output. For the classification tasks (i.e., singer identification and singing technique classification), the feature is mean-pooled over the time axis to derive a clip-wise output.

C. Fine-tuning

In order to solve the downstream tasks, we fine-tune the models. There are various strategies for fine-tuning large-scale pre-trained models, we follow the two-stage training as Gu et al. [18] did. First, we freeze the parameter of the SSL models and make them learnable only on downstream models (i.e., the value of the weighted sum and the linear model). After several epochs, we unfreeze the Transformer encoders and fine-tune them.

IV. Experiments and Results

A. Experiment on Singer Identification

Singer identification is the classification task that identifies who is singing in a given sung audio clip.

1) Experimental Condition: We demonstrate 20-way singer identification using Artist20 [44] dataset, which collects 20 singers' music tracks. The dataset contains six albums for each singer in the data set, for a total of 1,413 songs. We split the dataset per album in order to avoid the leakage of production information about an album over the training and test set. We assign four albums for *train*, one album for *validation*, and the rest one album for *test* subset. Since the audio clips of the dataset include accompaniment of musical instruments, we applied vocal separation using Demucs V4 [45]. Then, we split them into five-second chunks without overlapping at a sample rate of 16kHz and discarded non-vocal chunks by RMS filtering [17].

For training the models, we used Adam optimizer [46] with 30 epochs. We set the learning rate of 3×10^{-3} for the first stage on the first six epochs and 5×10^{-5} for the second stage with the remaining epochs. The batch size is set to 32.

We evaluated the models by the following metrics: F1-score, Top-2 accuracy, and Top-3 accuracy. For the baseline for the comparison, we adopt the **CRNN** model by Hsieh et al.[23]. The model takes a 128-dimensional mel spectrogram as input and consists of four convolutional layers and two GRU [47] layers. We re-implemented the model in order to measure Top-2 and Top-3 accuracy since [23] only reported F1-score.

2) Results: Table I shows the results of singer identification. SSL models are demonstrating superior performance compared to the conventional SoTA model (i.e., CRNN) of singer identification. Notably, WavLM exhibited the highest performance in terms of F1 score, while MapMusic2Vec excelled in achieving the highest accuracy for Top-2 and Top-3 accuracy. These outcomes collectively suggest that the pre-training of SSL models with either music or speech data is leveraged in encoding the information associated with the singers.

TABLE I
THE RESULTS OF SINGER IDENTIFICATION.

Methods	F1-score	Top-2	Top-3
Wav2Vec2.0	60.0	70.7	76.3
WavLM	**61.9**	70.2	76.4
MERT	56.8	68.4	75.6
MapMusic2Vec	59.6	**71.5**	**77.0**
CRNN [23]	49.5	63.4	71.3

B. Experiment on Singing Voice Transcription

Singing voice transcription refers to the process of converting sung audio signals into corresponding musical notes. In this paper, we employed the piano roll representation as the target for the singing voice transcription.

1) Problem Definition: We follow the settings of Wang et al. [48]. The target has four attributes: *onset*, *silence*, *pitch class*, and *octave*. The beginning of silence is considered as the offset instead of a direct estimation of them due to its difficulty. We set the pitch range from C2 (MIDI number 36, 65.41Hz) to B5 (MIDI number 83, 987.77Hz), therefore the target of *octave* is four classes (i.e., 2-5.) In addition, the class of inactive is added on *octave* and *pitch class*, respectively. Eventually, each frame contains 20-dimensional vectors as a target (i.e., *onset* and *silence* are binary, *pitch class* is five classes, and *octave* is 13 classes).

2) Experimental Condition: We use MIR-ST500 [48], which consists of 500 Chinese pop songs with manually annotated vocal melody notes. The authors of [48] provide the official data split that allocates 400 songs for the training set and 100 songs for the test set. Therefore, we followed the split as is, using the training set for the model training and the test set for the evaluation. Since the audio clips of the dataset include accompaniment of musical instruments, we applied vocal separation using Demucs V4 [45]. During the training of the model, we split the input audio into five-second chunks without overlaps at a sample rate of 16kHz. Given the input, the model outputs the prediction of the aforementioned 20-dimensional target vector per frame. The frame length is about 20ms. Suppose the prediction for *onset*, *silence*, *pitch class* and *octave* are $\hat{O}, \hat{S}, \hat{P}, \hat{V}$, the objective functions are as follows:

$$\mathcal{L}_{svt} = \frac{1}{T}\sum_{t=1}^{T}\Big[BCE(\sigma(\hat{O}_t), O_t, w_o) + BCE(\sigma(\hat{S}_t), S_t, w_s) + CE(\hat{P}_t, P_t) + CE(\hat{V}_t, V_t)\Big] \tag{1}$$

Where T denotes the number of frames in the input, $\sigma(\cdot)$ denotes the sigmoid function, BCE denotes binary cross-entropy loss, and CE denotes cross-entropy loss. Considering the imbalance between positive and negative samples, the weight is applied to the binary cross entropy loss. The values are $w_o = 15.0$ for onset, and $w_s = 1.0$ for silence, respectively. For training the models, we used Adam optimizer [46] with 30 epochs. We set the learning rate of 3×10^{-3} for the first stage and 5×10^{-5} for the second stage.

We follow the strategy of postprocessing as Gu et al. [18] for deriving the actual estimation. Briefly, each of the note properties is determined as follows:

- onset: Setting a threshold value of 0.4. If the prediction value is higher than the threshold and the local maximum, the frame is set to onset.
- offset: $\arg\min(\hat{S}_t > 0.5)$ of the estimated silence sequence and after the onset time.
- pitch class and octave (i.e., midi number): Assign the mode of the estimated value between the onset and the offset time.

To evaluate the performance of our model, we adopted three evaluation metrics proposed in [49], namely F1-score of COn (correct onset), COnP (correct onset and pitch), and COnPOff (correct onset, offset, and pitch). We utilized the mir_eval library to calculate these metrics, using the default parameters: 50 cents for pitch tolerance, 50 ms for onset tolerance, and the larger value between 50 ms and 0.2 of the note duration for offset tolerance.

In order to establish baselines for comparison, we considered several conventional works:

1) **EfficientNet-b0**: This approach is based on utilizing the EfficientNet-b0 model [50], which was originally proposed as the baseline for the MIR-ST500 task [48].
2) **JDC$_{note}$**: This model was trained on pseudo-labeled data obtained through quantization of automatically detected vocal melody contours [51].
3) **Wav2Vec2-Large**: This model employed the Wav2Vec2.0-Large model for the frontend and feeds only the last layer's output to the downstream model [18].

3) Results: Table II shows the results of singing voice transcription. MERT achieved the best score on COn and COnP among the four SSL models, while MapMusic2Vec demonstrated the best score on COnPOff. We observed that the speech models (i.e., Wav2Vec2.0 and WavLM) exhibit lower COnP compared to the music models (i.e., MERT and MapMusic2Vec). It suggests that the music models have already acquired the representation related to musical notes while the speech models lack such incorporation due to the gap between speech and singing voice (i.e., the length of stable pitch region, musical expression, etc.). In terms of performance comparisons with conventional works, every SSL model showed comparable performance with [48] and [51]. In addition, MERT outperforms Wav2Vec2Large in the COnP with fewer parameters.

TABLE II
RESULTS OF SINGING VOICE TRANSCRIPTION. ALL VALUES ARE EXPRESSED IN %. THE BEST-PERFORMING CONDITION AMONG ALL CONDITIONS IS HIGHLIGHTED IN BOLD, AND THE BEST-PERFORMING CONDITION AMONG SSL MODELS IS UNDERLINED.

Methods	COnPOff	COnP	COn
Wav2vec2.0	44.8	67.0	76.3
WavLM	44.4	67.3	76.9
MERT	46.7	**71.6**	78.2
MapMusic2Vec	50.7	70.0	77.9
EfficientNet-b0 [48]	45.8	66.6	75.4
JDC$_{note}$ [51]	42.2	69.7	76.2
Wav2Vec2-Large [18]	**52.4**	70.7	**78.3**

C. Experiment on Singing Technique Classification

Singing technique classification is the task that identifies a singing technique that appeared in a given input audio clip.

1) Experimental condition: We used VocalSet [52], which is a publicly available dataset that annotated singing techniques. VocalSet contains singing voices by 20 different professional singers (9 female and 11 male), performing 17 different singing techniques in various contexts. We selected ten techniques ("belt," "breathy," "inhaled singing," "lip trill," "spoken excerpt," "straight tone," "trill," "trillo," "vibrato," and "vocal fry") by all singers for the classification. We used the officially provided data split: 15 singers for the training set and 5 singers for the test set. We trimmed the silence from the audio and split it into non-overlapping chunks of 3 seconds. Typically the sampling rate of the audio tracks of VocalSet is 44.1kHz, the audio is resampled to 16kHz. For training the models, we used Adam optimizer [46] with 20 epochs. We set the learning rate of 3×10^{-3} for the first stage on the first five epochs and 5×10^{-5} for the second stage with the remaining epochs. The batch size is set to 16.

TABLE III
SELECTED SAMPLES FROM VOCALSET.

Label name	Type of fluctuation	Samples #
straight	None	1241
belt	Timbre	423
breathy	Timbre	455
vocal fry	Timbre, Modulation	587
vibrato	Modulation	1034
trill	Modulation	323
trillo	Modulation	242
lip trill	Modulation	376
inhaled	Other	151
spoken	Other	73

The data distribution of VocalSet is imbalanced over the classes that affect the classification performance [53]. Therefore, we adopt the inverse frequency weight for the loss function. The typical weight value w_c for the class c is as follows:

$$w_c = \frac{1}{(n_c)^\alpha} \tag{2}$$

where n_c is the number of training samples in class c, and α is the smoothing factor, which controls the smoothing of the loss weights. Note that α = 0 corresponds to the value of 1 (i.e., no weighting) and α = 1 corresponds to a reciprocal number (i.e., weighting by the inverse class frequency). We set α = 0.2, which performed the best score in [53]. We evaluated the models by the following metrics: F1-score, Accuracy, Balanced accuracy, Top-2 accuracy, and Top-3 accuracy. We consider several conventional works as baselines.

1) **1DCNN**: This model utilizes a CNN architecture that directly takes raw waveform as inputs. It serves as the official baseline model of the Vocalset dataset [52].
2) **OblongCNN**: This model employs a CNN architecture that takes a multi-resolution spectrogram, consisting of stacked representations with three different time-frequency resolutions as input. Additionally, it incorporates four convolutional layers of varying shapes [8].
3) **D-CNN-cRT**: This model replaces the standard convolutional layers with Deformable convolution and employs Classifier Retraining (cRT) [54] for training with a focus on addressing class imbalance [53].

2) Results: Table IV shows the results of singing technique classification. MapMusic2Vec exhibits the best performance in four SSL models and comparable performance to other conventional approaches. It also achieved higher accuracy compared to the best-performing method among the conventional works, D-CNN-cRT.

D. Layer-wise contribution analysis

We further analyze the weight of each encoder layer's output for each SSL model. Figure 3, 4, and 5 show the weights after training on singer identification, singing voice transcription, and singing technique classification, respectively. In each figure, 'Ln' denotes the weight of the n-th encoder layer's output (i.e., L0 is for the input of the first layer.).

TABLE IV
THE RESULTS OF SINGING TECHNIQUE CLASSIFICATION.

Methods	F1	Acc	BAcc	Top-2	Top-3
Wav2Vec2.0	56.1	58.3	60.1	74.8	82.1
WavLM	55.6	60.8	57.9	75.3	83.8
MERT	54.1	58.5	58.5	76.1	85.3
MapMusic2Vec	<u>60.8</u>	**<u>66.0</u>**	<u>62.1</u>	<u>79.0</u>	<u>86.9</u>
1DCNN [52]	48.8	58.4	48.4	76.4	86.3
OblongCNN [8]	51.3	55.4	57.5	74.3	85.8
D-CNN-cRT [53]	**62.0**	65.6	**65.5**	**81.5**	**88.7**

For singer identification, the strong contribution lies in the early layers of each SSL model. This finding aligns with previous research investigating the layer-wise contribution in various speech-related tasks, such as those presented in several works [13], [55]. These studies suggest that speaker-related information tends to be captured in the early layers of the models. Consequently, it can be inferred that a similar pattern holds true for singers, indicating that the crucial information for singer identification is also encoded in the early layers of the SSL models.

For singing voice transcription, except for MERT, the contribution also tends to lie in the early layers of each SSL model. According to [41], low-level prosodic features such as pitch or loudness tend to locate the early layers of speech SSL models. Since pitch information is the most important for singing voice transcription, the results that align with the work are unsurprising. In the case of MERT, CQT spectrogram is utilized as a prediction target. Therefore, it is plausible that the last layers of MERT contain pitch-related information. As several works [56], [57] reported, singing voice transcription is relating the information of phonemes as well as the pitch (i.e., onsets are often accompanied by the transition of the lyrics). It might cause this "unsmooth-shaped" distribution compared to other tasks.

In the case of singing technique classification, the early layers exhibit greater values compared to other layers in each model. Specifically, the first layer holds the greatest significance. It might be because singing techniques are influenced by pitch modulation and timbre variation. However, there is also a possibility that it is affected by the data imbalance where vibrato and straight, whose characteristics are the status of pitch modulation, are the majority classes.

V. CONCLUSION

In this study, we address the challenge of limited data availability in singing voice understanding tasks by leveraging transfer learning of pre-trained self-supervised (SSL) models. We employ four different SSL models as the frontend of our target task model. The models are subjected to comprehensive experiments encompassing singer identification, singing voice transcription, and singing technique classification. Our experimental results demonstrate that each SSL model achieves comparable and in some cases superior, performance when compared to conventional state-of-the-art models. Additionally, we conduct layer-wise analysis to inspect the behaviors, specif-

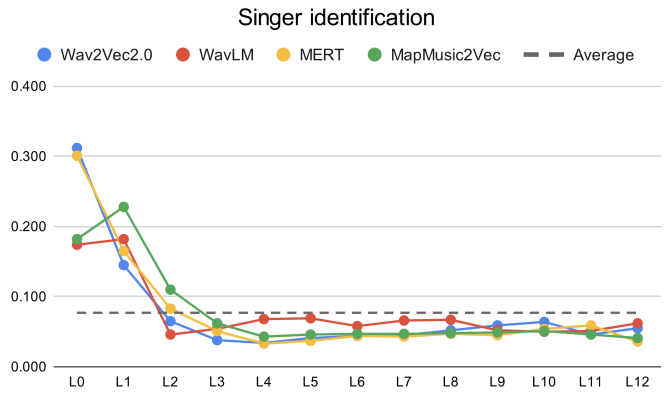

Fig. 3. The weights after training on singer identification.

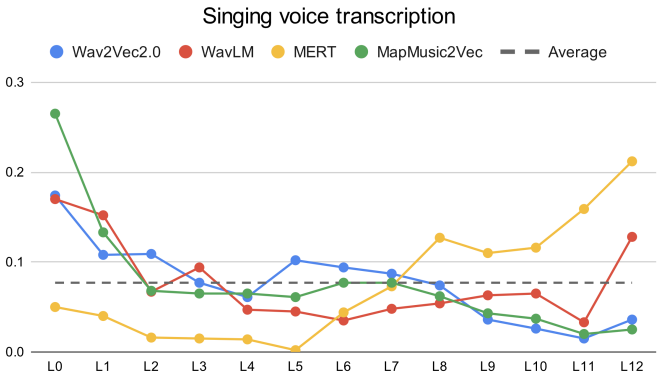

Fig. 4. The weights after training on singing voice transcription.

ically analyzing the weights of each layer. Moving forward, our future research endeavors will focus on further investigating the impact of feature representation in addressing the data scarcity issue in automatic singing voice understanding tasks. Furthermore, we propose that future studies can explore other singing voice understanding tasks, such as vocal melody extraction [58], lyric transcription [59], and singer diarization [60], among others, to expand the scope of research in this domain.

VI. Acknowledgements

I am grateful to Hiroko Terasawa and Juhan Nam, for their fruitful comments on the methods and evaluation of models. I also appreciate Jun-You Wang from National Taiwan University, for assisting in the preparation of *MIR-ST500*.

***Abstract*—We detect out-of-vocabulary (OOV) words from spoken utterances. A straightforward cascade model, where syllable recognition and word segmentation are simply concatenated, often fails to correctly segment syllables around OOV words. Because OOV words in spoken dialogues with systems do not appear in the training data, some reasonable constraints in such situations are necessary. In this study, we propose a method combining two ideas to detect OOV words. First, we jointly decode syllable sequences and word boundaries in them using user response patterns, which exist in the user responses to explicit confirmations from a spoken dialogue system. These patterns serve as constraints on vocabulary in utterances and the positions of OOV words. We represent OOV words as arbitrary syllable sequences and use finite-state transducers (FSTs) containing both OOV words and in-vocabulary words as constraints during decoding. Joint decoding with these constraints can also reduce syllable recognition errors. Second, we automatically select the better results between the baseline cascade model and the joint model through model selection. This effectively improves the detection performance as not all user utterances follow the patterns. Experimental results show improvement in the F-score for OOV word detection.**

I. Introduction

A. Motivation

It is important for spoken dialogue systems to recognize out-of-vocabulary (OOV) words. These are words not included in a vocabulary list utilized by automatic speech recognition (ASR) in a dialogue system. Traditional ASR having a finite set of words as its vocabulary cannot recognize OOV words. If OOV words are not recognized, the system cannot respond appropriately. Therefore, we need an ASR that can recognize OOV words. This process also leads to acquiring them as a new vocabulary [1].

Syllable recognition [2] is a promising approach for recognizing OOV words instead of word-based ASRs. Since the performance of syllable recognition by a deep neural network (DNN) has improved [2], [3], we use it in this study. A straightforward approach for recognizing OOV words is to simply concatenate syllable recognition and word segmentation [4]. We call this approach the cascade model. This model is effective for segmenting frequent syllable patterns in the training data. However, OOV words in spoken dialogue systems do not generally appear in large training data. Thus, some reasonable constraints are required on the appearance positions of OOV words and vocabulary in user utterances.

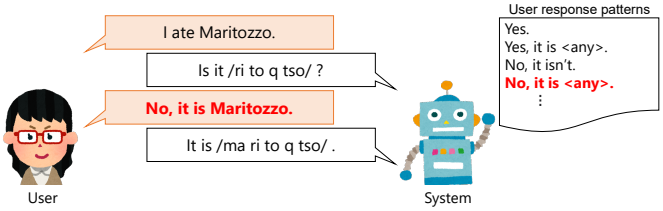

Fig. 1. Ideal example of OOV word detection using explicit confirmation from a spoken dialogue system. Although the first user's utterance is incorrectly recognized as "/ri to q tso/," the correct recognition of "/ma ri to q tso/" is obtained by using the user response pattern.

We focus here on a situation after receiving explicit confirmations from spoken dialogue systems. An example is shown in Fig. 1. In this situation, after recognizing the user's first utterance "I ate Maritozzo," the system explicitly confirms it by repeating recognized syllable sequences. In situations where a system asks a question as an explicit confirmation, the user often responds using specific patterns. These patterns can be used as reasonable constraints for OOV word detection. We aim to correctly detect OOV words by using these user response patterns as constraints (shown on the right in Fig. 1). In Fig. 1, although the user's utterance is initially misrecognized as "/ri to q tso/," the correct recognition of "/ma ri to q tso/" is obtained thanks to the use of the user response patterns.

In this study, we propose a method that combines two ideas for OOV word detection. The first is a joint decoding of syllable recognition and word segmentation with the user response patterns. The patterns are described as a finite-state transducer (FST) [5], [6] and are used during decoding. In addition, the joint decoding of syllable recognition and word segmentation can reduce errors in syllable recognition.

The second is automatic model selection, that is, to select either of the recognition results obtained from two models: the cascade or joint model. Because users can speak arbitrarily, not all user responses can be included in the FST. OOV word detection with model selection is expected to yield better results for user utterances that do not match the user response patterns. We then automatically select an OOV word detection result

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

from the two, leading to improved performance. We compared the logarithmic scores of syllable sequences recognized by the two models during the model selection.

B. Related Works

Recently, there have been many studies on end-to-end speech recognition for OOV word detection. Each of these studies has varied in terms of approaches [7]. One example is a study that accurately recognizes OOV words using external information such as knowledge graphs [7]. However, this method assumes that OOV words are included in the entities of the knowledge graph, making it unsuitable for scenarios involving entirely new words not present in the existing knowledge. Another approach is to use a hybrid system that combines multiple models, such as word, subword, and phoneme models [8]–[11]. In particular, [9] takes advantage of the trend to repeat OOV words in dialogue.

There are also several studies that aim to acquire OOV words from speech without using end-to-end speech recognition [12], [13]. Neubig et al. created a language model by extracting word-phoneme sequences and transition probabilities from spoken utterances without using any prior linguistic information [12]. Shinozaki et al. extracted phoneme sequences of OOV words from spoken utterances and expanded the system's internal pronunciation dictionary [13]. Their study assumes the system has an existing pronunciation dictionary in advance.

In addition, there are several studies on unsupervised word segmentation directly from speech [14]. Kamper et al. focused on infants' language acquisition from speech in their native language. In their experiment, only 11 vocabulary words, from "zero" to "nine" and "oh", were used in the evaluation. However, this is a very primitive method that uses clustering to identify words, which makes it very difficult to recognize thousands of words in real dialogues.

The biggest difference between the aforementioned studies and our study is the situation of asking back to OOV words. Unlike ASR systems, spoken dialogue systems can ask questions to the user as needed.

II. Preliminaries

A. Problem Settings

Our goal is to detect OOV words contained in a user's speech. Specifically, we estimate a syllable sequence and word boundaries from the user's speech signal, to obtain a word sequence. We regard words that are not included in the vocabulary list as OOV words. Syllable sequences are represented in katakana. The vocabulary list is a set of unique words, which are registered in the form of syllable sequences.

We treat the simultaneous estimation of syllable sequences and word boundaries in OOV word detection as a search problem to maximize the posterior probability.

$$\hat{\mathbf{c}}, \hat{\mathbf{z}} = \mathrm{argmax}_{\mathbf{c},\mathbf{z}} p(\mathbf{c}, \mathbf{z}|\mathbf{X}) \tag{1}$$

where $\mathbf{X} = [\mathbf{x}_1, ..., \mathbf{x}_T], \mathbf{x}_t \in \mathbb{R}^D$ $(t = 1, ..., T)$ is the input speech feature sequences of length T, $\mathbf{c} = [c_1, ..., c_L]$ is a corresponding syllable sequence of length L, and $\mathbf{z} = [z_1, ..., z_L], z_l \in \{0, 1\}$ $(l = 1, ..., L)$ denotes a sequence of binary indicator variables of length L representing word boundaries. If a word boundary immediately follows a syllable c_l, $z_l = 1$; otherwise, $z_l = 0$. For example, if $\mathbf{c} =$ [a, me, ka, ze] , and $\mathbf{z} = [0, 1, 0, 1]$, we will obtain two word tokens, "ame" and "kaze". If there is no entry for "kaze" in the vocabulary list V, "kaze" is recognized as an OOV word.

For simplicity, we approximate the posterior probability by the following conditional probability. We then reformulate it using syllable recognition.

$$p(\mathbf{c}, \mathbf{z}|\mathbf{X}) \approx p(\mathbf{c}|\mathbf{X}) p(\mathbf{z}|\mathbf{c}), \tag{2}$$

where we define two models. We define $p(\mathbf{c}|\mathbf{X})$ as the syllable recognition model and $p(\mathbf{z}|\mathbf{c})$ as the word segmentation model. Our goal is to find $\hat{\mathbf{c}}, \hat{\mathbf{z}}$ that maximizes the posterior probability.

B. Simple OOV Word Detection Method: Cascade Model

The cascade model is that in which syllable recognition and word segmentation are concatenated sequentially. Syllable recognition and word segmentation are performed in accordance with the formula as:

$$\hat{\mathbf{c}} = \mathrm{argmax}_{\mathbf{c}} p(\mathbf{c}|\mathbf{X}), \text{and} \tag{3}$$

$$\hat{\mathbf{z}} = \mathrm{argmax}_{\mathbf{z}} p(\mathbf{z}|\hat{\mathbf{c}}) \tag{4}$$

In syllable recognition, we estimate a syllable sequence $\hat{\mathbf{c}}$ from a sequence of speech features $\mathbf{X}$. In word segmentation, we estimate a word boundary variable sequence $\hat{\mathbf{z}}$ from the estimated syllable sequence $\hat{\mathbf{c}}$. We then obtain a word sequence from the estimated syllable sequence $\hat{\mathbf{c}}$ and the word boundary variable sequence $\hat{\mathbf{z}}$, and OOV word judgment is performed. After that, we check if these words are included in the vocabulary list, and regard words that are not included as OOV words.

III. Joint Decoding with the User Response Pattern

OOV word detection using the cascade model is often incorrect because this model does not utilize information about the context of the dialogue and the location of OOV words. Therefore, we use the joint model. In this model, we utilize a specific situation where a user responds to an explicit confirmation from the system. During decoding, we jointly decode syllable sequences and word boundaries. By using a model specialized for this situation based on the user response pattern, we aim to detect OOV words more accurately than the cascade model.

User responses to explicit confirmations from the system show several patterns, particularly regarding the position of OOV words and the vocabulary included in the user's responses. To construct the user response pattern model, we first prepare a set of user response patterns U from the user response data (syllable sequences and word boundaries) provided, which are represented using an FST. Subsequently, we use the FST for joint decoding of syllable recognition and word segmentation.

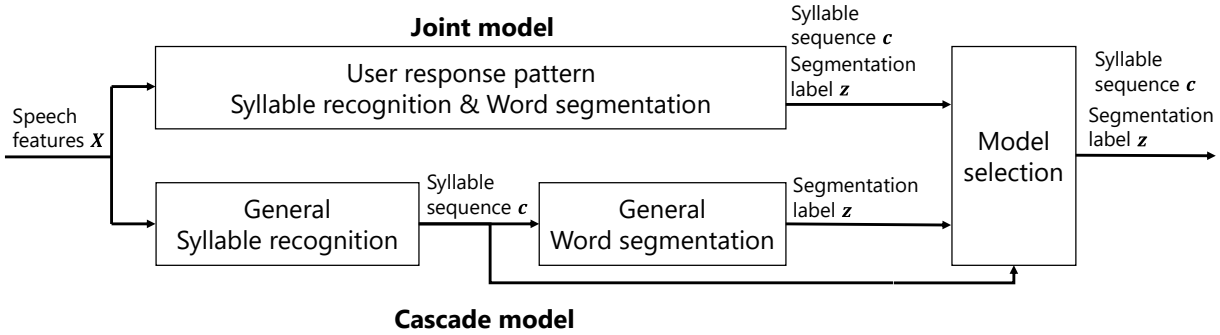

Fig. 2. Framework for our proposed method. The cascade and joint models are used together with model selection.

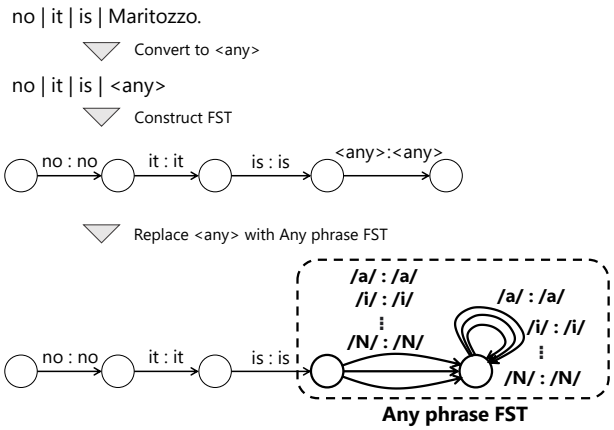

Fig. 3. How to construct FST from user utterances data.

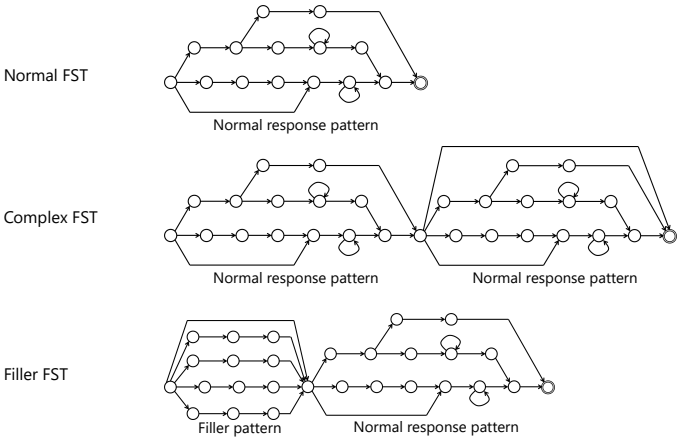

Fig. 4. Three kinds of FST.

Because not all user utterances follow the patterns, we use the model selection to flexibly detect OOV words for utterances that do not match the user response patterns. We select either of the recognition results obtained from the two models as shown in Fig. 2.

A. Joint Model

1) Formulation: In joint decoding, in accordance with Eq. (2), we jointly estimate syllable sequences $\mathbf{c}$ and binary indicator variable sequences $\mathbf{z}$ from speech features $\mathbf{X}$. We incorporate the user response pattern FST into an end-to-end ASR recognition model that uses language model scores, such as the hybrid CTC/Attention model [2]. $p(\mathbf{z}|\mathbf{c})$ corresponds to the language model.

By replacing the language model with the following function $f(\mathbf{z}, \mathbf{c})$, we can express the equivalent of excluding syllable sequences that are not accepted by FST from the candidate recognition results.

$$f(\mathbf{z}, \mathbf{c}) = \begin{cases} \text{const.} & \text{if } [\mathbf{z}, \mathbf{c}] \in U \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

2) Construction of User Response Pattern FST: In this method, a user response pattern FST is constructed from the user response data to explicit confirmations from the system. First, candidate OOV words, which can be replaced with OOV words, in the user response data are converted into an "any tag": <any>. In Fig. 3, Maritozzo is replaced with "any tag": <any> as a candidate OOV word. Then, an FST is constructed from the converted data to ensure only the response data can be recognized. Next, "any tags" are converted to Any phrase FST, which accepts an arbitrary syllable sequence in accordance with the following two rules to make it a natural Japanese word. In syllable recognition, if the Any phrase FST is generated without any constraints, syllable sequences that do not follow Japanese syllable chain rules may be generated, so it is necessary to add rules to make it natural Japanese.

The first rule is to reject only single-syllable words because a word corresponding to an OOV word rarely has only one syllable. The second rule is to reject sequences of syllables that cannot exist in the Japanese language. This FST only accepts patterns that are contained in the training data.

In addition to the normal response pattern FST, we construct two FST: one for complex responses (Complex FST) and one for responses with a filler (Filler FST), which increases the number of utterances that the FST accurately matches (in Fig. 4). This is because the normal response pattern FST accepts only the response patterns included in the user response data used to construct the FST. There will be cases in which a

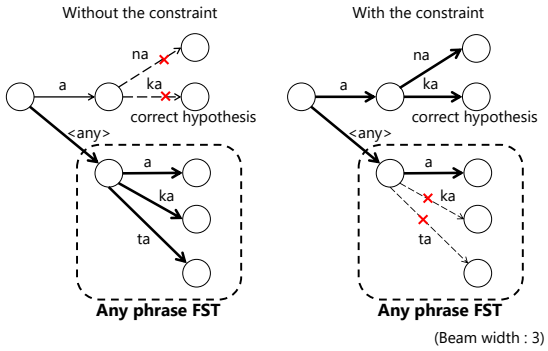

Fig. 5. The constraint in which only one hypothesis in the Any phrase FST is retained in order not to overflow the correct hypothesis. In this figure, all candidates except for the best candidate ("a") are excluded.

response is given in complex sentences, such as "No, it isn't. It is Maritozzo." There will also be cases in which a reply is given in sentences with a filler, such as "Uh, it is Maritozzo." Therefore, we construct three kinds of FST in Fig. 4 to accept such utterances. The Complex FST includes additional patterns that repeat the normal response pattern twice. The Filler FST includes additional patterns that contain filler at the beginning of a sentence in Fig. 4.

3) Decoding with User Response Pattern FST and post-processing: In decoding, hypotheses are searched for using beam search. Since the FST includes the Any phrase FST, we need to apply certain constraints. The correct hypothesis out of the Any phrase FST will overflow from the beam width without any constraints. Consequently, the correct hypothesis may not be recognized.

We set a constraint where only one hypothesis is retained in the Any phrase FST (Fig. 5). In Fig. 5, only the best hypothesis "a" is retained, while the other hypotheses are rejected. This reduction in the Any phrase FST can help streamline the beam search process.

After obtaining the word sequence by using the FST, word segmentation is performed again for "any phrase", which is compatible with the Any phrase FST (post-processing). This meant that "any phrase" may include known words in this constraint. By post-processing, our approach can handle cases where "any phrase" contains a known word.

B. Model Selection

It is possible to flexibly recognize utterances that do not match the pattern by selecting which recognition results to adopt, either from the cascade model or the joint model. The joint model is inflexible and does not accurately recognize utterances that do not match the FST. Thus, we recognize such utterances by using the cascade model.

Model selection is determined by the score of the syllable recognition model $p(\mathbf{c}|\mathbf{X})$. This is because utterances that do not match the FST are recognized as syllable sequences that are significantly different in the joint model. Thus, we measure the difference between the log scores of the results obtained from the cascade model and those from the joint model to determine the more suitable recognized results on the basis of threshold θ. The search for $\hat{\mathbf{c}}, \hat{\mathbf{z}}$ is performed as:

$$\hat{\mathbf{c}}, \hat{\mathbf{z}} = \begin{cases} \mathbf{c}_d, \mathbf{z}_d & \text{if } \log(p(\mathbf{c}_g|\mathbf{X})) - \log(p(\mathbf{c}_d|\mathbf{X})) \leq \theta \\ \mathbf{c}_g, \mathbf{z}_g & \text{otherwise} \end{cases} \quad (6)$$

where $\mathbf{c}_g, \mathbf{z}_g$ and $\mathbf{c}_d, \mathbf{z}_d$ are the syllable sequences and the sequences representing the word boundaries of the recognition results using the cascade and joint models.

OOV words	0	0	169

IV. EXPERIMENTS

We examined the effect of the proposed method on OOV word detection. The cascade model described in Section 2 was used as a baseline for comparison. We discussed the detection of OOV words on the basis of the experimental results using the proposed method.

A. Configuration

In syllable recognition, we used ESPnet [15], in which we used the hybrid CTC/Attention model and Transformer for the encoder and decoder. In word segmentation of the cascade model and post-processing of the joint model, we used the Nested Pitman-Yor Language Model (NPYLM) [4]. To construct the FSTs, we used OpenFst [16]. Then, the nouns corresponding to foreign foods such as "Maritozzo" were assumed to be OOV words and replaced with "any tag" <any>. The value of the constant in Eq. (5) was set to 1.0. The model selection's threshold θ in Eq. (6) was set to 0.5 as the best threshold by experimenting with several values.

The cascade model was used as the baseline in the experiment. We compared the performance of the proposed method, which involved the model selection methods of the cascade and joint models. To compare FSTs, OOV word recognition was performed for the methods using the normal FST, Complex FST, and Filler FST. In addition, we also experimented with the joint model only without model selection, to confirm the effect of model selection.

The evaluation metrics used were precision, recall, and F-score of OOV word detection. We also evaluated the character error rate (CER) of syllable recognition, and precision, recall, and F-score of word segmentation to assess the performance of syllable recognition and word segmentation. For OOV word detection, we evaluated the correctness of the start and end positions of OOV words in a syllable sequence. For OOV word recognition, we evaluated whether the estimated OOV words matched the OOV words in the reference data.

B. Train Data and Test Data

The Corpus of Spontaneous Japanese (CSJ) [17] full dataset was used to train syllable recognition models for ESPnet. The CSJ core dataset was used to train the word segmentation model using NPYLM. CSJ full dataset contains 660 hours of Japanese speech data from individuals of various ages and genders. CSJ core dataset is part of the CSJ full dataset, about 500,000 words. In addition, spoken dialogues between users and the system were used for the construction of the user response patterns FST and test data. These dialogues were originally recorded in our laboratory and were conducted on the theme of food in foreign countries, which was decided in advance. The system prompted the user for utterances containing OOV words in dialogues. In this experiment, we used only the responses in the dialogue data and performed 4-fold cross-validation. The data was divided into four blocks, with one block as the test data, and the remaining for constructing the FST for the user response patterns.

Table I shows the size of the data used in this experiment. The set of unique words in CSJ was used as the vocabulary list for the system, resulting in 54,463 words. The row of OOV words in Table I indicates the number of words in the data that are not included in the vocabulary list.

C. Results

Table II shows the results of OOV word detection for three models. In the table, the Complex FST was used in the proposed method, which had the highest F-score for OOV word detection among the three FSTs. The F-score serves as the main evaluation criterion, while recall and precision indicate a reference. A comparison of each FST will be presented later.

First, for the F-score in OOV word detection, the proposed method increased by 0.012 points from 0.352 to 0.364, compared with the baseline. Second, the proposed method also increased the F-scores for both word segmentation and OOV word recognition. The proposed method increased the F-score for word segmentation by 0.007 points from 0.926 to 0.933, and that for OOV word recognition by 0.006 points from 0.283 to 0.289, compared with the baseline. Third, model selection is an effective method. For comparison, we also experimented with the method of decoding with only the FST without model selection in the row "Only FST." This method yielded lower values than the proposed method and the baseline for the F-score in OOV word detection. The F-score decreased by 0.081 points from 0.364 to 0.283, compared with the proposed method. This lower performance is likely due to the usage of the FST for utterances that did not match the FST.

Table III shows the results of each FST model: normal FST, Complex FST, and Filler FST. Among these models, the Complex FST model achieved the highest F-score for OOV word detection. The Complex FST model increased the F-score by 0.005 points from 0.359 to 0.364, compared with the normal FST model. In addition, the Complex FST model also has the highest F-score among the three models for word segmentation and OOV word recognition. The Complex FST model increased the F-score of word segmentation by 0.009 points from 0.924 to 0.933 and the F-score of OOV word recognition by 0.003 points from 0.286 to 0.289, compared with the normal FST model.

Next, we discussed the performance of syllable recognition. Table IV shows the CER for each model. The correctness in the first row represents the rate of syllables recognized without character errors. The proposed method reduced the error rate by 0.002 from 0.041 to 0.039 and increased the correctness by 0.003 points from 0.935 to 0.938, compared with the baseline. This indicates that the proposed method improves the performance of syllable recognition. We also compared the method of decoding with only FST without model selection. In the only FST model, the insertion error

TABLE V
RECOGNITION EXAMPLE. THE FST MODEL CAN SPLIT CORRECTLY. THE CASCADE MODEL RECOGNIZED A KNOWN WORD AS AN OOV WORD.

Cascade model	ma | ri to q cho: | de su | i ta ri a | no | ta be mo no | de su	/ri to q cho:/
Normal FST model	ma | ri to q cho: | de su | i ta ri a | no | ta be mo no | de su | mi su | mi ta i | na | ka N ji	/ri to q cho:/
Complex FST model	ma | ri to q cho | de su | i ta ri a | no | ta be mo no | de su	/ri to q cho:/

TABLE VII
RECOGNITION EXAMPLE. THERE ARE MANY INSERTION ERRORS IN THE RESULT OF THE USER RESPONSE PATTERN MODEL

Model	Recognized text	Syllable recognition score
Reference	e: q to | ne | ne pa: ru | no | ta be mo no | de | da ru ba: to | da | yo	-
Cascade model	e: q to | ne | ne pa: ru | no | ta be mo no | de | da ru ba: to | da | yo	-0.119
FST model	e: q to | ne | ne pa: ru | no | ta be mo no | q te | yu: | o | ka shi | na | N | da | ke do | ne pa: ru | no | ta be mo no | da | yo	-4.308

increased significantly by 0.152 points from 0.012 points to 0.164 points, compared with the proposed method. In addition, only the FST model reduced the correctness by 0.031 points from 0.938 to 0.907. Thus, model selection is effective for reducing errors in syllable recognition.

An example of OOV word detection using user response patterns is shown in Table V. The cascade model split "/o ra N da/ (Netherlands)" into "/o/" and "/ra N da/," and "/ra N da/" was incorrectly regarded as an OOV word. On the other hand, the user response pattern model did not split "/o ra N da/ (Netherlands)" and guessed that it is a known word.

Next, we compared the models using the normal FST and the Complex FST. Table VI shows an example of the recognition results. For utterances that do not match the user response pattern, the normal FST model recognition result differs significantly from the reference. On the other hand, the Complex FST model can correctly recognize them because they correspond to the response pattern. However, in the situation of Fig. VI, "any phrase" is "/ma ri to q cho:/" in accordance with the response pattern, but the post-processing split it into "/ma/" and "/ri to q cho:/". Therefore, the Complex FST model resulted in incorrect OOV word detection.

Table VII shows increasing insertion error of recognition results. The syllable recognition score in the table is the difference between the syllable recognition scores of the two models. In this example, this utterance matches the Complex FST but does not match normal FST. When the FST model was used for utterances that did not match the FST, many insertion errors "/mi su/ /mi ta i/ /na/ /ka N ji/" occurred in the normal FST. The increase in insertion errors results in a lower likelihood of syllable recognition. Therefore, by setting an appropriate threshold, we could choose the appropriate model between the cascade model and the user response pattern model.

V. CONCLUSION

In this paper, we focused on OOV word detection of user responses during explicit confirmations. We proposed a method that contains two ideas, the joint model and model selection. In the joint model, we constructed the user response pattern FST and applied it to syllable recognition and word segmentation. In model selection, we choose the recognition results of the joint model and those of the cascade model. The proposed method improved the F-score of OOV word detection. The use of the user response pattern model in syllable recognition also improved its performance.

In addition to the normal response pattern FST, we also constructed the Complex FST and Filler FST, and compared their OOV word detection performance. The performance of the Complex FST model was higher than that of the normal FST model. The Filler FST model did not perform better than the normal pattern FST model.

One of the issues to be addressed in the future is the consideration of post-processing of the "any phrases." Currently, word segmentation is performed for all phrases identified as "any phrases". However, this method can lead to over-segmentation splitting OOV words that could have been correctly extracted. We believe that post-processing with proper conditions can reduce over-segmentation and achieve higher performance in OOV word detection.

Another issue is how to construct the FST. In the proposed method, we recognized utterances that did not match the FST by using the cascade model. However, it often failed to correctly detect OOV words. Although we constructed the normal FST that only accepts patterns that the user response data contains, the performance of OOV word detection may be improved if we construct an FST that accepts more user response patterns.

***Abstract*—Recent studies have shown that synthetic speech can effectively serve as training data for automatic speech recognition models. Text data for synthetic speech is mostly obtained from in-domain text or generated text using augmentation. However, obtaining large amounts of in-domain text data with diverse lexical contexts is difficult, especially in low-resource scenarios. This paper proposes using text from a large generic-domain source and applying a domain filtering method to choose the relevant text data. This method involves two filtering steps: 1) selecting text based on its semantic similarity to the available in-domain text and 2) diversifying the vocabulary of the selected text using a greedy-search algorithm. Experimental results show that our proposed method outperforms the conventional text augmentation approach, with the relative reduction of word-error-rate ranging from 6% to 25% on the LibriSpeech dataset and 15% on a low-resource Vietnamese dataset.**

Index Terms: speech recognition, domain filtering, semantic similarity maximization, vocabulary coverage maximization

I. Introduction

The conventional automatic speech recognition (ASR) approach involves using separately trained acoustic, language, and pronunciation models. In contrast, the more recent end-to-end (E2E) ASR system integrates all these components into a single neural network that directly predicts text sequences from input speech waveforms [1]. Despite its impressive performance, the end-to-end (E2E) ASR system has some limitations. It necessitates a significant amount of training data to achieve optimal results and is extremely sensitive to out-of-vocabulary (OOV) words, which can negatively impact its performance [2]. This presents a significant challenge when developing a new E2E-ASR model for many real-world applications with limited in-domain training data, including low-resource language ASR.

Several methods have been proposed to tackle this low-resource problem for E2E-ASR, including unsupervised-pretraining [3]–[5], transfer learning [6]–[8], and data augmentation [9]–[13]. Of all the approaches mentioned, this paper focuses on data augmentation as it is easy to implement and has demonstrated outstanding performance. Recently, a deep-neural-network-based text-to-speech (TTS) model has been shown to generate speech with comparable quality to human speech. Therefore, many recent studies have tried to use synthetic data generated from a TTS model [14]–[21] to train an E2E-ASR model.

Most prior studies rely on transcribing the in-domain text data or generating simulated text with predefined templates to synthesize speech (cf. Section II). However, text data obtained with these methods might not have enough lexical diversity as seen in the real text, yielding the OOV issue. One possible solution is to use text data from a generic-domain source, which can diversify lexical context with large-scale data. However, using a generic-domain source is challenging since it results in a domain mismatch and can negatively impact the ASR performance.

To avoid this problem, this paper focuses on a domain filtering technique that can remove irrelevant sentences from the target domain and increase the performance of ASR. To achieve the best efficiency with augmented synthetic speech, we raise the following two desired factors for the text selection:

- Semantic similarity: the augmentation text should be similar to the in-domain text data (i.e., refers to the same topics, same writing styles, etc.).
- Vocabulary coverage: The vocabulary of the augmentation data should be diverse to minimize the OOV.

To satisfy these factors, this study proposes to use a domain filtering method based on semantic similarity maximization using the Sentence-BERT language model [22]. The proposed method also involves diversifying the vocabulary during data selection by using a greedy search algorithm to maximize the vocabulary size iteratively. We referred to this step as vocabulary coverage maximization.

The rest of this paper is organized as follows. In Section II, we introduce the related works to this study. In Section III, we introduced the proposed text selection algorithm based on semantic similarity and vocabulary maximization. In Section IV, we demonstrate the effectiveness of the proposed method on a common ASR framework in low-resource settings. Finally, we conclude our paper in Section V.

II. Related Work

Recently, neural speech synthesis models have gained significant advancements and shown to generate synthetic speech that achieves a naturalness level comparable to human speech [23], [24]. The advantage of synthetic speech is that it can be easily generated and manipulated to create diverse training data. In a study by Mimura, et al. [25], synthetic

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

speech generated by the Tacotron-2 sequence-to-sequence TTS model is used to alleviate the OOV problem of acoustic-to-word (ASW) E2E-ASR. The results suggest that adding synthetic speech, even from a single female speaker, can significantly improve ASR performance compared to using only real speech. In [16]–[20], acoustic variations in synthetic speech, such as speaker characteristics and speaking styles are introduced to further improve the robustness of ASR models across different conditions. This paper builds upon these recent advancements but places more emphasis on linguistic variations.

Conventionally, the text data needed to generate synthetic speech is collected from the transcription of the in-domain data [15] or generated using a language model. For example, it was proposed to utilize a MaxEnt language model [26] to generate new utterances, which increase the lexical diversity of the text data [16]. Unlike our approach of selecting real text from a generic domain, this method requires retaining generated sequences with a length of fewer than 20 words and a perplexity score under 500 to avoid utilizing unrealistic utterances. SynthASR was also proposed to utilize synthetic speech to improve ASR performance in specific low-resource domains [21]. The authors randomly combine predefined text utterance templates with common medication names to augment the text data. Then, for each generated sentence, synthetic speech with different voice profiles is generated. In study [27], the authors generate text based on data augmentation for natural language understanding using semantic frames [28]. The text augmentation comprises four steps: delexicalization, diversity classification, text generation using a sequence-to-sequence model, and surface realization. The result from the text augmentation process is a paraphrased version of the source sentence. Unlike these techniques that rely on task-specific knowledge, such as medication names or semantic frame information, our proposed methods are entirely data-driven based on a Sentence-BERT language model.

III. Proposed Method

This paper proposes to maximize the effectiveness of text selection by choosing text that resembles the target data domain (for example, audiobooks or conversations). To minimize errors resulting from OOV words, it is important to ensure diversity in the vocabulary, while maintaining not to cause the domain mismatch between real and synthetic data. Therefore, we propose a domain filtering method to maximize both the semantic similarity and the vocabulary coverage of the synthetic speech. Figure 1 shows the overview of the proposed domain filtering method for synthetic speech generation. The proposed method is two-staged: semantic similarity maximization (SSM) and vocabulary coverage maximization (VCM), each of which is described in the following subsections.

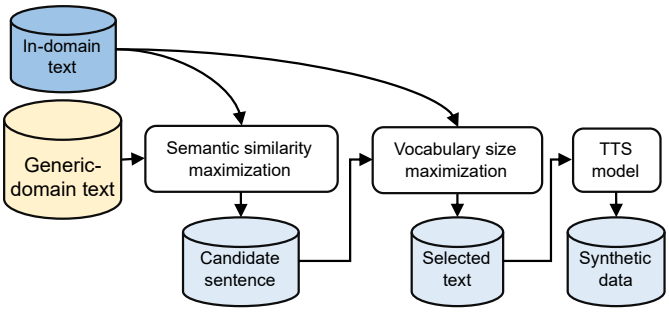

Fig. 1: Overview of the proposed text domain filtering method for synthetic speech generation.

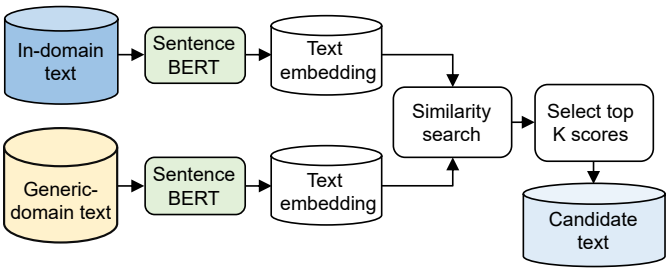

Fig. 2: Flow diagram of semantic similarity maximization.

A. Semantic similarity maximization

To exploit the training E2E-ASR advantages, the text data used for generating synthetic speech should ideally belong to the same domain as the in-domain text. Taking a virtual assistant ASR as an example, text from a casual conversation dialog is preferable to those from news articles.

The flow of the proposed text selection method is depicted in 2.

We first select relevant sentences that have high similarity to the in-domain text from the generic-domain text. To evaluate the semantic similarity, we use sentence embeddings extracted using a pre-trained Sentence-BERT model [22]. Sentence-BERT, which is a variant of BERT designed for processing sentences, has shown effectiveness in various natural language processing tasks, including semantic similarity, question-answering, and text classification. To assess the semantic similarity between the generic-domain and in-domain text, we initially extract embeddings for each sentence in both texts. Since the amount of generic-domain sentences is usually very large, we use the fast similarity search and clustering technique to reduce the search time [29]. For every sentence in the in-domain text, we search for 3 to 10 similar sentences in the generic-domain corpus based on the cosine similarity between embeddings. Finally, we eliminate duplicate sentences to obtain the final candidate sentence set.

B. Vocabulary coverage maximization

There is a trade-off between semantic similarity and vocabulary coverage. Relying only on semantic similarity to select text data often leads to limited vocabulary coverage

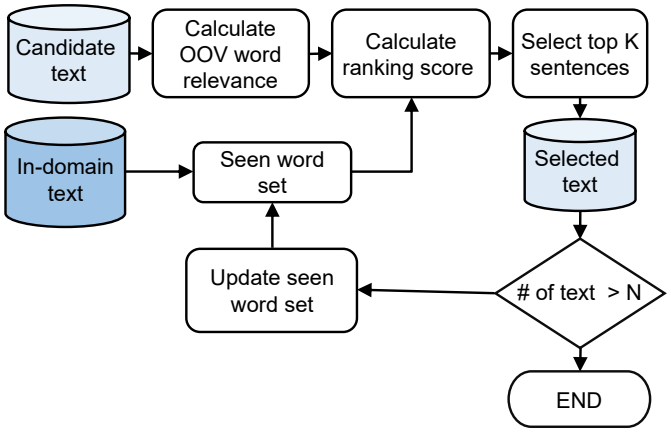

Fig. 3: Flow diagram of vocabulary coverage maximization.

because almost the same sentences may be selected. Selecting a larger set of sentences can increase vocabulary coverage, but an excessive amount of synthetic speech may degrade ASR performance due to the acoustic mismatch between real and synthetic speech data [16]. To overcome this issue, we propose a greedy search algorithm that maximizes the vocabulary coverage of the selected data while reducing the amount of text. Given a set of sentences that are selected to maximize semantic similarity using the method described in Section III-A, the second selection stage chooses a smaller set of sentences with maximum vocabulary coverage iteratively.

The process flow of the greedy-search algorithm is illustrated in Figure 3. To find which sentences should be included, we score each sentence in the set of candidate sentences based on how the sentence can increase the coverage. Let $\mathcal{D}$ be a set of words that have already appeared in either the in-domain text or in the text that has already been selected. The score of the i-th sentence is defined as

$$s_i = \frac{r_i}{|\mathcal{W}_i \cap \mathcal{D}|}, \tag{1}$$

where $\mathcal{W}_i$ is a set of words in the i-th sentence; thus, the denominator means the number of seen words in the sentence. r_i is the relevance of the unseen words to the target domain defined as

$$r_i = \sum_{u \in \mathcal{D} \setminus \mathcal{W}_i} r_i^{(u)}, \tag{2}$$

$$r_i^{(u)} = \max_{\substack{\mathcal{D}' \subset \mathcal{D} \\ |\mathcal{D}'|=K}} \frac{1}{K} \sum_{w \in \mathcal{D}'} \mathrm{sim}\left(w, u\right), \tag{3}$$

where $\mathrm{sim}\left(\cdot, \cdot\right)$ is a semantic similarity between two words. The similarity is calculated as a cosine similarity between two embeddings extracted using the GloVe model [30]. Eq. 3 intends to calculate the relevance score of the unseen word u on the basis of the top-K similar words in $\mathcal{D}$. The value of K is set to 20 in this paper.

With the calculated ranks, we select the sentence with the highest score and remove it from the set of candidate sentences. The word set $\mathcal{D}$ is also updated using the selected sentence. The steps above are repeatedly conducted until the predetermined number of sentences N is selected in total.

IV. Experiments

A. End-to-end Automatic Speech Recognition

For the E2E-ASR model, we used a Conformer-based connectionist temporal classification (CTC) / attention architecture [31]. The model consists of an encoder with 12 Conformer blocks and a decoder with six Transformer blocks. To train the model, we employed the ESPnet toolkit [32].

B. Experiment on LibriSpeech

We used the LibriSpeech [33] dataset as the in-domain data. LibriSpeech is derived from the larger LibriVox project, which contains free public-domain audiobooks. The dataset contains about 1,000 hours of speech from approximately 2,500 speakers.

Generic-domain text data was derived from the OSCAR corpus [34], which consists of text crawled from web pages. This text data covers different types of genres, reflecting the practical situation where only general domain text data is available. To reduce the computational amount, we used the subset of the corpus that includes 2 million sentences. As the OSCAR corpus text data is not in spoken form, we utilized the NeMo toolkit [35] for text normalization.

We adopted the Variational Inference with adversarial learning for end-to-end Text-to-Speech (VITS) model [24] as our synthetic speech generation model. VITS is an end-to-end TTS model that generates raw speech waveform directly conditioned on the input text and speaker identity. We used the VITS model pretrained on speech data of 108 speakers of the VCTK dataset from the ESPNet toolkit [32]. For each sentence in the selected text, we randomly sampled a speaker embedding from the list of 108 speaker embeddings to synthesize speech.

According to [15], the amount of real speech should be at least 20% in the training data to avoid degrading ASR performance for the LibriSpeech dataset. Therefore, we empirically selected 30 hours of real speech from the train-clean-100 subset of LibriSpeech and kept the amount of synthetic speech consistent at 70 hours for all selection methods. The synthetic speech consists of 108 speakers from the VCTK dataset. Combining the real and synthetic data, we obtained a total of 100 hours of training data. We also included the results of using all 100 hours of clean speech to demonstrate the top-line performance of the E2E-ASR model. The experiment's specifications for synthetic speech are summarized below:

- In-domain: we directly use the transcription from the train-clean-360 subset of LibriSpeech. This provides the upper-bound performance of the ASR when in-domain text data is accessible.
- Synthetic text: we use the transcription of training data and generate synthetic text by text augmentation method

TABLE I: Results on LibriSpeech dataset. %OOV is the ratio between the number of OOV words and the total word count in each evaluation set.

	Speech data (hours)			%OOV				WER (%)			
Text for TTS	Real	Synthetic	# of vocab.	dev-clean	dev-other	test-clean	test-other	dev-clean	dev-other	test-clean	test-other
N/A	30	0	19,995	4.7	4.3	4.5	4.8	13.9	27.9	14.3	29.0
N/A	100	0	32,550	**2.5**	**2.5**	**2.4**	**2.8**	**6.4**	**17.5**	**6.7**	**17.6**
In-domain	30	70	38,071	2.1	2.1	1.9	2.3	8.3	20.3	8.7	20.5
Synthetic text	30	70	25,504	4.0	3.6	3.7	4.0	11.6	23.5	11.8	23.9
Random	30	70	54,249	2.7	2.7	2.5	2.8	9.4	22.6	9.6	22.6
SSM (ours)	30	70	47,846	2.3	2.4	2.2	2.6	**8.7**	**21.1**	**8.8**	**21.4**
SSM+VCM (ours)	30	70	**71,901**	**1.5**	**1.8**	**1.6**	**1.9**	8.8	22.0	9.0	22.2

using the nlpaug toolkit[1]. We used the contextual word embeddings substitution augmenter using BERT.

- Random: we randomly select sentences from the generic-domain text and synthesize 70 hours of speech.
- SSM: we selected text data from generic-domain sources using only semantic similarity maximization. After the selection, we obtained 22K sentences for generating synthetic speech.
- SSM+VCM: we selected approximately 136K sentences from a generic-domain source using SSM, and then further filtered to synthesize the necessary amount of data using the vocabulary maximization method.

Table I shows the experimental results. We observed that all the methods using synthetic data successfully improved the word-error-rate (WER). In terms of the text used for synthesizing speech, using in-domain text (i.e., transcriptions of the train-clean-360 subset) yields the lowest WER, indicating the importance of domain-specific augmented text.

Using synthetic text to keep the domain similarity between real and synthetic data outperforms the randomly selected text by approximately 7% to 9%. This result confirms the importance of selecting semantically similar text to that of the target domain. However, compared with 100 hours of clean speech, the WER is relatively 20% higher due to the mismatch of the acoustic characteristics of real and synthetic speech. Using VCM to further reduce the number of OOV words resulted in slightly higher WERs although the number of OOV words is significantly reduced. This might be because the ASR model is trained on sub-words instead of words, which enables the ASR model to recognize OOV words.

Our proposed method also exhibits better performance compared to the text augmentation method, with improvements ranging from 6% to 30% in terms of relative WER reduction.

C. Experiment with low-resource language

We conducted an experiment using the Vivos dataset [36], which includes 15 hours of Vietnamese speech recordings from 50 native speakers. The dataset is relatively small for training any E2E-ASR model, with a training set of 11,660 utterances and a testing set of 760 utterances. The recordings consist of excerpts mainly from news articles and conversational dialogues. We randomly selected 10% of the training utterances for validation. For generic-domain text sources, we used the Vietnamese text corpus collected from Wikipedia[2]. After performing text cleaning, we obtained approximately 1.2M unique sentences. We used the pretrained *paraphrase-multilingual-mpnet-base-v2*[3] Sentence-BERT model to evaluate the semantic similarity. To generate synthetic speech, we adopted the multi-speaker TTS model using BiLSTM acoustic model and HiFi-GAN vocoder [37] pretrained on Vivos dataset[4]. We conducted experiments with three different amounts of synthetic speech: 15 hours, 30 hours, and 60 hours. As the multi-speaker TTS model was trained from the Vivos dataset, the final synthetic dataset consists of 50 speakers from the Vivos dataset.

We conducted experiments following similar settings in Section IV-B. The specifications are summarized below:

- Synthetic text: synthetic text generated using Vietnamese text augmentation toolkit[5] with the substitution rate of 0.9.
- Random: synthetic speech is generated from random sentences collected from a generic-domain source.
- SSM: synthetic speech is generated from approximately 11K sentences using semantic similarity maximization from a generic-domain source.
- SSM+VCM: 55K sentences are collected from a generic-domain source using semantic similarity, then we further selected using vocabulary maximization to synthesize the required amount of speech.

We used the same ASR model described in Section IV-A and an LSTM-based language model (LM) for rescoring. The E2E-ASR model was trained for 120 epochs with the learning rate gradually increasing to 1×10^{-4} in the first 15K steps and then exponentially decaying. We used the raw speech waveform as an acoustic feature. We applied speed perturbation at ratios 0.9, 1.0, and 1.1 [12] and SpecAugment

[13] for the data augmentation. Given that Vietnamese is a monosyllabic language comprising approximately 8,000 prevalent syllables, we train ASR model directly on word units instead of sub-word units, as detailed in Section IV-B. In our preliminary experiment, the model trained on word units demonstrates superior performance compared to the one trained on sub-word units. During inference, we averaged the weight of the top 10 models based on their validation accuracy. The search beam width was set to 20, while the CTC weight and LM weight were set to 0.3 and 0.1, respectively.

Table II illustrates the outcomes achieved by the proposed method in terms of ASR performance. When utilizing only 15 hours of synthetic speech, the proposed method exhibited a relative improvement of 15% and 9% compared to the synthetic text and random selection methods, respectively, on the test set with LM. Notably, a consistent reduction in WER was observed when augmenting the amount of synthetic speech to 30 and 60 hours. In all cases, the proposed data selection method outperformed the random selection approach. We also show the OOV error rate, which is measured as the ratio of correctly recognized OOV words (of the real speech data) to the total number of OOV words. The results in Table II indicate that while the baseline method without data augmentation failed to recognize any OOV word, our proposed method can reduce the OOV error rate to approximately 55.6% and 78.8%. Different from the experiment in Section IV-B, we have observed the efficacy of vocabulary expansion within the contexts of 15 hours and 30 hours of synthetic data configurations. This observation arises from the fact that OOV words cannot be accurately recognized, given that the ASR model is trained on word units rather than sub-word units. Consequently, the sole means of mitigating errors associated with OOV words is by increasing the vocabulary coverage. When the volume of synthetic speech was increased to 60 hours, the impact of vocabulary maximization on WER became less significant. Comparing the WER values between SSM and SSM+VCM, the difference was marginal (7.9% vs. 8.1% without LM, 7.5% vs. 7.5% with LM). This behavior was expected since, with the addition of more synthetic data, the most commonly occurring words were already included using the SSM alone. Consequently, the vocabulary maximization step did not further enhance the ASR performance.

V. Conclusions

In this paper, we proposed a data augmentation method using synthetic speech with text domain filtering to identify relevant text from generic-domain sources. The experiment results showed that combining semantic similarity search and vocabulary maximization gave better ASR performance than random selection and text augmentation methods. For future work, we aim to expand our data selection method into the acoustical domain to further improve the performance of E2E-ASR models in low-resource settings.

Abstract — **Throat microphones (TMs) can record sounds and mitigate the effects of external noise. Ongoing works seek to apply TMs to speech recognition in high-noise environments. However, building a TM-based speech recognition model is difficult in the absence of a large-scale TM speech database. We previously proposed a speech recognition method using latent representations obtained from pretrained self-supervised learning (SSL) models for each speech recognition task and subsequent feature mapping. However, SSL models are built for speech recognition tasks and are not appropriate for feature mapping tasks. Therefore, in this work, fine-tuning is applied to the feature extraction part of the SSL model so that the SSL model can derive latent representations useful for the feature mapping task. In the training process of the TM speech recognition model, we first perform fine-tuning using a large amount of pseudo-TM speech data generated by the feature mapping model and then perform a second fine-tuning using a small amount of *real*-TM speech data. In the second fine-tuning, the parameters of the transformer part of the SSL model are fixed in order to retain the linguistic information. The character error rate was reduced by 21.38% (from 8.14% to 6.35%) compared to the conventional method.**

Introduction

Throat microphones (TMs) detect vibrations directly from the skin covering the throat. They record sounds with less interference from external noise compared with ordinary microphones. Several studies on speech recognition have been conducted using TMs in high-noise environments. However, TMs record speech with less high-frequency bands than speech captured by close-talk microphones (CM). Thus, detection accuracy is reduced when TMs are utilized in common speech recognition systems. Although a speech recognition system that directly recognizes TM speech is currently under study, the development of this system is difficult without a large-scale database of speech recorded using TM. Several approaches have been proposed to solve this problem, including knowledge distillation using many pseudo-TM speech features. These features are created using a Deep Neural Network to map CM speech features to TM speech features [1] and eliminate mismatches through domain adaptation [2]. However, the training process in these methods is complex and costly. Therefore, we focused on pretrained self-supervised learning (SSL) models. We constructed a speech recognition model for TM speech by employing a fine-tuning method using pseudo-TM speech generated by feature mapping [3]. This method can be easily learned and yields high recognition accuracy from a small amount of TM speech data. We also proposed using pretrained SSL models in feature mapping tasks to mitigate the shortage of training data for feature mapping models [4]. This method improved the feature mapping model and the recognition accuracy of the TM speech recognition model. However, the SSL model opposes the framework for speech recognition tasks; fine-tuning only the transformer part of the SSL model does not yield latent representations suitable for feature mapping tasks. Hung et al. proposed a method of adapting the SSL model to speech enhancement tasks, wherein the feature extractor part of the SSL model is also simultaneously fine-tuned [5]. Thus, we fine-tuned the feature extractor part of the SSL model to derive latent representations benefiting feature mapping. We trained the speech recognition model by first fine-tuning the model based on a large amount of generated pseudo-TM speech and, subsequently, fine-tuning the model using a small amount of TM speech. The second fine-tuning improved recognition accuracy by apprehending the acoustic features of TM speech. However, the second fine-tuning decreased the linguistic information attained from the large-scale speech data. We prevented the reduction of linguistic information by fixing the weight of the transformer part of the SSL model during the second fine-tuning.

PROPOSED METHOD

A. *Feature Mapping Based on SSL Model*

We use an SSL model for the feature mapping method. Huang et al. [6] demonstrated that the use of an SSL model in speech enhancement tasks significantly improves recognition accuracy compared to conventional supervised learning approaches. In addition, Hung et al. [5] proposed adapting the SSL model for speech enhancement tasks by simultaneously training the feature extractor part of the SSL model. Inspired by this approach, we apply the SSL model to a feature mapping task that converts CM speech into TM acoustic features. Figure 1 shows the method of training in the feature mapping model. Parallel speech data was recorded simultaneously by a CM and a TM. The feature mapping model is time-frequency (T-F) mask-based and comprises a pretrained SSL model and long short-term memory networks (LSTM). The SSL model inputs raw CM speech and outputs a latent representation of speech. The LSTM estimates a short-time Fourier transform (STFT) mask of the pseudo-TM speech-based on the latent representation from the SSL model. Previously [4], we employed a training method that minimized losses between the STFT mask and the previously defined ideal phase-sensitive mask [7]. In this work, we estimate the STFT features of pseudo-TM speech by multiplying the estimated pseudo-TM speech STFT mask by the CM speech STFT features. Then, the parameters of the SSL model and the LSTM are updated by minimizing the mean square error (MSE) between the estimated pseudo-TM speech STFT features and the TM speech STFT features. More end-to-end learning can be performed using his method compared with conventional methods. This method enables us to perform end-to-end training of the feature mapping model.

The LSTM for the SSL model consists of three layers, 1,024 memory cells, and wav2vec 2.0 [8]. The pretrained wav2vec 2.0 model includes the feature extractor, the quantization, and the transformer. The weighted sum of the outputs from all layers of the transformer is utilized as the latent representation of speech rather than merely the output of the last layer of the transformer. The output of the last transformer layer is suitable for speech recognition tasks, while the outputs of layers close to the feature extractor part, such as the first layer, are suitable for tasks like speech enhancement and speaker separation. The wav2vec 2.0 model is pretrained with 56,000 h of speech data in 53 languages published by Conneau [9]. Pretraining models in various languages deliver better universal representations across multiple languages.

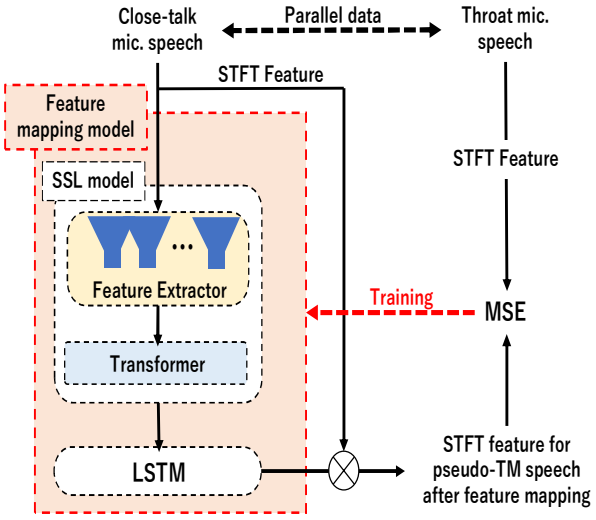

Fig. 1 The training procedure of the feature mapping model

B. *Data Augmentation and Fine-tuning of TM Speech Recognition Model*

At this stage, the acoustic features of TM speech are learned by fine-tuning the pretrained SSL model for speech recognition. The data is extended by generating pseudo-TM speech using the feature mapping model to compensate for the lack of training data for TM speech. Figure 2 shows the training process of the TM speech recognition model. Large-scale CM speech is input into the feature mapping model to obtain the STFT features of pseudo-TM speech, which are subsequently converted to a time domain using iSTFT to generate pseudo-TM speech. The pseudo-TM speech is used to fine-tune the pretrained SSL model. We use wav2vec 2.0 pretrained from 53 languages and 56,000 h of speech data as the SSL model for the speech recognition task and the feature mapping task. The fine-tuning method entails adding a linear layer to the final output layer of the SSL model and minimizing the connectionist temporal classification loss through correct labels. Training the acoustic features of TM speech by fine-tuning with only pseudo-TM speech is insufficient. Therefore, the speech recognition model is trained with two fine-tuning stages. The first fine-tuning for the SSL model is performed using pseudo-TM speech generated by feature mapping. The second fine-tuning is conducted using a small amount of TM speech. One problem with this method, however, is that the final fine-tuning is performed using a small amount of speech data, and therefore the linguistic information necessary for speech recognition cannot be extracted well. In other words, the first fine-tuning can be expected to acquire sufficient

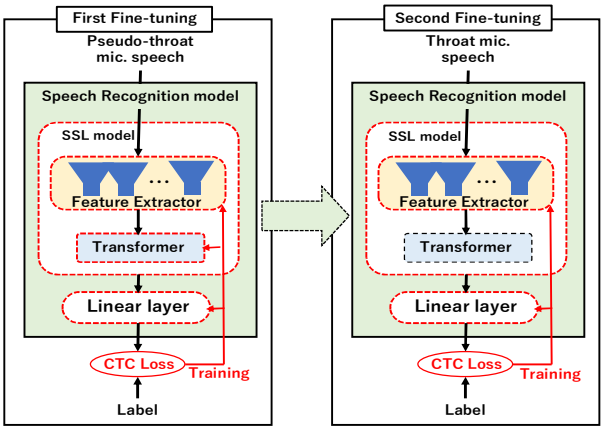

Fig. 2 Training process of throat microphone speech recognition model.

linguistic information from a large amount of data, but this information is replaced by poor ones in the second (final) fine-tuning. For this problem, we fix (freeze) the parameters of the transformer part trained in the first fine-tuning, and then perform the second fine-tuning with the fixed parameters. This method prevents the updating of linguistic information during the second fine-tuning. We also construct a speech recognition model using pseudo-TM speech generated via a feature mapping model without tuning the parameters of the feature extractor of the SSL model and compare this model with conventional methods. Additionally, we construct a speech recognition model without fixing the parameters of the transformer part of the SSL model to determine the influence of the extracted linguistic information. To determine if the linguistic problem could be prevented when different SSL models were used, the experiments were also carried out using HuBERT [10] and WavLM [11] as different SSL models.

EXPERIMENT

A. Experimental Conditions

Phonemically balanced, read-aloud parallel speech data (about 10 h) encompassing both CM and TM speech were used. The data were collected from ten male speakers and used as training data for the feature mapping model and fine-tuning the speech recognition model. We also utilized recordings of a newspaper-read speech (around 50 min) obtained from ten male speakers using TMs to evaluate the speech recognition model. All data were recorded in a quiet environment, and the speakers for the evaluation data were different from the speakers for the training data. Speech from the Corpus of Spontaneous Japanese (230 h), an existing large-scale Japanese dataset recorded through a CM, was also used. Pseudo-TM speech was created by applying feature mapping to the Corpus of spontaneous Japanese.

B. Experimental Results

The recognition experiment was accomplished by changing the dataset used to fine-tune the speech recognition model. The character error rate (CER) was used as an evaluation index. Table 1 displays the CERs for each model.

Table. 1 The character error rate of each throat microphones speech recognition model. Evaluation data are newspaper-read TM speech of 10 male speakers.

	SSL Model	Fine-tuning data	Feature mapping model	Speech Recognition model	CER[%]
1	Wav2vec	Thorat	–	Fine-tuning of all parts	25.86
2		Close talk			24.02
3		Close talk^{1st}→TM^{2nd}			14.38
4		Pseudo throat^{1st}→TM^{2nd}	Fine-tuning of only the Transformer part	Fine-tuning of all parts	8.14
5			Fine-tuning of all parts	Fine-tuning of all parts	7.5
6				Fine-tuning of only the Feature extractor part	6.35
7	HuBERT	Pseudo throat^{1st}→TM^{2nd}	Fine-tuning of all parts	Fine-tuning of all parts	6.94
8				Fine-tuning of only the Feature extractor part	4.8
9	WavLM	Pseudo throat^{1st}→TM^{2nd}	Fine-tuning of all parts	Fine-tuning of all parts	7.23
10				Fine-tuning of only the Feature extractor part	5.32

Models one–three denote the recognition results when the speech recognition model was fine-tuned without using pseudo-TM speech generated by feature mapping. We used existing speech data such as large-scale CM speech and a small amount of TM speech. In model one, fine-tuning was performed using only 10 h of TM speech. In model two, fine-tuning was performed using 230 h of CM speech. In model three, the first fine-tuning was accomplished using 230 h of CM speech, and the second fine-tuning was conducted using 10 h of TM speech. The recognition results for models one and two were 24%–25%, indicating that the small amount of TM speech was inadequate for training the speech recognition mode. The acoustic features of TM speech could not be recognized by training with only CM speech. The recognition results obtained from model three were significantly better than the results from models one and two. Thus, the efficacy of the advanced acquisition of general acoustic features and linguistic information by fine-tuning the model using large-scale CM speech before learning the acoustic features of TM speech by fine-tuning using TM speech was demonstrated. However, the

recognition accuracy was inadequate for fine-tuning the model with these datasets.

Models four–six denote the recognition results when the speech recognition model was fine-tuned using pseudo-TM speech generated by the feature mapping model. Model four represents a conventional method that only updates the parameters of the transformer part of the SSL model when fine-tuning the feature mapping model, to minimize the loss from the STFT masks. The recognition results from model four surpassed the recognition results from models one–three. Therefore, the use of pseudo-TM speech for fine-tuning eliminates the lack of training data for the speech recognition model, indicating that more acoustic features of TM speech were learned.

In models five–six, the parameters of all modules of the SSL model were updated during fine-tuning of the feature mapping to minimize the loss from the STFT features. Model five was constructed by updating the parameters of all modules of the SSL model during the second fine-tuning of the speech recognition model, as in model four. Model six was constructed by updating only the parameters of the feature extractor part of the SSL model during the second fine-tuning of the speech recognition model. The recognition results for models five and six were superior to the recognition results for model four, indicating that the SSL model can derive useful latent representations for feature mapping tasks by updating the parameters of the feature extractor part of the SSL model when fine-tuning the feature mapping. It was also found that minimizing STFT features instead of STFT masks when computing losses increases end-to-end learning. The results from model six were better than the results from model five. Hence, the linguistic information learned in the first fine-tuning was not reduced by fixing the parameters of the transformer part of the SSL model in the second fine-tuning of the speech recognition model and updating only the parameters of the feature extractor part; the recognition accuracy of the speech recognition model was further improved by this method.

In models seven–eight, HuBERT was used for the SSL model for speech recognition. Model seven was constructed by updating the parameters of all modules of the SSL model during the second fine-tuning of the speech recognition model as in model five. Model eight was constructed by updating only the parameters of the feature extractor part of the SSL model during the second fine-tuning of the speech recognition model as in model six. Models nine–ten used WavLM as the SSL model for the speech recognition model. Model nine was constructed by updating the parameters of all modules of the SSL model during the second fine-tuning of the speech recognition model as in model seven. Model ten was constructed by updating only the parameters of the feature extractor part of the SSL model during the second fine-tuning of the speech recognition model as in model eight. The recognition accuracy of fixing the transformer parameters in the second fine-tuning was good regardless of which SSL model was used, indicating that fixing the transformer part in fine-tuning is effective in preventing the reduction in linguistic information. Additionally, these results showed that HuBERT provides the best recognition accuracy as an SSL model.

CONCLUSIONS

In this study, in order to further improve the recognition performance of a speech recognition model suitable for TM speech, an approach was taken for both the feature mapping task and the speech recognition task. In the feature mapping task, by updating the parameters of the feature extractor part in the fine-tuning of the SSL model, the SSL model was able to derive a latent representation suitable for the feature mapping task and to learn more acoustic features of TM speech from pseudo-TM speech. It was shown to learn more features. In the speech recognition task, by fixing the parameters of the transformer part in the second fine-tuning of the SSL model, linguistic information obtained by fine-tuning using the large-scale pseudo-TM speech is ficed, and only the acoustic features of the TM speech are learned, which is more effective. We confirmed that by fixfing the parameters of the transformer part in fine-tuning, the recognition rete of the TM speech recognition model is further improved by learning only the acoutic features of the TM speech.

ACKNOWLEDGMENT

These results were obtained with a consignment project (JPNP 20006) by the New Energy and Industrial Technology Development Organization (NEDO).

ASR Model Adaptation for Rare Words Using Synthetic Data Generated by Multiple Text-To-Speech Systems

Kwok Chin Yuen*, Li Haoyang* and Chng Eng Siong
Nangyang Technological University, Singapore
E-mail: kwok002@e.ntu.edu.sg, li0078ng@e.ntu.edu.sg, aseschng@ntu.edu.sg

***Abstract*—Automatic speech recognition (ASR) for rare words is difficult as there are little relevant text-audio data pairs to train an ASR model. To obtain more text-audio pairs, text-only data are fed to Text-To-Speech (TTS) systems to generate synthetic audio. Previous works use a single TTS system conditioned on multiple speakers to produce different speaker voices to improve the output data's speaker diversity, and they show that training an ASR model on the more diverse data can avoid overfitting and improve the model's robustness. As an alternative way to improve the diversity, we study the speaker embedding distribution of audios synthesized by different TTS systems and found that the audios synthesized by different TTS systems have different speaker distributions even when they are conditioned on the same speaker. Inspired by this, this paper proposes to condition multiple TTS systems repeatedly on a single speaker to synthesize more diverse speaker data, so ASR models can be trained more robustly. When we apply our method to a rare word dataset partitioned from National Speech Corpus SG, which contains mostly road names and addresses in its text transcripts, experiments show that a pretrained ASR model adapted to our multi-TTS-same-SPK data gives relatively 9.8% lower word error rate (WER) compared to the ASR models adapted to same-TTS-multi-SPK data of the same data size, and our overall adaptation improves the model's WER from 57.6% to 16.5% without using any real audio as training data.**

I. Introduction

Rare words pose an ongoing challenge in the development of high-quality automatic speech recognition (ASR) systems [1]. These rare words, often associated with named entities like names and locations, play a vital role in preserving the intended meaning within the decoded transcript. Due to their limited occurrence in the audio-text pairs forming the training set of an ASR system, correctly predicting these "tail" words becomes inherently difficult.

One way to increase the number of text-audio training data pairs containing these rare words is to generate synthetic data using a Text-To-Speech (TTS) system. This method requires only text data as inputs to a TTS system, and does not require any change in the parameter or architecture of ASR models. Although there are many other methods like language model integration [2] and speech augmentation methods [3] [4] that can achieve a similar goal, [5] shows that the performance improvements are mostly independent.

As improving the speaker diversity of the synthetic training data can improve an ASR model's robustness [6] [7], previous works use a single TTS system conditioned on multiple speakers to produce different speaker voices. Alternatively, we found that using multiple TTS systems conditioned on a single speaker can also produce slightly different speaker voices. This is in line with several studies [8] [9], which shows that there can be noticeable differences in the real and TTS synthesized speaker voices. An analysis of the speaker embedding distribution of audios synthesized by conditioning different TTS systems on the same speaker is shown in Section V-C.

Inspired by this, we propose to synthesize data by repeatedly conditioning multiple TTS systems on the same speaker to synthesize more diverse speaker voices. Compared to methods that use a single TTS system to improve the speaker diversity by either conditioning the TTS system on multiple speakers or by tuning its parameters to control the speaker characteristics [10] of the synthesized audio, our method is less restricted by the trade-off [11] between the data's diversity and naturalness, i.e. improving the diversity of the synthesized audios costs less degradation in their quality. Also, our method can be applied to single-speaker TTS as the diversity can be compensated by the use of multiple TTS.

Our contributions are fourfold: 1) We explore the use of multiple TTS systems to synthesize training data to perform ASR adaptation. 2) We show that to generate diverse synthetic data, using multiple TTS systems conditioned on the same speaker is more effective than using a single TTS system conditioned on multiple speakers. 3) We show that freezing part of an ASR model when adapting to synthetic data gives better result than adapting the whole ASR model. 4) We provide baseline results on a high quality, publicly available rare word dataset, which consists of 13K utterances containing road names and addresses from National Corpus SG[1] [12]. The dataset is also released online[2].

II. Related Works

A. Rare Word Recognition

Several directions have been explored for improving rare word recognition. The Contextual Listen, Attend, and Spell (CLAS) model [13] represents an end-to-end ASR system that builds upon the foundational Listen, Attend and Spell (LAS) model initially proposed by Chan et al. [14]. A notable distinguishing characteristic of the CLAS model is its incorporation of contextual information in an entirely end-to-end fashion, setting it apart from the LAS model. In [15], phonetic fuzzing of proper nouns are used to find hard negative examples for training CLAS. These methods requires real text-audio pairs during training.

Several techniques requires text-only data to bias ASR model outputs to rare words. They include shallow fusion [16]–[18], cold fusion [19], and deep fusion [20] of an external language model. Other techniques focus on modifying the training data by either data augmentation [3] [4] or TTS data generation [21] [22] [23] [24]. Our work aims to synthesize training data of diverse speaker voices for rare word ASR.

B. Diverse TTS Synthetic Data Generation

Numerous efforts are made to improve a TTS systems ability to synthesize data with diverse speaker voices. [6] uses a Tacotron 2 model through conditioning the network on multiple speaker embeddings. [5] investigates the use of different types of speaker embeddings for conditioning the TTS. [7] increases the speaker diversity through conditioning a Tacotron 2 model on randomly chosen virtual speakers sampled from a latent space.

All the above mentioned works, however, focuses on using just a single TTS system to improve the speaker diversity of the synthetic data. In our work, we show that an ASR model's robustness can be further improved by increasing the speaker diversity of the synthetic training data using multiple TTS systems. To the best of our knowledge, we are the first to leverage multiple TTS systems to improve the speaker diversity of the synthetic data for ASR adaptation.

III. Methodology

We now introduce our method to improve the speaker diversity of TTS synthetic speech. Specifically given a set of N transcripts $\{u_1, \ldots, u_N\}$, we first feed each transcript u_n to a TTS system M_1 and condition M_1 on a randomly sampled speaker s_i, where $i \in \{1, \ldots, K\}$ and K is the number of speakers. We then synthesize another audio for u_n by conditioning a different TTS system M_2 on the same speaker s_i. We call our approach multi-TTS-same-SPK as we use multiple TTS conditioned on the same speaker to generate audio for each transcript. In contrary, we call the approach used by previous works to synthesize audio as same-TTS-multi-SPK, as they use the same TTS conditioned on multiple different speakers for each transcript.

A. Multiple TTS Systems

We use two state-of-the-art TTS systems of different architecture to generate more diverse data. The first TTS system uses TransformerTTS [25] as the acoustic model and HiFi-GAN [26] as the vocoder. The second TTS system is VITS [27].

1) TransformerTTS and HiFi-GAN: TransformerTTS is an autoregressive TTS that utilizes transformers with multi-head attentions in an encoder-attention-decoder based architecture. It is the acoustic model in the TTS system which generates mel-spectrogram frames sequentially from textual input. The generated mel-spectrogram is then passed into HiFi-GAN, a GAN based vocoder to generate high-fidelity audio waveform by upsampling the input through a series of transpose convolutions with a Multi-Receptive Field Fusion module following each transpose convolution to process patterns of different lengths in parallel.

2) VITS: VITS is a fully end-to-end TTS that utilizes variational inference augmented with normalizing flows and an adversarial training phase to capture high-fidelity speech from textual input. VITS composes of a prior encoder for both text encoding and normalizing flow, a posterior encoder for spectrogram encoding, a duration predictor, a HiFi-GAN generator for decoding and a multi-period discriminator from HiFi-GAN.

B. Speaker Conditioning

To enable multi-speakers capability for the TTS systems, speaker embedding vectors that capture speaker style information are added into TransformerTTS and VITS so that the TTS systems can use the information to generate audios that sound similar to the target speaker.

Our TransformerTTS is made multi-speakers by first extracting Xvector [28] from audio recordings and normalize it. Then, a linear transformation is applied and the result is added to the output of the TransformerTTS encoder. The combination of Xvector with TTS has proven to be effective in creating multi-speakers TTS in [9].

To enable multi-speakers capability for VITS, an external speaker encoder based on GE2E [29] is used to extract speaker embedding vectors from audio recordings. The speaker embedding vectors are then added to the residual blocks within the posterior encoder, the normalizing flow within the prior encoder, the input latent space of the duration predictor and the decoder. Similar to Xvector, the GE2E speaker encoder has shown promising results in creating multi-speakers TTS in [30].

IV. Experimental Setup

A. TTS synthetic data generation

All the TTS models we use are trained on the same VCTK corpus [31], a popular benchmark dataset for TTS containing about 44 hours of speech data from 109 native English speakers with various accents. The ESPnet2-TTS toolkit [32] is used for all TransformerTTS and HiFi-GAN experiments, while the

Coqui-ai TTS toolkit [33] is used for all VITS experiments. All models uses 80-dimensional mel-spectrograms. Also, all input text are converted to phonemes before feeding into the models. As the TransformerTTS and VITS TTS systems originally generates waveforms at a sampling rate of 22050 Hz and 24000 Hz respectively, and the ASR model is trained to receive only 16000 Hz audio as input, down sampling of the TTS synthesized audio is required before they are fed into the ASR model. The process may cause the loss of high frequency acoustic information in the audio. However, we hypothesize that such information loss has little effect for ASR adaptation as a sampling rate of 16000 Hz is sufficient to cover most of the human voice frequency range [34] and keep most of the needed information for ASR. Future works are needed to study the effect of down sampling on ASR adaptation performance.

The TransformerTTS model and HiFi-GAN model we use is pretrained and released by ESPnet2-TTS [32]. The FFT, window, and hop size for both models were set to 2048, 1200, and 300, respectively. The TransformerTTS model uses 6 layers of transformer blocks in both its encoder and decoder with 8 heads for multi-head attention. The decoder prenet has 2 linear layers with 256 hidden units, and the postnet has 5 CNN layers with channel and filter size 256 and 5 respectively. The model was trained using the Adam optimizer [35] with the addition of a guided attention loss to help learning diagonal attentions [36]. The HiFi-GAN generator uses hidden dimension size of 512, kernel sizes of [10, 10, 8, 6] for the transposed convolutions, kernel sizes of [3, 7, 11] and dilation rates of [[1, 1], [3, 1], [5, 1]] × 3] for the MRF modules. The HiFi-GAN model was trained using the Adam optimizer with a learning rate of 0.0002.

The VITS model we use is pretrained and released by Coqui-ai TTS. The model's configurations follow the original work [27], with the FFT, window, and hop size set to 2048, 1024, and 256, respectively. The model was trained with the AdamW optimizer [37] with $\beta 1$ = 0.8, $\beta 2$ = 0.99, weight decay γ= 0.01 and learning rate of 0.001. A windowed generator training is used with a window size of 32 to improve efficiency and lowering memory consumption during training.

We subset 10 hours of real audio-text training data pairs containing road names and addresses from National Corpus SG [12] as our real train set. They are recordings of people asking for directions and consists of 13K unique utterances. We also partition 1.63h of parallel data as the test set. Table I shows the details of the rare word (road names and addresses) coverage for the train and test set. Table II shows some example sentences in the train and test set.

Given the 13K text-only transcripts we obtained from the

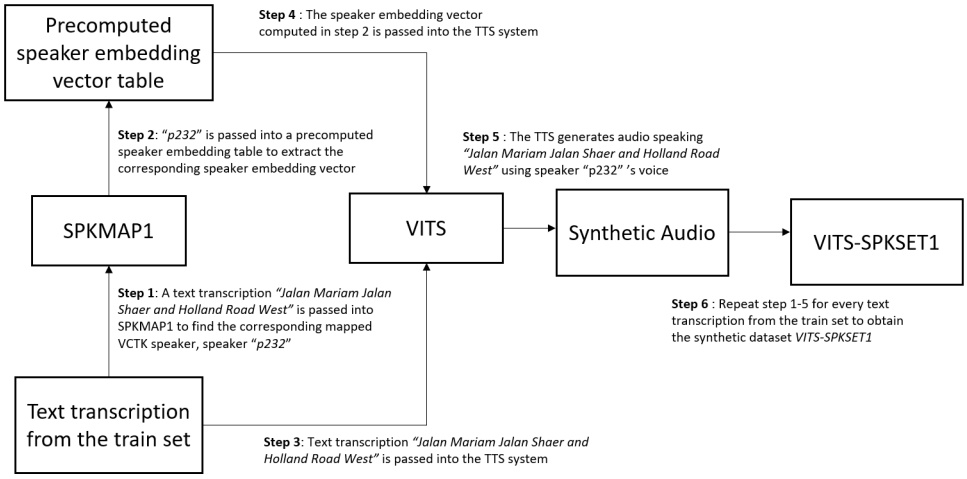

Fig. 1: Audio generation pipeline to obtain synthetic audio dataset *VITS-SPKSET1*. A similar pipline is also used to obtain synthetic audio dataset *VITS-SPKSET2*, *TRANS-SPKSET1* and *TRANS-SPKSET2*.

real train set, we first create a mapping named SPKMAP1 to map the text transcription of every utterance in the train set to a randomly sampled speaker in the VCTK corpus. We then obtain another mapping SPKMAP2 similarly, such that the mapped speaker for every text in SPKMAP2 is different from the mapped speaker in SPKMAP1. After creating SPKMAP1 and SPKMAP2, we generate 4 sets of synthetic audio data sets by varying the 2 speaker mappings SPKMAP1 and SPKMAP2 and varying the 2 TTS systems VITS and TransformerTTS systems used and name them VITS-SPKSET1, VITS-SPKSET2, TRANS-SPKSET1 and TRANS-SPKSET2.

Figure 1 shows the step-by-step procedure to obtain VITS-SPKSET1. In step 1, we first use SPKMAP1 to obtain the VCTK speaker id that is mapped to a text transcription in the train set. In step 2, we extract the speaker embedding vector that correspond to the VCTK speaker id obtained in step 1. In step 3, 4 and 5, we feed the text transcription (used in step 1) and the speaker embedding vector (extracted in step 2) into our VITS model to generate an synthetic audio file. We repeat step 1-5 for all text transcriptions in the train set, and the synthetic audio files obtained formed VITS-SPKSET1. To obtain VITS-SPKSET2, we simply replace SPKMAP1 with SPKMAP2, and repeat the pipeline just described. To obtain TRANS-SPKSET1 and TRANS-SPKSET2, we repeat the same steps using our TransformerTTS+HiFi-GAN TTS system in replacement of our VITS TTS system. Table III summarizes the basic information of all our datasets.

B. ASR adaptation

ESPnet [38] is used for all ASR experiments. Our pretrained ASR model is a SOTA Conformer model [39] trained on 960 hours of audio from the LibriSpeech dataset [40], which is a dataset containing audio recordings of English-language audiobooks recorded in 16kHz.

Our model follows an attention-encoder-decoder architecture [41], which consists of a Conformer encoder and an attention autoregressive (AR) decoder. Log Mel filterbank features [42] are extracted with a 25ms and 32ms window size and a 10ms and 16ms stride, model feature hidden dimension is 256 and 196, encoder Feed Forward Network (FFN) intermediate dimension is 1024 and 256 respectively. All our models use 80 dim. log Mel features, 4 attention heads, 6 decoder layers and 12 encoder layers. Swish activation [43] is used in FFN and the convolution modules [44] in the encoder has a convolution kernel of size 31. Decoder FFN intermediate dimension is 2048 and dropout rate is 0.1. Below the encoder is a convolutional subsampling module that receives log Mel feature inputs, and consists of a ReLU [45], two 2D convolution layers and a linear layer. A 2×2 stride and a 3×3 kernel is used in each convolution layer, effectively subsampling the input log Mel features by a factor of 4, and the convolution layer's channel size is the same as the model feature hidden dimension. We use joint CTC/attention decoding with CTC weight 0.3 [46] and beam size 20 during inference beam search [47].

We adapt the pretrained model to VITS-SPKSET1 (same-TTS-same-SPK) and TRANS-SPKSET1 (same-TTS-same-SPK) separately, to obtain 2 baseline ASR models. We then adapt the pretrained model to VITS-SPKSET1 + VITS-SPKSET2 (same-TTS-multi-SPK), and TRANS-SPKSET1 + TRANS-SPKSET2 (same-TTS-multi-SPK) respectively to form our second set of baselines. For our method, we adapt the pretrained model to VITS-SPKSET1 + TRANS-SPKSET1 (multi-TTS-same-SPK). Lastly we adapt the pretrained model to the real train set (ground-truth dataset) to find the performance upperbound.

During pretraining, we apply SpecAug [3] and set $m_F = 2$, $F = 27$, $m_T = 5$ and $p = 0.05$. Our dataset is augmented by speed perturbation with scaling factors of 0.9, 1.0, and 1.1. A joint CTC-attention loss function is employed with a CTC loss weight of 0.3. A label smoothing weight [48] of 0.1 is used in the attention loss, and the Adam optimizer [35] is used with a learning rate of 0.0025. For the learning

rate scheduling scheme, we follow ESPnet[38] implementation which has a warm-up and a decay stage. The warm-up stage has 25000 steps and the model is trained for 50 epochs. The final model is selected by averaging 10 checkpoints with the highest validation accuracy.

We also use the automatic mixed-precision (AMP) training implemented in PyTorch. During adaptation, we freeze the first 11 encoder layers and adapt only the last encoder layer, the CTC decoder and the attention decoder. We also reduce the learning rate to 0.000025 and the warmup steps to 1K, and train for 400 epochs.

V. Results and Discussion

Table IV shows that our model adapted to multi-TTS-same-SPK synthesized data outperforms all 4 baseline models adapted to same-TTS-same-SPK or same-TTS-multi-SPK synthesized data. Our model improves relative WER by 9.8% over the best baseline TRANS-SPKSET1+TRANS-SPKSET2, and improves relative WER by 71.4% over an unadapted model, showing the effectiveness of our adaptation method. However, there are still gaps between models adapted to real and synthesized data. Also, if we compare models adapted to single TTS data only, TransformerTTS performs better than VITS in all cases.

A. Discussion on why the multi-TTS-same-SPK approach outperform the same-TTS-multi-SPK approach in the experiments

As TTS synthesized data may contain artifacts that does not exist in the real data, we hypothesis that one factor contributing to the speaker diversity is the unique artifact pattern that exist in each TTS system. We further hypothesize that by adapting the ASR model to multiple TTS output distributions, it is less likely for the ASR model to over-fit to a specific TTS output distribution and therefore retaining the ASR model's capacity on processing real data.

B. Freeze model weights

Previous studies show that the top [49] or bottom [50] layers can be adapted to improve an ASR model performance in new domain data. Table V shows the result of adapting only the specific parts of the pretrained ASR model on VITS-SPKSET1. Compared to the unadapted results, adapting the last encoder layer improves relative WER by 31.6% and gives better result than adapting the first encoder layer. On the other hand, adapting both the CTC and attention-AR decoders improves relative WER by 52.3% and is the best adaptation result if the encoder is not adapted. Based on the results, we adapt the last encoder layer, the CTC and attention-AR decoders together and acheives the best WER of 21.1%, which improves relative WER 63.4% over the unadapted results, and improves relative WER by 8.3% over the results of adapting the whole ASR model.

C. Analysis on whether increasing the number of TTS systems can improve speaker diversity

Previous works have shown that conditioning a multi-speaker TTS system on a target speaker may produce synthesized speaker voice that sounds slightly different from the target speaker's ground-truth audio [8] [9]. We therefore hypothesize that a gap in speaker similarity may also exist between synthetic audios generated by different TTS systems conditioned on the same target speaker.

To investigate this hypothesis, we extract X-vector speaker embeddings from the ground-truth and synthesized audios and visualize the results using UMAP [51] in Figure 2. The structure of Figure 2 is as follows: It contains 4 sub-figures where each sub-figure shows the speaker embeddings of a target speaker. Within each sub-figure, there are 3 groups of speaker embeddings which corresponds to the ground-truth audio, the VITS TTS synthesized audio and the TransformerTTS synthesized audio respectively. Within each of the 3 groups, the speaker embeddings are extracted from audios speaking different transcripts.

From the results, we see that distinct clusters are formed from the ground-truth and synthetic audios. This shows that the speaker embeddings extracted from synthesized audios containing different transcripts are relatively close to each other if the audios are produced by the same TTS system conditioned on the same speaker, but the speaker embeddings are relatively far from each other if the audios are produced by different TTS systems conditioned on the same speaker.

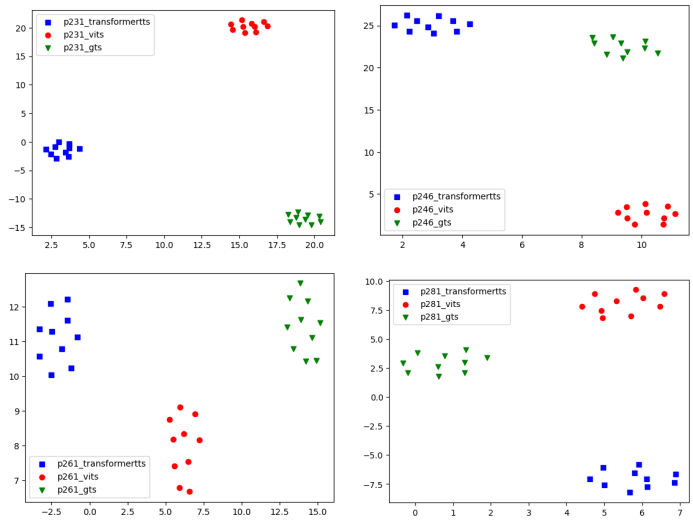

Fig. 2: UMAP plots of speaker embeddings extracted from ground-truth audios (gts), VITS TTS synthesized audios (vits) and TransformerTTS synthesized audios (transformertts). Best viewed in color.

TABLE IV: Effects of adapting a pretrained model on different combination of synthesized data. WER, substituion (sub.), insertion (ins.) and deletion (del.) errors are reported.

Data Combination	Data Type	Total # of sentences	WER (%)	Error (%) sub.	ins.	del.
None	n/a	0	57.6	44.0	5.5	8.2

layer 12	CTC + attention-AR	**21.1**	**16.2**	**1.1**	**3.8**

VI. Conclusion

In this work, we explore using multiple TTS systems to generate synthetic data for rare word ASR model adaptation, and show that it can improve the generated data's speaker diversity and improve ASR model adaptation results by up to relative 9.8% WER over same-TTS-multi-speaker systems. We also show a training strategy to freeze part of an ASR model when adapting to synthetic data, and it gives better result than adapting the whole ASR model. For future work, we will increase the number of TTS systems for ASR adaption and study the contributing factor of each TTS system.

***Abstract*—This study proposes a method of streaming automatic speech recognition (ASR) for Japanese speech using domain adaptation. The development of ASR technology has led to its employment in various fields, however several issues, such as the decline recognition accuracy which occurs due to domain mismatches between training and test data. In particular, the accuracy of online speech recognition, also known as streaming ASR, which is becoming popular in real-world applications, also suffers from this issue. To realize domain-adapted streaming ASR, in this study we utilize a method of domain adaptation known as the Density Ratio Adaptation (DRA), which uses Language Models (LMs) trained with extensive text data. Our proposed method employs DRA for streaming ASR of Japanese speech, in a model using a CTC decoder for recognition. To facilitate streaming ASR processing, the CTC decoder successively replaces linguistic information on a frame-by-frame basis, obtaining recognition results through greedy searches. Considering CTC's assumption of conditional independence, we used unigram LMs for the subtraction and addition of language information when using DRA, during which selected linguistic information is replaced. Experimental results demonstrate that the proposed method enhances speech recognition accuracy when there is data domain mismatch.**

I. Introduction

Improvements in the performance of Automatic Speech Recognition (ASR) models in recent years have led to the widespread use of this technology across various fields. End-to-End ASR models , in particular, have gained considerable attention, and are being utilized in smart speakers, transcript generators and voice dialogue systems. Models employing bidirectional Long Short-Term Memory (LSTM) [1] and Self-Attention [2] can perform ASR while taking into account the entire input sequence, which is known as "batch ASR", yielding highly accurate recognition results. This technique is useful for ASR tasks that do not demand rapid responses, such as the generation of meeting minutes, although it requires waiting until the end of speech segment to output ASR results, making immediate recognition impossible. For this reason, batch ASR models are inadequate for tasks requiring real-time responses, such as verbal dialogue, voice assistants, and subtitling. Therefore, a technique is needed that can process speech feature input, then output the results in a forward direction in real time, which is called "streaming ASR". Chunk-based and frame-based [3] methods for streaming ASR have both been proposed. Chunk-based methods sequentially store input features in fixed-length chunks, then perform ASR when the chunks are filled. Frame-based methods recognize speech step by step by improving the decoding algorithm. Streaming ASR models such as Connectionist Temporal Classification (CTC) models [4] and RNN Transducer (RNN-T) models [5], using a Recurrent Neural Network (RNN) or Convolutional Neural Network (CNN), have been proposed. One drawback of these methods, however, is lower recognition accuracy compared to batch ASR. This decrease in recognition accuracy is particularly evident when the domains of the data used to train the ASR model differ from the data to be recognized.

Various solutions have been proposed to tackle the issue of loss of recognition accuracy due to the domain mismatch, such as fine-tuning and domain adaptation methods using Language Models (LMs) [6], [7]. Fine-tuning requires both speech data and its transcription, from the domain to be recognized, which poses the challenge of time-consuming data collection. Thus, domain adaptation through fine-tuning, proves difficult when it is difficult to gather speech data and its transcription data. Conversely, domain adaptation methods using LMs have an advantage, as they use LMs trained solely on extensive text data, and thus require less time and effort to deploy, compared to acquiring speech and transcription data. The most common domain adaptation approach is Shallow Fusion, which combines the acoustic information from the ASR model and the linguistic information from the LM by adding their output probabilities in log-space with weighted coefficients [8]. Techniques for integrating LMs, such as Deep Fusion [9] and Cold Fusion [10], have also been proposed, but require retraining of the ASR model. Shallow Fusion, which does not require retraining of the ASR model, is commonly adopted due to its advantage of being able to easily integrate various types of LMs [11]–[13].

However, since the output of the ASR model already contains language information, overlapping of language information can occur when integrating an LM using Shallow Fusion. The Density Ratio Approach (DRA) [14], an extension of Shallow Fusion, has been proposed to address this issue. By using an LM trained with data from the same domain used for training the ASR model, and then subtracting the implicit language information contained within the ASR model, more precise domain adaptation has been demonstrated. It has been

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

shown that DRA is effective when using the RNN-T model for English, Spanish, and Italian speech data [15], and with the Hybrid CTC/Attention model and Joint CTC Attention Transformer model for Japanese data [16]. However, all of the methods using DRA incorporate decoding with a beam search [17], obtaining the final recognition results by reranking multiple candidates through substitution of the linguistic information using an LM. Although methods using beam searches can attain high recognition accuracy, they are slow to output the final recognition results, thus they cannot provide recognition results without a delay. In contrast, decoding using a greedy search allows sequential output of the recognition results at high speed, albeit at a lower level of recognition accuracy than that achieved by a beam search. DRA has been previously considered in the context of streaming ASR with RNN-T models [14], [15], however its application in streaming ASR models using CTC has yet to be explored. Although the recognition accuracy of CTC is lower than that of RNN-T, CTC offers advantages such as easier ASR model training, lower computational complexity, and smaller latency. Consequently, improving the recognition accuracy of streaming ASR models that utilize CTC is a significant issue yet to be resolved.

In this study, we refine the CTC decoder of a streaming ASR model that uses greedy searches, perform DRA on a per-time-frame basis, and demonstrate that domain adaptation is effective for enhancing accuracy, which is demonstrated through a performance evaluation using Character Error Rates (CERs).

II. Related work

A. Connectionist Temporal Classification (CTC)

CTC is a method specifically for labeling time-series data in ASR. To assign labels to time-series data, the probability of the occurrence of these labels in each frame is computed for a predefined set of labels. These labels include sets of words, phonemes and characters, as well as a `<blank>` symbol, which is neither a phoneme nor a character. The sequence of labels that maximizes the occurrence probability at each frame is determined, and a string is then obtained by eliminating repeated characters and `<blank>`. The loss function of CTC is expressed by the following formula:

$$\mathcal{L}_{\mathrm{CTC}} = -\log P(y|x), \tag{1}$$

Here, $P(y|x)$ represents the conditional probability of the correct that label sequence y is the correct label for input sequence x. This probability is calculated as the sum of the probabilities for all possible paths π. For instance, if the correct character string is $y = \texttt{cat}$, examples of the set of π of length 8 include:

$$\begin{aligned}\pi \;=\; & \{\texttt{c},_,\texttt{a},\texttt{a},\texttt{a},_,\texttt{t},_\},\{\texttt{c},\texttt{c},\texttt{a},\texttt{a},_,_,_,\texttt{t}\},\\ & \{_,_,_,\texttt{c},\texttt{a},\texttt{t},_,_\},\{_,_,\texttt{c},_,\texttt{a},_,\texttt{t},\texttt{t}\}.\end{aligned}$$

The sum of probabilities for all π that can lead to $y = \texttt{cat}$ becomes $P(y|x)$. Therefore, $P(y|x)$ can be represented as:

$$P(y|x) = \sum_{\pi \in B^{-1}(y)} P(\pi|x), \tag{2}$$

where B is a mapping from a path to a label sequence, and $B(\pi)$ is the label sequence corresponding to path π. $B^{-1}(y)$ is the inverse mapping of y, i.e., the set of paths corresponding to y. Because there are many such paths, it is difficult to calculate $P(y|x)$ directly. Therefore, in CTC, the forward-backward algorithm of Hidden Markov Models (HMMs) is employed to efficiently compute $P(y|x)$.

CTC calculates the probability of label appearance for the output of the ASR model at each frame, enabling streaming ASR by performing post-processing on the output for each frame.

B. Shallow Fusion

Shallow Fusion is a method that combines the outputs of an LM and an ASR model by taking a weighted sum in the log-space. This technique combines the acoustic information held by the ASR model and the linguistic information held by the LM. Shallow Fusion is a standard method for domain adaptation using an LM, and is formulated by the following equation:

$$y = \arg\max_{y} \{\log P_{\mathrm{ASR}}(y|x) + \lambda \log P_{\mathrm{LM}}(y)\}, \tag{3}$$

where $P_{\mathrm{ASR}}(y|x)$ is the probability of the ASR model outputting string y when given acoustic feature x, and $P_{\mathrm{LM}}(y)$ is the output probability of the LM trained with target domain recognition data. The advantage of Shallow Fusion is that it allows the training of the ASR model and an external LM with data from different domains.

C. Density Ratio Approach (DRA)

DRA, which is an extension of Shallow Fusion, is formulated by the following equation:

$$\begin{aligned}y = \arg\max_{y} \{&\log P_{\mathrm{ASR}}(y|x) - \lambda_{\mathrm{sub}} \log P_{\mathrm{LM,src}}(y)\\ &+ \lambda_{\mathrm{add}} \log P_{\mathrm{LM,tgt}}(y)\},\end{aligned} \tag{4}$$

Here, $P_{\mathrm{ASR}}(y|x)$ and $P_{\mathrm{LM,tgt}}(y)$ are the output probabilities of the ASR model and the LM trained with target domain data, respectively, similar to Shallow Fusion. $P_{\mathrm{LM,tgt}}(y)$ is called the "additive LM". $P_{\mathrm{LM,src}}(y)$ is the output probability of the LM trained using the same transcribed text used to train the ASR model, and is referred to as the "subtractive LM". By using this subtractive LM, the implicit language information included in the output of the ASR model is subtracted, and the language information of the target domain is added. This allows for the replacement of source domain language information with target domain information, enabling more accurate domain adaptation.

Algorithm 1 Decoding algorithm for applying DRA in a streaming CTC decoder. <none> is the symbol for nothing, which is removed during decoding. pack is a function that removes <none> from each element of the input and combines them into a string.

  for $i \leftarrow 0$ to N **do**
    if $i \neq \mathrm{idx}_{t-1}$ **then**
      $\mathbf{y}_t[i] \leftarrow \mathbf{y}_t[i] - \lambda_{\mathrm{sub}} \cdot \mathrm{LM}_{\mathrm{src}}[\mathcal{D}(i)] + \lambda_{\mathrm{add}} \cdot \mathrm{LM}_{\mathrm{tgt}}[\mathcal{D}(i), \mathrm{pack}(S_{0:t-1})]$
    end if
  end for
  return $\arg\max_i(\mathbf{y}_t[i])$
end function

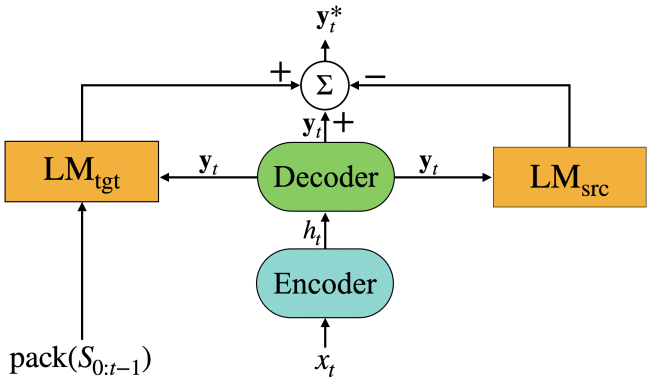

Fig. 1. Extension of DRA to apply to frame-by-frame output, where $\mathrm{LM}_{\mathrm{tgt}}$ and $\mathrm{LM}_{\mathrm{src}}$ are LMs trained with the target and source domain data, respectively. x_t is an acoustic feature, h_t is its embedding, $\mathbf{y}_t$ is a vector consisting of the output probabilities of the ASR model's decoder at the t-th frame.

III. Proposed Method

In this study, we apply DRA to streaming ASR in an end-to-end ASR model with a unidirectional LSTM encoder and a CTC decoder, using a greedy decoding algorithm[1], and a unigram LM. DRA replaces the implicit language information contained in text data by subtracting it via an LM. Ideally, the subtractive LM would be a suitable LM derived from the data used to train the ASR model, as with Hybrid Autoregressive Transducer (HAT) [18], but it is not feasible to identify the implicit language information from the training of the ASR model when using CTC.

CTC assumes conditional independence, i.e., that the output of the ASR model does not depend on the preceding or following context. We hypothesized that a unigram LM, which does not contain preceding or following context information, would be suitable as the subtractive LM used to apply DRA to the output of each frame.

In the frame-by-frame output of the CTC module, consecutive characters are eventually combined into a single character. Therefore, the timing of changes in language information occurs in two instances; when transitioning from <blank> to character, and when transitioning from one character to another. Thus, when we apply DRA to a frame defined as t, DRA is only applied to labels other than the character in the $(t-1)$-th frame. Here, we assume no LM processing for transitions to <blank>.

Figure 1 shows the extended form of DRA that was used on a frame-by-frame basis. The output of the CTC decoder on a frame-by-frame basis is typically the output probability of each label, and the recognition result is obtained by performing best path decoding, i.e., selecting the solution with the maximum likelihood value. However, in our proposed method, DRA is applied to each label in the frame-by-frame output before performing best path decoding. DRA as used in the proposed method is expressed by the following equation:

$$\begin{aligned}\mathrm{idx}_t = \arg\max_i \{&\log P_{\mathrm{ASR}}(\mathcal{D}(i)|x_t) \\ &- \lambda_{\mathrm{sub}} \log P_{\mathrm{uniLM,src}}(\mathcal{D}(i)) \\ &+ \lambda_{\mathrm{add}} \log P_{\mathrm{LM,tgt}}(\mathcal{D}(i)|\mathrm{pack}(S_{0:t-1}))\}, \end{aligned} \quad (5)$$

where $P_{\mathrm{ASR}}(\mathcal{D}(i)|x_t)$ is the label probability of the ASR model at the t-th frame, and where $P_{\mathrm{uniLM,src}}(\mathcal{D}(i))$ is the label probability of the unigram LM at the t-th frame. $P_{\mathrm{LM,tgt}}(\mathcal{D}(i)|\mathrm{pack}(S_{0:t-1}))$ is the label probability of the LM that is added to the output of the ASR model up to the $(t-1)$-th frame, excluding <blank> and continuous labels. $\mathcal{D}$ is a dictionary containing a character set and <blank> for ASR, i.e., $\mathcal{D}(i)$ indicates the i-th character, and $\mathrm{pack}(S_{0:t-1})$ is a determined string that does not change depending on the output of the ASR model after the t-th frame. Therefore, by outputting the string $\mathrm{pack}(S_{0:t-1})$ we can achieve streaming ASR. The pseudo-code for this approach is shown in Algorithm 1.

IV. Experiments

A. Experimental conditions

In our experiment, we used NVIDIA/NeMo [19], an audio processing toolkit, for training, inference and evaluation of the ASR and LMs. The data used in the experiment was taken from the Academic Presentation Speech (APS) and Spontaneous Presentation Speech (SPS) datasets of the Corpus of Spontaneous Japanese (CSJ). The APS and SPS datasets were each divided into "train", "dev" and "test" sets, which were

[1]In this paper, we propose a DRA algorithm which uses the greedy decoding algorithm. Note that our algorithm can be easily applied to beam search-based recognition by retaining multiple histories.

TABLE I
DETAILS OF APS AND SPS DATASETS

Dataset	Data Split	# of Speakers	Duration (h)
APS	train	889	253
	dev	49	10
	test	25	5
SPS	train	1555	303
	dev	80	13
	test	40	6

TABLE II
PERPLEXITY IN THE TEST SETS OF THE LANGUAGE MODELS USED FOR ADDITION AND SUBTRACTION

LM	Training set	Test set	
		APS	SPS
unigram	APS	184.1	199.9
unigram	SPS	232.2	162.5

used for training, development and cross-domain evaluation. Details of APS and SPS datasets are shown in Table I.

We used the LSTM-CTC ASR model and model architecture proposed in [20]. The encoder consisted of a 4-layer unidirectional LSTM, while the decoder used a single-layer conv1d, which applies 1D convolution over a multi-plane input signal. The input to the ASR model was an 80-dimensional log-mel spectrogram, and the per-frame output dimensionality of the ASR model was 3219, including the character set and <blank>. The learning rate was set at 1.0, AdamW [21] was used as the optimization algorithm, batch size was 128, and the maximum number of epochs was 50. The model used was selected based on the highest recognition accuracy evaluated using the dev dataset after each epoch.

We employed a unigram LM for both the subtractive and additive LMs. The unigram LM was trained using the training sets of both the APS and SPS datasets. We evaluated the performance of three LM integration methods (Baseline, Shallow Fusion and DRA) with different training and test sets. When using the baseline method, no addition or subtraction was performed by the LM, and the output of the ASR model was used "as is". The Shallow Fusion test approximated the ASR and additive unigram LM outputs through a weighted sum in the logarithmic domain. The DRA test subtracted the output of the subtractive unigram LM from the ASR model output, and added the output of the additive unigram LM, that the linguistic information contained in the two corpora differs. The addition and subtraction weights of the LM were tuned using the "dev" set. The evaluation metric used was the speech recognition CER.

In addition, we conducted experiments to confirm the accuracy of the timing of DRA application when using our proposed method, in which DRA is applied only to labels at the t-th frame, excluding the output label at the $(t-1)$-th frame. For our comparison experiment, DRA was also applied to all labels at the t-th frame, regardless of the output label at the $(t-1)$-th frame. The CERs when using each timing method were then compared.

TABLE III
RESULTS OF LM FUSION EXPERIMENT

Training set	Test set	Method	CER (%)
APS	SPS	Baseline	20.0
		Shallow Fusion	20.2
		DRA	**19.5**
SPS	APS	Baseline	23.2
		Shallow Fusion	23.0
		DRA	**22.2**

B. Experimental results

The results of the experiment are shown in Table III. We can see that the proposed DRA method achieved the lowest CER for both the APS and SPS test data. This suggests that implicit linguistic information can be replaced using a unigram LM to provide the language information to be subtracted from or added to, the per-frame output of CTC. We can also see that no improvement in CER from the baseline method was observed when LM integration was performed using the Shallow Fusion method, in contrast to the CER achieved when using DRA, which was slightly lower than the baseline method's CER. This can be attributed to the overlap of linguistic information contained in the output of the ASR model, and that contained in the output of the LM, when using Shallow Fusion. These results demonstrate the effectiveness of DRA for LM integration in streaming ASR using CTC.

The results of the experiment comparing the timing of DRA application showed that the proposed method achieved a higher ASR accuracy, with an improvement in CER of approximately 0.2%, compared to when DRA was applied without taking into consideration the output label at the $(t-1)$-th frame. We believe this is due to the fact that the proposed method was able to replace the linguistic information with the appropriate timing, by applying DRA at two points during the CTC ASR model's streaming output; when it changes from <blank> to a character and when it changes from one character to another.

V. CONCLUSIONS

In this study, we experimentally verified the effectiveness of domain adaptation through DRA in streaming ASR using a CTC decoder by demonstrating that the proposed method enhances speech recognition accuracy in cross-domain settings. We confirmed the efficacy of using a unigram LM for subtraction in DRA, and designed an algorithm for streaming ASR using DRA. Future work includes the choice of LMs for the addition of language information, measuring latency and real-time factor, and validating the results by using various dataset combinations because we used only two datasets.

***Abstract*—Biometric Template Protection (BTP) is an approach to protect biometric data in online biometric authentication. A hopeful scheme for BTP is *Biometric Signatures (BSs)*, which generates a digital signature for a given message using fuzzy biometric data as a private key, utilizing cryptographic tools such as fuzzy extractors. By advancing BTP, we introduce *Authenticated Sample Recoverability (ASR)*, a property that raw biometric samples such as images and videos of biometric traits having captured during past procedures can be recovered from the stored data and a biometric feature generated from the genuine user's sample captured again, while it is difficult to recover the past samples or features only from the stored data. This property is desired in various use cases. For example, in forensics, it is required to post-verify whether the genuine user used the system or fake sample was input during a past specific procedure, because the recovered sample is a strong evidence that the past sample was real or fake. Other examples include investigation of a cause when authentication accuracy in operation is low, and biometric reference update with multi-sample fusion using samples having captured in past procedures. To realize a template protected online biometric authentication system with ASR, we propose *Sample Recoverable Biometric Signatures (SRBSs)*. We present a generic construction of a SRBS scheme with EUF-CMA security, and give a specific construction in the random oracle model.**

I. Introduction

A. Background

As the spread of online services such as banking, shopping, file storage, and social media, online user authentication technology is becoming more and more important. Authentication procedures are performed with secret information, so it is crucial to prevent the secret information leakage. In addition, it is required to be secure against online attacks such as a replay attack and a real-time phishing. User convenience is also important because inconvenience hinders widespread use.

Widely used authentication methods are based on passwords, but it is difficult for password-based schemes to achieve both security and convenience. If users set a password to a simple one, it becomes more easy to guess. On the other hand, asking the user for a complex password reduces convenience.

Another method is based on a secret key stored on devices such as user's computer, IC cards, and hardware tokens. In particular, digital signature-based schemes such as FIDO[1] can protect online attacks such as a replay attack and a real-time phishing, and makes it difficult to guess the secret key from the verification key (or the public key) stored in the server and signatures transmitted during authentication procedures. However, users have to bring a device storing the secret key to authenticate themselves, which reduces convenience. Furthermore, if users lose the device, it leads to the risk of unauthorized use of the secret key[2].

A hopeful alternative is online biometric authentication, beginning to be used in commercial and governmental services [2][3]. In online biometric authentication systems, users can authenticate themselves using their own biometric traits such as face, fingerprint, and iris without remembering complex passwords or bringing a device for storing the secret key. A simple scheme might be one in which the server stores biometric data captured during an enrollment procedure, and compares it to biometric data captured during an authentication procedure. However, this scheme leads to the risk of biometric data leakage from the data stored in the server[3]. The leakage causes privacy invasion and increases impersonation risk. Furthermore, unlike passwords, it is difficult for users to change their biometric data if compromised. Also, there is a risk of online attacks for the simple scheme.

To protect biometric information from leakage, *Biometric Template Protection (BTP)* [5][6] has been studied and standardized. In BTP, biometric data is transformed into a biometric reference so that it is difficult to recover the original biometric data from the biometric reference. In particular, BTP which protects online attacks can be realized by schemes such as *Fuzzy Extractors (FEs)* [7][8] and *Fuzzy Signatures (FSs)* [9][10]. FEs generate a pair (r, p) of a secret key r and a helper string p from a fuzzy biometric feature y. The secret key r can be reproduced from the helper string p and a feature y' sufficiently close to y, and it is difficult to guess y or r from the helper string p alone. By using the secret key r for generating a digital signature, secure online authentication can

[1]FIDO is a trademark of FIDO Alliance.

[2]In order to lower the risk of unauthorized use, the device can perform additional authentication locally for access to the secret key. However, it is difficult for password-based schemes to achieve both security and convenience. Using biometric authentication locally is less convenient as compared to online biometric authentication because the former requires users to bring their devices after all.

[3]For example, due to a vulnerability in the Aadhaar system, anybody had access to biometric data of more than 1 billion Indian citizens [4].

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

be realized. FSs generate a digital signature using biometric data as a private key without a helper data. We call schemes which generate a digital signature for a given message using biometric data as a private key a *Biometric Signature (BS)*. BSs include FE-based digital signatures and FSs.

B. Motivation for Authenticated Sample Recoverability (ASR)

BTP makes it difficult for biometric data to be recovered from the stored biometric reference. By advancing this, we introduce *Authenticated Sample Recoverability (ASR)*, a property of achieving the following two: (a) From the stored data and a biometric feature generated from the genuine user's sample captured again, raw biometric samples such as images and videos of biometric traits having captured during past procedures can be recovered[4]. (b) It is difficult to recover the past samples or features only from the stored data. ASR is desired in the following cases, for example.

(Case 1) *Post-verification of past procedures in forensics.* Consider a situation in which a suspect of a crime wants to prove an alibi by showing that he/she used the authentication system at a specific time and place. The fact that the authentication was successful might be insufficient for the proof when he/she is claimed that another person might have input a fake biometric sample imitating that of the subject. Conversely, there is a situation when a user wants to prove that he/she did not use the system at a specific time and place, e.g., when an attacker spoofed the system by a presentation attack [11]. In these situations, if samples during past procedures can be recovered with the help of the genuine user's feature, it is a strong evidence that the user did or did not use the system at a specific time and place. In other words, this property ensures the accountability of the procedure.

(Case 2) *Investigation of a cause of low authentication accuracy.* Consider a case in which a user is relatively frequently rejected from the system (e.g., the false rejection rate of the system is 0.1% by specification but the user is rejected with the probability 10%). If samples during past procedures can be recovered with the help of the genuine user's feature, they can be a powerful clue for investigating the cause in more detail. One can check, for example, whether the past samples were captured under appropriate lighting conditions and whether the biometric traits are presented in an appropriate posture.

(Case 3) *Biometric reference update.* When a biometric authentication system upgrades algorithms such as feature extraction, it has to update enrolled biometric references to reflect the upgrade. It is known as *multi-sample fusion* that authentication accuracy can be improved by the system generating a biometric reference from multiple samples (e.g., [12][13][14]). If samples during past procedures can be recovered during the update procedure, they can be used for multi-sample fusion.

C. Limitation of Previous Work on ASR

Online biometric authentication systems with authenticated recoverability can be realized to some extent by BEs based on Dodis et al.'s FE [7]. Biometric authentication systems based on their FE[5] can recover the feature y obtained in the enrollment procedure from the helper string and a feature y' sufficiently close to y. Also, biometric features generated in authentication procedures can also be recovered with a sufficiently close feature if the system runs the generation algorithm additionally and stores the generated helper string during each authentication procedure[6]. In this way, BEs based on their FE can realize a property that biometric *features* having generated during past procedures can be recovered from the stored data and a feature generated from the genuine user's sample captured again, while it is difficult to recover the past samples or features only from the stored data, which we call *Authenticated Feature Recoverability (AFR)*.

However, for (Case 1)–(Case 3) described above, ASR is needed rather than AFR. In BEs with AFR, the recoverable features are elements of a metric space such as a Hamming space, generated from samples by image processing and pattern recognition techniques. On the other hand, for (Case 1)–(Case 3), raw biometric samples such as images and videos of biometric traits is needed. The samples are a stronger evidence in (Case 1), a more helpful clue in (Case 2), and required to generate biometric references in (Case 3).

D. Our Contribution

Our goal is to construct a template protected online biometric authentication system with ASR. For this goal, we propose *Sample Recoverable Biometric Signatures (SRBSs)*. Our technical contributions are threefold.

(i) *Formal definition for SRBSs* (Sect. III). We formalize a biometric data setting which specifies how biometric data are generated. We then give a formal definition of SRBSs associated with the biometric data setting.

(ii) *Generic construction* (Sect. IV). We propose a generic construction of a SRBS scheme with EUF-CMA security based on a FE, a digital signature scheme, and a symmetric encryption scheme satisfying a specific property.

(iii) *Instantiation* (Sect. V). We present a specific construction of a SRBS scheme with EUF-CMA security in the random oracle model.

By using SRBSs with EUF-CMA security, we can construct online biometric authentication systems with ASR (Sect. VI). As described above, the systems ensure the accountability of past procedures, enable more detail investigation of the cause

[4]Strictly, our definition of recoverability is the property that past samples can be recovered from the stored data and a feature sufficiently close to ones generated from the past samples. We use the expression "the genuine user" because features generated from samples of the genuine user should be close with high probability.

[5]In their FE, the helper string includes a *secure sketch* $\mathrm{SS}(y)$ generated from a feature y so that y can be recovered from $\mathrm{SS}(y)$ and a feature y' sufficiently close to y.

[6]Strictly, when helper strings are generated multiple times, *reusable* FEs [8] have to be used for security.

if authentication accuracy in operation is low, and can apply multi-sample fusion for biometric reference update using past samples.

II. Preliminaries

In this section, we review basic notations and definitions of primitives.

A. Basic Notation

Let $\mathbb{N}$ denote the set of all positive integers, and let $\mathbb{R}$ and $\mathbb{R}_{>0}$ denote the sets of real numbers and positive real numbers, respectively. Throughout the paper, k denotes the security parameter. A function $f : \mathbb{N} \to [0,1]$ is said to be *negligible* if for all polynomials p and all sufficiently large k it holds $f(k) < 1/p(k)$. For random variables X and Y, the *min-entropy* $\mathbf{H}_\infty(X)$ of X is defined by $\mathbf{H}_\infty(X) := -\log_2(\max_x \Pr[X = x])$, and the average min-entropy $\tilde{\mathbf{H}}_\infty(X \mid Y)$ of X given Y is defined by $\tilde{\mathbf{H}}_\infty(X \mid Y) := -\log_2 \mathbf{E}_{y \leftarrow \mathrm{Y}}\big[\max_x \Pr[X = x \mid Y = y]\big]$, where Y denotes the probability distribution of Y. The *statistical distance* $\mathbf{SD}(X, X')$ between random variables X and X' is defined by $\mathbf{SD}(X, X') := (1/2)\sum_z |\Pr[X = x] - \Pr[X' = x]|$. For $\ell \in \mathbb{N}$, U_ℓ denotes a random variable uniformly distributed on $\{0,1\}^\ell$. For a positive function f, we write $f(k) = \Theta(k)$ if there exist c_1, c_2, and k_0 such that for any k larger than k_0 it holds that $c_1 < f(k)/k < c_2$.

B. Fuzzy Extractors

We review the definition of a fuzzy extractor introduced by Dodis et al. [7]. A $(\mathcal{Y}, \mu, \ell, t, \epsilon)$-fuzzy extractor Σ_{FE} is defined by the following algorithms $(\mathrm{Gen}_{\mathrm{FE}}, \mathrm{Rep}_{\mathrm{FE}})$.

- $\mathrm{Gen}_{\mathrm{FE}}(y) \to (r, p)$: The generation algorithm takes an element $y \in \mathcal{Y}$ as an input, and outputs an extracted string $r \in \{0,1\}^\ell$ and a public string $p \in \{0,1\}^*$. We require that for any random variable Y on $\mathcal{Y}$ of min-entropy μ, if $(R, P) \leftarrow \mathrm{Gen}_{\mathrm{FE}}(Y)$, then $\mathbf{SD}((R, P), (U_\ell, P)) \le \epsilon$.
- $\mathrm{Rep}_{\mathrm{FE}}(y', p) \to r'$: The reproduction algorithm $\mathrm{Rep}_{\mathrm{FE}}$ takes an element $y' \in \mathcal{Y}$ and a bit string $p \in \{0,1\}^*$ as inputs, and outputs a string r'. We require that for any $y, y' \in \mathcal{Y}$ satisfying $\mathtt{dist}(y, y') \le t$ and (r, p) generated by $(r, p) \leftarrow \mathrm{Gen}_{\mathrm{FE}}(y)$, it holds that $\mathrm{Rep}_{\mathrm{FE}}(y', p) = r$.

C. Digital Signature Schemes

A digital signature scheme Σ_{SIG} is defined by the following algorithms $(\mathrm{Gen}_{\mathrm{SIG}}, \mathrm{Sign}_{\mathrm{SIG}}, \mathrm{Ver}_{\mathrm{SIG}}, \mathrm{KeyVer}_{\mathrm{SIG}})$.

- $\mathrm{Gen}_{\mathrm{SIG}}(1^k) \to (sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}})$: The generation algorithm takes the security parameter 1^k as an input, and outputs a signing key sk_{SIG} and a verification key vk_{SIG}.
- $\mathrm{Sign}_{\mathrm{SIG}}(sk_{\mathrm{SIG}}, m) \to \sigma_{\mathrm{SIG}}$: The signing algorithm takes a signing key sk_{SIG} and a message $m \in \mathcal{M}$ as inputs, and outputs a signature σ_{SIG}.
- $\mathrm{Ver}_{\mathrm{SIG}}(vk_{\mathrm{SIG}}, m, \sigma_{\mathrm{SIG}}) \to result$: The verification algorithm takes a verification key vk_{SIG}, a message $m \in \mathcal{M}$, and a signature σ_{SIG} as inputs, and outputs the verification result $result \in \{\top, \bot\}$. We require that for any $k \in \mathbb{N}$, message $m \in \mathcal{M}$, and $(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}, \sigma_{\mathrm{SIG}})$ generated by $(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \leftarrow \mathrm{Gen}_{\mathrm{SIG}}(1^k)$ and $\sigma_{\mathrm{SIG}} \leftarrow \mathrm{Sign}_{\mathrm{SIG}}(sk_{\mathrm{SIG}}, m)$, it holds that $\mathrm{Ver}_{\mathrm{SIG}}(vk_{\mathrm{SIG}}, m, \sigma_{\mathrm{SIG}}) = \top$.
- $\mathrm{KeyVer}_{\mathrm{SIG}}(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \to result$: The key verification algorithm[7] takes a key pair $(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}})$ as an input, and outputs the verification result $result \in \{\top, \bot\}$. We require that for any $(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}})$ generated by $(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \leftarrow \mathrm{Gen}_{\mathrm{SIG}}(1^k)$ and sk'_{SIG}, if $sk_{\mathrm{SIG}} = sk'_{\mathrm{SIG}}$ then $\mathrm{KeyVer}_{\mathrm{SIG}}(sk'_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) = \top$ holds, and otherwise $\mathrm{KeyVer}_{\mathrm{SIG}}(sk'_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) = \bot$ holds.

EUF-CMA security for a digital signature scheme Σ_{SIG} is defined as follows. Consider the following EUF-CMA experiment $\mathrm{Exp}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SIG}},\mathcal{A}}(k)$ for $\Sigma_{\mathrm{SIG}} = (\mathrm{Gen}_{\mathrm{SIG}}, \mathrm{Sign}_{\mathrm{SIG}}, \mathrm{Ver}_{\mathrm{SIG}}, \mathrm{KeyVer}_{\mathrm{SIG}})$ and an adversary $\mathcal{A}$:

$$\begin{aligned}\mathrm{Exp}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SIG}},\mathcal{A}}(k) : [\ & (sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \leftarrow \mathrm{Gen}_{\mathrm{SIG}}(1^k);\ \mathcal{Q} := \emptyset;\\ & (m', \sigma'_{\mathrm{SIG}}) \leftarrow \mathcal{A}^{\mathcal{O}_{\mathrm{Sign}_{\mathrm{SIG}}}(\cdot)}(vk_{\mathrm{SIG}});\\ & \text{if } m' \notin \mathcal{Q} \wedge \mathrm{Ver}(m', vk_{\mathrm{SIG}}, \sigma'_{\mathrm{SIG}}) = \top\\ & \text{then return } 1 \text{ else return } 0\ ],\end{aligned}$$

where $\mathcal{O}_{\mathrm{Sign}_{\mathrm{SIG}}}$ is a signing oracle that takes a message $m \in \mathcal{M}$ as an iuput and operates as follows: $[\ \mathcal{Q} := \mathcal{Q} \cup \{m\};\ \sigma_{\mathrm{SIG}} \leftarrow \mathrm{Sign}_{\mathrm{SIG}}(sk_{\mathrm{SIG}}, m);$ return $\sigma_{\mathrm{SIG}}\ ]$. We say that a digital signature scheme Σ_{SIG} is *EUF-CMA secure* if for any PPTA adversary $\mathcal{A}$, $\mathrm{Adv}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SIG}},\mathcal{A}}(k) := \Pr[\mathrm{Exp}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SIG}},\mathcal{A}}(k) = 1]$ is negligible.

D. Symmetric Encryption Schemes

A symmetric encryption scheme Σ_{SE} is defined by the following algorithms $(\mathrm{Gen}_{\mathrm{SE}}, \mathrm{Enc}_{\mathrm{SE}}, \mathrm{Dec}_{\mathrm{SE}})$.

- $\mathrm{Gen}_{\mathrm{SE}}(1^k) \to sk_{\mathrm{SE}}$: The generation algorithm takes the security parameter 1^k as an input, and outputs a symmetric key sk_{SE}.
- $\mathrm{Enc}_{\mathrm{SE}}(sk_{\mathrm{SE}}, m) \to c$: The encryption algorithm takes a symmetric key sk_{SE} and a message $m \in \mathcal{M}$ as inputs, and outputs a ciphertext c.
- $\mathrm{Dec}_{\mathrm{SE}}(sk_{\mathrm{SE}}, c) \to m'$ or $\bot$: The decryption algorithm takes a symmetric key sk_{SE} and a string c as inputs, and outputs a decrypted message $m' \in \mathcal{M}$ or $\bot$. We require that for any $m \in \mathcal{M}$, $k \in \mathbb{N}$, and (sk_{SE}, c) generated by $sk_{\mathrm{SE}} \leftarrow \mathrm{Gen}_{\mathrm{SE}}(1^k)$ and $c \leftarrow \mathrm{Enc}(sk_{\mathrm{SE}}, m)$, it holds that $\mathrm{Dec}(sk_{,\mathrm{SE}}, c) = m$.

In Section IV, we define a specific security property of Σ_{SE} in order to use it as a building block of SRBSs. The property can be considered as a kind of *Key Dependent Message (KDM) security* [15], which is on encryption of messages depending on the secret key[8]. Specifically, KDM security in the single key setting[9] is defined as follows. Consider the

[7] $\mathrm{KeyVer}_{\mathrm{SIG}}$ is not included in the syntax of general digital signature schemes, but we include it because we use it for constructing a SRBS scheme. Most digital signature schemes can construct $\mathrm{KeyVer}_{\mathrm{SIG}}$ satisfying the requirement.

[8] When $\mathcal{F}$ contains all constant functions, $\mathcal{F}$-KDM security implies IND-CPA [16].

[9] In general, KDM security is considered in the multiple key setting. However, the property we define in Section IV is related to KDM security in the single key setting, so we explain the setting here.

following KDM experiment $\mathrm{Exp}^{\mathrm{KDM}}_{\Sigma_{\mathrm{SE}},\mathcal{F},\mathcal{A}}(k)$ for a symmetric encryption scheme $\Sigma_{\mathrm{SE}} = (\mathrm{Gen}_{\mathrm{SE}}, \mathrm{Enc}_{\mathrm{SE}}, \mathrm{Dec}_{\mathrm{SE}})$, a class $\mathcal{F}$ of functions, and an adversary $\mathcal{A}$:

$$\mathrm{Exp}^{\mathrm{KDM}}_{\Sigma_{\mathrm{SE}},\mathcal{F},\mathcal{A}}(k) : [\ b \leftarrow \{0,1\};\ sk_{\mathrm{SE}} \leftarrow \mathrm{Gen}_{\mathrm{SE}}(1^k);\ b' \leftarrow \mathcal{A}^{\tilde{O}_{\mathrm{Enc}_{\mathrm{SE}}}(\cdot)}();\ \text{return } b'\ ],$$

where $\tilde{O}_{\mathrm{Enc}_{\mathrm{SE}}}$ is a encryption oracle that takes a function $f \in \mathcal{F}$ as an input and operates as follows: $[\ m_1 := f(sk_{\mathrm{SE}});\ m_0 := 0^{|f(sk_{\mathrm{SE}})|};\ c \leftarrow \mathrm{Enc}_{\mathrm{SE}}(sk_{\mathrm{SE}}, c_b);\ \text{return } c\ ]$. We say that a symmetric encryption scheme Σ_{SE} is $\mathcal{F}$-KDM secure if for any PPTA adversary $\mathcal{A}$,

$$\mathrm{Adv}^{\mathrm{KDM}}_{\Sigma_{\mathrm{SE}},\mathcal{F},\mathcal{A}}(k) := \big|\Pr[\mathrm{Exp}^{\mathrm{KDM}}_{\Sigma_{\mathrm{SE}},\mathcal{F},\mathcal{A}}(k) = 1 \mid b = 1] - \Pr[\mathrm{Exp}^{\mathrm{KDM}}_{\Sigma_{\mathrm{SE}},\mathcal{F},\mathcal{A}}(k) = 1 \mid b = 0]\big|$$

is negligible.

III. Definitions for SRBSs

In this section we define how biometric data are generated, and the syntax and requirements of SRBSs.

A. Biometric Data Setting

In BSs, a raw biometric sample is an input of key generation and signing algorithms. In SRBSs, a sample is also required for recovery of samples. We define a setting of samples for these algorithms. Let $\mathcal{X}$ be the sample space. Let X be the distribution of a sample for key generation. We assume that when a sample $x_{\mathrm{G}} \leftarrow \mathrm{X}$ is captured from a user for key generation, a sample from the user for signing and recovery is generated according to the probability distribution denoted by $\Delta(x_{\mathrm{G}})$. In general, biometric authentication systems calculate closeness of features generated from samples. To formalize this, let $\mathcal{Y}$ denote the feature space, and let Feat be the feature generation algorithm. A feature y is generated from a sample x by $y \leftarrow \mathrm{Feat}(x)$. Features generated from samples of the genuine user should be close with high probability. This can be formalized with a threshold $t \in \mathbb{R}_{>0}$ and an error parameter $\alpha \in [0,1]$ as follows: $\Pr\{x_{\mathrm{G}} \leftarrow \mathrm{X};\ x' \leftarrow \Delta(x_{\mathrm{G}}) : \mathtt{dist}(\mathrm{Feat}(x_{\mathrm{G}}), \mathrm{Feat}(x')) > t\} \le \alpha$. We call $\mathcal{B} = (\mathcal{X}, \mathrm{X}, \Delta, \mathcal{Y}, \mathrm{Feat}, \mathtt{dist}, t, \alpha)$ satisfying the above conditions a *biometric data setting*.

Remark 1. If the system adopt multi-sample fusion, multiple samples may be required for each algorithm. We can treat this multi-sample setting by modifying the definition of the feature generation algorithm. Specifically, we can treat the case in which a_{G}, a_{S}, and a_{R} samples ($a_{\mathrm{G}}, a_{\mathrm{S}}, a_{\mathrm{R}} \in \mathbb{N}$) are required for key generation, signing, and recovery, respectively, by defining feature extraction algorithms[10] $\mathrm{Feat}_{\mathrm{G}}, \mathrm{Feat}_{\mathrm{S}}, \mathrm{Feat}_{\mathrm{R}}$ such that from samples $x_{\mathrm{G}} \in \mathcal{X}^{a_{\mathrm{G}}}, x_{\mathrm{S}} \in \mathcal{X}^{a_{\mathrm{S}}}, x_{\mathrm{R}} \in \mathcal{X}^{a_{\mathrm{R}}}$ features $y_{\mathrm{G}}, y_{\mathrm{S}}, y_{\mathrm{R}} \in \mathcal{Y}$ are generated by $y_{\mathrm{G}} \leftarrow \mathrm{Feat}_{\mathrm{G}}(x_{\mathrm{G}}), y_{\mathrm{S}} \leftarrow \mathrm{Feat}_{\mathrm{S}}(x_{\mathrm{S}}), y_{\mathrm{R}} \leftarrow \mathrm{Feat}_{\mathrm{R}}(x_{\mathrm{R}})$. Hereafter, we use the single-sample setting because discussions in the multi-sample setting can be done essentially in the same way.

[10] An example of generating a feature y from multiple samples $(x_1, \ldots, x_a)$ is to select the most appropriate one by a specific rule. Another example when $\mathcal{Y} = \{0,1\}^n$ is as follows. For each sample x_i, the algorithm extracts a feature y_i by $y_i = \mathrm{Feat}(x_i)$. Then, for each $j \in [n]$ it determines the j-th bit $y[j]$ of y by 1 if the j-th bit is 1 for more than half of $(y_i)_{i\in[a]}$, and determines $y[i]$ by 0 otherwise. Also, an example when $\mathcal{Y} = \mathbb{R}^n$ is to determine y by the average of $(y_i)_{i\in[a]}$.

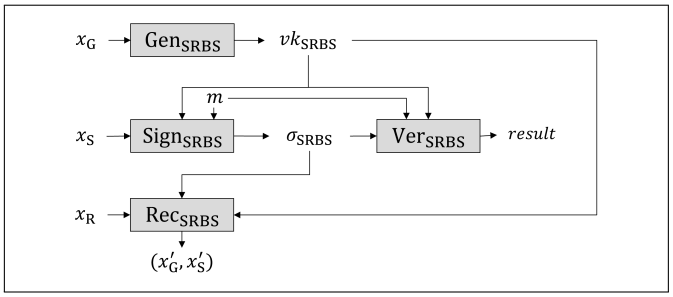

Fig. 1. Data Flow of a SRBS Scheme

B. SRBS Schemes

A SRBS scheme Σ_{SRBS} for a biometric data setting $\mathcal{B}$ is defined by the following algorithms $(\mathrm{Gen}_{\mathrm{SRBS}}, \mathrm{Sign}_{\mathrm{SRBS}}, \mathrm{Ver}_{\mathrm{SRBS}}, \mathrm{Rec}_{\mathrm{SRBS}})$. The data flow is shown in Fig. 1.

- $\mathrm{Gen}_{\mathrm{SRBS}}(1^k, x_{\mathrm{G}}) \to vk_{\mathrm{SRBS}}$: The key generation algorithm takes a sample $x_{\mathrm{G}} \in \mathcal{X}$ as an input, and outputs a verification key vk_{SRBS}.
- $\mathrm{Sign}_{\mathrm{SRBS}}(x_{\mathrm{S}}, vk_{\mathrm{SRBS}}, m) \to \sigma_{\mathrm{SRBS}}$: The signing algorithm takes a sample $x_{\mathrm{S}} \in \mathcal{X}$, a verification key vk_{SRBS},[11] and a message $m \in \mathcal{M}$ as inputs, and outputs a signature σ_{SRBS} The signature σ_{SRBS} may be $\perp$.
- $\mathrm{Ver}_{\mathrm{SRBS}}(vk_{\mathrm{SRBS}}, m, \sigma_{\mathrm{SRBS}}) \to result$: algorithm takes a verification key vk_{SRBS}, a message $m \in \mathcal{M}$, a signature σ_{SRBS} as inputs, and outputs the verification result $result \in \{\top, \perp\}$.
- $\mathrm{Rec}_{\mathrm{SRBS}}(x_{\mathrm{R}}, vk_{\mathrm{SRBS}}, \sigma_{\mathrm{SRBS}}) \to (x'_{\mathrm{G}}, x'_{\mathrm{S}})$ or $\perp$: algorithm takes a sample $x_{\mathrm{R}} \in \mathcal{X}$, a verification key vk_{SRBS}, and a signature σ_{SRBS} as inputs, and outputs recovered samples $(x'_{\mathrm{G}}, x'_{\mathrm{S}}) \in \mathcal{X} \times \mathcal{X}$ or $\perp$.

We require correctness defined as follows: for any $x_{\mathrm{G}}, x_{\mathrm{S}}, x_{\mathrm{R}} \in \mathcal{X}$ satisfying $\mathtt{dist}(\mathrm{Feat}(x_{\mathrm{G}}), \mathrm{Feat}(x_{\mathrm{S}})) \le t$ and $\mathtt{dist}(\mathrm{Feat}(x_{\mathrm{G}}), \mathrm{Feat}(x_{\mathrm{R}})) \le t$, $m \in \mathcal{M}$, and $(vk_{\mathrm{SRBS}}, \sigma_{\mathrm{SRBS}})$ generated by $vk_{\mathrm{SRBS}} \leftarrow \mathrm{Gen}_{\mathrm{SRBS}}(1^k, x_{\mathrm{G}})$ and $\sigma_{\mathrm{SRBS}} \leftarrow \mathrm{Sign}_{\mathrm{SRBS}}(x_{\mathrm{S}}, vk_{\mathrm{SRBS}}, m)$, it holds that $\mathrm{Ver}_{\mathrm{SRBS}}(vk_{\mathrm{SRBS}}, m, \sigma_{\mathrm{SRBS}}) = \top$ and $\mathrm{Rec}_{\mathrm{SRBS}}(x_{\mathrm{R}}, vk_{\mathrm{SRBS}}, \sigma_{\mathrm{SRBS}}) = (x_{\mathrm{G}}, x_{\mathrm{S}})$.

Next, we define EUF-CMA security for Σ_{SRBS}. Consider the following EUF-CMA experiment $\mathrm{Exp}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SRBS}},\mathcal{A}}(k)$ for a SRBS scheme $\Sigma_{\mathrm{SRBS}} = (\mathrm{Gen}_{\mathrm{SRBS}}, \mathrm{Sign}_{\mathrm{SRBS}}, \mathrm{Ver}_{\mathrm{SRBS}},$

[11] As Section I, some biometric schemes called FSs generate a signature without using the verification key. However, it is natural in applications such as online biometric authentication systems that the device for signing is connected to the network and can access the verification key. Therefore, in our definition, the inputs of the signing algorithm includes the verification key.

$\mathrm{Rec}_{\mathrm{SRBS}}$) and an adversary $\mathcal{A}$:

$$\begin{aligned}&\mathrm{Exp}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SRBS}},\mathcal{A}}(k):\\&[\ x_{\mathrm{G}} \leftarrow \mathrm{X};\ vk_{\mathrm{SRBS}} \leftarrow \mathrm{Gen}_{\mathrm{SRBS}}(1^k, x_{\mathrm{G}});\\&\ \ \mathcal{Q} := \emptyset;\ (m', \sigma'_{\mathrm{SRBS}}) \leftarrow \mathcal{A}^{\mathcal{O}_{\mathrm{Sign}_{\mathrm{SRBS}}}(\cdot)}(vk_{\mathrm{SRBS}});\\&\ \ \text{if } m' \notin \mathcal{Q} \wedge \mathrm{Ver}(vk_{\mathrm{SRBS}}, m', \sigma'_{\mathrm{SRBS}}) = \top\\&\ \ \text{then return } 1 \text{ else return } 0\ ],\end{aligned}$$

where $\mathcal{O}_{\mathrm{Sign}_{\mathrm{SRBS}}}$ is a signing oracle that takes a message $m \in \mathcal{M}$ as an input and operates as follows: [$\mathcal{Q} := \mathcal{Q} \cup \{m\}$; $x_{\mathrm{S}} \leftarrow \Delta(x_{\mathrm{G}})$; $\sigma_{\mathrm{SRBS}} \leftarrow \mathrm{Sign}_{\mathrm{SRBS}}(x_{\mathrm{S}}, vk_{\mathrm{SRBS}}, m)$; return σ_{SRBS}].

We say that a SRBS scheme Σ_{SRBS} is EUF-CMA secure if for any PPTA adversary $\mathcal{A}$, $\mathrm{Adv}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SRBS}},\mathcal{A}}(k) := \Pr[\mathrm{Exp}^{\text{EUF-CMA}}_{\Sigma_{\mathrm{SRBS}},\mathcal{A}}(k) = 1]$ is negligible.

Remark 2. SRBS schemes with EUF-CMA security satisfy ASR by storing vk_{SRBS} and σ_{SRBS}. Indeed, by correctness, a sample x_{G} having captured for $\mathrm{Gen}_{\mathrm{SRBS}}$ and x_{S} for $\mathrm{Sign}_{\mathrm{SRBS}}$ satisfying $\mathtt{dist}(\mathrm{Feat}(x_{\mathrm{G}}), \mathrm{Feat}(x_{\mathrm{S}})) \le t$ can be recovered from vk_{SRBS}, σ_{SRBS}, and a feature y satisfying $\mathtt{dist}(\mathrm{Feat}(x_{\mathrm{G}}), y) \le t$. Also, by EUF-CMA security, it is difficult to recover y satisfying $\mathtt{dist}(\mathrm{Feat}(x_{\mathrm{G}}), y) \le t$ from the stored vk_{SRBS} and σ_{SRBS}.

IV. Generic Construction

In this section, we give a generic construction of a SRBS scheme $\Sigma_{\mathrm{SRBS}} = (\mathrm{Gen}_{\mathrm{SRBS}}, \mathrm{Sign}_{\mathrm{SRBS}}, \mathrm{Ver}_{\mathrm{SRBS}}, \mathrm{Rec}_{\mathrm{SRBS}})$ for a biometric data setting $\mathcal{B} = (\mathcal{X}, \mathrm{X}, \Delta, \mathcal{Y}, \mathrm{Feat}, \mathtt{dist}, t, \alpha)$. For construction, we use a $(\mathcal{Y}, \mu, \ell, t, \epsilon)$-fuzzy extractor $\Sigma_{\mathrm{FE}} = (\mathrm{Gen}_{\mathrm{FE}}, \mathrm{Rep}_{\mathrm{FE}})$, a digital signature scheme $\Sigma_{\mathrm{SIG}} = (\mathrm{Gen}_{\mathrm{SIG}}, \mathrm{Sign}_{\mathrm{SIG}}, \mathrm{Ver}_{\mathrm{SIG}}, \mathrm{KeyVer}_{\mathrm{SIG}})$, and a symmetric encryption scheme $\Sigma_{\mathrm{SE}} = (\mathrm{Gen}_{\mathrm{SE}}, \mathrm{Enc}_{\mathrm{SE}}, \mathrm{Dec}_{\mathrm{SE}})$ as building blocks.

In order to describe requirements of the primitives, we define the *Biometric Encryption (BE) security* as follows. We assume that all samples $x \in \mathcal{X}$ are represented by the same bit-length $|x|$. Consider the following BE experiment $\mathrm{Exp}^{\text{BE}}_{\mathcal{B},\Sigma_{\mathrm{FE}},\Sigma_{\mathrm{SE}},\mathcal{A}}(k)$ for $\mathcal{B}, \Sigma_{\mathrm{FE}}, \Sigma_{\mathrm{SE}}$, and an adversary $\mathcal{A}$:

$$\begin{aligned}&\mathrm{Exp}^{\text{BE}}_{\mathcal{B},\Sigma_{\mathrm{FE}},\Sigma_{\mathrm{SE}},\mathcal{A}}(k):\\&\ \ [\ b \leftarrow \{0,1\};\ x_{\mathrm{G}} \leftarrow \mathrm{X};\ y_{\mathrm{G}} \leftarrow \mathrm{Feat}(x_{\mathrm{G}});\\&\ \ \ \ (r, p) \leftarrow \mathrm{Gen}_{\mathrm{FE}}(y_{\mathrm{G}});\\&\ \ \ \ c_1 \leftarrow \mathrm{Enc}_{\mathrm{FE}}(r, x_{\mathrm{G}});\ c_0 \leftarrow \mathrm{Enc}_{\mathrm{FE}}(r, 0^{|x_{\mathrm{G}}|});\\&\ \ \ \ b' \leftarrow \mathcal{A}^{\tilde{\mathcal{O}}_{\mathrm{Enc}_{\mathrm{SE}}}(\cdot), \tilde{\mathcal{O}}'_{\mathrm{Enc}_{\mathrm{SE}}}(\cdot)}(p, c_b);\ \text{return } b'\ ],\end{aligned}$$

where $\tilde{\mathcal{O}}_{\mathrm{Enc}_{\mathrm{SE}}}$ and $\tilde{\mathcal{O}}'_{\mathrm{Enc}_{\mathrm{SE}}}$ are defined as follows.

- The oracle $\tilde{\mathcal{O}}_{\mathrm{Enc}_{\mathrm{SE}}}$ takes a message m as an input, and operates as follows: [$m_1 := m$; $m_0 := 0^{|m|}$; $c \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, m_b)$; return c].
- The oracle $\tilde{\mathcal{O}}'_{\mathrm{Enc}_{\mathrm{SE}}}$ takes no input, and operates as follows: [$x_{\mathrm{S}} \leftarrow \Delta_{\mathrm{S}}(x_{\mathrm{G}})$; $y_{\mathrm{S}} \leftarrow \mathrm{Feat}(x_{\mathrm{S}})$; $r' \leftarrow \mathrm{Rep}_{\mathrm{FE}}(y_{\mathrm{S}}, p)$; if $r' \neq r$ then return $\perp$; $x_1 := x_{\mathrm{S}}$; $x_0 := 0^{|x_{\mathrm{S}}|}$; $c \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, x_b)$; return c].

We say that a symmetric encryption scheme Σ_{SE} is *BE secure* with respect to a biometric data setting $\mathcal{B}$ and a fuzzy extractor scheme Σ_{FE} if for any PPTA adversary $\mathcal{A}$,

$$\begin{aligned}\mathrm{Adv}^{\text{BE}}_{\mathcal{B},\Sigma_{\mathrm{FE}},\Sigma_{\mathrm{SE}},\mathcal{A}}(k) := \big|\ &\Pr[\mathrm{Exp}^{\text{BE}}_{\mathcal{B},\Sigma_{\mathrm{FE}},\Sigma_{\mathrm{SE}},\mathcal{A}}(k) = 1 \mid b = 1]\\&- \Pr[\mathrm{Exp}^{\text{BE}}_{\mathcal{B},\Sigma_{\mathrm{FE}},\Sigma_{\mathrm{SE}},\mathcal{A}}(k) = 1 \mid b = 0]\big|\end{aligned}$$

is negligible.

We require the following for the building blocks:

1) The $(\mathcal{Y}, \mu, \ell, t, \epsilon)$-fuzzy extractor Σ_{FE} satisfies $\ell = \Theta(k)$ and $\mu = \mathbf{H}_\infty(Y_{\mathrm{G}})$, where X_{G} denotes a random variable distributed according to X, and Y_{G} denotes a random variable defined by $Y_{\mathrm{G}} := \mathrm{Feat}(X_{\mathrm{G}})$.
2) The digital signature scheme Σ_{SIG} is EUF-CMA secure.
3) The symmetric encryption scheme Σ_{SE}
   a) is BE secure with respect to $\mathcal{B}$ and Σ_{FE},
   b) has the key space $\{0,1\}^\ell$, and
   c) satisfies that for any distinct $sk_{\mathrm{SE}}, sk'_{\mathrm{SE}} \in \{0,1\}^\ell$ and any m, $\Pr[c \leftarrow \mathrm{Enc}_{\mathrm{SE}}(sk_{\mathrm{SE}}, m);\ m' \leftarrow \mathrm{Dec}_{\mathrm{SE}}(sk'_{\mathrm{SE}}, c) : m' = m]$ is negligible.

Also, we assume that all signing keys sk_{SIG} generated by $(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \leftarrow \mathrm{Gen}_{\mathrm{SIG}}(1^k)$ are represented by the same bit-length $|sk_{\mathrm{SIG}}|$.

Construction: Let k' be the security parameter for Σ_{SE} when the key space is $\{0,1\}^\ell$. We note that $k' = \Theta(k)$ follows from $\ell = \Theta(k)$. The construction is provided in Fig. 2. For any algorithm, if it fails a to operate "parse", then it returns $\perp$.

Theorem 1. $\Sigma_{\mathrm{SRBS}} = (\mathrm{Gen}_{\mathrm{SRBS}}, \mathrm{Sign}_{\mathrm{SRBS}}, \mathrm{Ver}_{\mathrm{SRBS}}, \mathrm{Rec}_{\mathrm{SRBS}})$ defined by the above construction is a SRBS scheme with EUF-CMA security.

Proof: It is easy to show correctness. We show EUF-CMA security. Let $\mathcal{A}$ be any PPTA adversary against Σ_{SRBS} that makes at most q signing queries. Let E_i be the event that $\mathcal{A}$ wins in Game_i.

$\underline{\mathrm{Game}_1}$: We define Game_1 as the actual EUF-CMA game for Σ_{SRBS}. In this game, the verification key vk_{SRBS} is generated as follows:

$$\begin{aligned}&[\ x_{\mathrm{G}} \leftarrow \mathrm{X};\ y_{\mathrm{G}} \leftarrow \mathrm{Feat}(x_{\mathrm{G}});\ (r, p) \leftarrow \mathrm{Gen}_{\mathrm{FE}}(y_{\mathrm{G}});\\&\ \ (sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \leftarrow \mathrm{Gen}_{\mathrm{SIG}}(1^k);\\&\ \ c_{\mathrm{G}} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, x_{\mathrm{G}});\ z \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, sk_{\mathrm{SIG}});\\&\ \ vk_{\mathrm{SRBS}} := (vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)\ ].\end{aligned}$$

Furthermore, for $i \in [q]$, when $\mathcal{A}$ makes the i-th signing query on a message m_i, the challenger generates a signature $\sigma_{\mathrm{SRBS},i}$ as follows:

$$\begin{aligned}&[\ y_{\mathrm{S},i} \leftarrow \mathrm{Feat}(x_{\mathrm{S}});\ \text{parse } vk_{\mathrm{SRBS}} \text{ as } (vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z);\\&\ \ r'_i \leftarrow \mathrm{Rep}_{\mathrm{FE}}(y_{\mathrm{S},i}, p);\ sk'_{\mathrm{SIG},i} \leftarrow \mathrm{Dec}_{\mathrm{SE}}(r'_i, z);\\&\ \ \text{if } \mathrm{KeyVer}_{\mathrm{SIG}}(sk'_{\mathrm{SIG},i}, vk_{\mathrm{SIG}}) = \perp \text{ then return } \perp;\\&\ \ \sigma_{\mathrm{SIG},i} \leftarrow \mathrm{Sign}_{\mathrm{SIG}}(sk'_{\mathrm{SIG},i}, m_i);\ c_{\mathrm{S},i} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r'_i, x_{\mathrm{S},i});\\&\ \ \sigma_{\mathrm{SRBS},i} := (\sigma_{\mathrm{SIG},i}, c_{\mathrm{S},i})\ ].\end{aligned}$$

$\underline{\mathrm{Game}_2}$: In this game, the challenger generates $\sigma_{\mathrm{SRBS},i}$ as

$\mathrm{Gen}_{\mathrm{SRBS}}(1^k, x_{\mathrm{G}})$:
$y_{\mathrm{G}} \leftarrow \mathrm{Feat}(x_{\mathrm{G}})$;
$(r, p) \leftarrow \mathrm{Gen}_{\mathrm{FE}}(y_{\mathrm{G}})$;
$(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \leftarrow \mathrm{Gen}_{\mathrm{SIG}}(1^k)$;
$c_{\mathrm{G}} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, x_{\mathrm{G}})$;
$z \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, sk_{\mathrm{SIG}})$;
$vk_{\mathrm{SRBS}} := (vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$;
return vk_{SRBS}.

$\mathrm{Sign}_{\mathrm{SRBS}}(x_{\mathrm{S}}, vk_{\mathrm{SRBS}}, m)$:
$y_{\mathrm{S}} \leftarrow \mathrm{Feat}(x_{\mathrm{S}})$;
parse vk_{SRBS} as $(vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$;
$r' \leftarrow \mathrm{Rep}_{\mathrm{FE}}(y_{\mathrm{S}}, p)$;
$sk'_{\mathrm{SIG}} \leftarrow \mathrm{Dec}_{\mathrm{SE}}(r', z)$;
if $\mathrm{KeyVer}_{\mathrm{SIG}}(sk'_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) = \perp$ then return $\perp$;
$\sigma_{\mathrm{SIG}} \leftarrow \mathrm{Sign}_{\mathrm{SIG}}(sk'_{\mathrm{SIG}}, m)$;
$c_{\mathrm{S}} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r', x_{\mathrm{S}})$;
$\sigma_{\mathrm{SRBS}} := (\sigma_{\mathrm{SIG}}, c_{\mathrm{S}})$;
return σ_{SRBS}.

$\mathrm{Ver}_{\mathrm{SRBS}}(vk_{\mathrm{SRBS}}, m, \sigma_{\mathrm{SRBS}})$:
if $\sigma_{\mathrm{SRBS}} = \perp$ then return $\perp$;
parse vk_{SRBS} as $(vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$;
parse σ_{SRBS} as $(\sigma_{\mathrm{SIG}}, c_{\mathrm{S}})$;
result $\leftarrow \mathrm{Ver}_{\mathrm{SIG}}(vk_{\mathrm{SIG}}, m, \sigma_{\mathrm{SIG}})$;
return *result*.

$\mathrm{Rec}_{\mathrm{SRBS}}(x_{\mathrm{R}}, vk_{\mathrm{SRBS}}, \sigma_{\mathrm{SRBS}})$:
$y_{\mathrm{R}} \leftarrow \mathrm{Feat}(x_{\mathrm{R}})$;
parse vk_{SRBS} as $(vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$;
parse σ_{SRBS} as $(\sigma_{\mathrm{SIG}}, c_{\mathrm{S}})$;
$r'' \leftarrow \mathrm{Rep}_{\mathrm{FE}}(y_{\mathrm{R}}, p)$;
$x'_{\mathrm{G}} \leftarrow \mathrm{Dec}_{\mathrm{SE}}(r'', c_{\mathrm{G}})$;
$x'_{\mathrm{S}} \leftarrow \mathrm{Dec}_{\mathrm{SE}}(r'', c_{\mathrm{S}})$;
return $(x'_{\mathrm{G}}, x'_{\mathrm{S}})$.

Fig. 2. Generic construction of a SRBS scheme.

follows (where the difference is underlined):

[$y_{\mathrm{S},i} \leftarrow \mathrm{Feat}(x_{\mathrm{S}})$; parse vk_{SRBS} as $(vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$;
$r'_i \leftarrow \mathrm{Rep}_{\mathrm{FE}}(y_{\mathrm{S},i}, p)$; $sk'_{\mathrm{SIG},i} \leftarrow \mathrm{Dec}_{\mathrm{SE}}(r'_i, z)$;
if $\underline{sk'_{\mathrm{SIG},i} \neq sk_{\mathrm{SIG}}}$ then return $\perp$;
$\sigma_{\mathrm{SIG},i} \leftarrow \mathrm{Sign}_{\mathrm{SIG}}(\underline{sk_{\mathrm{SIG}}}, m_i)$; $c_{\mathrm{S},i} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r'_i, x_{\mathrm{S},i})$;
$\sigma_{\mathrm{SRBS},i} := (\sigma_{\mathrm{SIG},i}, c_{\mathrm{S},i})$].

Because $\mathrm{KeyVer}_{\mathrm{SIG}}(sk'_{\mathrm{SIG},i}, vk_{\mathrm{SIG}}) = \perp$ is equivalent to $sk'_{\mathrm{SIG},i} \neq sk_{\mathrm{SIG}}$, $\Pr[\mathrm{E}_1] = \Pr[\mathrm{E}_2]$ holds.

$\underline{\mathrm{Game}_3}$: In this game, the challenger generates $\sigma_{\mathrm{SRBS},i}$ as follows:

[$y_{\mathrm{S},i} \leftarrow \mathrm{Feat}(x_{\mathrm{S}})$; parse vk_{SRBS} as $(vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$;
$r'_i \leftarrow \mathrm{Rep}_{\mathrm{FE}}(y_{\mathrm{S},i}, p)$; $sk'_{\mathrm{SIG},i} \leftarrow \mathrm{Dec}_{\mathrm{SE}}(r'_i, z)$;
if $\underline{r'_i \neq r}$ then return $\perp$;
$\sigma_{\mathrm{SIG},i} \leftarrow \mathrm{Sign}_{\mathrm{SIG}}(sk_{\mathrm{SIG}}, m_i)$; $c_{\mathrm{S},i} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(\underline{r}, x_{\mathrm{S},i})$;
$\sigma_{\mathrm{SRBS},i} := (\sigma_{\mathrm{SIG},i}, c_{\mathrm{S},i})$].

Because $\Pr[(sk'_{\mathrm{SIG},i} = sk_{\mathrm{SIG}}) \wedge (r'_i \neq r)]$ is negligible, $\left|\Pr[\mathrm{E}_2] - \Pr[\mathrm{E}_3]\right|$ is negligible.

$\underline{\mathrm{Game}_4}$: In this game, the verification key vk_{SRBS} is generated as follows:

[$x_{\mathrm{G}} \leftarrow \mathrm{X}$; $y_{\mathrm{G}} \leftarrow \mathrm{Feat}(x_{\mathrm{G}})$; $(r, p) \leftarrow \mathrm{Gen}_{\mathrm{FE}}(y_{\mathrm{G}})$;
$(sk_{\mathrm{SIG}}, vk_{\mathrm{SIG}}) \leftarrow \mathrm{Gen}_{\mathrm{SIG}}(1^k)$;
$c_{\mathrm{G}} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, \underline{0^{|x_{\mathrm{G}}|}})$; $z \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, \underline{0^{|sk_{\mathrm{SIG}}|}})$;
$vk_{\mathrm{SRBS}} := (vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$].

Furthermore, the challenger generates $\sigma_{\mathrm{SRBS},i}$ as follows:

[$y_{\mathrm{S},i} \leftarrow \mathrm{Feat}(x_{\mathrm{S}})$; parse vk_{SRBS} as $(vk_{\mathrm{SIG}}, c_{\mathrm{G}}, p, z)$;
$r'_i \leftarrow \mathrm{Rep}_{\mathrm{FE}}(y_{\mathrm{S},i}, p)$; $__$;
if $r'_i \neq r$ then return $\perp$;
$\sigma_{\mathrm{SIG},i} \leftarrow \mathrm{Sign}_{\mathrm{SIG}}(sk_{\mathrm{SIG}}, m_i)$; $c_{\mathrm{S},i} \leftarrow \mathrm{Enc}_{\mathrm{SE}}(r, \underline{0^{|x_{\mathrm{S},i}|}})$;
$\sigma_{\mathrm{SRBS},i} := (\sigma_{\mathrm{SIG},i}, c_{\mathrm{S},i})$].

Because Σ_{SE} is BE secure and the key space is $\{0,1\}^\ell$ with $\ell = \Theta(k)$, $|\Pr[\mathrm{E}_3] - \Pr[\mathrm{E}_4]|$ is negligible. In addition, in order for $\mathcal{A}$ to win Game_4, $\mathcal{A}$ has to find a pair $(m', \sigma'_{\mathrm{SIG}})$ satisfying $m' \notin \{m_i\}_{i\in[q]}$ and $\mathrm{Ver}_{\mathrm{SIG}}(m', \sigma'_{\mathrm{SIG}})$. For finding such a $(m', \sigma'_{\mathrm{SIG}})$, the meaningful information contained in $(vk_{\mathrm{SRBS}}, \{(m_i, \sigma_{\mathrm{SRBS},i})\}_{i\in[q]})$ is $(vk_{\mathrm{SIG}}, \{(m_i, \sigma_{\mathrm{SIG},i}\}_{i\in[q]})$. Hence, it follows from EUF-CMA security of Σ_{SIG} and $k' = \Theta(k)$ that $\Pr[\mathrm{E}_4]$ is negligible.

Therefore, the advantage $\Pr[\mathrm{E}_1]$ for the original EUF-CMA game, upper-bounded as $\Pr[\mathrm{E}_1] \leq \sum_{i=1}^{3} |\Pr[\mathrm{E}_i] - \Pr[\mathrm{E}_{i+1}]| + \Pr[\mathrm{E}_4]$, is negligible. ■

V. Instantiation

In this section, we show that we can construct a SRBS scheme with EUF-CMA security in the random oracle model by giving an example of the building blocks $\Sigma_{\mathrm{FE}}, \Sigma_{\mathrm{SIG}}, \Sigma_{\mathrm{SE}}$ which satisfies the requirements in the generic construction.

We consider Σ_{SRBS} constructed by Section IV with the following building blocks. We use an $(\mathcal{Y}, \mu, \ell, t, \epsilon)$-fuzzy extractor Σ_{FE} such that $\ell = \Theta(k)$, $\mu = \mathbf{H}_\infty(Y_{\mathrm{G}})$, and ϵ is negligible. Such a scheme can be constructed if $\mathbf{H}_\infty(Y_{\mathrm{G}}) = \Theta(k)$ holds[12]. For example, Dodis et al. [7] showed that

[12]Considering keeping FNMR small, $\tilde{\mathbf{H}}_\infty(Y_{\mathrm{G}} \mid \mathrm{SS}(Y_{\mathrm{G}})) = \Theta(k)$ is required instead of $\mu = \mathbf{H}_\infty(Y_{\mathrm{G}})$. For example, in the case of a $[n, k, 2t+1]$ binary error-correcting code, $\mathbf{H}_\infty(Y_{\mathrm{G}}) + k - n = \Theta(k)$ is required.

for any $[n, k, 2t+1]$ binary error-correcting code and any μ, ϵ, one can construct an $(\mathcal{Y}, \mu, \ell, t, \epsilon)$-fuzzy extractor with $\ell = \mathbf{H}_\infty(Y_{\rm G}) + k - n - 2\log(1/\epsilon)$. By setting $\epsilon = 2^{(\log k)^2}$, it holds that ϵ is negligible and $\ell = \Theta(k)$. Also, as $\Sigma_{\rm SIG}$, we can use any digital signature scheme with EUF-CMA security, e.g., schemes in Ref. [17][18]. Furthermore, as $\Sigma_{\rm SE}$, we use a symmetric encryption scheme by Black et al. [15][13] with the key space $\{0,1\}^\ell$. It can be described as follows. Let $\mathcal{H}$ be the random oracle, and let $\mathcal{H}_n(x)$ be the first n bits of $\mathcal{H}(x)$. Then, $\Sigma_{\rm SE} = ({\rm Gen}_{\rm SE}, {\rm Enc}_{\rm SE}, {\rm Dec}_{\rm SE})$ is defined as follows:

- ${\rm Gen}_{\rm SE}(1^\ell) : sk_{\rm SE} \leftarrow \{0,1\}^\ell$; return $sk_{\rm SE}$.
- ${\rm Enc}_{\rm SE}(sk_{\rm SE}, m) : u \leftarrow \{0,1\}^\ell$; $c \leftarrow (u, \mathcal{H}_{|m|}(sk_{\rm SE} \parallel u) \oplus m)$; return c.
- ${\rm Dec}_{\rm SE}(sk_{\rm SE}, c)$: parse c as (u, b); $m \leftarrow \mathcal{H}_{|b|}(sk_{\rm SE} \| u) \oplus b$; return m.

Theorem 2. $\Sigma_{\rm SRBS}$ defined by the above construction is a SRBS scheme with EUF-CMA security in the random oracle model under the assumption necessary for EUF-CMA security of $\Sigma_{\rm SIG}$.

Proof: It is sufficient to show that the requirements 3(a) and 3(c) in Section IV because the other requirements are satisfied by the definition of the construction. 3(c) holds because ${\rm Dec}(sk', {\rm Enc}(sk_{\rm SE}, m)) = m$ implies $\mathcal{H}_{|m|}(sk_{\rm SE} \| u) = \mathcal{H}_{|m|}(sk'_{\rm SE} \parallel u)$ for $u \leftarrow \{0,1\}^\ell$, the probability of which is negligible.

We show 3(a), i.e., the BE security. In the BE experiment, consider replacing r with $\tilde{r}$, where $\tilde{r}$ satisfies $(r, p) = (\tilde{r}, p)$ with probability not less than $1 - \epsilon$, and $\tilde{r}$ is uniformly distributed and statistically independent of p. We can set $\tilde{r}$ in this way because of the requirement of $\Sigma_{\rm FE}$. The advantage difference is ϵ, which is negligible. Furthermore, in the modified BE experiment, the attacker cannot identify the ciphertexts $({\rm Enc}_{\rm SE}(\tilde{r}, x_{\rm G}), {\rm Enc}_{\rm SE}(\tilde{r}, x_{\rm S}), {\rm Enc}_{\rm SE}(\tilde{r}, sk_{\rm SIG}))$ and the fake ones, because both ciphertexts are uniformly distributed. Therefore, the BE security holds, which concludes the proof. ■

Remark 3. Theorem 2 holds in the random oracle model because $\Sigma_{\rm SE}$ relies on a random oracle. On the other hand, $\mathcal{F}$-KDM security without resorting to the use of random oracles is studied [19][20][21], which aims at enlarging the function class $\mathcal{F}$ or deriving a bound on $\mathcal{F}$. It is future work to construct a SRBS scheme which satisfies EUF-CMA security without random oracles.

VI. Application to Online Biometric Authentication

In this section, we show that by using SRBS schemes with EUF-CMA security we can construct an online biometric authentication system with ASR.

We consider an online biometric authentication system which consists of client devices and an authentication server, and assume that the server follows the protocol but data that appears in the server may leak. Also, we assume that the risk of leaking data that appears temporarily in client devices during procedures for legitimate users are sufficiently low. Under these assumptions, by using an SRBS scheme $\Sigma_{\rm SRBS} = ({\rm Gen}_{\rm SRBS}, {\rm Sign}_{\rm SRBS}, {\rm Ver}_{\rm SRBS}, {\rm Rec}_{\rm SRBS})$ with EUF-CMA security, we can construct an online biometric authentication system with ASR as follows.

During the enrollment procedure, An client device creates a user ID, captures a sample $x_{\rm G} \leftarrow {\rm X}$, and generates $vk_{\rm SRBS}$ by $vk_{\rm SRBS} \leftarrow {\rm Gen}_{\rm SRBS}(1^k, x_{\rm G})$. Then, the user ID and $vk_{\rm SRBS}$ are sent to and stored in the server.

During the authentication procedure, an client device gets the user ID, and sends it to the server. The server sends a fresh challenge m and $vk_{\rm SRBS}$ corresponding to the user ID to the client device. Then, the client device captures a sample $x_{\rm S} \leftarrow \Delta(x_{\rm G})$ from the user, generates $\sigma_{\rm SRBS}$ by $\sigma_{\rm SRBS} \leftarrow {\rm Sign}_{\rm SRBS}(x_{\rm S}, vk_{\rm SRBS}, m)$, and sends $\sigma_{\rm SRBS}$ to the server. The server determines the authentication result *result* by *result* $\leftarrow {\rm Ver}_{\rm SRBS}(vk_{\rm SRBS}, m, \sigma_{\rm SRBS})$. If *result* $= \top$, then the server stores $\sigma_{\rm SRBS}$.

During the recovery procedure, an client device gets the user ID, and sends it to the server. The server sends $vk_{\rm SRBS}$ and $\sigma_{\rm SRBS}$ corresponding to the user ID to the client device. Then, the client device captures a sample $x_{\rm R} \leftarrow \Delta(x_{\rm G})$ from the user, and recovers samples $(x'_{\rm G}, x'_{\rm S})$ by $(x'_{\rm G}, x'_{\rm S}) \leftarrow {\rm Rec}_{\rm SRBS}(x_{\rm R}, vk_{\rm SRBS}, \sigma_{\rm SRBS})$.

The above system satisfies ASR as follows. If the captured samples $(x_{\rm G}, x_{\rm S}, x_{\rm R})$ satisfy $\mathtt{dist}({\rm Feat}(x_{\rm G}), {\rm Feat}(x_{\rm S})) \le t$ and $\mathtt{dist}({\rm Feat}(x_{\rm G}), {\rm Feat}(x_{\rm R})) \le t$, then $(x_{\rm G}, x_{\rm S})$ can be correctly recovered by the recovery procedure. Also, EUF-CMA security of a SRBS scheme implies that it is difficult to recover the past samples or features only from the stored data $(vk_{\rm SRBS}, \sigma_{\rm SRBS})$, because the attacker who can recover the feature from $(vk_{\rm SRBS}, \sigma_{\rm SRBS})$ can forge a signature.

We further discuss biometric reference update. If the system executes the update procedure during an authentication procedure, the feature generated for authentication can be used for the recovery, so the user does not have to input additional biometric samples for the update, which keeps user convenience[14]. For example, consider the case in which the system requires $n_{\rm G}$ and $n_{\rm S}$ samples[15] for biometric reference generation and authentication, respectively, and assume that $n_{\rm G} > n_{\rm S}$ holds[16]. Then, when the system updates a biomeric reference of a user for whom the system performed q successful authentication procedures, the system can use $n_{\rm G}$ samples during the enrollment procedure, $n_{\rm S}$ samples during each of the past q authentication procedures, and $n_{\rm S}$ samples during the authentication procedure with biomeric reference update.

[13]The scheme in Ref. [15] is $\mathcal{F}^{\rm all}$-KDM secure in the random oracle model, where $\mathcal{F}^{\rm all}$ consists of all functions such that the bit-length $|f(sk_{\rm SE})|$ is independent of $sk_{\rm SE}$ and the random oracle accessed in f.

[14]An alternative for applying multi-sample fusion to generating a new biometric reference might be to capture multiple samples during the update procedure, but it is inconvenient for users.

[15]Examples of a fusion scheme is described in Remark 1 in Section III-A.

[16]The authentication procedures are performed more than the enrollment ones, so it is convenient for users if they are required to input less samples during the authentication.

Therefore, in order to generate a new biometric reference, the system can use n_{G} samples chosen from the $(n_{\mathrm{G}}+(q+1)n_{\mathrm{S}})$ samples. This is a merit of the proposed system, because systems without ASR have only n_{S} samples during the authentication procedure with update, which is insufficient for generating a new biometric reference when n_{G} samples are required.

We note that in the above update scheme a new biometric reference vk_{SRBS} is enrolled to the server. In order to make the system secure even when both of an old and a new vk_{SRBS} may leak, it suffices to use a reusable FE [8], which has the property that the randomness r does not leak even if multiple helper strings leak.

IPFed: Identity protected federated learning for user authentication

Yosuke Kaga*, Yusei Suzuki*, Kenta Takahashi*
* Hitachi, Ltd., Japan

***Abstract*—With the development of laws and regulations related to privacy preservation, it has become difficult to collect personal data to perform machine learning. In this context, federated learning, which is distributed learning without sharing personal data, has been proposed. In this paper, we focus on federated learning for user authentication. We show that it is difficult to achieve both privacy preservation and high accuracy with existing methods. To address these challenges, we propose IPFed which is privacy-preserving federated learning using random projection for class embedding. Furthermore, we prove that IPFed is capable of learning equivalent to the state-of-the-art method. Experiments on face image datasets show that IPFed can protect the privacy of personal data while maintaining the accuracy of the state-of-the-art method.**

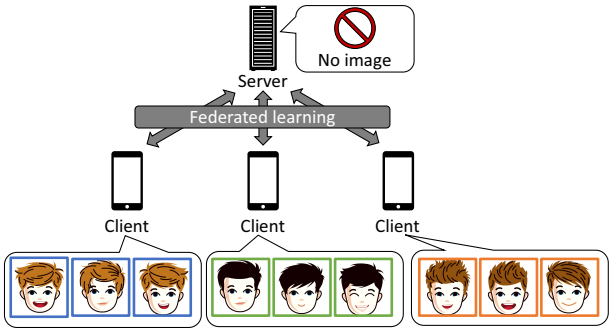

Fig. 1. Federated learning for user authentication.

I. Introduction

User authentication, such as face recognition, has recently achieved dramatic improvements in accuracy through the application of deep learning, and one of the reasons for this is that large numbers of images have been collected through web crawling and used as training data [1]. However, in recent years, GDPR [2] and other privacy-related regulations have made it more difficult to collect personal data. In order to continue to improve the accuracy of user authentication, Privacy-Preserving Machine Learning (PPML) [3] is needed, which performs machine learning without directly collecting personal data. One of the most popular methods in PPML is federated learning [4], which can perform privacy-preserving distributed learning using personal data on the client, and it has attracted attention. Federated learning has been applied to user authentication [5]–[8]. However, these methods face the challenges of privacy of training data [5], [6] and model accuracy [7], [8]. We propose Identity Protected Federated Learning (IPFed) as a solution to this problem. The main contributions of our work are as follows.

- We develop IPFed, which is a method to perform federated learning for user authentication while preserving the privacy of personal data using random projection for class embeddings.
- We prove mathematically that IPFed can perform equivalent learning to the state-of-the-art method while preserving the privacy of the training data.
- Experiments on face image datasets show that the proposed method can learn models with equivalent accuracy to the state-of-the-art method.

II. Related works

A. Federated learning

Federated learning is a method of machine learning in which training data is not shared but distributed across multiple devices. A typical federated learning algorithm is federated averaging (FedAvg) [4]. In this method, machine learning is performed while the personal data is kept in the clients, thus the privacy of training data can be preserved.

B. Federated learning for user authentication

Federated learning for user authentication is a method of learning a discriminator based on personal data such as fingerprints, faces, veins, etc., to determine a person's identity. An overview of federated learning for user authentication is shown in Fig.1. Since a client is often occupied by a single person in user authentication, it is natural for a single client to contain the personal data of only one user. Under this assumption, it is difficult to train a model that can discriminate between others because it is not possible for the client to refer to the personal data of others.

Two main approaches have been proposed to solve this problem. The first one is [5], [6], a method where the learning server performs the learning to increase the distance between the embeddings of the others, and the second is [7], [8], a method where the clients randomly assign representative embeddings for each class (called class embedding). In the following, we will give an overview of each method.

FedAwS [5], FedFace [6]: Federated Averaging with Spreadout (FedAwS) [5] is the algorithm to realize federated learning for user authentication by learning to increase the distance between each other's embeddings on the learning

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

server side. Furthermore, Aggarwal et.al. introduce FedFace, which applies FedAwS to face recognition[6].

Here, we introduce the algorithm of FedFace. The learning server contains a pre-trained model parameter θ_1, and the i^{th} client contains a local dataset S^i and a class embedding w_1^i. In federated learning, the goal is to improve accuracy by updating the model parameters θ_1 without sharing the local dataset S^i with other clients other than the learning server and the i^{th} client. In the t^{th} round, the i^{th} client receives the model parameter θ_t from the learning server. The model parameter θ_t and the class embedding w_t^i are updated by optimizing the positive loss function l_{pos} using the local data S^i.

$$l_{pos}(f_{\theta_t}(x), i) = \max\left(0, m - (w_t^i)^T f_{\theta_t}(x)\right)^2, \qquad (1)$$

where m denotes the margin parameter, $w_t^i \in \mathbb{R}^d$ represents the class embedding for the i^{th} client and $x \in S^i$ is training data, $f_{\theta_i} : X \to \mathbb{R}^d$ is a face feature extractor whose parameters are θ_i.

The updated model parameters θ_t^i and the class embedding w_t^i are sent to the learning server. The learning server aggregates the parameters θ_t^i by taking a weighted average and generates new model parameter $theta_{t+1}$. Then, the learning server obtains the class embedding matrix $W_t = [w_t^1, w_t^2, \ldots, w_t^C]^T$ where C is the number of clients.

Finally, the learning server performs spreadout regularization that minimizes the following equation:

$$reg_{sp}(W_t) = \sum_{c\in[C]} \sum_{\hat{c}\neq c} \left\{\max\left(0, v - d(w_t^c, w_t^{\hat{c}})\right)\right\}^2, \qquad (2)$$

where v represents the margin parameter and $d(\cdot,\cdot)$ is the function to calculate Euclidean distance. In this way, FedFace optimizes the model parameters θ_t and the class embedding matrix W_t and obtains the model with improved accuracy.

Hosseini at.el. [7], [8]: Next, we outline the second approach [7], [8]. In this method, class embeddings are randomly initialized and frozen on the client side, and are not shared with the learning server in order to preserve the privacy of the training data. The clients use the fixed class embedding to train the model, and the learning server aggregates the training results and updates the model parameter.

C. Challenging of related works

Next, we will describe the challenges of federated learning for user authentication. The first approach [5], [6] discloses the class embeddings w_t^i that contain information about the subject identity of the training data to the learning server. These class embeddings are representative embeddings for each subject. By using the class embeddings, the learning server could perform reconstruction of the original training data based on the model inversion attack [9]. Therefore, user privacy is not protected by this approach, since an attacker with access to the data held by the learning server can infer certain personal data, and the class embedding w_t^i should be kept secret from the learning server. On the other hand, in the second approach [7], [8], the class embeddings are assigned independently and randomly for each client, so it does not take into account the similarity of the class e.g. race or gender. Therefore, the performance of the model obtained in the second approach is inferior to the first approach that optimizes the class embedding.

From the above discussion, as far as we know, there is no method that can perform federated learning for user authentication with both high accuracy and privacy preservation of training data. Satisfying these two requirements is an important problem to be solved in the field of federated learning for user authentication.

Algorithm 1: Training algorithm of IPFed.

Input : A pre-trained face feature extractor f_{θ_1} at the learning server and the local dataset S^i at the i^{th} client.

i The i^{th} client initializes the class embedding w_t^i by average embedding obtained by inputting S^i into f_{θ_1}.;

for $t = 1, \ldots, T$ **do**

ii The learning server communicates the current global parameters θ_t to the i^{th} client;

iii The parameter server generates random transformation parameter r^t and send it to all clients;

for *each of the clients* $i = 1, 2, \ldots, C$ **do**

iv The client updates the model parameters based on the local data $x_j^i \in S^i$
$(\theta_t^i, \tilde{w}_t^i) \leftarrow (\theta_t, w_t^i) - \eta\nabla_{(\theta_t^i, w_t^i)} L_{pos}(S^i)$
where $L_{pos}(S^i) = \frac{1}{n_i}\sum_{j=1}^{n_i} l_{pos}(f_{\theta_t^i}(x_j^i), i)$;

v The i^{th} client perform random projection of class embedding $\bar{w}_t^i \leftarrow r_t \tilde{w}_t^i$;

vi The i^{th} client sends the updated parameters $(\theta_t^i, \bar{w}_t^i)$ back to the learning server

end

vii The learning server aggregates the updated parameters from all the clients
$\theta_{t+1} \leftarrow \frac{1}{n}\sum_{i\in[C]} n_i \cdot \theta_t^i$
where n represents the total number of samples on all the clients;

viii Finally, the learning server employs the spreadout regularizer to separate the class embeddings and obtain
$\hat{w}_t^i \in \hat{W}_t$
$\bar{W}_t = [\bar{w}_t^1, \ldots, \bar{w}_t^C]$
$\hat{W}_t \leftarrow \bar{W}_t - \lambda\nabla_{\bar{W}_t} reg_{sp}(\bar{W}_t)$;

ix The learning server sends $\hat{w}_t^i$ to the i^{th} client where $\hat{W}_t = [\hat{w}_t^i]$;

x The i^{th} client decodes class embedding and stores it:
$w_{t+1}^i \leftarrow (r_t)^{-1}\hat{w}_t^i$

end

xi **Output:** Output θ_{T+1}

III. IPFED

We propose a new method to solve the privacy and accuracy problems described in Sec.II. We call our proposed method Identity Protected Federated Learning (IPFed). The overview of IPFed and the training algorithm of IPFed are shown in Fig.2 and Algorithm 1, respectively.

IPFed consists of three entities: clients, a learning server, and a parameter server. The parameter server is managed separately from the learning server, and we assume that it is difficult to

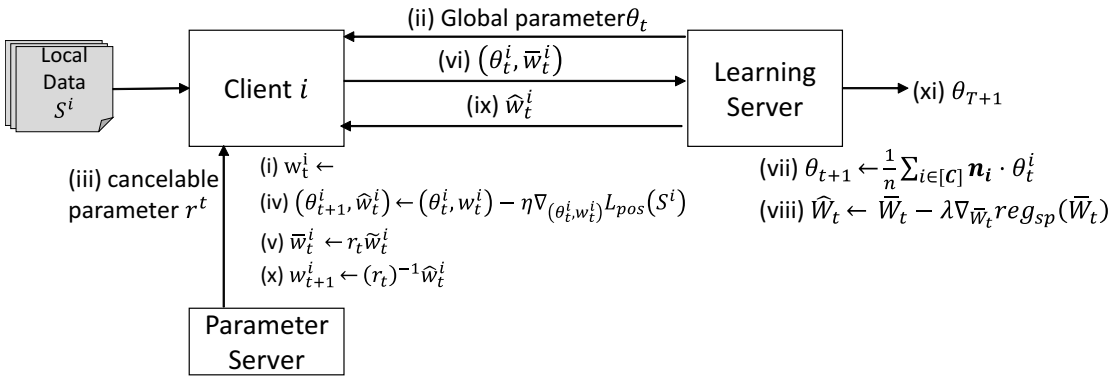

Fig. 2. The overview of IPFed.

steal data in the parameter server and the learning server at the same time. In the following, we explain the steps of IPFed. In the IPFed, a class embedding w_i^t is initialized and stored on each client (step (i)). The learning server sends the global parameter θ_t to each client (step (ii)). This parameter server randomly generates a transformation parameter $r^t \in \mathbb{R}^{d\times d}$ at each round of the federated learning and sends it to each client (step (iii)), where d is the dimension of the embeddings. Each client i updates the global parameter θ_t^i and the class embedding $\hat{w}_{t+1}^i$ (step (iv). In addition, the client calculates the inner product of the class embedding $\tilde{w}_t^i$ and the transformation parameter r^t (step (v)), and sends it to the learning server (step (vi)). The learning server aggregates the global parameters θ_t^i to θ_{t+1} (step (vii)). The learning server optimizes the received class embeddings $\bar{W}_t$ with spreadout similar to FedFace (step (viii)), and sends the result back to each client (step (ix)). The client transforms the received class embedding $\hat{w}_t^i$ by the inverse matrix of the transformation parameter $(r^t)^{-1}$ (step (x)), and keeps it as its own class embedding. After T times rounds, the trained global parameter θ_{T+1} is output.

In IPFed, the class embedding is multiplied by a random transformation parameter which is secret to the learning server. Furthermore, the updated class embedding is returned to the original feature space using the inverse matrix of the transformation parameters. This makes it possible to perform the optimization while keeping the class embeddings secret from any server. In the following, we show in Section III-A that our method can perform the same optimization as FedFace even when the class embedding is kept secret, and we also show in Section III-B that it is difficult for an attacker on any entity to obtain the user's personal data.

A. Derivation of IPFed

In this section, we analyze how the introduction of transformation parameters changes the spreadout process on the server side, and derive the conditions for learning equivalent to FedFace even with class embedding tramsformation. First, the loss function of spreadout reg_{sp} in FedFace is formulated in Eq.(2)[6]. Then, the update equation using this loss function is as follows.

$$\begin{aligned}\hat{w}_t^c &= \tilde{w}_t^c - \lambda\tfrac{\partial}{\partial\tilde{w}_t^c} reg_{sp}(\tilde{W}_t)\\ &= \tilde{w}_t^c - \lambda\tfrac{\partial}{\partial\tilde{w}_t^c}\left\{\textstyle\sum_{c\in[C]}\sum_{\hat{c}\neq c}\left(\max\left\{0, v - d(\tilde{w}_t^c, \tilde{w}_t^{\hat{c}})\right\}\right)^2\right\}\\ &= \tilde{w}_t^c - \lambda\tfrac{\partial}{\partial\tilde{w}_t^c}\left\{\textstyle\sum_{\hat{c}\in[C]} 2\left(\max\left\{0, v - d(\tilde{w}_t^c, \tilde{w}_t^{\hat{c}})\right\}\right)^2\right\}\\ &= \tilde{w}_t^c - \lambda\textstyle\sum_{\hat{c}\in[C]} 4(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})\cdot\min\left\{0, 1 - \frac{v}{d(\tilde{w}_t^c, \tilde{w}_t^{\hat{c}})}\right\}\end{aligned} \quad (3)$$

On the other hand, in Eq.(3) of the IPFed, the inner product of the transformation parameter and the class embedding is input to spreadout, so if we replace $\tilde{w}_t^c$ with $r_t\tilde{w}_t^c$, we get the following equation.

$$\begin{aligned}\hat{w}_t^c = &\quad r_t\tilde{w}_t^c - \lambda\sum_{\hat{c}\in[C]} 4(r_t\tilde{w}_t^c - r_t\tilde{w}_t^{\hat{c}})\cdot\min\{0, 1 - \tfrac{v}{d(r_t\tilde{w}_t^c, r_t\tilde{w}_t^{\hat{c}})}\}\\ \hat{w}_t^c = &\quad r_t\left\{\tilde{w}_t^c - \lambda\sum_{\hat{c}\in[C]} 4(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})\ \min\{0, 1 - \tfrac{v}{||r_t(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})||^2}\}\right\}\end{aligned} \quad (4)$$

In addition, the learning server sends the obtained class embedding to the client, and the client transforms it into the original feature space by taking the inner product with the inverse matrix of the transformation parameters $(r_t)^{-1}$. After adding this process, Eq.(4) can be expressed as follows.

$$(r_t)^{-1}r_t\left\{\tilde{w}_t^c - \lambda\sum_{\hat{c}\in[C]} 4(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})\cdot\min\left\{0, 1 - \frac{v}{||r_t(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})||^2}\right\}\right\} \quad (5)$$

Here, if the update equation of FedFace (Eq.(3)) and the update equation of IPFed (Eq.(5)) are equivalent, then IPFed can perform equivalent learning to FedFace even if the class embeddings are kept secret. The condition that the update equations of IPFed and FedFace are equivalent is expressed by the following equation.

$$(r_t)^{-1}r_t = I \quad (6)$$

$$||r_t(\tilde{w}_t^c - \tilde{w}_t^c)||^2 = ||(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})||^2 \quad (7)$$

where I is an identity matrix. Eq.(6) is valid if r_t is a regular matrix. Transforming Eq.(7), we obtain

$$\begin{aligned}(r_t(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}}))^T(r_t(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})) &= (\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})^T(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})\\ (\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})^T(r_t)^T r_t(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}}) &= (\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})^T(\tilde{w}_t^c - \tilde{w}_t^{\hat{c}})\\ (r_t)^T r_t &= I\end{aligned} \quad (8)$$

Therefore, Eq.(8) is valid if r_t is an orthonormal matrix. From the above, IPFed is equivalent to FedFace in terms of spreadout if the transformation parameter r_t is an orthonormal matrix.

B. Privacy analysis of IPFed

In this section, we discuss how privacy protection is achieved by our IPFed. We assume that an attacker against IPFed can obtain the data stored or communicated on any one of the three entities. We also assume a semi-honest model in which each entity follows correct protocols. We also assume that the goal of the attack is to obtain personal data of a specific individual.

Attacker against a client: From c^{th}client, the attacker can obtain the personal data S^c, the global parameter θ_t, the transformation parameter r_t, and the class embedding w_t^c,$\tilde{w}_t^c$. The attacker's goal is to obtain the personal data S^i (but $i \neq c$) stored on other clients from these data . S^c and r_t are completely independent of the personal data S^i ($i \neq c$) and do not contribute to the inference of the personal data. The attack to estimate training data from the global parameter θ_t is called Model Inversion Attack (MIA). However, in order to recover the training data using MIA, auxiliary information such as class labels and class embeddings are required [9]. Since they are kept secret in the IPFed, it is difficult to perform MIA. In addition, the class embedding w_{t+1}^c is obtained by updating w_t^c according to the distance from the class embeddings of other classes, and some information about other class embeddings may be leaked from the class embedding. However, in federated learning, [10] suggests that it is difficult enough to recover the original data from the result of aggregating many gradients, and it is difficult to estimate other class embeddings from one class embedding.

Attacker against the parameter server: From the parameter server, the attacker can obtain the transformation parameter r_t. Since the transformation parameter is randomly generated data independent of the personal data, it is difficult to obtain any personal data.

Attacker against the learning server: From the learning server, the attacker can obtain the global parameters θ_t,θ_{t+1}, the updated global parameters θ_{t+1}^i, the transformed class embeddings $\bar{w}_t^i$ can be obtained. The attacker's goal is to obtain specific personal data S^i from these data. Estimation of personal data from the global parameters θ^t and θ_{t+1} is possible by gradient inversion attack, but it is extremely difficult on practical settings [10]. Moreover, it is known that an attack to estimate training data from the updated global parameter θ_t^i can be made difficult by using secure aggregation [11] to calculate θ_{t+1} while keeping θ_t^i secret. By using these methods, user privacy can be protected under our assumption. On the other hand, random projection is used for template protection, called cancelable biometrics [12]. This random projection is known to make it difficult to estimate the original data from the transformed data when the transformation parameter is unknown. In general, it is known that the original data can be estimated when multiple random projections are available for the same data, but in federated learning for user authentication, the class embedding is updated and different each round, making the attack difficult. Furthermore, by setting up a shuffle server between the learning server and the client and hiding the client's ID from the learning server, it is possible to make it difficult to assign class embeddings in different rounds. This shuffle server can increase security. From the above discussion, it is difficult for the learning server to infer the class embedding $\tilde{w}_t^i$ from $\bar{w}_t^i$.

In conclusion, we have confirmed that IPFed can strongly protect the privacy of training data under the assumptions defined in this paper.

C. Efficiency analysis of IPFed

In this section, we discuss the efficiency of IPFed. In Fig.2, steps (4), (7), (11) are newly introduced steps in IPFed. Step (4) is related to communication efficiency. A transformation parameter $r^t \in \mathbb{R}^{d \times d}$ is very small data compared to the global parameter θ_t, and its transmission has a negligible effect on the learning efficiency. Furthermore, steps (7), (11) are related to computational efficiency on the client. In these steps, the inner product of the matrix is computed only once, thus it has a negligible impact on learning efficiency compared to updating the global parameter in step (6).

Note that the parameter server is a newly introduced and its operating costs are newly incurred. However, since the role of the parameter server is only to generate and send the transformation parameter, there is no problem even if the server has very little computing power.

From the above discussion, it can be said that the efficiency of IPFed is comparable to that of the conventional method [6]. However, quantitative evaluation of the efficiency of IPFed is a future work.

IV. Experiments

In this chapter, we show the effectiveness of the proposed method through experiments on face image datasets.

A. Setting

Datasets: We follow the setting in [6] and used CASIA-WebFace [14] for training. CASIA-WebFace consists of 494,414 images of 10,575 subjects. We randomly select 9,000 subjects for pre-training and 1,000 subjects for federated learning. To evaluate the performance of face verification, we use three datasets: LFW [15], IJB-A [16] and IJB-C [17].

Implementation: We use CosFace [18] for the face feature extractor. Only CosFace was used as the face feature extractor according to [6], but evaluation using more recent multiple the face feature extractors is a subject for future work. We use the scale parameter of 30 and the margin parameter of 10 for the CosFace loss function. The margin parameters are $m = 0.9$ and $v = 0.7$. The parameter λ = 25 in Eq.(3). We perform federated learning with a communication round of 200 and a learning rate of 0.1.

B. Evaluation

First, the face verification performance of each method for 1000 clients is shown in the Table.I. The comparison methods are shown below:

TABLE I
FACE VERIFICATION PERFORMANCE ON STANDARD FACE RECOGNITION BENCHMARKS LFW, IJB-A AND IJB-C.

Method	Training data	Class embedding	LFW Accuracy (%)	IJB-A TAR @ FAR=0.1%	IJB-C TAR @ FAR=0.1%
Baseline	Centrally aggregated	-	99.15%	74.21%	80.60%
Fine-tuning	Centrally aggregated	Not protected	99.30%	77.10%	82.71%
FCE	Distributed	Protected	99.17%	72.71%	80.06%
FedFace	Distributed	Not protected	99.22%	74.76%	79.77%
IPFed	Distributed	Protected	99.22%	75.70%	80.73%

TABLE II
IJB-A TAR @FAR=0.1% ON NUM. OF SUBJECTS.

Method	Num. of subjects			
	50	100	500	1000
Fine-tuning	75.15%	75.15%	75.76%	77.10%
FCE	72.54%	72.21%	74.38%	72.71%
IPFed	73.60%	72.82%	76.65%	75.70%

Baseline A typical CosFace model, pre-trained on 9000 subjects.

Fine-tuning A fine-tuned model of Baseline using CosFace on 1000 subjects.

FedFace A model trained according to [6].

IPFed A model trained based on the proposed random projection approach.

Fixed class embedding (FCE) A model trained by fixing the class embedding to the initial data. In FCE, the class embedding does not need to be shared with the server, and secure federated learning can be performed.

As shown in Table.I, IPFed achieves the same level of accuracy as FedFace. This means that the random projection based spreadout in IPFed is equivalent to the spreadout in FedFace. On the other hand, FCE is less accurate than IPFed. This is due to the lack of class embedding optimization, which means that the spreadout in IPFed contributes to the accuracy improvement.

Furthermore, the accuracy against the number of subjects used for federated learning is shown in TableII. The IPFed achieves higher accuracy than the FCE for any of the number of the subjects. This indicates that sharing and optimizing class embedding improve the accuracy. However, while Fine-tuning has a monotonic increase in accuracy for the number of the subjects, IPFed does not. This may be due to the fact that the hyperparameters in learning are not optimal for the number of the subjects, so automatic adjustment of hyperparameters is a future task.

In addition, in our experiments, only accuracy was evaluated, and attack defense performance was only theoretically evaluated. This is also a topic for future work.

V. CONCLUSION

In this paper, we focused on the problem of personal data leakage from class embedding in federated learning for user authentication, and proposed IPFed, which performs federated learning while protecting class embedding. We proved that IPFed, which is based on random projection for class embedding, can perform learning equivalent to the state-of-the-art method. We evaluate the proposed method on face image datasets and confirm that the accuracy of IPFed is equivalent to that of the state-of-the-art method. IPFed can improve the model for user authentication while preserving the privacy of the training data.

Privacy-Preserving Image Transformation Method for Person Detection and Re-ID

Yumo Ouchi, Hidetsugu Uchida and Narishige Abe
FUJITSU LIMITED, Japan

Abstract — **In recent years, the number of surveillance cameras is on the rise, and the limitation on image recognition including person re-identification (Re-ID) is lifted to ensure a safer and more convenient world. However, this has led to increasing privacy concerns. To address this issue, numerous privacy-preserving technologies have been proposed but they focused primarily on detection or classification of people. In this study, we propose a novel image transformation method to preserve privacy in detecting and re-identifying people. Privacy-preserving images visually protect images of people, but a machine can detect and classify them without any additional information. Our results show that the privacy-preserving images, transformed by our method, maintained the accuracy of person detection and Re-ID compared to that of the images with gaussian noise, blur, and pixelation.**

I. INTRODUCTION

With the evolving Artificial Intelligence technology, machine-learning techniques such as face recognition are being explored in the field of biometrics. Recently, the use of security camera images has advanced to ensure a safe and more convenient world. Moreover, the accuracy of the person re-identification (Re-ID)—which is the core technology in the technical field—has substantially improved. The Re-ID is a technique through which the person's identity is matched in video sequences captured by different cameras. Utilization of Re-ID for security camera images installed in the city can ensure surveillance (such as tracking suspicious persons and searching for lost and wandering persons), and marketing (such as analyzing customer traffic lines in stores).

However, psychological anxiety and discomfort are undeniable concerns owing to the possibility of privacy leakage due to continuous monitoring of the user. This has prompted the creation of many privacy-preserving technologies [1] [2] [3] [4]. Research in nonvisibility technology, which involves direct processing the data acquired from cameras and sensors obscuring the person's identity, is actively ongoing. The Re-ID system can be used in many situations if the psychological anxiety of the users can be minimized. There are two approaches to the nonvisibility of a person that involves 1) use of hardware instead of a camera and 2) use of software-based conversion techniques of general camera images.

In the hardware-based approach, Ohno et al. [5] proposed a method that tracks people using 3D point cloud information captured by multiple LiDAR sensors. Cheng et al. [6] also proposed a less precise and cheaper method than LiDAR using Radar to Re-ID a person using 4D Point Cloud information with 3D point cloud and Doppler velocity. Fan et al. [7] demonstrated a method for re-identifying signals using radio signals such as Wi-Fi. However, LiDAR and Radar are not commonly used in general settings, and their applications are limited. In addition, they are costly to install.

In the software-based approaches, RBG images captured by general cameras were made nonvisible by image processing. This could entail blurring or adding noise to the detected person or the face region [8]; however, the accuracy of the Re-ID is poor, and this approach is not practical. This prompted the creation of methods that ensure nonvisibility while suppressing deterioration in accuracy of Re-ID. For example, Ahmad et al. [9] proposed a Re-ID method using different information (Event Frame) from the image several frames before. Moreover, adding a patch image to a part of the face and using face anonymization to convert a detected face region into a face image of another person [10] have been elucidated. In addition, Kiya et al. [11] proposed a method in which the image data encrypted with a secret key is trained using vision transformer [12] and the images were encrypted with the same secret key during inference to identify images. Dou et al. [13] proposed a method that changes the appearance while maintaining the accuracy of Re-ID: using De-Identification technology with variational autoencoder [14], while utilizing the existing feature extraction model.

However, in the aforementioned techniques, the necessity to retrain the person detection model or the Re-ID feature

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

extraction model or focus on any one of the "person detection" and the "Re-ID feature extraction" cannot be overemphasized. Therefore, in this study, we propose a technology that ensures the nonvisibility of a person in a video image acquired from a camera while maintaining the accuracy of detecting and re-identifying the person without retraining the models. The following remarks were obtained in our study:

- We aimed at exploring nonvisibility technology for person detection and Re-ID
- We evaluated the usefulness of the proposed method by comparing with the Re-ID accuracy in the plain image
- We confirmed that the proposed method achieves effective nonvisibility by comparing the results with the Re-ID accuracy of pseudo-nonvisibility images with gaussian noise, blur, and pixelation

Section II describes the proposed method, Section III describes experiments and their results, and Section IV provides conclusions.

II. PROPOSED METHOD

The proposed method aims is to visually exclude the individuality of a person in a video frame acquired from a camera while suppressing the accuracy degradation of in detecting and re-identifying the person. Ito et al. [15] focused only on the image classification task. We extended this training framework and defined loss functions that suppress accuracy degradation in person detection and Re-ID feature extraction.

The model for transforming a plain frame image into a nonvisibility image is trained using pretrained person detection and Re-ID feature extraction models. First, plain frame images are fed to the transformation network to obtain transformed images. We have used U-net [16] as the image transformation network. The plain frame images and the transformed frame images are cropped as the bounding box area of the ground truth and input to the image similarity loss function. The image similarity loss function $L_{similarity}$, is L1 loss, which is calculated as follows:

$$L_{similarity}(B, \hat{B}) = \frac{1}{n}\sum_{i=1}^{n} l_i \tag{1}$$

$$l_i = |b_i - \hat{b}_i| \tag{2}$$

Here, let $B = \{b_1, b_2, \dots, b_n\}$ a cropped plain image set, $\hat{B} = \{\hat{b}_1, \hat{b}_2, \dots, \hat{b}_n\}$ is a cropped transformed image set, and n is the batch size.

Next, the detection result is obtained using the transformed frame image and the pretrained person detection model. In the experiment, among object classes detected using Faster RCNN [17], only person detection results are used for training. The person detection result and ground truth labels are input to the person detection network loss function, and we obtain a loss L_{object} from the person detection network loss function. L_{object} is the loss defined by Faster RCNN.

Thereafter, the Re-ID feature of the cropped transformed images is obtained using the cropped transformed image and the pretrained Re-ID feature extraction model. At the same time, the Re-ID feature amount is also obtained from the cropped plain image. In our experiment, the method proposed by Zheng et al. [18] is used as a Re-ID feature extraction model. The Re-ID features of the cropped transformed images and the Re-ID features of the cropped plain images are input into the Re-ID Network Loss function. The loss, L_{reid} is obtained from the Re-ID Network Loss function. L_{reid} is the cosine similarity of the features and is calculated as follows:

$$L_{reid}(F, \hat{F}) = 1 - \frac{1}{n}\sum_{i=1}^{n} s_i \tag{3}$$

$$s_i = \frac{f_i \cdot \hat{f}_i}{\max\left(\|f_i\|_2 \cdot \|\hat{f}_i\|_2, \in\right)} \tag{4}$$

Here, $F = \{f_1, f_2, \dots, f_n\}$ is the Re-ID feature set of the cropped plain image, $\hat{F} = \{\hat{f}_1, \hat{f}_2, \dots, \hat{f}_n\}$ is the Re-ID feature set of the cropped transformed images and n is the batch size. Using $L_{similarity}$, L_{object}, and L_{reid}, the image transformation network minimizes the loss function, L_{trans}. L_{trans} is defined as:

$$L_{trans} = L_{object} + L_{reid} - \alpha \cdot L_{similarity} \tag{5}$$

Here, α is adjustment parameter. However, the number of epochs in the first half of the training is defined as follows:

$$L_{trans} = L_{object} + L_{reid} + L_{similarity} \tag{6}$$

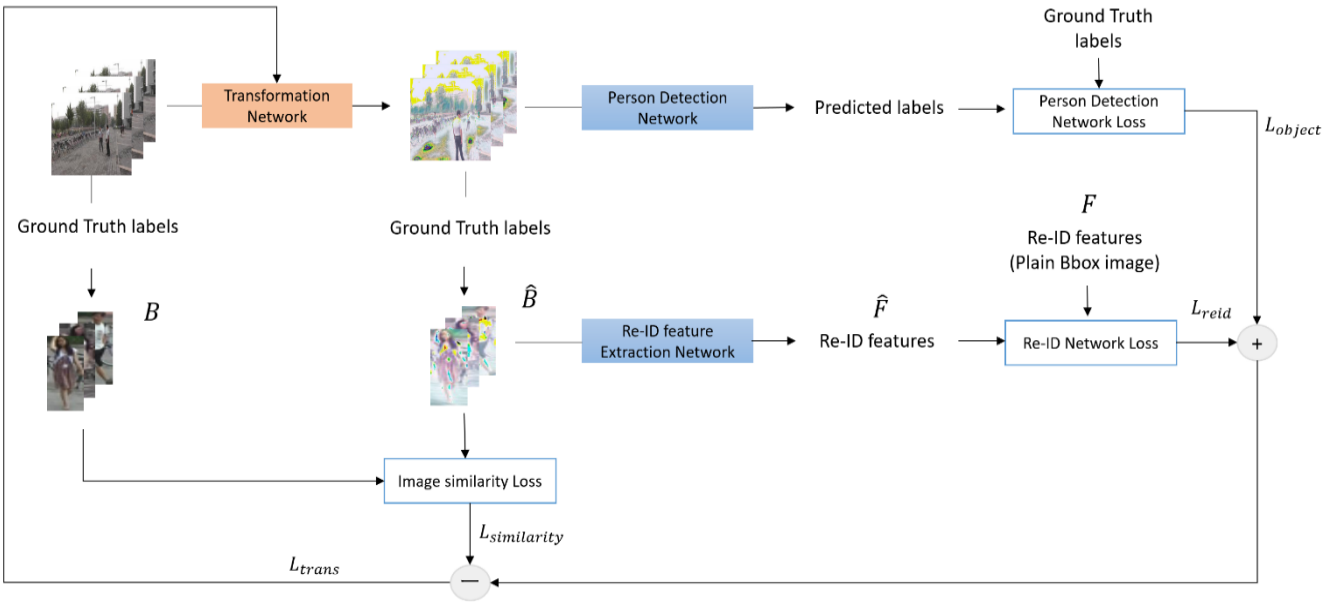

Figure 1: Proposed training process of transformation network

This ensures that the image transformation network generates an image close to the plain image.

III. EXPERIMENT

The degree of nonvisibility is evaluated in terms of the person detection accuracy, Re-ID accuracy from Re-ID feature extraction, and similarity with the plain image.

A. Experimental method

Faster RCNN—used as a person detection model—is a pretrained model provided by PyTorch[1]. The Re-ID feature extraction model is pretrained on the Market-1501 dataset [19] using the method proposed by Zheng et al. [18]. Using the two pretrained models, U-net was trained according to the training framework shown in Figure 1. In this training, we have used 5,703 images of Person Re-identification in the Wild (PRW) Dataset [20]: 4,563 images used as training data and 1,140 images as verification data. The activation function was Adam, the learning rate was 0.001, the batch size was 4, the number of epochs was 20, and the model of the epoch with the lowest loss was used for the evaluation. In the first half of training was conducted using the loss of equation (6) from one epochs to seven epochs. In the last half of training was conducted using the loss of equation (5) from eight epochs to twenty epochs, where the loss was sufficiently reduced. The adjustment parameter of equation (5) is $\alpha = 0.1$.

The evaluation data comprised 1,000 images extracted from the PRW Dataset. We used the average of Intersection over Union as the evaluation method of the person detection. We used the detection result classified as evaluation data of person detection. Moreover, we used Rank-1 accuracy and mean Average Precision (mAP) as evaluation method for Re-ID. The bounding box regions of the ground truth were cropped from the frame images and used for evaluation of Re-ID.

B. Privacy-Preserving Image for person detection

First, we conducted an ablation study to confirm the learning process shown in Figure 1. In addition, we created privacy-preserving image transformation model to detect persons only. The learning process is described in Section AThe loss function shown in Eq. (5) was used as $L_{reid} = 0$ between 8 epochs and 20 epochs. The performance of the transformed image is shown in Table 1. "Re-ID" in Table 1 indicates its matching accuracy using Re-ID feature extraction. From Table 1, the privacy-preserving image transformation model to solely detect persons maintained its accuracy. However, the Rank-1 accuracy of Re-ID decreased by 27% and mAP decreased by 37%. Therefore, the learning process of Figure 1 functioned as intended.

[1] https://pytorch.org/vision/main/models/faster_rcnn.html

C. *Privacy-Preserving Image for person detection and Re-ID*

Second, we created a privacy-preserving image transformation model for person detection and Re-ID. The learning method is described in Section A. The resulting transformed image is shown in Figure 2. Table 1 demonstrates that the person detection accuracy was equivalent to its performance using plain images. However, although the Rank-1 accuracy and mAP of Re-ID reduced by 14%, the accuracy of Re-ID was higher than that of privacy-protected images that solely detected person in Section B. This shows that the model learned using loss for person detection and Re-ID.

D. *Comparison of accuracy with image processing method*

Third we compared the accuracy in three image processing methods: gaussian noise, blur, and pixilation, to verify whether transformed images were as intended such that the person detection accuracy and Re-ID accuracy were not lowered. To evaluate person detection, we first evaluated transformed images with Peak signal-to-noise ratio (PSNR)—an image quality evaluation index and a higher PSNR value provides a higher image quality—and added gaussian noise to plain images to have the same PSNR value. The PSNR of blur and pixilation could not be reduced to the same level, and image processing was performed to such an extent that the face of the person in the image could not be identified. So, images of blur and pixelation were of higher image quality than those generated by the proposed method. Next, to evaluate Re-ID, we evaluated the cropped transformed images with PSNR, and added gaussian noise to plain cropped images to have the same PSNR value. Since the PSNR for blur and pixelation could not be reduced to the same level, bounding box image processing was performed such that the face of the person in the image could not be identified. Examples of a gaussian noise, blur, pixelation images are shown in Figure 2. Table 1 shows the results of the accuracy of person detection and Re-ID for the three methods. However, the PSNR values for blur and pixelation were not shown, since they could not generate an image based on PSNR.

From Table 1, we found that the transformed images generated by the proposed method were more accurate than that obtained from the three methods in person detection and Re-ID. Thus, the proposed method caused deterioration in image quality, maintained the accuracy of the Re-ID processing, and ensured nonvisibility.

IV. CONCLUSION

In this paper, we propose the novel image transformation method. Pretrained person detection model and Re-ID feature extraction model can be used to develop the proposed image transformation network. In the experiment, the Re-ID accuracy of the generated nonvisibility images were evaluated using the pretrained models. Our experimental results showed that the accuracy of person detection was maintained as that obtained using plain images, though the Re-ID feature extraction accuracy decreased by 14%. In addition, the nonvisibility images of the proposed method exhibited better accuracy compared to that of the images with gaussian noise, blur, and pixelation.

In the future, we will focus on improving the feature extraction accuracy and evaluating the nonvisibility images using more effective nonvisibility technology.

***Abstract*—In this paper, we propose an eye biometric recognition method, which is combined with periocular and iris recognition. The proposed method extracts features using convolutional neural networks (CNNs) dedicated to periocular and iris recognition, respectively. The matching score is calculated by weighting scores from periocular and iris recognition. Through a set of experiments using public datasets, we demonstrate the effectiveness of the proposed method compared with conventional methods.**

I. Introduction

Accurate and reliable person authentication is essential for immigration control and electronic payment systems, which require high security. One of such personal authentication techniques is biometrics, which identifies individuals using their physical and behavioral characteristics [1]. Biometric characteristics include face, iris, fingerprints, gait, signature, and so on, which have different characteristics from each other. A fingerprint, for example, is highly reliable due to its high discrimination and permanence, while acceptability is low due to the contact with the sensor when a fingerprint is captured. A face is highly collectable and convenient since it can be captured using a common RGB camera, while it is unreliable since its features change with aging, makeup, facial expressions, and so on. Thus, biometric recognition using a single biometric characteristic has both high reliability but low convenience and high convenience but low reliability, and it is difficult to achieve both reliability and convenience in biometric recognition using a single biometric characteristic. In this paper, we focus on the region around the eyes, which has multiple biometric characteristics.

There are two types of biometric recognition using the region around the eye: iris and periocular. Iris recognition uses an iris, which is a ring-shaped region between the pupil and the sclera [2]. The iris has a fine pattern called the iris pattern, which is highly discriminative even in the eyes of two identical twins or the left and right eyes of the same person. Furthermore, the iris is invariant throughout life, and it is difficult to change the pattern through surgery and so on. As a result of these advantages of the iris, iris recognition is one of the most reliable biometric recognition methods, and is used in situations where high security is required. On the other hand, iris recognition is not convenient since it requires the user to look into the camera to capture the iris image. Periocular recognition uses features around the eyes such as eyebrows, eye shape, eyelid wrinkles, and skin texture [3]. Unlike iris recognition, periocular recognition can be performed without facing the camera, making it convenient and suitable for situations that require high throughput, such as walk-through authentication. On the other hand, periocular features are not very discriminative since they may be similar even among different people, such as identical twins, and they change with age, makeup, facial expressions, etc. Therefore, periocular recognition is not very reliable compared with iris recognition.

In this paper, we propose an eye biometrics system that combines reliable iris recognition and convenient periocular recognition. The proposed method extracts iris and periocular features using SE-ResNet-18, which is a combination of ResNet [4] and the attentional mechanism used in Squeeze-and-Excitation Networks [5]. For iris recognition, we basically adopt our proposed method [6]. The final matching score is calculated by fusing the matching scores calculated from the iris and periocular features. We improve the recognition accuracy by applying data augmentation that reproduces the variation of the iris and periocular images. Through experiments using the public datasets CASIA-Iris-Thousand, CASIA-Iris-Distance, and CASIA-Iris-Mobile-V1.0 [1] consisting of periocular images, we demonstrate the effectiveness of the proposed method compared with conventional methods.

II. Related Work

This section presents an overview of related work on iris recognition, periocular recognition, and their combination.

A. Iris Recognition

The most well-known iris recognition is iriscode [7], [8] proposed by Daugman, and many derivatives have been proposed. Among them, OSIRIS [9], which is an open-source iris recognition software modified from iriscode, is often used as a baseline for performance evaluation. OSIRIS first segments the iris region from a high-resolution periocular image and detects the iris contour from a low-resolution periocular image. Using

[1] http://biometrics.idealtest.org

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

both results, the parameters of the inner and outer bounding circles of the iris are obtained. Next, the iris region is normalized to a rectangle by polar coordinate mapping, and iriscodes are generated using a 2-D Gabor filter. Finally, the Hamming distance between iriscodes is used as the matching score. The accuracy of iris segmentation is significantly degraded by narrowing the eyes or wearing glasses, and iriscode cannot be generated accurately when the image is blurred. UniNet, which introduces deep learning into Iriscode, has been proposed [10]. UniNet is based on Fully-Convolutional Network (FCN) [11], which can preserve local features by keeping positional relationships between inputs and outputs, since iris consists of random patterns and has high discriminative capability in local features. UniNet consists of two types of FCNs: FeatNet and MaskNet. FeatNet plays the role of feature extraction by Gabor filter in iriscode, and MaskNet generates iris masks from normalized iris images.

B. Periocular Recognition

AttNet [12] has been proposed for periocular recognition using deep learning, which focuses on the high discriminability of the region between the eyes and eyebrows in periocular recognition, and applies an attention to this region. First, a mask representing the eye and brow regions in the periocular image is generated using an improved version of FCN called FCN-Peri. Next, the mask is multiplied by the intermediate features of AttNet, which extracts features from the periocular image, and the highly discriminative feature are extracted by applying attentions to these regions.

C. Periocular and Iris Recognition

A method combining UniNet [10] and AttNet [12] has been proposed to combine periocular and iris recognition [13]. Matching scores are calculated by inputting the iris features obtained by UniNet and the periocular features obtained by AttNet into a dynamic fusion block consisting of four FC layers. The recognition accuracy is significantly degraded when there is occlusion in the iris since iris segmentation is performed using RTV-L1 [14] which is based on handcrafted features.

III. Eye Biometrics Using CNN

This section describes the proposed method, which is a multi-biometric recognition method combining iris and periocular recognition. Fig. 1 shows an overview of the proposed method. We segment and localize the iris region in the periocular image to perform iris recognition. Three masks (iris mask, outer iris circle mask, and pupil circle mask) are generated from the periocular image using U-Net [15], and the ellipse parameters of the outer iris circle and the pupil circle are estimated. Based on the estimated ellipses, the iris region is localized, the iris is divided into four sub-regions, and each sub-region is normalized to a rectangular region. CNN-based feature extractors are used to extract features from the normalized iris image and the periocular image, respectively. The proposed method uses SE-ResNet-18 [4], [5] as feature extractors. In training the feature extractors, we introduce data augmentation that produces images similar to the variations in the iris and periocular images. When training the iris feature extractor, the training data is selected based on the ratio of non-iris regions in the iris image to reduce the influence of non-iris regions such as eyelids and eyelashes that are included in the iris image. The final matching score is calculated by integrating the matching score calculated from the iris and periocular regions. We describe the details of the iris detection, feature extraction, data expansion, and matching processes in the following.

A. Iris Detection

This section describes iris detection from periocular images. A segmentation network based on U-Net [15] is used to generate three binary masks of the iris. The proposed method uses U-Net whose encoder is replaced by SE-ResNet-18 [4], [5]. SE-ResNet-18 is a CNN model that introduces a Squeeze-and-Excitation block (SE block), which is an attention mechanism, into ResNet, which is a CNN model used in image recognition. In SE block, feature maps output from the convolutional layer are averaged in the channel direction and aggregated into a vector, and then passed through two fully-connected layers and activation functions (ReLU and Sigmoid) to convert it into a vector that represents the weights for each channel. The weight vectors are then multiplied by the feature map to obtain a refined feature map. U-Net outputs an iris mask representing the iris segmentation result, an outer mask representing the outer circle of the iris, and an inner mask representing the pupil segmentation result. The iris mask corresponds to the iris region detected at the pixel level, excluding occlusions such as eyelids, while the outer and inner masks represent the boundary circle between the iris and sclera, and the boundary circle between the iris and pupil, respectively. The outer and inner masks are not exact circles since a part of the circle may be lacking due to the occlusion. By applying ellipse fitting to both masks, we can estimate the center coordinates, the lengths of the major and minor axes, and the rotation angle of the outer and inner circles. The upper and lower parts of the iris are often occluded by the eyelids and eyelashes, making it more difficult to acquire features than the right and left sides of the iris. Therefore, the iris region is divided into four sub-regions: Upper (U), Bottom (B), Left (L), and Right (R), which are used for training and recognition. This approach effectively suppresses the effect of occlusion on the recognition accuracy. Each iris region is normalized to a rectangle by polar coordinate mapping. The normalized iris image has 512×64 pixels, and each sub-region has 128×64 pixels.

The loss function for training U-Net is defined by

$$L_{seg} = L_{iris} + \lambda_1 L_{outer} + \lambda_2 L_{inner}, \tag{1}$$

where L_{iris}, L_{outer}, L_{inner} indicate the dice loss [16] computed between the estimated and ground-truth values of the iris mask, inner mask, and outer mask, respectively, and λ_1 and λ_2 indicate the parameters for adjusting the weight of each loss.

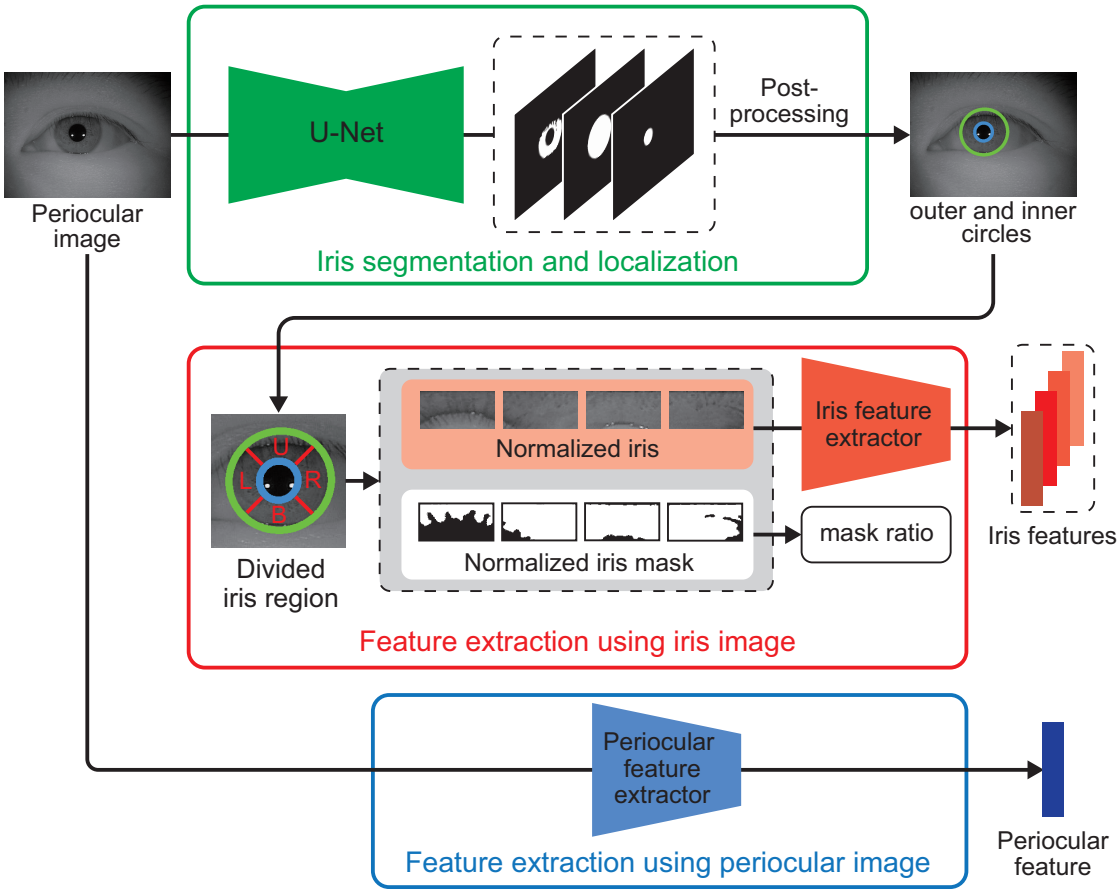

Fig. 1. Overview of the proposed method that combines periocular recognition and iris recognition.

The dice loss L_D is defined by

$$L_D = \frac{2\sum_{i=1}^{N} p_i g_i}{\sum_{i=1}^{N} p_i^2 + \sum_{i=1}^{N} g_i^2}, \tag{2}$$

where $p_i \in P$ indicates the pixel value of the estimated mask, $g_i \in G$ indicates the pixel value of the ground-truth mask, and N is the number of pixels in the mask. Although the number of pixels in the iris region and the number of pixels in the non-iris region are significantly different, the use of Dice loss allows for efficient training even when there is class bias.

B. Feature Extraction

We describe CNNs for feature extraction from iris and periocular images. In the proposed method, SE-ResNet-18 shown in Fig. 2 is used as feature extractors for iris and periocular images. The feature extractors are independent for the iris and periocular images as shown in Fig. 1. Their network architecture is the same, they do not share the weight parameters, and they are trained separately. The feature extractors extract 512-dimensional feature vectors from the iris and periocular images, respectively. The feature extractors are trained by inputting feature vectors to the classifier, which consists of a fully-connected layer and a softmax layer, and performing class classification. The cross entropy loss L_{CE} is used as the loss function. The feature extractor is trained to extract features that take into account the small differences in iris patterns by classifying the U, B, L, and R sub-regions as independent classes, even if the images are of the same person. Occlusions such as eyelids and eyeglasses may occupy the majority of the sub-regions obtained by iris segmentation. In particular, the U sub-region is often hidden by the eyelids and eyelashes. It is difficult to obtain features that are effective in identifying individuals from sub-regions that are mainly occlusions. Such low-quality training data degrades the CNN performance, and thus we have to select effective training data. To select sub-regions to be used for training, we use the mask ratio R defined by

$$R = \frac{A_{mask}}{A_{iris} + A_{mask}}, \tag{3}$$

where A_{iris} indicates an area of iris region, and A_{mask} indicates an area of non-iris region. The sub-regions with R higher than a threshold are excluded from the training data.

C. Data Augmentation

We introduce data augmentation to the training data to add variability to the periocular and iris images to improve the accuracy of the feature extractor. For the periocular image,

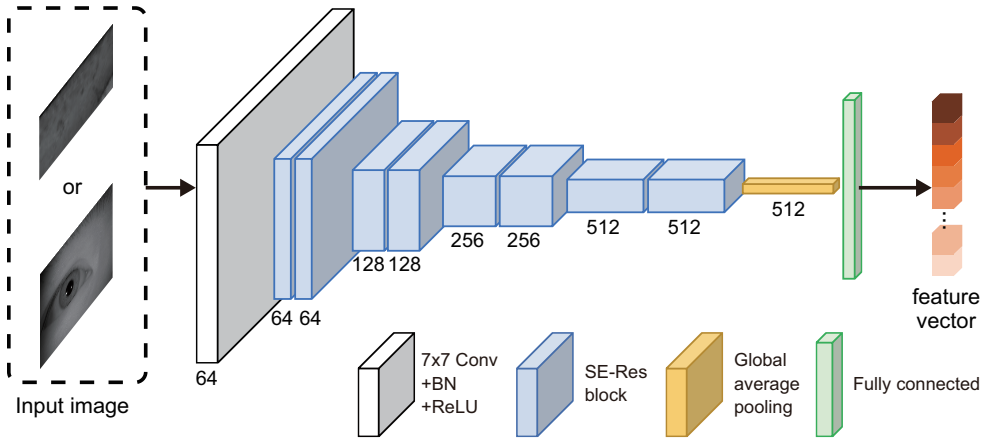

Fig. 2. Network architecture of the iris and periocular feature extractors, where the numbers under the blocks represent the number of output channels in each block.

we introduce the data augmentation of random crop, color jitter, random erasing, and random perspective. Random crop reproduces shifts in eye position by cropping random regions of the image. Color jitter reproduces changes in the ambient brightness of an image by randomly changing the brightness of the image. Random erasing replaces some pixel values in the image with zeros to reproduce the loss of periocular pattern due to glasses and others. Random perspective reproduces the orientation of a face by applying random deformations to the image. For iris images, we introduce the data augmentation of random erasing [17] and random horizontal shift. Random erasing is similar to data augmentation for periocular images. Random horizontal shift reproduces the rotation of the iris before rectangle normalization by randomly circularly shifting the image in the horizontal direction.

D. Matching

In the proposed method, the scores are calculated based on the features extracted from the iris and the periocular images, respectively, and the two matching scores are fused. Let us consider the image pair (α, β) to be verified. The iris features $v_U^\alpha, \ldots, v_R^\alpha$ and $v_U^\beta, \ldots, v_R^\beta$ are extracted from the single-regions, and the cosine similarity $S_U, \ldots, S_R$ are calculated for each sub-region. The iris similarity S_{iris} obtained by fusing $S_U, \ldots, S_R$ is defined by

$$S_{iris} = \frac{w_U S_U + w_B S_B + w_L S_L + w_R S_R}{w_U + w_B + w_L + w_R}, \tag{4}$$

where $w_U, \ldots, w_R$ indicate the weight according to the mask ratio for each sub-region and are defined by

$$w_X = \min(1 - R_X^\alpha, 1 - R_X^\beta), \tag{5}$$

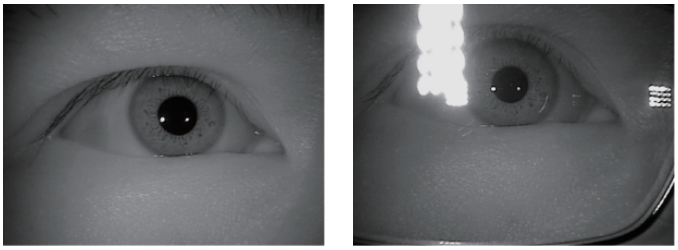
where $X \in \{U, B, L, R\}$, and R_X^α and R_X^β indicate the mask ratio for region X in each image. The iris similarity S_{iris} is a weighted average of the similarity of each subregion based on the mask ratio, resulting in a score that gives more weight to subregions with less occlusion. The periocular features v_{peri}^α and v_{peri}^β are extracted from the periocular images, and the periocular similarity S_{peri} is calculated as the cosine similarity. The matching score S of the proposed method is defined by

$$S = (1 - \lambda) S_{iris} + \lambda S_{peri}, \tag{6}$$

where λ is a parameter within the range of 0 to 1.

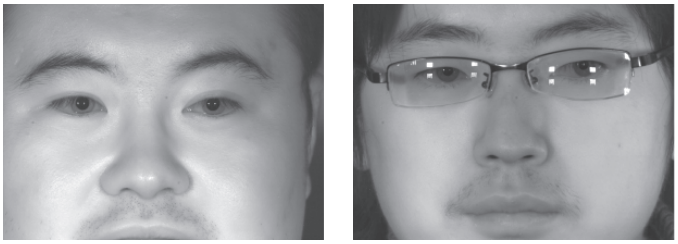
IV. Experiments and Discussion

This section demonstrates the effectiveness of the proposed method through experiments using public datasets of periocular images.



A. Dataset

In this experiment, we use three datasets provided by CASIA[2]: the CASIA-Iris-Thousand database, the CASIA-Iris-Distance database, and the CASIA-Iris-Mobile-V1.0 database. The details of the databases are described below.



1) CASIA-Iris-Thousand (Thousand): Thousand consists of images taken around the eyes of subjects using a near-infrared camera, and contains a total of 20,000 images taking 10 images for each of the left and right eyes of 1,000 subjects. Fig. 3 (a) shows an example of images in Thousand. Most of the images show the iris clearly, although some images show the iris partially occluded or blurred by the reflections of the glasses. According to the evaluation protocol in [9], 13,980 images from subjects S5301 to S5999 were used for training and 6,020 images from subjects S5000 to S5300 were used for evaluation.

2) CASIA-Iris-Distance (Distance): Distance consists of images taken of the upper part of faces of the subjects with a near-infrared camera from a distance of 3m, and contains a total of 2,567 images taking from 142 faces. Fig. 3 (b) shows an example of images in Distance. Most of the images are blurred and do not show the iris clearly, making iris recognition particularly difficult. We detect the eyes using Mediapipe FaceMesh[3] and crop images around the eyes in the

range of 640×480 pixels. According to the evaluation protocol in [13], 2,567 images of the right eye are used for training and 2,567 images of the left eye are used for evaluation.

3) CASIA-Iris-Mobile-V1.0 (M1-S3): The CASIA-Iris-Mobile-V1.0 database consists of three subsets. In this experiment, we use subset M1-S3, which consists of images taken from faces using cell phones with near-infrared cameras. M1-S3 contains a total of 3,600 images of 10 images each of 360 subjects. Fig. 3 (d) shows an example of the images in M1-S3. Some of the images clearly show the iris, while most of them are blurred. Similar to Distance, we detect the eyes using Mediapipe FaceMesh and crop images around the eyes in the range of 640×480 pixels. According to the evaluation protocol in [18], we use 3,600 images from subject M30001 to M30191 for training and 3,600 images from subject M30192 to M30380 for evaluation.

B. Evaluation Metrics

We describe the evaluation metrics used in this experiment. False Rejection Rate (FRR) is calculated from the matching score of genuine pairs and False Acceptance Rate (FAR) is calculated from the matching score of impostor pairs. We use Equal Error Rate (EER), which is equal to FRR and FAR. In practical authentication systems that require high security, such as immigration control systems, it is necessary to operate the system so that the FAR is low. Therefore, we use FRR@FAR0.01%, which is FRR when the threshold is set so that FAR is 0.01%. The smaller the value of EER and FRR@FAR0.01%, the higher the recognition accuracy. Note that the left and right eyes of the same person are considered as others, and the periocular image of one eye is used to determine the identity of the person in the experiments.

C. Training Setting

This section describes the training settings of the network used for iris detection and feature extraction. U-Net for iris detection is trained under the following conditions. The hyperparameters λ_1 and λ_2 of the loss function L are set to 1. The initial value of the learning rate is set to 0.0001, and the learning rate is multiplied by 0.1 if the loss to the validation data does not improve for 5 consecutive epochs. If the loss relative to the validation data does not improve for 30 consecutive epochs, training is terminated and the test data is evaluated using the weights from the epoch with the lowest loss. The batch size is set to 8 and Adam [19] is used as optimizer. Feature extractors for the iris and periocular images are trained under the following conditions. The initial value of the learning rate is set to 0.0001. If EER for the test data does not improve for 10 consecutive epochs, the learning rate is multiplied by 0.1. If EER does not improve for 30 consecutive epochs, training is terminated and evaluation is performed using EER at the minimum. All data augmentation methods are applied with a probability of 50%. The random horizontal shift is a circular shift within a range of 10 pixels on the left and right sides, respectively. Similar to traiing U-Net, the batch size is set to 8, and Adam is used as optimizer.

D. Combination of Periocular and Iris Recognition

We evaluate the effectiveness of the combination of periocular and iris recognition in the proposed method. In the proposed method, the matching scores calculated from iris and periocular are combined and used as the final matching score. We empirically explored the optimal value of λ by a grid search varying λ in Eq.(6) at intervals of 0.1 in the range [0.0, 1.0]. The closer λ is to 0, the stronger the matching score is for iris recognition, and the closer λ is to 1, the stronger the matching score is for periocular recognition. For Thousand, λ set to 0.4 resulted in the highest accuracy. The performance is improved by focusing on iris recognition, since the iris pattern is often clearly visible despite the occlusion caused by glasses and others. For Distance, λ set to 0.6 resulted in the highest accuracy. The performance is improved by focusing on periocular recognition since the iris pattern

TABLE I
COMPARISON OF PERIOCULAR RECOGNITION, IRIS RECOGNITION, AND OPTIMAL FUSION OF IRIS AND PERIOCULAR RECOGNITION, WHERE THE UNIT OF EACH VALUE IS %.

Modality	Thousand		Distance	
	EER	FRR @FAR0.01%	EER	FRR @FAR0.01%
Periocular	0.858	10.089	1.586	16.341
Iris	0.879	9.011	6.846	44.484
Periocular & Iris	**0.366**	**2.089**	**1.128**	**11.167**

TABLE II
EXPERIMENTAL RESULTS FOR DISTANCE, WHERE THE UNIT OF EACH VALUE IS %.

Method	Modality	EER	FRR@FAR0.01%
AttNet [12]	Periocular	14.27	38.4
OSIRIS [9]	Iris	17.13	100.0
UniNet [10]	Iris	5.54	24.7
UniNet+AttNet [13]	Periocular & Iris	2.29	13.7
Proposed	Periocular & Iris	**1.13**	**11.2**

is rarely captured clearly due to the distance between the camera and the subjects. Table I shows the comparison of iris recognition, periocular recognition, and optimal fusion of iris and periocular recognition. In both datasets, the combination of iris and periocular recognition significantly improves the accuracy.

E. Comparison with Conventional Methods

We compare the recognition performance of the proposed method with that of conventional methods using Distance and M1-S3. We chose Distance since many conventional methods have been evaluated. In Distance, we used the following conventional methods: AttNet [12] for periocular recognition, OSIRIS [9] for iris recognition, UniNet [10] for iris recognition, and UniNet+AttNet [10] for a combination of periocular and iris recognition. Table II shows the experimental results for Distance. The combination of periocular and iris recognition is more accurate than iris recognition alone. The proposed method has higher recognition accuracy than UniNet+AttNet [13], which combines periocular and iris recognition. In M1-S3, we evaluate the recognition accuracy when using one eye and both eyes. Note that the matching score is calculated by the average of the matching scores of the left and right eyes. Table III shows the experimental result for M1-S3. The proposed method has higher recognition accuracy in all cases than the method using Maxout-based CNN [18]. The proposed method can identify individuals with high accuracy even for low quality images such as those captured by mobile phone cameras.

V. CONCLUSION

We proposed an eye biometrics system that combines reliable iris recognition and convenient periocular recognition. The proposed method extracts iris and periocular features using SE-ResNet-18 and obtains the final matching score by fusing the matching scores calculated from the iris and periocular features. Through experiments using the public periocular image datasets: Thousand, Distance, and M1-S3, we demonstrated the effectiveness of the proposed method compared with conventional methods.

***Abstract*—In recent years, multimodal authentication combining multiple authentication methods such as face recognition, iris recognition, and ear recognition has attracted attention. Ear recognition can achieve nearly 100% recognition accuracy in ideal conditions. However, it suffers from a significant decrease in recognition accuracy in the presence of occlusion, pose variations, and lighting variations. In this study, we focused on the influence of variations in ear poses on recognition accuracy. To address this issue, we employed a method of data augmentation for the training set, incorporating a variety of ear poses using plane approximation techniques. The results confirmed a noticeable improvement in recognition accuracy due to the inclusion of multiple poses.**

I. INTRODUCTION

Biometric authentication is a technology that uses biometric information to identify individuals. Compared to traditional authentication methods such as knowledge or possession-based authentication methods, biometric authentication is a convenient method that eliminates the need for memorization and the risk of loss, as it leverages individual characteristics [1]. In addition, biometric information has unique and immutable characteristics that reduce the risks associated with impersonation and theft.

However, there are challenges to its widespread adoption, such as the need for specialized sensors in certain cases, such as fingerprint recognition, or user resistance due to sensor contact. In light of these factors, facial recognition, a non-contact method that can be performed using simple sensors such as cell phone cameras, is gaining popularity. Facial recognition is primarily designed to recognize frontal faces or a significant portion of the face in input images. However, in real-world scenarios, it is not always guaranteed that a frontal face will be captured. For example, surveillance camera footage used in criminal investigations often captures only profiles, which significantly reduces the authentication accuracy [2]. To address this problem, an authentication method known as ear recognition has been proposed to improve authentication accuracy in such scenarios [3][4][5]. Ear recognition offers advantages over facial recognition because ear features exhibit minimal changes due to age, expression, or health conditions. In addition, ear images are expected to have fewer privacy concerns than facial images.

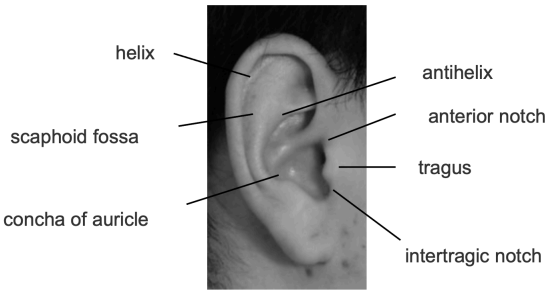

Fig. 1: The different parts of the ear

In this paper, we aim to construct an ear recognition system that achieves high accuracy in a wide range of capturing situations, including criminal investigations, by investigating methods to improve the robustness to capturing angles, which is a major challenge in ear recognition.

As shown in Fig. 1, the shape of the ear can be divided into several regions, including the tragus, concha of auricle, anterior notch, helix, scaphoid fossa, and intertragic notch. These regions exhibit variations in shape, appearance, and relative positions among individuals, leading to strong individuality.

In fact, studies conducted by Abaza et al. [6] and Emeršič et al. [7] have achieved near 100% identification rates in controlled experiments with controlled factors such as pose and lighting in ear recognition. Even in cases where suspects cover their faces with hats, sunglasses, masks, etc., and only the ears are observable, it is possible to identify individuals if the ears are clearly observed [8]. Furthermore, ear recognition can complement other biometric authentication methods, even when the face is visible, and it is being used in multimodal authentication systems [9].

On the other hand, ear recognition faces challenges related to occlusion, pose, lighting, capture devices, and variations in resolution, which can lead to a decrease in authentication accuracy. According to the research by Emeršič et al. [7], the recognition rates for ear images that were not controlled for occlusion, pose, lighting, capture devices, and resolution

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

were significantly lower than ear images captured in controlled environments suitable for existing ear recognition methods.

To address with these variations, there are two approaches: improving feature extraction methods and building robust recognition systems that can handle such variations, and training models with data that includes different variations to deal with them. In particular, in face recognition, an approach that constructs a 3D model of a person using some method and generates training data that includes various pose and lighting variations is used to build robust authentication systems [10]. The situation in ear recognition is considered similar to face recognition, and it is believed that using a 3D model-based approach can be effective in ear recognition as well.

On the other hand, in applications such as criminal investigations, there is a need for non-cooperative environments where it is difficult to perform 3D scanning of the subjects. Therefore, it is necessary to consider the generation of 3D models from captured 2D images. 1) Due to the limited number of registered images, only a few images are available for 3D modeling. 2) Ear images lack significant brightness gradients, and the features required for correspondence point extraction do not work effectively. These conditions make 3D reconstruction difficult in practice. Therefore, in this study, we propose a method based on *planar approximation*, which considers the non-planar ear as an object with additional convexity and concavity, aiming to approximate the ear to a planar object with texture applied to its surface. This method simplifies the process of data augmentation by using planar approximation techniques to manipulate the captured 2D ear images, rather than having to capture additional images or create 3D models. This can improve the effectiveness of ear recognition systems under practical conditions.

In Section II, we discuss related studies focusing on angle variations. Section III, we present our proposed method. Section IV, we describe the detail of evaluation experiments. Section V, we show the evaluation results and discuss their implications. Finally, Section VI, we address future challenges and provide a summary of our findings.

II. RELATEDWORK

In the field of ear recognition, some studies have been conducted using both three-dimensional models and two-dimensional models to address angle variations.

A. 3D model-based methods

One example of a study utilizing a three-dimensional model is the research conducted by Mursalin et al. [11]. They employed a 3D model of the ear to extract shape features such as curves, contours, and concavities. The registered ear model is then compared with the input ear model to evaluate the authentication accuracy. This database consists of images of the ears of selected volunteers taken from a variety of angles, including frontal, lateral, and oblique, under varying distance and lighting conditions. Three-dimensional models of the ears were created using specialized imaging equipment. However, these images were not taken under non-cooperative conditions, a practical scenario often encountered in ear recognition.

B. 2D models-based method

One example of a study utilizing a two-dimensional model is the research conducted by Watabe et al. [12]. They used Gabor filters to extract features from collected ear images in a database that produced angle variations. Their method assuming that the given database had known angle variations and extracting features through the transformation using Gabor filters. However, in practical scenarios, it is anticipated that estimating angles itself could be challenging, especially in non-cooperative environments. Additionally, the HOIP face image database used in this study, which included angle variations of the ear, has been discontinued. Regarding these prior researches, we propose a ear recognition method that takes into account angle variations in ear images captured in non-cooperative environments. Our approach involves approximating the ear to a planar surface to simulate pseudo pose variations. We experimentally show the effectiveness of this method.

III. METHOD

A. Planar approximation

As shown in Fig. 1, the human ear exhibits various concavities and convexities. This characteristic gives rise to regions that are impossible to capture (referred to as self-occlusion). The patterns of self-occlusion are influenced by the depth of concavities and the angle variations during image acquisition, leading to a decrease in authentication accuracy. In this paper, we propose a method for generating pseudo-rotated ear images that take into account various shooting angles and self-occlusion in non-cooperative environments. By utilizing these images for classifier training, we achieve a high-accuracy ear recognition system. We employ a planar approximation technique regarding the ear, which is not strictly flat, as an object with a textured surface, thereby approximating it to a planar object. Here, Fig. 2 illustrates an image of the ear captured from the side view. On the other hand, Fig. 3 depicts the same ear after being pressed against a transparent acrylic plate to eliminate the influence of concavities. It can be observed that the ear shape is maintained with similarity between Fig. 2 and Fig. 3

Indeed, this indicates that the concavities and convexities present on the surface of the ear are relatively small compared to the overall size of the ear. In this case, by using a planar approximation image derived from the three-dimensional shape, it becomes feasible to create pseudo-rotated ear images that account for the rotation of the ear.

B. Pseudo-rotation image generation method

The overview of the method for generating pseudo-rotated ear images is depicted in Fig. 4. In this approach, initially, an ear image captured from the lateral perspective is projected onto a virtual planar. Subsequently, the planar is rotated in a three-dimensional space to produce an image resembling

Fig. 2: A normal ear

Fig. 3: A ear pressed into a transparent acrylic plate

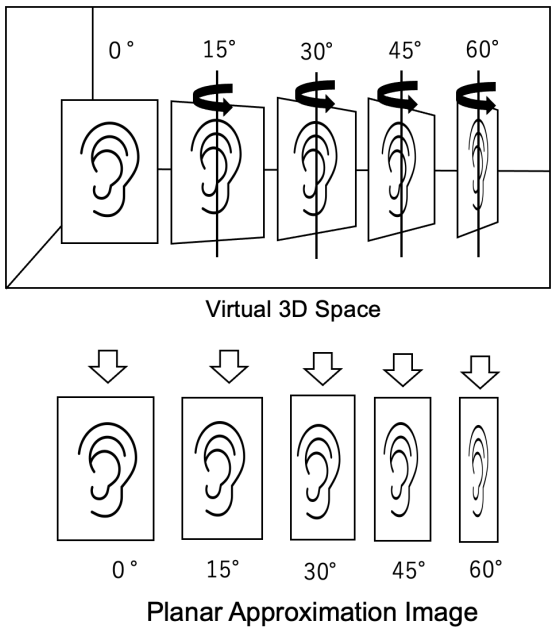

Fig. 4: Generation of Psudo spin ear image

the frontal view. This process enables the creation of pseudo-rotated ear images within the applicable range of the planar approximation.

In the proposed method, we assume a model that rotates an ear image on the face of a cylinder with radius r, using an axis that passes vertically through the cylinder. Here, the distance r between the rotation axis and the face determines the image generated after the rotation. In this method, we set r as zero.

IV. Experiment

We experimentally investigated the effectiveness of the proposed method. In the following sections, we will describe the database used, the detailed settings of the ear recognition system, and the procedure for generating pseudo-rotated images.

A. Environment

We have conducted the following experiment on a system running Windows 10, with an Intel(R) Core(TM) i5-8350U CPU @ 1.70GHz 1.90 GHz processor and 8.00 GB of installed RAM.

B. Database

Based on the best of our knowledge, there is no explicitly controlled database specifically for ear rotation. The AWE database (Annotated web ear database extended) is available and includes ear images with uncontrolled rotations. Emersic et al. constructed this unconstrained ear image database from images of celebrities available online[7]. The AWE database comprises 1,000 images, with 10 samples per individual for 100 individuals, simulating realistic scenarios with various disturbances that could occur in ear recognition systems. However, the database contains a mix of diverse disturbances, making it difficult to determine the specific disturbances that negatively affect the authentication accuracy. Nevertheless, the images in this database include intra-image rotation, yaw rotation, and pitch rotation of the ears. If the proposed data augmentation method demonstrates an improvement in authentication accuracy, it would serve as evidence of the effectiveness of the proposed approach.

C. Ear recognition system

The ear recognition system consists of preprocessing, shape descriptor, and classifier components.

1) Preprocessing: In this study, the objective is to investigate the impact of angle variations. Therefore, the normalization process, which corrects for angle variations, was not performed during the preprocessing stage. Instead, the image sizes varied during the database creation and were standardized to 128 $\times$ 128px.

2) Shape descriptor: Histogram of Oriented Gradients (HOG) was used, which is a well-known and effective shape descriptor for ear recognition[13].

3) Classifier: As for the classifier, we employed a 1-Nearest Neighbor (1-NN) classifier based on Euclidean distance. The 1-NN classifier is advantageous in that it can operate effectively even with a small number of training samples and allows for easy reproducing.

D. Protocol

1) Training: For the training phase, 9 samples per person were randomly selected from the AWE database, resulting in a training dataset of 100 individuals with 9 samples each. To introduce angle variations, the proposed method described in Section III was used for data augmentation. This method generated pseudo-rotated images at 0 degrees, 15 degrees, 30 degrees, 45 degrees, and 60 degrees from the frontal view for each sample. Consequently, the training dataset consisted of 4,500 images (100 individuals $\times$ 9 samples $\times$ 5 angles).

TABLE I: Rank-1 recognition rate: Compare the probability of the label determined to be the closest in the 1-NN classifier being the true label between the proposed method and the baseline.

	Proposed	Baseline
Rank-1 recognition rate	40.1%	35.5%

2) Testing: For the testing phase, the remaining data from the AWE database ware used. One sample per person, without pseudo-rotation, was selected, resulting in an evaluation dataset of 100 images(100 individuals $times$ 1 samples $times$ 1 angles). To demonstrate the effectiveness of the proposed method, the performance was compared to a baseline approach, which used a 1-NN classifier without the inclusion of pseudo-rotated images in the training data. The recognition rates of the proposed method and the baseline approach were compared. To ensure the generalization of the authentication results, 10-fold cross-validation was performed.

E. Metric

The evaluation metric used was the Rank-1 recognition rate, which represents the probability that the label output by the 1-NN classifier matches the true label.

V. Results and discussions

A. Qualitative evaluation with actual captured ear

Fig.5 shows (a) images of the human ear captured at various rotation angles, and (b) images generated by planar approximation based on a 0-degree actual image. Each column represents images rotated by 0 degrees, 15 degrees, 30 degrees, 45 degrees, and 60 degrees, respectively. Fig.5 shows differences due to the shadowing of the helix and tragus. However, the shape changes are not significant and the influence of self-occlusion appears to be small. Therefore, particularly in the case of actual ear image datasets with little rotation variation, it is expected that the use of plane approximation image data as training data will contribute to improved accuracy.

B. Rank-1 recognition rate

Table I shows the Rank-1 recognition rates described in IV-E. According to these results, the baseline method achieved a 1st rank authentication accuracy of 72.7%, while the proposed method achieved an accuracy of 75.2%. This demonstrates the effectiveness of the proposed approach.

In the following discussion, we will examine to what extent the improvement in accuracy is due to the planar approximation.

C. Limitations

1) Other rotation angles: In this study, we applied a planar approximation focusing solely on lateral rotation. This consideration is based on the premise that surveillance camera footage commonly used in criminal investigations is likely to capture a significant number of ear images that include lateral rotation. On the other hand, the AWE database used in this study includes not only lateral rotation but also rotations in the Roll and Pitch directions. Furthermore, actual ear images taken in practical situations are expected to contain even more diverse rotations in the yaw, roll and pitch directions than those in the AWE database used in this study.

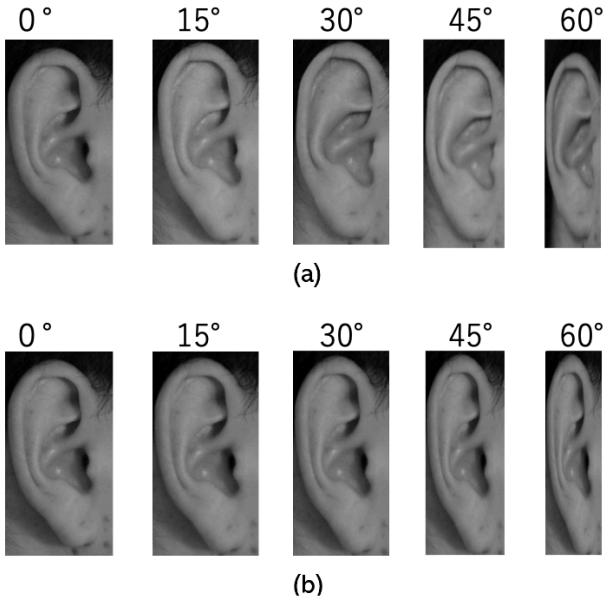

Fig. 5: Comparison with actual ear

(a) represents actual images of a person's ear captured by physically rotating it. (b) shows images of the person's ear captured at 0 degrees and then simulating angle variations using a planar approximation. Each column, from left to right, represents images rotated at angles of 0 degrees, 15 degrees, 30 degrees, 45 degrees, and 60 degrees, respectively.

In our experiment, as shown in I, we were able to achieve a 4.6% of improvement in accuracy by increasing the variations in the yaw direction, demonstrating the effectiveness of data augmentation using the proposed method. However, considering the roll and pitch directions in the plane approximation method may lead to further improvements in accuracy. These are issues that need to be addressed in future research.

2) Occurrence of self-occlusion: The proposed method assumes that the influence of the depth of the ear's concavity on the images, as shown in Fig. 2 and Fig. 3, is below a certain threshold, making self-occlusion less likely to occur and enabling the application of planar approximation. Therefore, it is expected that subjects with extremely large concavities in their ears or difficulties in accommodating certain levels of angle variations may pose challenges for the method. However, the optimal determination method for handling such cases has not been discussed in this paper, and further investigations are left as future work.

3) Other factors affecting accuracy: In addition to the angle variations addressed in this study, there are various factors in real-world environments that can reduce the accuracy of ear recognition, including occlusion, lighting conditions,

acquisition devices, and variations in resolution. To address these elements, it is necessary to develop more robust feature extraction systems and train them on data that encompasses various variations. By addressing these challenges, it is believed that the development of more practical ear recognition technology can be achieved.

VI. Conclusion and Future Work

In this paper, we proposed a novel data augmentation method for ear recognition using planar approximation and conducted authentication experiments based on the generation of rotated ear images. The results demonstrated the effectiveness of the proposed method. In future work, we plan to evaluate other types of rotations such as roll rotation, pitch rotation, in addition to the yaw rotation. We also aim to create an ear image database with controlled pose variations and further experimentally verify the effectiveness of the proposed method. Furthermore, we would like to explore the application of planar approximation to address lighting variations. Overall, the findings will open up new areas of research for developing more robust and accurate ear recognition systems.

Abstract — **There are two main types of domain name-generating algorithms (DGAs) – random-looking and word-looking. While existing methods can effectively distinguish between the two types of DGAs with high accuracy, classifying different types of word-looking DGAs has proven to be challenging, as they are often mistaken for legitimate domains. To address this issue, previous methods used character encoding with long short-term memory networks (LSTM) or convolutional neural networks (CNN) to model the character distribution of different word-looking DGAs. Since most word-looking DGAs are constructed using various dictionaries, we propose using word encoding instead of character encoding. Word encoding can provide a better characterization as it is based on the usage of different words in the dictionaries and their associations. Experimental results show that the classification accuracy for word-based DGAs increases by more than 7% (from 87% to 94%) using word encoding as compared to character encoding.**

I. INTRODUCTION

Domain name generation algorithms (DGAs) are techniques to generate a large number of domain names to facilitate the establishment of covert communication between bots and the command and control (C&C) server. By constantly changing domain names in communication, it makes the tracking and identification of malicious network traffic difficult. In this way, DGAs help to prevent the takedown of the C&C servers [1].

There are two main types of DGA: random-looking and word-looking [2-3]. Random-looking DGAs are produced by concatenating random strings of characters. In contrast, the word-looking DGAs are generated from concatenating words taken from a dictionary. Various methods have been proposed for detecting and classifying DGAs. Detection means to determine if the domain names are legitimate or generated by the DGA-based botnets, while classification identifies which method has been used to generate the DGA. Hence detection is a binary problem while classification is a multi-class problem. As reported in [4], the accuracy of the binary detection and multi-class classifications are over 90% and around 70% respectively using machine learning-based (ML) algorithms. Thus, it is much more difficult to classify the DGAs than to detect these domains from legitimate domains [5-7].

Various methods, including ML and deep learning-based (DL) approaches, have been proposed for detecting and classifying these domain names. In ML approaches, features about character distributions in the domain names have been used. Examples include vowels and consonant ratios or the numerals and English characters ratios [8]. Most of the extracted features were primarily targeted at random-looking domains and are effective in characterizing the randomness in the domain names. It, however, resulted in inferior performance in characterizing word-looking domain names [6]. In contrast, existing DL methods explore character encoding to characterize the character distribution and association within the domain names. Thus, DL methods are more effective in characterizing word-looking domain names than ML methods. Despite that, word-looking DGAs are produced by using different dictionaries. Instead of using character encoding, word-level encoding can better characterize the nature of the words used in the dictionary and their associations. We thus explore the use of word encoding and DL techniques for word-looking DGA classification.

This paper is organized as follows. First, a comparative study of existing methods is given in Section II. Then, our proposed method is described in Section III. Experimental results are given in Section IV. Finally, we conclude our work in Section V.

II. STUDY OF EXISTING METHODS

Domain name generation algorithms (DGAs) detection and classification are important problems in network security, as

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

these algorithms generate a large number of domain names to facilitate covert communication between bots and command and control servers. Table 1 illustrates the differences between the DGA detection and the classification problems. In detection, we only target to distinguish the legitimate and the DGAs. However, in classification, we want to know which algorithm has been used to generate the DGAs too.

A way to detect DGAs is to check if the domain names can be resolved into IP addresses successfully. This is based on the fact that only a small number of the generated domain names are registered. If it cannot be resolved, an error signal called NXDomain response will be received. Thus, one approach to DGA detection is to analyze network traffic characteristics and detect the error signal returned through network communication. However, the network traffic analysis can only detect DGAs, but not classify them. Classifying DGAs requires analyzing the patterns of the algorithmically generated domain names. To address this issue, both ML and DL methods have been used for DGA classification [5-12].

Feature extraction is a crucial step in ML methods. Features representing expert knowledge are extracted from the domain names to characterize the nature of domain names. Common types of features include statistical features, information theory features, and lexicographic features. For example, features like vowel-consonant ratio, TF-IDF features, n-gram distributions, the longest consecutive consonant/number/vowel sequences, pronounceability score, and entropy [9, 13-14] have been used to characterize the nature of the algorithmically generated domain names. While these features are somewhat effective in characterizing random-looking DGAs, accurately classifying word-looking DGAs remains a significant challenge. As reported in [4], the average F1 scores for classifying 11 word-looking DGAs are 0.54, 0.57, and 0.68 for kNN, decision tree, and random forest respectively. This suggests that the extracted features are not sufficient for characterizing different DGA classes. This is consistent with findings from other authors [6]. One main reason for this is that words in word-looking DGAs of different dictionaries are indeed valid English words. Thus, extracted features across different dictionaries would likely be similar.

DL has also been used for DGA classification. Unlike ML approaches, DL does not require feature extraction. Instead, the domain name is treated as a string of characters. With the use of a sufficient number of examples, a learning model is trained to distinguish and characterize the DGAs. As domain names are made up of characters, character encoding is commonly used to convert the domain names to numerical sequences. This process involves breaking down the domain name into individual characters and representing these characters as numerical values.

Convolutional neural networks (CNN) and long short-term memory networks (LSTM) are popular DL models [15-17]. LSTM is often used for acquiring patterns in long sequences [7, 10-11, 18]. CNN, on the other hand, uses a filter kernel with varied sizes to characterize sequential relationships [19-20]. Previous studies have shown that combining CNN and LSTM can improve detection and classification performance [6, 21]. According to a study in [5], the average F1 scores for classifying eleven word-looking DGAs are 0.87 and 0.90 for character-based Bi-LSTM and CNN-Bi-LSTM respectively. Comparing the performance of ML and DL approaches, we can see that the DL approach has shown a significant improvement in accurately classifying word-looking DGAs. It is promising to investigate whether the deep learning techniques can be improved further to classify the word-looking DGAs.

Table 1: DGA detection and classification problems.

III. PROPOSED METHODS

In existing character-based DL models for DGA classification, characteristics among the connecting characters are considered. However, in word-looking DGAs, words from different dictionaries are concatenated. Table 2 shows details regarding the dictionary used in constructing word-looking DGAs. As all dictionaries contain valid English words, character-based encoding may not be effective in distinguishing the English words in different dictionaries.

To better capture the linguistic and semantic structure [22, 23] of the word-looking DGAs, a word-based encoding method can be used. In this section, we discuss a DL method for characterizing the word relationships in word-looking DGAs. In particular, we consider both CNN and LSTM models. These models can learn to identify patterns and relationships among words in a way that is not possible with character-based encoding. In this way, the word-looking DGA classification can be done more accurately.

To extract the relevant parts of domain names from URLs, we followed the procedures outlined in [20]. If the URL contains a second-level domain name, we extract the second-level part. If the URL contains a third-level domain name, we check if the second-level domain name is from a popular dynamic domain name service such as "no-ip.com" or "ddns.net". If it is, we extract the third-level domain part. If the second-level domain name is not from a popular dynamic domain name service, we extract the longer string consisting of the second-level and the third-level domain names. This procedure helps extract the most relevant parts of the domain name while avoiding any unnecessary information.

DGAs	Dictionaries
gozi	gpl: 4379 words, luther: 1537 words nasa: 558 words, rfc: 2460 words
matsnu	Use two dictionaries: verb dictionary (878 words) and noun dictionary (1008 words)
nymaim	Use two dictionaries: the first has 2450 words and the second has 4387 words
pizd	The dictionary contains 384 words
rovnix	Uses the US Declaration of Independence as the dictionary
suppobox	The dictionary in all versions contains 384 words

Table 2: Dictionaries used in different DGAs

The next step in processing the domain names is to decompose them into words, which can help capture the semantic meaning of the domains. For example, the domains "preparetwenty" and "coveredpublicandfrom" can be decomposed into {"prepare", "twenty"} and {"covered", "public", "and", "from"} respectively. These words are valid English words that carry meaning and can provide important information for DGA classification. The subsequent DL model will be trained to characterize the association among the connecting words. Both CNN and Bi-LSTM will be used for DGA classifications. CNNs are effective at learning local features and patterns in the data [15-17], while Bi-LSTM can capture sequence dependencies and relationships among the words [22-23].

The proposed CNN and Bi-LSTM structure for DGA classification consists of an embedding layer with an M number of units, which maps each word to a vector representation. For CNN, the convolutional layer has 128 filters and a kernel size of 2, which applies the filter to the word embeddings to extract local features. The Bi-LSTM layer consists of 200 units to capture long-term dependencies and relationships among the words in the domain names. The output of the convolutional layer or the Bi-LSTM layer is then passed through three fully connected layers with 256, 128, and 128 units respectively, before being fed into the output layer with L units, corresponding to the L number of classes in the DGA classification.

IV. Experimental results

UMUDGA is a public dataset designed for detecting and profiling algorithmically generated domain names in DGA-based botnet detection [4]. It contains over 30 million domain names from 50 DGA classes. In addition to the domain names, UMUDGA contains also basic statistical features, n-gram features, and NLP (natural language processing) features. In our study, we focus on the word-looking DGAs classification. To train and evaluate our proposed models, the dataset contains 10,000 legitimate domain names and 10,000 algorithmically generated domains for each of the word-looking DGA classes. This dataset allows us to test the effectiveness of our models in classifying different types of word-looking DGAs.

To evaluate and compare the performance, the precision, recall, and F1 scores are used. Precision is defined as the ratio between TP and (TP+FP) where TP is the number of samples that are in class A and are identified as A, and FP is the number of samples that are not in class A but are identified as A. Recall is the ratio between TP and (TP+FN) where FN is the number of samples that are in class A but is identified as not in A. In a perfect classification, both precision and recall should be equal to 1. In practice, increasing precision may decrease recall. The F1 score is the weighted average of precision and recall.

Table 3 shows the average F1 scores of the proposed CNN and Bi-LSTM models. We can see that both models achieved an average F1 score of 0.94 for DGA classifications. We compared our proposed models with both ML models and other character-based DL models. For DL models such as CNN (character), LSTM.MI [24], and Bi-LSTM [5], their average F1 scores are smaller than 0.88. Hence, our proposed models can achieve an increase of at least a 7.7% improvement in the F1 score. The improvement was much larger as compared to the ML models such as RF, DT, and kNN. Hence word encoding is beneficial for word-looking DGAs classification.

Table 4 and Table 5 show respectively the percentage improvement in the F1 scores of the proposed CNN and Bi-LSTM models against different ML and DL models for different DGAs. It clearly shows that deep learning models can always outperform machine learning models. Compared to

other character-based DL models, our proposed word encoding CNN and Bi-LSTM improve the F1 scores for all classes.

Besides, F1 scores, precision, and recall are also considered. Fig. 1 and Fig. 2 show respectively the boxplot of the precision and recall achieved by different models. Consistent with the F1 scores results, DL models have better performance than the ML models. In addition, word encoding methods perform better than character encoding methods.

	F1 score

V. CONCLUSIONS

Existing state-of-the-art DGA classifications are ineffective at classifying word-looking DGAs. It is because word-looking DGAs are constructed by concatenating words from dictionaries. Features used in machine learning models are not designed to identify such patterns. The character encoding adopted by existing deep learning models achieves a better performance. To further improve the performance, the word encoding technique is applied to study the association of different words in the domain names. Experimental results show that the proposed word encoding-based CNN and Bi-LSTM models achieve better classification performance than both the machine learning models and character encoding-based deep learning models.

***Abstract*—Deep-fake speech detection aims to develop effective techniques for identifying fake speech generated using advanced deep-learning methods. It can reduce the negative impact of malicious production or dissemination of fake speech in real-life scenarios. Although humans can relatively easy to distinguish between genuine and fake speech due to human auditory mechanisms, it is difficult for machines to distinguish them correctly. One major reason for this challenge is that machines struggle to effectively separate speech content from human vocal system information. Common features used in speech processing face difficulties in handling this issue, hindering the neural network from learning the discriminative differences between genuine and fake speech. To address this issue, we investigated spectro-temporal modulation representations in genuine and fake speech, which simulate the human auditory perception process. Next, the spectro-temporal modulation was fit to a light convolutional neural network bidirectional long short-term memory for classification. We conducted experiments on the benchmark datasets of the Automatic Speaker Verification and Spoofing Countermeasures Challenge 2019 (ASVspoof2019) and the Audio Deep synthesis Detection Challenge 2023 (ADD2023), achieving an equal-error rate of 8.33% and 42.10%, respectively. The results showed that spectro-temporal modulation representations could distinguish the genuine and deep-fake speech and have adequate performance in both datasets.**

I. Introduction

The development of deep learning technology is rapidly advancing. It offers numerous conveniences to our daily lives, such as the production of audiobooks[1], the creation of intelligent speech robots [2], and even aiding those who have lost their voices due to throat disease or other medical conditions. Speech is considered the most essential and natural way for humans to convey both linguistic and non-linguistic information. However, the emergence of malicious fake speech generated by deep learning poses significant threats to societal stability and individual property security. This form of fake speech is commonly known as "deep-fake speech". It deceives both human listeners and automatic speaker verification systems. Furthermore, it carries the risk of spreading false and harmful information, including distorting politicians' statements [3]. Therefore, it is crucial to develop a reliable method for effectively detecting deep-fake speech.

Several challenges have been organized to advance the field of deep-fake speech detection. One of the most renowned global challenges is the automatic speaker verification and spoofing countermeasures challenge (ASVspoof) [4]. Its primary objective is to promote the development of robust countermeasures against such spoofing attempts. Another notable recent challenge is the audio deep synthesis detection (ADD) challenge [5]. It specifically focuses on detecting deep-fake audio in realistic scenarios. This challenge aims to address the unique challenges posed by deep-fake situations encountered in real-life settings.

Although many challenges and methods are proposed in deep-fake speech detection tasks, it is difficult for machines to accurately distinguish them. The main reason for this difficulty lies in the inherent difference between genuine speech and fake speech. Genuine speech not only contains speech information but also reflects human vocal system activity, including characteristics like glottal vibration. On the other hand, fake speech generated by machines lacks these human-like characteristics. This disparity makes it challenging for machines to accurately distinguish between the two types of speech. Common features struggle to effectively capture the unique patterns associated with genuine speech information and human vocal system activity, resulting in insufficient discriminative information for neural network training. Therefore, achieving effective detection of deep-fake speech can be accomplished by successfully separating these components.

To address this issue, we were inspired by the human auditory mechanism. The human auditory cortex possesses dynamic and adaptive properties that enable us to effectively differentiate between speech from humans and machines [6]. Building upon this understanding, a study [7] has revealed that neurons in the auditory cortex can decompose spectrograms into spectro-temporal modulation (STM) content. This finding has led to the development of the STM, which is a multi-scale representation for speech analysis and has been shown to explain various psychoacoustic phenomena [8]. Another study [9] proposed an STM-based method for audio classification inspired by human auditory mechanisms. By utilizing an auditory model to capture relevant features, these methods have demonstrated their effectiveness in classification. Therefore, it is reasonable to consider that STM representation has the potential to discriminate deep-fake speech and enhance detection accuracy.

This paper focuses on exploring the cues and effectiveness of the STM representation which is based on the human auditory mechanisms for detecting deep-fake speech. We conducted an investigation into the role of various feature expressions and

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

implemented STM representations. To enhance the ability of neural networks to capture feature information within STM representations. We combined STM with a light convolutional neural network and bidirectional long short-term memory (LCNN-BiLSTM), which is a model widely used in classification tasks. We performed experiments on two datasets: the Automatic Speaker Verification and Spoofing Countermeasures Challenge 2019 (ASVspoof2019) and the Audio Deep synthesis Detection Challenge 2023 (ADD2023). The results clearly demonstrated that the STM representations were highly effective in distinguishing between genuine and fake speech, achieving adequate performance on both datasets.

II. Related work

A. ASVspoof challenge

To promote research and development in combating voice spoofing attacks, the ASVspoof challenge was first held in 2015 and has since become a significant platform in the field. The competition provides datasets containing various types of voice spoofing attacks, such as speech synthesis, playback, and voice conversion. The objective of the ASVspoof challenge is to evaluate and improve the robustness of ASV systems, enabling them to reliably distinguish between genuine and fake speech. Through the competition, researchers collaborate and propose innovative methods to address the challenges posed by voice spoofing attacks.

B. ADD challenge

However, there has been a recognition that many real-life scenarios have not been adequately covered in ASVspoof challenge. To address this gap, the Audio Deep synthesis Detection challenge (ADD) was motivated. The ADD challenge encompasses three tracks: low-quality fake audio detection, partially fake audio detection, and the fake audio game. These tracks aim to provide a more comprehensive evaluation of ASV systems' ability to detect various types of voice spoofing attacks, including both low-quality and partially manipulated audio samples. The inclusion of these tracks in the ADD challenge aims to advance research in the field and encourage the creation of more robust and efficient solutions to counter voice spoofing attacks.

C. Common methods and limitations

Many common methods have been proposed for detecting deep-fake speech, typically involving front-end feature extraction and back-end classification [10–16]. Baseline models in the two challenges applied linear frequency cepstral coefficients (LFCC) as feature and Gaussian mixture models (GMM) for classification [17]. Meanwhile, many features were explored for deep-fake speech detection, including Mel-frequency cepstral coefficients (MFCC) [18, 19], constant-Q cepstral coefficients (CQCC) [20, 21], Gammatone cepstral coefficients (GTCC) [22], etc. For classification, a variety of models are commonly employed, such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs), etc.

Despite many features are employed in deep-fake speech detection tasks, it is difficult for machines to accurately distinguish them. On the other hand, humans can distinguish genuine and fake speech through our sense of hearing. Taking inspiration from the human auditory mechanism, our approach involves exploring feature representations that not only capture the speech content but also the subtle cues associated with human vocal system activity.

III. Spectro-Temporal modulation representation

A. Definition

Temporal modulation refers to the changes in modulations over time in the spectrogram, while spectral modulation represents variations along the frequency axis. The concept of STM combines both temporal and spectral modulations simultaneously. In the field of auditory psychophysics and neuroscience, the auditory model is divided into two essential stages. One involves transforming the acoustic signal into an internal neural representation called an auditory spectrogram. Another analyzes this spectrogram to estimate the spectral and temporal modulation content using specialized filters that respond to specific modulations[23, 24]. This stage aims to separate different cues and characteristics associated with distinct auditory percepts [25–27]. It can be compared to the adaptive and masking properties of the human auditory system, where important information can still be perceived even in a noisy environment. Therefore, incorporating STM analysis provides a more comprehensive understanding of human perception. By examining STM, we can potentially uncover meaningful characteristics in the speech signal that can aid in the detection of deep-fake speech.

To obtain the STM representation from the original signal, a series of steps is followed. Initially, the input signal undergoes decomposition into frequency components using filterbanks. This process separates the speech signal into different frequency bands. Subsequently, squaring and low-pass filtering are used for computing power envelope from the output of the filterbank. In the final step, a two-dimensional spectro-temporal analysis is conducted on this power envelope to derive the STM spectrogram. The STM spectrogram thus provides a representation of the dynamic variations present in the speech signal across different spectral and temporal scales.

B. Investigation the role of feature expressions

In order to investigate the role of feature expressions, three filterbanks were employed to implement the STM independently. The Mel filterbank (Mel FB) and Gammatone filterbank (ERB FB) are both widely utilized filterbanks in the realm of speech signal processing [28]. Constant bandwidth filterbank (CBW FB) maintains a constant bandwidth across the frequency range.

1) Mel filterbank: The Mel FB is based on the Mel scale, which is derived from psychoacoustic experiments and provides a nonlinear mapping of frequency. Triangular-shaped filters are employed by the Mel FB, with each filter centered at a specific Mel frequency and possessing a bandwidth determined

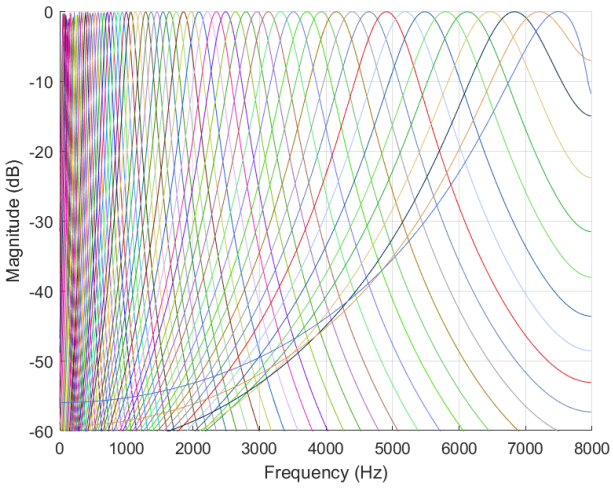

Fig. 1: Frequency response of ERB FB

by the adjacent filters. This triangular shape enables the Mel FB to approximate the perceptual frequency resolution of the human auditory system [29]. The formula to convert a linear frequency (f) to the Mel scale (m) is as follows:

$$m = 2595 \log_{10}\left(1 + \frac{f}{700}\right), \tag{1}$$

2) Gammatone filterbank: The ERB FB is designed to accurately model the response characteristics of the cochlea in the human auditory system [30, 31]. It utilizes filters based on the Gammatone function, derived from a combination of complex exponential functions and low-pass filters. These filters effectively capture the shape of cochlear filters and the frequency selectivity of the auditory system. As a result, the filterbank enhances the representation of low-frequency components with narrow bandwidths and reduces the presence of high-frequency components with wider bandwidths, as shown in Figure 1. The integration of the ERB scale further enhances the accuracy by approximating the frequency resolution of the human auditory system. This integration allows the ERB FB to better capture the spectral characteristics of auditory signals and align with human auditory perception [32].

In the ERB FB, the center frequencies are based on the specified upper and lower frequency limits and the number of channels. These center frequencies are proportional to the corresponding bandwidths of the filters [33]. The output obtained from the ERB FB is as follows:

$$g_k(t) = \mathrm{A}t^{(n-1)} \exp(-2\pi b_f \mathrm{ERB}(f_k)t) \cos(2\pi f_k t), \tag{2}$$

where $At^{(n-1)} \exp(-2\pi b_f \mathrm{ERB}(f_k t))$ is the amplitude term represented by the Gamma distribution, A, n, and b_f are the amplitude, filter order, and bandwidth of the filter respectively. We apply the fourth order Gammatone. The formula to convert a linear frequency (f) to the ERB scale is as follows:

$$\mathrm{ERB} = 24.7(4.37 f_k + 1), \tag{3}$$

where f_k is the k-th center frequency (in kHz) of filterbank.

3) Constant bandwidth filterbank: Unlike Mel FB and ERB FB, which have variable bandwidths. CBW FB has a fixed bandwidth for each filter, regardless of their center frequency. It is constructed by employing a consistent bandwidth parameter, whereby the center frequencies and channel count are computed using the provided lower and upper frequency limits.

To analyze the differences between genuine and fake speech signals as illustrated in spectrograms. Figure 2 provides visualizations of the spectrogram representations.

C. Procedure of STM analysis

In the front-end input, the speech signal $s(t)$ is first filtered by a bank of filters. The output of the k-th channel is given by

$$y_k(t) = g_k(t) * \mathrm{s}(t), \tag{4}$$

where * represents the convolution, $g_k(t)$ is the impulse response of the k-th channel of filterbank. The power envelope is extracted by the Hilbert transform and squared. LPF represents a low-pass filter at cut-off frequency in 64Hz.

$$e_k^2(t) = \mathrm{LPF}\left[|\mathrm{y}_k(t) + j\mathrm{Hilbert}(y_k(t))|^2\right], \tag{5}$$

Finally, STM representation can be obtained by applying a two-dimensional Fourier transform to the squared envelope $e_k^2(t)$, as shown in Eq. (6). It is important to note that the result of the two-dimensional Fourier transform is typically a matrix comprising complex numbers, where each element consists of both real and imaginary parts. To obtain the STM representation utilized in this study, the absolute value of the result is taken. The STM representations of genuine and fake speech signals are shown in Figure 3.

$$\mathrm{STM} = \mathrm{2DFFT}(\log e_k^2(t)). \tag{6}$$

where 2DFFT represents a two-dimensional fast Fourier transform.

IV. Proposed Method

In this section, we present a deep-fake speech detection model that utilizes an LCNN and BiLSTM, as shown in Figure 4. LCNN is a convolutional neural network variant that is purposefully developed to strike a balance between computational complexity and performance. The advantage of LCNN is the implementation of a max feature map activation strategy, which involves using a max-out activation function. This characteristic enables faster training and inference times while minimizing the impact on overall performance. In order to extract useful information from STM, deep learning models such as BiLSTM have been widely used. It can effectively model the temporal dependencies in the STM, which are critical for deep-fake speech detection tasks. Specifically, BiLSTM has a "memory" mechanism that allows it to keep track of past information and use it to inform the current prediction. During the task using BiLSTM, the speech feature sequences are individually fed into the hidden layers of both the forward LSTM (LSTM_F) and the backward LSTM (LSTM_B). This process generates two feature vectors that encapsulate the forward and

TABLE II: statistic for datasets of the ASVspoof2019. (Durations with three values denoted with minimum/average/maximum)

Dataset	Number of utterances			Duration (sec)
	Genuine	Fake	Total	
Training	2,580	24,072	26,625	0.65/3.42/13.19
Development	2,548	22,296	24,844	0.69/3.49/16.51
Evaluation	7,355	63,882	71,237	0.47/3.14/16.55

backward information of the speech. Subsequently, the output vectors from these two layers are combined, forming a merged vector that is passed through two fully connected layers. Finally, the classification is performed by applying a sigmoid activation function to compute the score. This is particularly useful for distinguishing between genuine and fake speech, as speech signals often contain long-term dependencies. The dimensions of the BiLSTM layers are set to match the output dimensions of the LCNN. To optimize the model parameters, a binary cross entropy (BCE) objective function is utilized. The BCE objective function is defined as follows:

$$\text{BCE} = -\frac{1}{N}\sum_{i=1}^{N}[y_i \log(\hat{y}_i) + (1-y_i)\log(1-\hat{y}_i)] \quad (7)$$

where N represents the total number of samples in the dataset, y_i and $\hat{y}_i$ denote the ground truth of the i-th training sample and its corresponding output probability from the model.

V. EXPERIMENT

A. Database and Metrics

In this study, two datasets were employed. The Automatic Speaker Verification Spoofing and Countermeasures Challenge (ASVspoof2019) pioneered the comprehensive treatment of all major attack types, including text-to-speech, voice conversion, and replay spoofing attacks, effectively covering real-world voice spoofing scenarios [34]. Another dataset used is the Audio Deep synthesis Detection challenge (ADD2023) [35].

The ADD2023 dataset (as shown in Table I) consists of Mandarin speeches with neutral emotions. The training and development sets have high signal-to-noise ratios (SNR), while the evaluation set has low SNR with various real-world background noises. The evaluation set lacks publicly accessible labels provided by the organizers, therefore the final scores are required to be submitted to the ADD2023 challenge's website CODALAB for online evaluation.

The ASVspoof2019 dataset is divided into three subsets: the training set, development set, and evaluation set, as presented in Table II.

Notably, the evaluation dataset in ASVspoof2019 includes provided labels, facilitating local evaluation without the need to submit results for external assessment. The performance of the proposed method was evaluated using the equal error rate (EER). By comparing the results obtained from the two datasets, the objective was to prove the generalization ability and reliability of the proposed methods. This was achieved by utilizing a diverse and challenging collection of samples provided by the two datasets.

B. Experiment setup

The Mel FB, CBW FB, and ERB FB were implemented with consistent parameters. The frequency range was set from 50 Hz to 8000 Hz, utilizing 64 channels. This frequency range was chosen due to the typical perception of speech signals by the human auditory system. The lower limit of 50 Hz captures the fundamental frequency component of speech, while the upper limit of 8000 Hz includes high-frequency resonances and harmonics.

Setting the channel number to 64 aims to enhance spectral information and improve sound resolution. With 64 channels, a finer frequency division is achieved, enabling precise capture of speech characteristics across various frequency ranges. The increased channel count provides more frequency detail, leading to a more accurate representation of spectral features and capturing a wider range of speech features. However, it's important to consider the computational and memory costs associated with higher channel numbers, as they can impact real-time performance and computational efficiency. Thus, a careful balance was struck by selecting 64 channels. To accommodate the high-resolution STM representations, the TM domain underwent resampling at a rate of 1000 Hz, resulting in an STM representation size of [64, 1000]. Then the LCNN-BiLSTM model is trained using the labels, the batch size of all data is 64, and the epoch number is 30. An Adam optimizer with a learning rate of 0.0001 was used. Validation was performed using the development dataset, and the model achieving the lowest EER score was considered the best-performing one.

C. Comparison with different classic features

In addition to our proposed method, we conducted a comparative analysis by re-implementing three well-known features: MFCC, LFCC, and GTCC. This allowed us to assess the performance of our approach against these established methods [18–21].

Figure 5 illustrates the calculation diagram for the classic features. In the feature extraction stage, the input signal undergoes initial pre-processing, including windowing with a window length of 25 ms and a step length of 10 ms. The window type used is Hamming. Subsequently, a fast Fourier

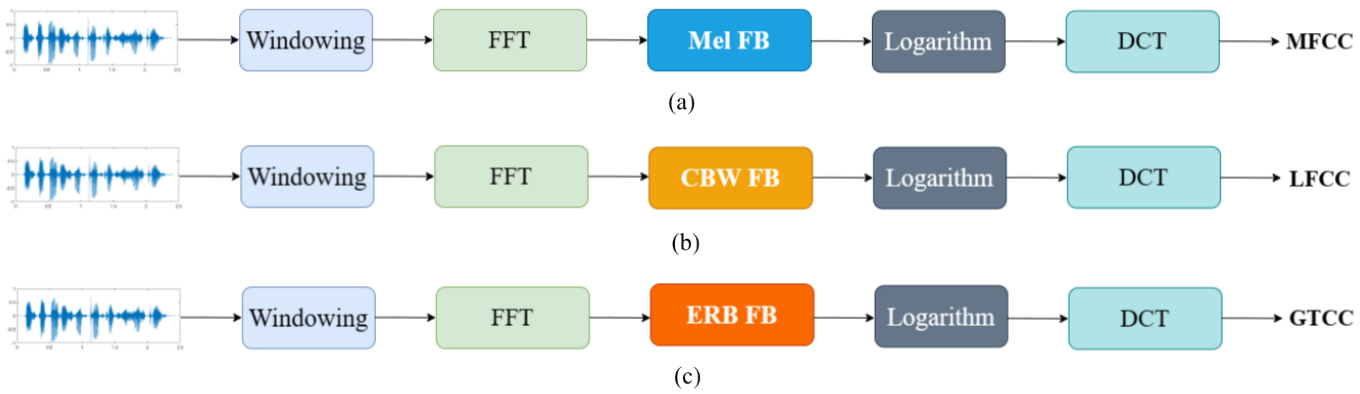

Fig. 5: Flow process diagram of classic features: (a) MFCC, (b) LFCC, and (c) GTCC.

transform (FFT) is applied to the windowed signal with 512 points. This yields the Mel spectrum, Linear spectrum, and Gammatone spectrum after passing through the respective Mel FB, CBW FB, and ERB FB. Finally, the resulting spectrum is subjected to logarithmic transformation and discrete Cosine transform (DCT) to obtain the MFCC, LFCC, and GTCC. The back-end classifier used here is LCNN-BiLSTM, which shares the same architecture as the STM experiment.

VI. Results and Discussion

To identify effective features for deep-fake speech detection, we analyze the STM representation among genuine and fake speech. Subsequently, we applied STM and common features to LCNN-BiLSTM model and performed comparative experiments to evaluate the performance of the proposed method.

We conducted experiments using the ASVspoof2019 dataset (Table III) and the ADD2023 dataset (Table IV). The baseline model in ASVspoof2019 utilized LFCC and GMM, achieving an EER of 18.89%. In comparison, our STM-based approach with the ERB FB achieved an EER of 8.33%, representing a significant improvement of 10.56%. Notably, the STM (ERB FB) outperformed both STM (Mel FB) and STM (CBW FB) in terms of performance. These results emphasize the effectiveness of integrating STM and the advantages of using the ERB FB for deep-fake speech detection. The improved performance can be attributed to the STM's ability to capture fine-grained temporal and spectral details, facilitating more precise discrimination between genuine and fake speech samples.

In the evaluation of the ADD2023 dataset, we compared the performance of our proposed method with the baseline published by the organizer, which utilized LFCC-LCNN and achieved an EER of 70.37%. In our experiments, we first applied Mel FB, CBW FB, and ERB FB as input features to the classifier. The results showed EERs of 77.61%, 83.37%, and 73.34%, respectively. Then we conducted further comparison experiments and found that the classic features outperformed the filterbanks. Meanwhile, the STM representations performed better than the classic features. Specifically, STM based on ERB FB achieved an EER of 42.10%, outperforming not only the baseline but also common features like MFCC (53.36%) and GTCC (63.69%). These results indicate that STMs provide critical information to detect genuine and fake speech.

While our method has demonstrated successful deep-fake speech detection and achieved superior results, it is important to discuss its underlying principles and address the remaining issues. The STM can be considered as a cepstrum, which can capture the subtle cues of human vocal system activity information and speech information in a two-dimensional representation. In the case of genuine speech, the vocal system activity information tends to concentrate near the origin of the STM representation, while the speech information spreads around it. On the other hand, the STM representation of fake speech lacks this characteristic pattern observed in genuine speech. Natural speech produced by humans exhibits a more regular pattern in the STM representation due to the commonalities in the human vocal system. However, machine-generated speech lacks this consistent pattern across individuals, resulting in a less regular waveform in speech signals. Leveraging this feature, we can effectively distinguish between fake and genuine speech.

Therefore, we investigated the role of different feature expressions and implemented STMs. Then combined STM representations with an LCNN-BiLSTM model, and experiments on the datasets of the ASVspoof2019 and the ADD2023. The results showed that STM can effectively distinguish genuine and fake speech with good performance both in two datasets.

VII. Conclusion

This study showed the effectiveness of utilizing STM based on the ERB FB, inspired by the human auditory mechanism for deep-fake speech detection. First, we investigated the role of different feature expressions and implemented STM representations. We then developed a classifier by combining LCNN with BiLSTM and conducted experiments. Additionally, we compared the performance of three classical features with the STM method. The proposed method was evaluated

on the ASVspoof2019 and ADD2023 datasets. Remarkably, our method exhibited significant results for ASVspoof2019 and ADD2023, achieving performance of 8.33% and 42.10% respectively. These results demonstrate the proposed method could effectively detect deep-fake speech. While the focus of this study was on evaluating the performance against baseline models, conducting comparisons with other existing deep-fake speech detection systems could provide a more comprehensive assessment of the proposed method's effectiveness. Future work will involve further investigation of the specific physics-based acoustic features that can be accurately captured and represented by the STM representation. Moreover, it is essential to expand the evaluation to encompass other state-of-the-art methods and to assess the system's performance across a diverse range of datasets.

***Abstract*—Missing-data automatic speech recognition (ASR) can use the uncertainty of speech enhancement (SE) results to improve ASR performance without joint-training. Such uncertainty is represented by a probabilistic evidence model, whose design affects the performance. Previous evidence models have utilized a specific distribution regardless of the ASR model, and do not consider their robustness, i.e., the ability to recognize both clean and noisy speech (robust ASR). The SE uncertainty depends on the degree of speech cleanness, which causes an uncertainty mismatch between SE and a robust ASR model, resulting in recognition failures. We thus propose a flexible evidence model to reduce the mismatch. Our model features several parameters to control its distribution shape and can reweight the SE uncertainty via an encoder-decoder architecture by automatically selecting parameters in accordance with the ASR scores. Experiments showed that the character error rate improved by more than 3 points over the best baseline even with a robust ASR model under a -5-dB SNR condition.**

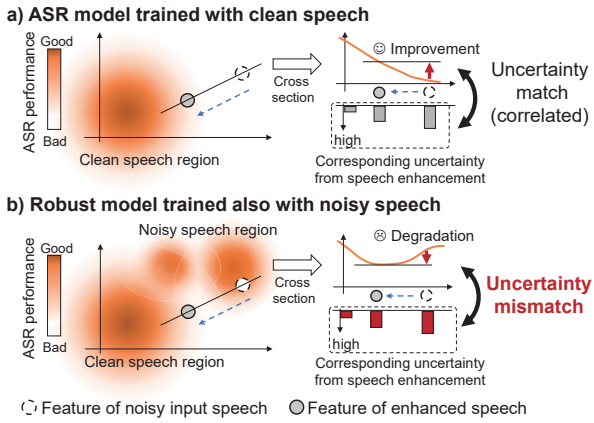

Fig. 1. Problem: uncertainty mismatch due to ASR models. Contour maps of ASR model space show ASR performance vs. feature space.

I. Introduction

Technologies for the integration of automatic speech recognition (ASR) and frontend signal processing (such as speech enhancement (SE)) have attracted more interest as their performance improves. Developers can easily apply state-of-the-art ASR or SE based on deep neural networks (DNNs) with various programming libraries [1], frameworks, and pretrained models [2], [3]. On the other hand, the training cost, including that required for the data-set and computer resources, increases as each DNN model becomes larger. This has made the joint-training or fine-tuning of the models for different applications and acoustic environments increasingly difficult for developers. For example, when we develop a robust ASR under noisy environments (low SNR conditions), ASR and SE are usually combined to reduce the influence of noise signals in advance. However, the training conditions of these two large models are usually different, which forces us to joint-train them in order to improve the performance. We believe that a *joint-training-free* interface between ASR and SE would make each model more flexible and portable for real applications.

Missing-data ASR (MD-ASR) is a promising approach that does not necessarily require *re-training* of models. This approach utilizes the *uncertainty* of speech features in the decoding process [4]–[6], which can propagate statistical information from SE to MD-ASR [7]–[10]. A probabilistic model of such uncertainty is called an *evidence* model [6], [11], [12] and is represented as a probability density function (pdf), which reduces misclassification risks by evaluating the *expectation* of target values such as the classification score or hidden vectors used in ASR. The formulation of the evidence model and MD-ASR usually depends on the base ASR structure, such as a hidden Markov model (HMM) with a Gaussian mixture model (GMM) [6], [11], DNN-HMM [13]–[16], or end-to-end ASR [17] based on encoder-decoder architectures [18]–[21]. Note that recent research [17] has extended the conventional frame-wise evidence models (e.g., [11]) to utterance-wise ones, which enables us to apply missing data techniques to the end-to-end ASR based on encoder-decoder model. The evidence model also utilizes the uncertainty pdf of enhanced speech to reduce the influence of noise or distortions, which also improves the ASR performance. Here, the uncertainty of enhanced speech usually represents how far its characteristics are from those of clean speech.

The problem with previous MD approaches and evidence models is that they ignore the influence of the ASR model, which sometimes causes an uncertainty mismatch between the

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

enhanced speech and the ASR model. Figure 1 illustrates this problem. The uncertainty of enhanced speech by SE is usually lower than that of an observed noisy speech signal because SE tries to recover a clean speech signal. An ASR model trained on clean speech can recognize such enhanced speech accurately because its features are close to those of clean speech, which means that the uncertainties of SE and the ASR model match (Fig. 1 a)). However, such a relationship does not always hold, and the uncertainties of the two speech signals are reversed for robust ASR models (Fig. 1 b)). ASR models trained on clean and noisy speech can often recognize observed noisy speech better than enhanced speech, because speech data enhanced in a method-specific manner are not usually included in the ASR training set. *As the actual behavior of ASR models (e.g., pretrained models) is usually unknown, this mismatch should be solved flexibly in accordance with the given ASR model*.

Hence, we propose a flexible evidence model to reduce the uncertainty mismatch between SE and the ASR model based on encoder-decoder architechture. Our evidence model can control the important region of the ASR model's feature space with several parameters by referring to the features of enhanced speech and noisy speech. Effective parameters for a certain ASR model are selected automatically in accordance with the ASR recognition scores in an *offline* unsupervised manner. A beta distribution is used to represent the evidence model, which is a natural extension of the uniform model proposed in [17]. The posterior pdf from a neural SE based on a variational auto encoder (VAE) is also modified by this evidence model to further improve the ASR performance. Additionally, we eliminate the stochastic sampling procedure of Monte-Carlo implementation by applying the unscented transform and resampling technique used in filtering methods [22], [23]. Experiments were conducted with three types of ASR model trained on (1) clean speech, (2) clean, reverberant speech, and (3) clean, reverberant, noisy speech.

Our key contributions are as follows:

- We propose a flexible evidence model based on beta distribution and unsupervised model selection to reduce the model mismatch between SE and a given end-to-end ASR model, especially under low SNR conditions.
- We propose a Monte Carlo-based integration of SE and ASR featuring on encoder-decoder architecture to draw utterance-wise samples.
- We present a comprehensive investigation of the ASR performance in terms of SNRs, training data for ASR model, evidence models, integration frameworks with SE, and Whisper ASR models without fine-tuning.

II. Preliminary

We first present an overview of the existing end-to-end ASR, missing-data framework and evidence models. Note that conventional missing-data ASRs (e.g., GMM-HMM or DNN-HMM) cannot be applied to recent end-to-end ASRs because the assumption of independence among frames does not match these newer architectures. In this paper, we basically use almost the same notations as those in [11], [17].

A. Encoder-Decoder-Based Neural ASR

End-to-end ASR directly estimates a character sequence $c_{1:L} = [c_1, ..., c_L]$ with length L from a sequence of speech feature vectors $\mathbf{s}_{1:T} = [\mathbf{s}_1, ..., \mathbf{s}_T]$ with length T. The feature vector at frame t, $\mathbf{s}_t \in \mathbb{R}^D$, is a D-dimensional vector. The mapping from $\mathbf{s}_{1:T}$ to $c_{1:L}$, i.e., the posterior probability $p(c_{1:L}|\mathbf{s}_{1:T})$, is modeled by DNNs and obtained by supervised training.

The recent CTC/attention architecture [21] for end-to-end ASR comprises a shared encoder, CTC, and attention decoder networks. The shared encoder network converts the speech features $\mathbf{s}_{1:T}$ into a T'-length sequence of encoded hidden vectors $\mathbf{h}_{1:T'} = [\mathbf{h}_1, ..., \mathbf{h}_{T'}], \mathbf{h}_t \in \mathbb{R}^{D'} (t = 1, .., T')$. The CTC and attention decoder networks represent the posterior probabilities $p_{ctc}(c_{1:L}|\mathbf{h}_{1:T'})$ and $p_{att}(c_{1:L}|\mathbf{h}_{1:T'})$ in different schemes.

The score function J_{asr} in the decoding process is evaluated by a weighted sum with weights $w_i \in [0, 1], (i = 1, 2, 3)$:

$$\mathbf{h}_{1:T'} = \text{Encoder}(\mathbf{s}_{1:T}) := \mathbf{h}_{1:T'}(\mathbf{s}_{1:T}), \tag{1}$$

$$J_{asr}(c_{1:L}|\mathbf{h}_{1:T'}) = w_1 \log p_{ctc}(c_{1:L}|\mathbf{h}_{1:T'}) \tag{2}$$

$$+w_2 \log p_{att}(c_{1:L}|\mathbf{h}_{1:T'}) + w_3 \log p_{lm}(c_{1:L}), \tag{3}$$

where $p_{lm}(c_{1:L})$ denotes a language model. A character sequences that maximize this score function is searched for. Each of the functions ($\mathbf{h}_{1:T'}(\cdot)$, p_{ctc}, p_{att}, and p_{lm}) can be implemented with a recent NN model such as a Transformer.

B. Missing-Data Framework for End-to-End ASR

The *missing data/feature* in ASR means corrupted or distorted speech features caused by noise signals or signal processing methods, such as speech enhancement (SE). Missing-data ASR can recognize such distorted speech features $\hat{\mathbf{s}}_{1:T}$ by utilizing their uncertainty. In our SE scenario, an SE module estimates the original but distorted speech features $\hat{\mathbf{s}}_{1:T}$ from a single-channel, noisy observed spectrum $\mathbf{x}_{1:T} = [\mathbf{x}_1, ..., \mathbf{x}_T], \mathbf{x}_t \in \mathbb{C}^F (t = 1, ..., T)$ in the short-time Fourier transform (STFT) domain. The features extracted from the noisy spectrum $\mathbf{x}_{1:T}$ are represented as $\mathbf{u}_{1:T} = [\mathbf{u}_1, ..., \mathbf{u}_T]$, $\mathbf{u}_t \in \mathbb{R}^D (t = 1, ..., T)$. Hereafter, we assume 1) the same frame index t and length L for sequential variables in both the STFT and feature domains and 2) the mel-filterbank speech features for ASR.

The missing-data approach generally smooths a target function or target variables with an evidence model (pdf) that represents the uncertainty of input features [11]. *Small values of the evidence pdf represent large uncertainty.* The smoothing is implemented by evaluating the expectation of the target function or variables with the evidence pdf ε and a parameter set $\mathbf{\Theta}$. Note that the enhanced features $\hat{\mathbf{s}}_{1:T}$ and observed spectrum $\mathbf{x}_{1:T}$ can be included in $\mathbf{\Theta}$, i.e, $\{\hat{\mathbf{s}}_{1:T}, \mathbf{x}_{1:T}\} \in \mathbf{\Theta}$. For example, if the target function is a likelihood function, e.g., acoustic model $p(\mathbf{s}_{1:T}|c_{1:L})$ of ASR based on probabilistic

generative models, the smoothing is implemented by evaluating the expectation of the function with the evidence pdf ε.

$$\mathbb{E}[p(\mathbf{s}_{1:T}|c_{1:L})] := \int p(\mathbf{s}_{1:T}|c_{1:L})\varepsilon(\mathbf{s}_{1:T};\boldsymbol{\Theta})\mathrm{d}\mathbf{s}_{1:T} \quad (4)$$

The assumption or decomposition of (conditional) independence among frames (e.g., HMM) is usually applied to the likelihood and/or the evidence model to simplify the integral over a high dimensional variable $\mathbf{s}_{1:T}$, i.e., to evaluate each pdf of $\mathbf{s}_t$. Here, non-MD-ASR (i.e., conventional ASR) assumes a Dirac delta function for the evidence model: $\varepsilon(\mathbf{s}_{1:T};\boldsymbol{\Theta}) = \delta(\mathbf{s}_{1:T} - \hat{\mathbf{s}}_{1:T})$.

A missing-data approach for the end-to-end ASR based on an encoder-decoder model was recently proposed in [17], where experiments showed that the encoded vectors $\mathbf{h}_{1:T'}$ were effective as target variables. Frame-independent assumptions cannot be applied to the evaluation of the expectation calculation because end-to-end ASRs usually consider the correlation of features among frames by highly nonlinear networks such as self-attention networks. Therefore, the expectation is directly approximated as follows by a Monte-Carlo method:

$$\mathbb{E}[\mathbf{h}_{1:T'}(\mathbf{s}_{1:T})|\mathbf{x}_{1:T}] := \int \mathbf{h}_{1:T'}(\mathbf{s}_{1:T})\varepsilon(\mathbf{s}_{1:T};\boldsymbol{\Theta})\mathrm{d}\mathbf{s}_{1:T}, \quad (5)$$

$$\approx \frac{1}{N}\sum_{n=1}^{N}\mathbf{h}_{1:T'}(\mathbf{s}_{1:T}^{(n)}),\ \mathbf{s}_{1:T}^{(n)} \sim \varepsilon(\mathbf{s}_{1:T};\boldsymbol{\Theta}), \quad (6)$$

where $\{\mathbf{s}_{1:T}^{(n)}\}_{n=1}^{N}$ are N samples drawn from $\varepsilon(\mathbf{s}_{1:T};\boldsymbol{\Theta})$ and the encoded vectors are then smoothed by the samples.

C. Utterance-wise Uniform Evidence Model

The MD-framework for end-to-end ASRs requires a process of drawing samples from the *utterance-wise* evidence model $\varepsilon(\mathbf{s}_{1:T};\boldsymbol{\Theta})$, of which the dimensions are usually high ($D \times T$ dimensions). Since the sampling from such a large dimensional function is almost impossible, a latent space model is introduced to the utterance-wise evidence to reduce the complexity of the sampling [17]. The utterance-wise evidence model is usually decomposed into the following pdf form to keep the continuity of features among frames ($\boldsymbol{\Theta}$ is omitted here):

$$\varepsilon(\mathbf{s}_{1:T}) = \int p(\mathbf{s}_{1:T}|\eta)p(\eta)\mathrm{d}\eta = \int \Big[\prod_{t,d} p(s_{t,d}|\eta)\Big]p(\eta)\mathrm{d}\eta, \quad (7)$$

where η is a latent variable and the conditional independence among the t and d of $p(\mathbf{s}_{1:T}|\eta)$ is assumed. Note that we cannot adopt the frame-independent model $\varepsilon(\mathbf{s}_{1:T}) = \prod_t p(\mathbf{s}_t)$ for the utterance-wise evidence model, since the samples drawn from this pdf become *noisy features* due to the frame independence and the ASR performance is thus seriously degraded.

The basic evidence model is an utterance-wise uniform pdf [17] extended from the frame-wise uniform pdf [11]. This pdf utilizes only the enhanced features $\hat{\mathbf{s}}_{1:T}$ and the observed features $\mathbf{u}_{1:T}$, and the latent variable η controls the interpolation between $\hat{\mathbf{s}}_{1:T}$ and $\mathbf{u}_{1:T}$:

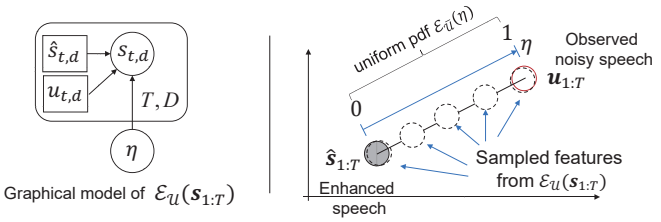

Fig. 2. Graphical model of utterance-wise uniform pdf (left) and samples drawn from it in feature space (right).

$$\varepsilon_{\mathcal{U}}(\mathbf{s}_{1:T};\hat{\mathbf{s}}_{1:T},\mathbf{u}_{1:T}) = \int \Big[\prod_{t,d}\varepsilon_{\bar{\delta}}(s_{t,d};(1-\eta)\hat{s}_{t,d}+\eta u_{t,d})\Big]\varepsilon_{\bar{\mathcal{U}}}(\eta;0,1)\mathrm{d}\eta, \quad (8)$$

$$\varepsilon_{\bar{\delta}}(\eta;\eta_m) = \delta(\eta-\eta_m),\ \varepsilon_{\bar{\mathcal{U}}}(\eta;\eta_l,\eta_u) = \frac{\mathbb{1}(\eta)}{(\eta_u-\eta_l)}, \quad (9)$$

where $s_{t,d}$, $\hat{s}_{t,d}$, and $u_{t,d}$ are the values of the d-th dimensions of $\mathbf{s}_t$, $\hat{\mathbf{s}}_t$, and $\mathbf{u}_t$, respectively. $\varepsilon_{\bar{\delta}}$ and $\varepsilon_{\bar{\mathcal{U}}}$ correspond to a scalar delta pdf and a scalar uniform pdf. η_u, η_l with $\eta_u > \eta_l$ specify the distribution boundaries, and $\mathbb{1}(\eta)$ is an indicator function that is equal to 1 if $\eta \in [\eta_l, \eta_u]$, and 0 otherwise. We can easily draw *frame-continuous* samples from this evidence model by applying ancestral sampling: specifically, we draw η from the uniform distribution and determine $s_{t,d}$ according to the delta function. The samples of η can be deterministically selected at even intervals in $[0, 1]$ with an arbitrary resolution. Figure 2 shows the graphical model of $\varepsilon_{\mathcal{U}}(\mathbf{s}_{1:T})$ and the samples drawn from it.

The posterior probability $p(\mathbf{s}_{1:T}|\mathbf{x}_{1:T})$ for SE can be integrated with the uniform pdf if additional SE statistics are available. The mixture pdf of $\varepsilon_{\mathcal{U}}(\mathbf{s}_{1:T})$ and the posterior is defined with $\boldsymbol{\Theta} = \{\mathbf{x}_{1:T}, \mathbf{u}_{1:T}, \hat{\mathbf{s}}_{1:T}, \pi_1, \pi_2\}$ as follows:

$$\varepsilon_m(\mathbf{s}_{1:T};\boldsymbol{\Theta}) = \pi_1 p(\mathbf{s}_{1:T}|\mathbf{x}_{1:T}) + \pi_2\varepsilon_{\mathcal{U}}(\mathbf{s}_{1:T};\hat{\mathbf{s}}_{1:T},\mathbf{u}_{1:T}), \quad (10)$$

where π_1 and π_2 are mixture weights satisfying $\pi_1 + \pi_2 = 1$. Independence among frames is usually assumed in the posterior of SE, such that $p(\mathbf{s}_{1:T}|\mathbf{x}_{1:T}) = \prod_t p(\mathbf{s}_t|\mathbf{x}_{1:T})$. However, *this assumption causes the generation of discontinuous features among frames when samples are drawn*, which results in performance degradation of ASR [17]. Therefore, such a posterior of SE cannot be used by itself as the evidence pdf, and the uniform evidence model is necessary as a probabilistic floor.

III. Proposed Method

We first explain the concept behind our new evidence model design by considering the relationship among the feature space of ASR and the uncertainty of SE in terms of ASR performance. We then explain our new evidence model and the unsupervised model selection method. Finally, we present the Bayesian integration of SE and MD-ASR based on a latent space model of SE.

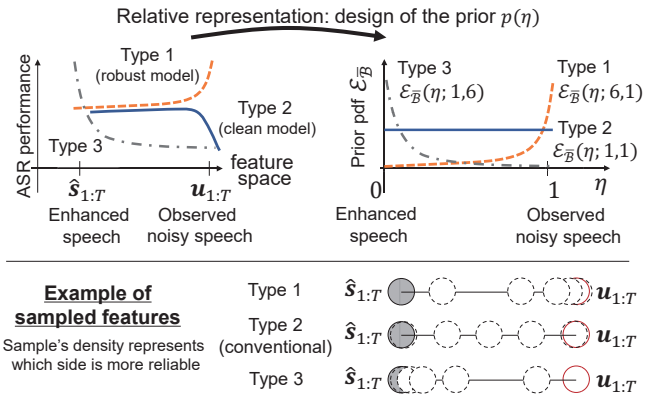

Fig. 3. Performance-feature curve (left) and its projection to our evidence model (right). The difference of drawn samples from each pdf type is also shown in the bottom.

A. Flexible Evidence Model for ASR Models

The structure of the ASR model's feature space is important for designing a new, flexible evidence model. For the ASR performance curve, we focus on a line segment defined by two end points: the enhanced features $\hat{\mathbf{s}}_{1:T}$ and the observed features $\mathbf{u}_{1:T}$, as shown on the upper left in Fig. 3. We assume that the curve can be roughly categorized into three types characterized by a peak around $\mathbf{u}_{1:T}$ (type 1), a dominant "good," flat region (type 2), or a peak around $\hat{\mathbf{s}}_{1:T}$ (type 3). An ASR model trained with clean speech corresponds to type 2, and a robust ASR model corresponds to type 1. The uniform pdf described above can only capture the curve of type 2 and its corresponding uncertainty. The pdf of type 1 is expected to capture the uncertainty-reverse phenomena in the case of robust ASR models.

Hence, we propose a new utterance-wise evidence model based on a beta distribution to represent the performance-feature curve in a relative coordinate space, as shown on the upper right in Fig. 3. This model can represent the previous uniform pdf as a special case. Our evidence model's structure is similar to the utterance-wise uniform pdf given by Eq. (8), but the prior distribution follows a beta distribution as follows:

$$\varepsilon_{\mathcal{B}}(\mathbf{s}_{1:T}; \hat{\mathbf{s}}_{1:T}, \mathbf{u}_{1:T}, \alpha, \beta) = \int \Big[\prod_{t,d} \varepsilon_{\delta}(s_{t,d}; (1-\eta)\hat{s}_{t,d} + \eta u_{t,d})\Big] \varepsilon_{\bar{\mathcal{B}}}(\eta; \alpha, \beta) \mathrm{d}\eta, \quad (11)$$

$$\varepsilon_{\bar{\mathcal{B}}}(\eta; \alpha, \beta) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} \eta^{\alpha-1}(1-\eta)^{\beta-1} \ (\eta \in [0,1]), \quad (12)$$

where α and β are the beta distribution's shape parameters. For example, a curve of type 1 can be obtained by setting $\alpha = 6$ and $\beta = 1$. For $\alpha = \beta = 1$, the distribution is equivalent to the uniform pdf. We can also deterministically select samples of η at even intervals in $[0, 1]$ from the cumulative density function by applying an inverse transform method, since $\varepsilon_{\mathcal{B}}$ is a scalar density function. The example of drawn samples from each parameter setting of the beta distribution is illustrated at the bottom of Fig. 3. The density of samples represents which side, i.e., $\hat{\mathbf{s}}_{1:T}$ or $\mathbf{u}_{1:T}$, is more reliable.

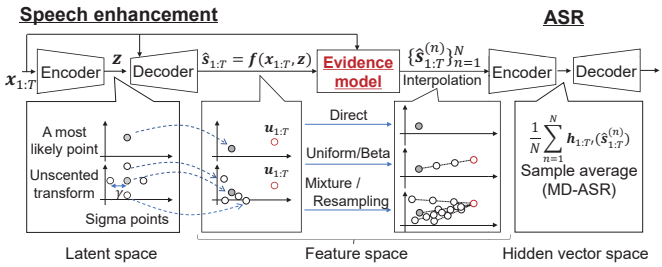

Fig. 4. Overview of deterministic sampling process and MD-ASR.

B. Unsupervised Selection of Appropriate Evidence Model

The flexible model requires us to select proper parameters (e.g., α and β) for the given ASR model and the target speech set $\mathcal{D} = \{\mathbf{x}_{1:T}^{(i)}\}_{i=1}^{N_d}$ (usually a test set). As mentioned above, the patterns of a typical parameter set or evidence model are usually limited; thus, we simply choose the best one from N_m preset models or parameters, $\mathcal{M} = \{\mathcal{M}_j\}_{j=1}^{N_m}$, by maximum likelihood estimation. Therefore, we need no back-propagation process of NNs and no transcriptions of speech data.

The criterion is the following length-normalized ASR score:

$$J(\mathcal{D}|\mathcal{M}_j) = \sum_{i=1}^{N_d} \frac{1}{L_i} \max_{\mathbf{c}_{1:L_i}} J_{asr}(\mathbf{c}_{1:L_i} | \mathbb{E}[\mathbf{h}_{1:T'} | \mathcal{M}_j, \mathbf{x}_{1:T}^{(i)}]). \quad (13)$$

Here, L_i is the length of the i-th recognized characters, and $\mathbb{E}[\mathbf{h}_{1:T'}|\mathcal{M}_j, \mathbf{x}_{1:T}^{(i)}]$ represents the smoothed encoded vector given the j-th parameters/model $\mathcal{M}_j$ and the i-th observed spectrum $\mathbf{x}_{1:T}^{(i)}$.

C. Bayesian Integration with Speech Enhancement

We also propose a Bayesian integration of the evidence model with a new posterior probability modeling of SE, since the posterior is also affected by the given ASR model. This means that mixture integration by Eq. (10) may not perform well for robust ASR models. Because our new posterior model does not assume the frame independence, we can draw samples directly from the pdf of SE without mixture models. Figure 4 presents an overview of the whole model and the sampling process.

An exactly integrated evidence model is derived by treating the enhanced features $\hat{\mathbf{s}}_{1:T}$ as random variables (the parameter set $\boldsymbol{\Theta}$ is omitted here):

$$\varepsilon_f(\mathbf{s}_{1:T}|\mathbf{x}_{1:T}) = \int \varepsilon(\mathbf{s}_{1:T}|\hat{\mathbf{s}}_{1:T}, \mathbf{x}_{1:T}) p(\hat{\mathbf{s}}_{1:T}|\mathbf{x}_{1:T}) \mathrm{d}\hat{\mathbf{s}}_{1:T}, \quad (14)$$

where $p(\hat{\mathbf{s}}_{1:T}|\mathbf{x}_{1:T})$ corresponds to the posterior pdf of SE, and $\varepsilon(\mathbf{s}_{1:T}|\hat{\mathbf{s}}_{1:T}, \mathbf{x}_{1:T})$ corresponds to, for example, $\varepsilon_{\mathcal{U}}$ or $\varepsilon_{\mathcal{B}}$. These two evidence models have $\hat{\mathbf{s}}_{1:T}$ and $\mathbf{u}_{1:T}$ (calculated from $\mathbf{x}_{1:T}$) as parameters. Obviously, the posterior pdf is re-weighted by the primary evidence models. Ancestral sampling method is applied to draw samples from $\varepsilon_f(\mathbf{s}_{1:T}|\mathbf{x}_{1:T})$: we first draw $\hat{\mathbf{s}}_{1:T}^*$ from $p(\hat{\mathbf{s}}_{1:T}|\mathbf{x}_{1:T})$ and then draw $\mathbf{s}_{1:T}^*$ from $\varepsilon(\mathbf{s}_{1:T}|\hat{\mathbf{s}}_{1:T}^*, \mathbf{x}_{1:T})$.

The sampling from the posterior pdf of SE is simplified by assuming the following new latent space model for the SE process:

$$p(\hat{\mathbf{s}}_{1:T}|\mathbf{x}_{1:T}) = \int p(\hat{\mathbf{s}}_{1:T}|\mathbf{x}_{1:T}, \mathbf{z})p(\mathbf{z})\mathrm{d}\mathbf{z}, \quad (15)$$

$$\hat{\mathbf{s}}_{1:T} = \mathbf{f}(\mathbf{x}_{1:T}, \mathbf{z}) + \mathbf{n}, \quad \mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}). \quad (16)$$

Here, $\mathbf{z} \in \mathbb{R}^K$ is a latent vector with dimension K, and $\mathbf{n}$ is a 0-mean noise random variable with *a small variance whose fluctuation is almost negligible*. The function $\mathbf{f}$ represents a deterministic process including SE and feature extraction from $\mathbf{x}_{1:T}$. When the dimension K is small, the sampling of $\mathbf{z}$ is easy because of the Gaussian assumption. The variational posterior pdf $q(\mathbf{z}|\mathbf{x}_{1:T})$ is utilized in the actual sampling phase instead of the prior, as explained in the next section.

We can eliminate the stochastic sampling process by applying the unscented transform (UT) [22] to the latent variable $\mathbf{z}$. The posterior pdf $p(\hat{\mathbf{s}}_{1:T}|\mathbf{x}_{1:T})$ can be approximated efficiently by a limited number of samples given by sigma points $\{\mathbf{z}^{(k)}\}_{k=1}^{2K+1}$ and their weights $\{W^{(k)}\}_{k=1}^{2K+1}$ under the assumption of $\mathbf{n}$:

$$p(\hat{\mathbf{s}}_{1:T}|\mathbf{x}_{1:T}) \approx \sum_{k=1}^{2K+1} \delta(\hat{\mathbf{s}}_{1:T} - \mathbf{f}(\mathbf{x}_{1:T}, \mathbf{z}^{(k)}))W^{(k)}. \quad (17)$$

The weight definition with a parameter κ follows [22], while the next section explains the sigma points. The deterministic sampling from $\varepsilon(\mathbf{s}_{1:T}|\hat{\mathbf{s}}_{1:T}, \mathbf{x}_{1:T})$ given $\{\mathbf{f}(\mathbf{x}_{1:T}, \mathbf{z}^{(k)})\}_{k=1}^{2K+1}$ and $\{W^{(k)}\}_{k=1}^{2K+1}$ is achieved by systematic resampling [24] without initial drawing.

D. Construction of Speech Enhancement Model

A framework similar to a VAE [25] is applied to learn the functions and parameters in Eqs. (15) and (16) from training data. Once a variational posterior probability q and the function $\mathbf{f}$ are specified by DNNs, training can be implemented by maximizing a lower bound of the log-likelihood given the observed noisy spectrum $\mathbf{x}_{1:T}$, the reference spectrum $\mathbf{y}_{1:T}$ and its features $\mathbf{s}_{1:T}$. We only describe key points here because the SE model itself and the improvement of the SE architecture are outside the scope of the present study.

The function $\mathbf{f}$ (called an decoder) comprises a spectrum mask process and feature extraction process $\mathbf{g}$. Mask-based SE estimates the reference spectrum, $\mathbf{y}_t$, by multiplying soft masks by the observed spectrum $\mathbf{x}_t$ [26], i.e., $\mathbf{y}_t \approx \mathbf{M} \circ \mathbf{x}_t$, where $\circ$ represents element-wise multiplication. The soft-mask vector $\mathbf{M}$ is a function of $\mathbf{x}_{1:T}$ or its subset modeled by DNNs, and each element of $\mathbf{M}$ is in $[0, 1]$.

$$\bar{\mathbf{y}}_t = \log(\mathbf{M}(\tilde{\mathbf{x}}_t, \mathbf{z}) \circ |\mathbf{x}_t|) + \mathbf{n}_t^y, \ \mathbf{n}_t^y \sim \mathcal{L}(\mathbf{0}, \epsilon\mathbf{I}), \quad (18)$$

$$\hat{\mathbf{s}}_t = \mathbf{g}(\bar{\mathbf{y}}_t) + \mathbf{n}_t^s, \quad \mathbf{n}_t^s \sim \mathcal{L}(\mathbf{0}, \epsilon\mathbf{I}), \quad (19)$$

where $\log(\cdot)$ and $|\cdot|$ represent element-wise logarithm and absolute functions, and $\mathcal{L}$ represents a 0-mean Laplace distribution. $\tilde{\mathbf{x}}_t$ is a concatenated vector of $\mathbf{x}_t$ from frame $(t-k)$ to $(t+k)$. ϵ represents a small variance for regularization, which means that $\mathbf{n}_t^y$ and $\mathbf{n}_t^s$ are small process noises. These processes are similar to those in [17] except for $\mathbf{z}$.

The variational posterior $q(\mathbf{z}|\mathbf{x}_{1:T}) = \mathcal{N}(\mathbf{m}, \mathbf{\Lambda})$ (called an encoder) is approximated by means of a VAE framework and used for sampling $\mathbf{z}$. The mean vector $\mathbf{m}$ and the diagonal covariance matrix $\mathbf{\Lambda}$ of q are inferred by DNNs from $\mathbf{x}_{1:T}$ similar to those used for the mask function $\mathbf{M}$, with a sliding window processing, networks to estimate the frame-wise mean and variance, and average pooling of the outputs. This inference networks may not be optimal, but it is enough to prove our concept of SE and MD-ASR integration. Specific configurations are described in the experiments.

Sigma points besides a mean are selected by adding a scaling parameter γ to the i-th element of $\mathbf{m}$, i.e., $m_i \pm \gamma$. The variances estimated by the DNN are empirically ignored for sigma points because they often take small values. In other words, the drawn samples become almost the same with the mean vector $\mathbf{m}$, which produces no effect for smoothing in MD-ASR.

IV. Experiment

We prepared several ASR models trained with different training data to evaluate our evidence model and determine *whether our unsupervised model selection can choose the appropriate one for each ASR model*. The detailed results using a robust ASR model are also discussed in the latter part of the results because of their high ASR performances. Note that our experimental conditions for the ASR models are open in terms of speaker, reverberation and noise sources. We also believe the language spoken in the data-set (e.g., English or Japanese) does not seriously affect the noise robustness of ASR and SE.

A. Experimental Setup

1) Data set for ASR and SE: We conducted experiments with speech data from the Corpus of Spontaneous Japanese (CSJ) [27]. The training set contained about 660 hours of speech (full set) for ASR and 190 hours (3–16 sec. of data in the core set) for SE. The official CSJ evaluation sets (eval{1, 2, 3}; 5 hours total) were used as test sets for MD-ASR. Each piece of speech data was segmented into utterances. The sampling rate for all data was set to 16 kHz. The WHAM! corpus [28] was utilized as a general background noise source for ASR training. The ProSoundEffects (PSE) corpus[1] (also used in [29]) was used as an application-specific, non-speech source for both the SE model's training set and the ASR test sets. The PSE corpus includes environmental sounds, animal noises, music signals, and so on. A validation set was also made from other data that were not included in either the training or test sets.

Three kinds of ASR model were trained on clean speech, reverberant speech, and reverberant speech with background noise, thus yielding (a) a clean speech model (clean), (b) a clean, reverberant speech model (clean+rev.), and (c) a clean, reverberant, noisy speech model (clean+rev.+bgn.). The reverberant speech signals were convolved with real impulse responses measured from 576 positions in a room (RT_{20} 640

ms) to simulate a real acoustic environment. The mixture SNRs of the background noise from WHAM! were randomly set to $0, 5, 10, 15, 20$ dB. Note that the speech data used for model (c) comprised $660 \times 3 = 1980$ hours in total.

The training data for the SE model were a mixture of reverberant speech and non-speech signals. Specifically, each speech signal was combined with a non-speech signal selected randomly from the PSE data. The mixture SNRs here were randomly set to $-5, 0, 5, 10, 15$ dB. The reference spectrum was the first arriving frame in the reverberant speech.

The test set data also were a mixture of reverberant speech and raw non-speech signals with different SNRs to investigate the robustness of our MD-ASR. We utilized a different impulse response recorded 1.5 m from a microphone in a different room. The speech source signals were from the CSJ test set, while the non-speech signals were from PSE data that were not used for the SE model's training set. The SNRs were $-5, 0, 5, 10$ dB.

2) DNN and MD-ASR Configurations: The ASR model was ESPnet [2] with a Transformer encoder-decoder acoustic model, which we selected because it performed the best for noisy data compared with a Conformer model [30]. The STFT parameters were a 512-point Hanning window and 128-point shift. An 80-dimensional mel-filterbank was used for the speech features, and global mean-and-variance normalization was applied. Speech-rate perturbation and *SpecAug* techniques were also applied to make the model more robust. See ESPnet's CSJ recipe and configuration files for the details of the networks, RNN language model, and hyper parameters.

The SE model was built from scratch with the PyTorch library and its pre-defined classes [1]. The STFT parameters were the same as those for ESPnet. The feature extraction networks comprised 80-dimensional complex filterbank networks, absolute and power activation functions, concatenation of 32 or 4 frames before and after the center frame, and positional encoding. A 6 and 2-layer transformer-encoder with eight heads and 512 hidden nodes was utilized as the main network to estimate the mask $\mathbf{M}$ and latent variable $\mathbf{z}$, respectively, and they were followed by a fully connected layer. The nonlinear function of the mask's head was a sigmoid function, and that for the frame-wise variance for $\mathbf{z}$ before average pooling was an absolute value function. Gradient clipping [31] and Adam [32] were applied. All parameters were updated for each utterance, i.e., the mini-batch size was 1. The learning rate was 1.0×10^{-4}. The parameter set at 50 epochs was used for the experiments.

TABLE II

CHARACTER ERROR RATE (CER: %) FOR EACH SNR CONDITION WITH ESPNET CONFORMER AND WHISPER MODEL

	Configuration	Test set SNR (dB)				Avg.
		-5	0	5	10	
ESPnet	Conformer (clean)	87.4	80.5	69.7	54.2	72.9
	Conformer (clean + rev.)	73.8	59.2	37.1	18.2	47.1
Whisper	large-v2	71.6	55.3	39.7	33.9	50.1
	large-v2 (text-normalized)	61.1	45.4	33.0	26.4	41.5

The decoding parameters of ASR were almost the same as those of the ESPnet CSJ recipe. The beam size was 20, and the respective weights for the CTC, attention, and language model were 0.5, 0.5, and 0.3. The number of samples N used for the isolated evidence models (e.g., uniform and beta) was 8. The sampling parameters in other cases were $N = 40$, $\pi_1 = 0.125$, and $\kappa = 0.5$. The parameters (α, β) of $\mathcal{E}_{\mathcal{B}}$ and γ were tested on the combinations of $\{(1,1),(2,1),(4,1),(6,1),(8,1)\}$ and $\{4, 8\}$, respectively. Our model selection method automatically chooses the best result from these parameter sets for each eval set and SNR.

B. Results among Different ASR Models for Evaluation of Unsupervised Model Selection

Table I lists the character error rate (CER) for each method with different ASR models and SNR conditions. A smaller CER means a better ASR performance, and the total number of characters over eval{1,2,3} was 115,745. The "Avg." columns indicate the averaged performance over all SNRs with each ASR model, while the "Total" column indicates the averaged performance over all ASR models. "No proc." refers to direct recognition of the noisy speech signal. The baselines were the methods with only SE and SE with the uniform evidence model. "ASR model (c)" is considered as a *robust* ASR model.

We found that SE seriously degraded the performance by 14 points compared to "No proc." in the case of the robust ASR model, which was due to the uncertainty mismatch between SE and ASR. The uniform evidence model improved the CER

TABLE III

but did not outperform "No proc." The same phenomena were found at 5 and 10 dB with the ASR model (clean+rev.). Thus, the simple connection of speech enhancement and ASR does not necessarily impove CERs.

As for isolated evaluation of the *fixed* evidence model, our "Beta" evidence model outperformed "No proc." by 1.3 points in "Avg." with the robust ASR model. Our evidence model design was matched for the robust ASR model. The sampling from speech enhancement (only UT by Eq. (17)) also improved the CER by 4.5 points compared to those of only SE in the "Avg." condition. This result indicated the effectiveness of speech enhancement based on encoder-decoder architechture for drawing utterance-wise samples . The Bayesian integration with SE (UT and beta) improved the CER by about 0.2 points more in the "Avg." condition. However, these settings did not work well with the ASR model trained by clean speech. In that case, the uniform evidence model and integration with SE outperformed the "Only SE" method in any SNRs.

On the other hand, our model selection could choose a better evidence model according to each eval set and SNR condition, and its total CER, 27.7, was the best. This result indicated that the ASR score from DNNs was reliable to some extent for model selection. However, some CERs deteriorated under certain conditions, and a more accurate criterion for model selection is necessary.

The CER (Avg.) of "No proc." for ESPnet Conformer and Whisper [33] are shown in Table II as references. The Conformer models were trained with clean and clean+rev. data sets, and fine-tuning was not applied to the Whisper "large-v2" model. Because the transcription rules used in CSJ and Whisper are different, normalization rules designed by manual (not perfect) were applied to the recognition results from the Whisper model. For example, we removed punctuation, symbols and abnormal recognition results, and we also unified representations of numbers and some orthographic variants. The CERs after the text normalization is represented as "large-v2 (text-normalized)." CERs of the Conformer models were obviously worse than those of Transformer in Table I (by over 9 points), which means the Conformer models are not robust against unknown noise sources that were not included in training data. CERs of Whisper models were also worse than those of Transformer trained with the "clean+rev.+bgn." dataset. This is partly because of a language model mismatch between the raw Whisper model and the CSJ dataset, e.g., orthographic variants and handling of fillers and hesitations.

C. Detailed Results using Robust ASR Model for Evaluation of Proposed Evidence Models

Table III lists the detailed CER for each method with the robust ASR model (clean+reverb.+bgn.) and SNR conditions to clarify the performance among different datasets and the effectiveness of our evidence models. This ASR model corresponds to "ASR model (c)" in Table I. The total number of characters of eval1, eval2, and eval3 was 43,897, 43,623, and 28,225, respectively. The "Avg." columns indicate the averaged performance over all SNRs, while the "Total" column indicates the averaged performance over eval sets. "No proc." refers to direct recognition of the noisy speech signal. The baselines were the methods with only SE and SE with the uniform evidence model. Since the 8.5, 6.8, and 7.3 CERs of "No proc." under the 10-dB condition were close to that of clean speech, the improvement under low SNR conditions is important in this experiment.

The overall tendency in terms of performance among different test sets (eval1, eval2, and eval3) was similar to the results in Table I. As for the isolated evaluation of the evidence model, our "Beta" evidence model outperformed "No proc." by 1.3 points in total and by over 3 points under the -5-dB condition. Since the CERs of only SE were worse than those of "No proc.", *our evidence model can utilize the poor results of SE*. The Bayesian integration with SE (UT and Beta) improved the CER by about 0.2 points more for some test sets. Although the unsupervised model selection also performed well, we can expect the selection accuracy to be improved in the future.

We found that our evidence models based on beta distribution could perform even with the robust ASR model, especially under noisy low SNR conditions. Therefore, the improvement under low SNR conditions (e.g., -10, -5, and 0 dB) will be the focus of future noise-robust ASR and MD-ASR research. The improvement without fine-tuning is challenging, so our findings here provide a useful setting for the era of integration

among huge neural model, such as ASR, SE, language models and dialogue models.

V. Conclusion

In this paper, we proposed a flexible evidence model to reduce the uncertainty mismatch between SE and ASR model. Our evidence model filters out the uncertainty of SE, and effective parameters for the model are selected in accordance with ASR scores in an unsupervised manner. Experiments showed that the CER improved by more than 3 points over the best baseline even with a robust ASR model under a -5-dB SNR condition.

Our future work will focus on evaluations using other pre-trained ASR models, real-time processing and the investigation of precise evidence models. The integration of MD-ASR with microphone array processing is another challenge, which will require a different design for the evidence model because the amount of available information (e.g., the directional patterns of arriving sound signals) increases.

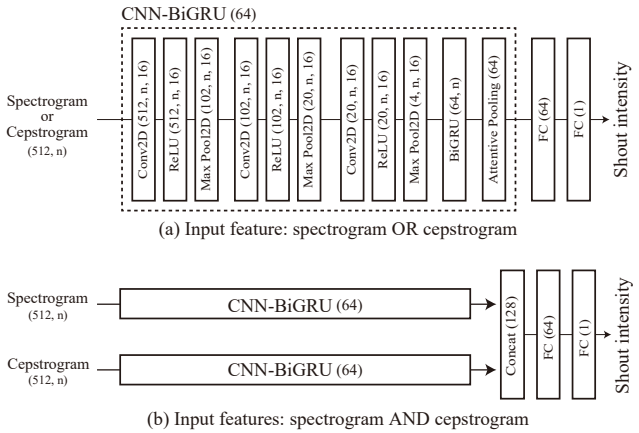
***Abstract*—The automatic detection of shouted speeches has attracted much research attention as a core technology of audio surveillance systems. A common strategy in the past literature has been to train a binary classifier using labels of shouted or normal speeches. Although it is known that the acoustic properties of shouted speech usually differ among speakers, especially male and female groups, the conventional methods did not pay attention to encoding such personal and gender-related style information. There are recent findings that speaker embeddings, which are produced by a model trained for speaker identification, can improve other tasks such as speech emotion classification. Thus, this paper investigates the effectiveness of such speaker embeddings for a shouted speech detection problem. Specifically, we verify whether x-vector embeddings can work as effective auxiliary features for the target problem compared with a simple gender label of an input speech whose ground truth is generally unavailable in real situations. Our experiments on predicting the shout intensity beyond the traditional binary classification demonstrated the x-vector embeddings achieved performance improvement over the single use of speech features.**

I. Introduction

The maintenance of a safe living environment within society has increasingly become a priority, in which the early detection of suspicious or dangerous situations is essential for efficient rescue operations. Shouted speech detection is the fundamental task involved in many audio surveillance systems, and several machine learning approaches have been presented based on labeled datasets [1]–[9]. Most conventional studies treated a shouted speech detection problem as a binary classification of "normal" and "shouted." Pohjalainen et al. [1] and Nandwana et al. [2] used Gaussian mixture models, in which normal and shouted speeches were separately modeled using acoustic features. Similarly, Huang et al. [3] and Sharma et al. [8] employed support vector machines to find a decision boundary of shouted and normal speeches. More recent studies often employ deep learning-based approaches to improve classification performance [4]–[6]. For example, Baghel et al. [6] trained convolutional neural networks (CNNs) to capture local features that were effective for classification. Saeed et al. [4] introduced long short-term memory to a classifier to capture temporal structures. Our previous study [5] presented an architecture combining the CNNs with gated recurrent units (GRUs), showing state-of-the-art classification performance.

Each of the above conventional studies trained a classification model from scratch using a dataset of speech labeled either shouted or normal, without considering speaker attributes. However, conventional studies analyzing the acoustic properties of speech have shown personal variations in shouting [10]. Moreover, it is well known that the fundamental frequency of speech is affected by the speaker's gender [11]. Our recent study also revealed that the average intensity of shouted speeches differed among speakers, especially between male and female groups [12]. Unfortunately, there is currently no method that considers these variations in shouted speech detection.



To extract such personal and gender-related speech features, we propose using an additional training resource from speaker identification research, a crucial technique in speech signal processing. Recent studies have demonstrated the applicability of models that were pre-trained for speaker identification to other related tasks, such as speech emotion classification [13]–[16]. For instance, in [14], a pre-trained speaker identification model converted variable-length speech segments to a fixed-length vector (namely, speaker embeddings), which complemented speech style information that other speech features lacked, enhancing the overall performance of the target speech classification task. Inspired by these pioneering findings, this paper aims to investigate whether the embeddings from the speaker identification model can also improve the performance of shouted speech detection.

Using existing neural architectures for shouted speech detection, this paper compares x-vector embeddings [17], a vector representation produced by a pre-trained speaker identification model, with gender labels. Since the gender label is generally unavailable in real situations, this comparison intends to confirm if x-vector embeddings can encode more effective, speaker-specific information than ground-truth gender labels under the target problem. We conducted experiments to predict shout intensity beyond the traditional binary classification using the dataset of Japanese speakers' speeches [12]. The results showed that the additional use of speaker embeddings effectively improved the prediction performance compared with the single use of speech features.

II. Methodology of shout intensity prediction

This section describes three elements of our shout intensity prediction method: speech features, speaker-specific features, and neural network architectures that use multiple features for prediction.

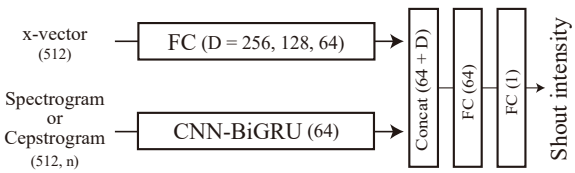
(a) Input feature: spectrogram OR cepstrogram

(b) Input features: spectrogram AND cepstrogram

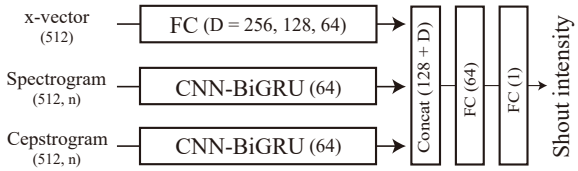
Fig. 1. Conventional network architectures used in our previous work [12]. The size of each layer's output is represented in parentheses. In addition, n indicates the total number of frames.

(a) Input features: gender label + spectrogram OR cepstrogram



(b) Input features: gender label + spectrogram AND cepstrogram

Fig. 2. Network architectures using a gender label as an auxiliary feature. The size of each layer's output is represented in parentheses. Additionally, n indicates the total number of frames.



A. Speech features

For a given audio segment, we first partition it into successive n frames using a Hamming window with a length of 1,024 points (i.e., 64 ms) and a hop length of 512 points (i.e., 32 ms). Then, we obtained two types of speech features, the spectrogram and the cepstrogram, similar to [12]:

- **Spectrogram**: A spectrogram represents the temporal variation of a spectrum. Specifically, by applying the short-term Fourier transform to a speech signal, we obtain a 512-dimensional vector representing the power spectrum for each frame. Concatenating these vectors for n frames results in a spectrogram vector of size $512 \times n$.
- **Cepstrogram**: Applying the inverse discrete Fourier transform to the log power spectrum yields the cepstrum, and concatenating the cepstra of multiple frames yields the cepstrogram. The cepstrogram represents the temporal variation in the vocal tract and vocal cords. We set the dimensionality of each cepstrum to be the same as that of the spectrogram, that is 512. This results in a cepstrogram vector of size $512 \times n$ dimensions.

(a) Input features: x-vector + spectrogram OR cepstrogram

(b) Input features: x-vector + spectrogram AND cepstrogram

Fig. 3. Proposed network architectures using x-vectors as auxiliary features with fully connected layers. The size of each layer's output is represented in parentheses. Moreover, n indicates the total number of frames.

B. Speaker-specific features

In this paper, we compare the following two types of speaker-specific features as auxiliary information for the speech features.

- **Gender label**: We employ a binary labeling scheme to represent a gender, where females are assigned the label "0" and males are assigned the label "1". In real situations, we should automatically predict these labels using a certain classification model for a given speech input. However, our experiments use ground-truth data to examine how gender information can guide shout intensity prediction.
- **X-vector embeddings**: The x-vector is a state-of-the-art speaker identification method based on a time delay neural network trained in a supervised manner. Once the training is completed, it is used for obtaining speaker embeddings from variable-length utterances. Since our shout-intensity-prediction experiments are based on a dataset of Japanese speakers' speeches, the x-vector model should also be constructed using a speaker-identified dataset of Japanese speeches. Thus, we use a Japanese model provided in [18], which was pre-trained using a Japanese corpus, JTubeSpeech [19]. For input speeches, the pre-trained model produces 512-dimensional x-vector embeddings.

Most conventional methods used speech features only, while our study additionaly uses speaker-specific features (either gender label or x-vector embeddings) to predict the shout intensity.

TABLE I
EXPERIMENTAL CONDITIONS.

Shouted speech	2,500 samples - 50 sentences × 50 speakers - Training: 2,000 samples - Testing: 1,000 samples
Sampling frequency	16 kHz
Quantization	16 bit
Number of epochs	100
Batch size	8
Learning rate	0.0001
Optimizer	Adam
Loss function	Root mean squared error (RMSE)

C. Network architecture

As shown in figures 1 to 3, we prepare different neural network architectures for each combination use of the features. Figure 1 depicts base architectures presented by our recent work [12], which uses only speech features (i.e., the spectrogram and the cepstrogram). Figure 1(a) corresponds to a model that uses only a single feature. Specifically, the speech features were fed into the convolutional neural network and bidirectional gated recurrent unit (CNN-BiGRU) block. The CNN-BiGRU block consists of three convolutional layers, two max pooling layers, one BiGRU layer, and one attentive pooling layer. When using both a spectrogram and a cepstrogram, they are fed into separate CNN-BiGRU blocks, as in Figure 1(b).

Figure 2 shows the architectures when using not only speech features but also a gender label, which has two cases depending on the number of speech features used. Since the gender label is one-dimensional, the feature is directly concatenated to the outputs of CNN-BiGRU blocks.

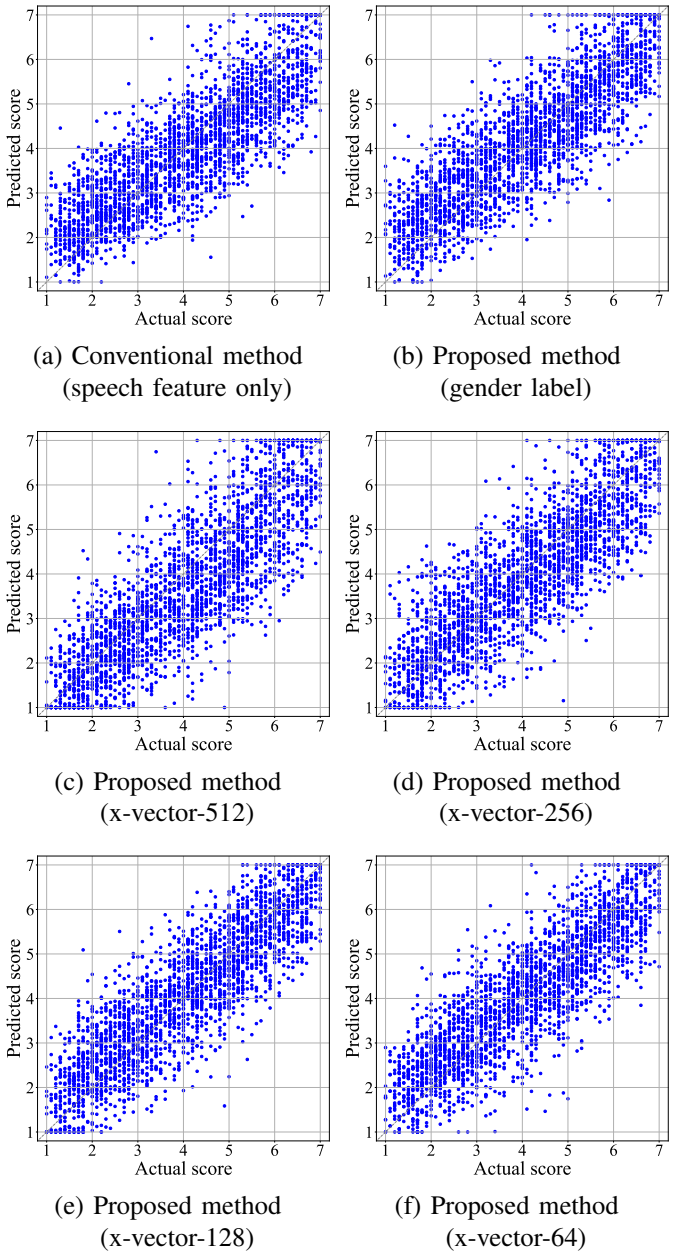


Figure 3 shows the architectures when using x-vector embeddings as auxiliary features. There are also two cases depending on the number of speech features used. The embeddings originally have 512 dimensions, and the dimension reduction can be achieved with a fully connected (FC) layer. The choices used in this paper are 256, 128, or 64 dimensions, in addition to 512 dimensions (i.e., no dimension reduction).

In all networks, two FC layers are placed at the end. When multiple speech features are used as shown in figures 1(b), 2(a)(b), and 3(a)(b), the outputs from the CNN-BiGRU and speaker information are concatenated using the concatenation block before being inputted to the FC layers. If only one feature is used, as described in figure 1(a), the output from the CNN-BiGRU block is directly fed into the FC layers.

III. EXPERIMENTS

A. Experimental settings

To investigate the effectiveness of the speaker-specific features described in Section II.B, we conducted an experiment using the Ritsumeikan shout corpus (RISC) [12], comprising Japanese speakers' shouted speeches. Each shouted speech in the RISC is assigned a numerical value corresponding to shout intensity, ranging from one to seven. The speeches having values of one are nearly equal to normal speeches. There are a total of 2,500 utterances (50 speakers × 50 sentences), collected from 50 speakers (21 females and 29 males).

(a) Conventional method (speech feature only)
(b) Proposed method (gender label)
(c) Proposed method (x-vector-512)
(d) Proposed method (x-vector-256)
(e) Proposed method (x-vector-128)
(f) Proposed method (x-vector-64)

Fig. 4. Scatter plot (Speech features: Spectorgram + Cepstrogram).

Table I presents the detailed experimental settings. We first normalized all speech data so that the maximum amplitude was one. The normalized data was then downsampled to a sampling frequency of 16,000 Hz. Subsequently, the 2,500 utterances were divided into 2,000 training utterances and 500 validation/test utterances, followed by a five-fold cross-validation. When extracting the speech features described in Section II.A from all speech samples to match the maximum frame length within each mini-batch, we performed zero-padding for each mini-batch. Regarding the learning conditions

TABLE II
RMSEs BETWEEN ACTUAL AND PREDICTED SCORES. (↓)

Speech features	Speech features only (Conventional)	Augmented with speaker-specific features (Proposed)				
		Gender label	x-vector-512	x-vector-256	x-vector-128	x-vector-64
Spectrogram	1.12	0.99	0.98	0.81	**0.79**	0.81
Cepstrogram	0.85	**0.79**	0.97	0.81	0.82	**0.79**
Spectorgram + Cepstrogram	0.87	0.82	0.92	0.82	**0.79**	0.80

TABLE III
CORRELATION COEFFICIENTS BETWEEN ACTUAL AND PREDICTED SCORES. (↑)

Speech features	Speech features only (Conventional)	Augmented with speaker-specific features (Proposed)				
		Gender label	x-vector-512	x-vector-256	x-vector-128	x-vector-64
Spectrogram	0.67	0.77	0.84	0.85	**0.86**	0.85
Cepstrogram	0.82	0.85	0.83	0.85	0.84	0.85
Spectorgram + Cepstrogram	0.82	0.84	0.84	**0.86**	**0.86**	0.85

of the network, we set the number of epochs to 100, the batch size to 8, and employed Adam [20] as the optimization method with a learning rate of 0.0001.

B. Results

We used the root mean square error (RMSE) and the correlation coefficient between the true and predicted intensity values as evaluation metrics. Tables II and III present the experimental results of intensity prediction for each combined use of features. The numbers following "x-vector-" in the table indicate the dimensionality after FC layer-based dimension reduction. Note that "x-vector-512" refers to the method that directly inputs the extracted x-vectors into the concatenation block without passing through the FC layer. Figure 4 shows scatter plots of the true and predicted intensity scores obtained using the "Spectrogram + Cepstrogram" feature combination, which achieved the higher prediction accuracy among all methods. We can see that the results of x-vector-128 displayed a small variance of the distribution compared with other models.

Comparing the overall conventional and proposed methods, the proposed method, which utilizes speaker information such as a gender label and an x-vector, demonstrated superior performance. The best scores for the RMSE and the correlation coefficient were 0.79 and 0.86, respectively, outperforming the conventional methods. When focusing on methods that utilize x-vectors, it was found that reducing the dimensionality through the FC layer, instead of directly using the 512-dimensional speaker embedding vectors, contributed to performance improvement.

The analysis based on each feature revealed that the use of both a spectrogram and a 128-dimensional x-vector resulted in improvements of 0.33 in RMSE and 0.19 in the correlation coefficient compared to the conventional method that only employed a spectrogram. Similarly, incorporating either a gender label or a 64-dimensional x-vector into a cepstrogram led to an RMSE improvement of 0.06 over the conventional method that exclusively utilized a cepstrogram. Furthermore, the combination of spectrogram, cepstrogram, and a 128-dimensional x-vector yielded improvements of 0.08 in RMSE and 0.04 in the correlation coefficient compared to not using an x-vector. Overall, the method that utilized x-vectors as a representation of the speaker demonstrated superior performance. These findings suggest that the utilization of information-rich x-vectors contributes to enhancing the performance of intensity prediction. Thus, the effectiveness of directly inputting speaker representation information into the prediction model has been confirmed by these results.

IV. CONCLUSION

This paper presented a shout intensity prediction method that augments speech features using x-vector embeddings as speaker-specific features. The results of the experiments demonstrated that incorporating x-vector embeddings or gender labels significantly improved the prediction performance. This indicates the effectiveness of leveraging a pre-trained model from the speaker identification task. In future work, we will conduct more large-scale experiments and further investigate how to characterize speaker styles in shouted speech detection.

Is the Ideal Ratio Mask Really the Best? — Exploring the Best Extraction Performance and Optimal Mask of Mask-based Beamformers

Atsuo Hiroe*, Katsutoshi Itoyama*†, and Kazuhiro Nakadai*
* Department of Systems and Control Engineering, School of Engineering, Tokyo Institute of Technology, Tokyo, Japan
† Honda Research Institute Japan Co., Ltd., Saitama, Japan
E-mail: {hiroe,itoyama,nakadai}@ra.sc.e.titech.ac.jp

***Abstract*—This study investigates mask-based beamformers (BFs), which estimate filters to extract target speech using time-frequency masks. Although several BF methods have been proposed, the following aspects are yet to be comprehensively investigated. 1) Which BF can provide the best extraction performance in terms of the closeness of the BF output to the target speech? 2) Is the optimal mask for the best performance common for all BFs? 3) Is the ideal ratio mask (IRM) identical to the optimal mask? Accordingly, we investigate these issues considering four mask-based BFs: the maximum signal-to-noise ratio BF, two variants of this, and the multichannel Wiener filter (MWF) BF. To obtain the optimal mask corresponding to the peak performance for each BF, we employ an approach that minimizes the mean square error between the BF output and target speech for each utterance. Via the experiments with the CHiME-3 dataset, we verify that the four BFs have the same peak performance as the upper bound provided by the ideal MWF BF, whereas the optimal mask depends on the adopted BF and differs from the IRM. These observations differ from the conventional idea that the optimal mask is common for all BFs and that peak performance differs for each BF. Hence, this study contributes to the design of mask-based BFs.**

I. Introduction

Target speech extraction is effective in improving speech intelligibility in telecommunication systems and the performance of automatic speech recognition systems [1]. Therefore, beamformers (BFs) are utilized to avoid nonlinear distortions such as musical noises and spectral distortions [2], [3]. In the last decade, combined frameworks comprising BFs and deep neural networks (DNNs), referred to as mask-based BFs, have been proposed [4]–[6]. In these frameworks, DNNs generate one or two time-frequency (TF) masks corresponding to the target, interferences, or both to inform the BF of the sound to be enhanced or suppressed. Afterward, the BF estimates a filter for extracting the target using masks. For filter estimation, the following BF methods are adopted: 1) maximum signal-to-noise ratio (max-SNR) or generalized eigenvalue (GEV) BF [4], [5], [7], 2) minimum variance distortionless response (MVDR) BF [5], [6], [8], and 3) multichannel Wiener filter (MWF) BF [9]–[11].

Several mask types have been examined to achieve improved extraction performance. Initially, ideal binary masks (IBMs) were employed to train DNNs for mask generation [4], [5]. Subsequently, ideal ratio masks (IRMs) have been utilized [6], [11], [12].

Overviewing these studies, we concluded that the following aspects are yet to be comprehensively investigated:

1) Which BF can achieve the best performance if an optimal mask is provided for each BF method?
2) Is an optimal mask common for all BF methods?
3) Are conventional ideal masks such as IRMs identical to an optimal mask?

Regarding these aspects, several studies such as [5], [13], and [14] considered that the mask optimal for the single-channel TF masking [12], [15] should commonly be optimal for all BF methods. However, this assumption was not verified in these studies. Moreover, they compared multiple BF methods that employed the same mask in terms of extraction performance. However, these results do not answer the first aspect unless the optimal mask is common.

The remainder of this paper is organized as follows. Sections II and III explain the related work and BF methods presented in this study, respectively. Section IV examines the method for obtaining the optimal mask for each BF method. Section V verifies the aforementioned points experimentally while Section VI discusses the experimental results. Finally, Section VII concludes the study.

II. Related work

First, we overview the history of mask-based BFs. The max-SNR, MVDR, and MWF BFs employ the statistics of the target, interferences, or both. The statistics are called target (or speech) and interference (or noise) covariance matrices. Given that the accuracy of both statistics affects the extraction performance, estimating them accurately is a fundamental issue [16], [17]. In [4], [5], both statistics were computed using two binary masks, each of which represents periods when only the target or interferences are present, and the masks were generated using a properly trained DNN. This idea was first adopted for the max-SNR and MVDR BFs [4]–[6], then applied to the MWF BF [18].

Second, we mention the studies that compare mask-based BFs. At least three methods have been adopted as aforementioned, and several studies have compared two or three of them,

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

as presented in Table I. However, the best-performing method depends on experimental setups. Moreover, it is reported in [18] that the difference between the max-SNR and MWF BFs is marginal and the performance depends on the number of microphones used.

Third, we mention the mask types considered to be optimal for the mask-based BFs. Initially, the IBMs were considered to be optimal [4], [5]; then, the IRMs were considered optimal [6], [12], [20]–[22]. These ideas were based on the findings in the single-channel TF masking [12], [15]. However, these studies did not investigate whether these findings really apply to the mask-based BFs or the optimal mask is common for any BF method.

III. Framework of Mask-Based BFs

In this study, we define the best extraction performance as the BF output closest to the target in the TF domain, considering that a significant goal of BFs is to extract (or estimate) the target. Moreover, similar to conventional TF masks, we have the constraint that mask values are nonnegative and real-valued.

Fig. 1 illustrates our idea. The vertical and horizontal axes indicate the closeness of the BF output to the target and the variation of the mask values, respectively. Although the mask values vary multidimensionally, this figure conceptually represents the variation as a single axis. In the mask-based BFs, the extraction performance should depend on the variation and exhibit the peak on a particular mask. We refer to this mask as the optimal one. Considering that multiple BF methods and mask types are employed, we can rephrase the questions mentioned in Section I as follows:

- **Issue 1:** Which BF method has the highest peak, or are all peaks of the same height?
- **Issue 2:** Is the optimal mask common for all BF methods, or dependent on each one?
- **Issue 3:** Can the mask considered to be ideal achieve peak performance? More particularly, is the IRM optimal?

We assumed that the studies presented in Table I considered these issues as in Fig. 2. This indicates that the mask mentioned in each study is optimal for multiple BF methods such as BFs 1 and 2, whereas each BF method demonstrates a different height of the peak. However, this idea is yet to be verified.

Considering that this study is the first to examine these issues, we focus on the following methods for simplicity:

TABLE I
Studies comparing multiple BF methods. Methods in bold type represent those that performed the best in each study. In [18], the performance depends on the number of microphones. (SNR: Signal-to-noise ratio, PESQ: Perceptual evaluation of speech quality, WER: Word error rate)

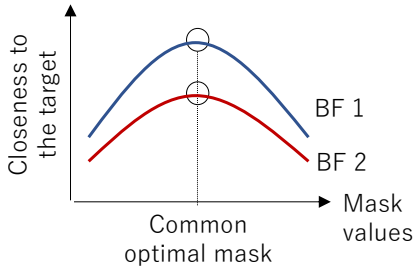

Fig. 2. Conventional ideas on the peak performance and optimal mask for multiple BF methods

- Mask-based MWF BF, which employs a single mask
- Mask-based max-SNR BF, which utilizes two masks, and its variants that employ a single mask

We do not include the MVDR BF in this study, given that the method has another issue regarding the accuracy of the estimation of the steering vector [23].

A. Signal models

In this study, all signals are in the TF domain. For simplicity, the frequency index is omitted, whereas the frame index t is adopted. Let $\boldsymbol{x}(t) = [x_1(t), \ldots, x_N(t)]^{\mathrm{T}}$ be an observation vector obtained with N microphones. The observation $\boldsymbol{x}(t)$ can be expressed as the following summation:

$$\boldsymbol{x}(t) = \boldsymbol{s}(t) + \boldsymbol{n}(t), \tag{1}$$

where $\boldsymbol{s}(t) = [s_1(1), \ldots, s_N(t)]^{\mathrm{T}}$ denotes the components arriving from the target and $\boldsymbol{n}(t) = [n_1(1), \ldots, n_N(t)]^{\mathrm{T}}$ represents the residuals called interferences. Using the observation $\boldsymbol{x}(t)$ and BF filter $\boldsymbol{w}$, the BF output $y(t)$ is expressed as

$$y(t) = \boldsymbol{w}^{\mathrm{H}} \boldsymbol{x}(t). \tag{2}$$

We use the following three covariance matrices:

$$\boldsymbol{\Phi}_x = \left\langle \boldsymbol{x}(t)\boldsymbol{x}(t)^{\mathrm{H}} \right\rangle_t, \tag{3}$$

$$\hat{\boldsymbol{\Phi}}_s = \left\langle m_s(t)\boldsymbol{x}(t)\boldsymbol{x}(t)^{\mathrm{H}} \right\rangle_t, \tag{4}$$

$$\hat{\boldsymbol{\Phi}}_n = \left\langle m_n(t)\boldsymbol{x}(t)\boldsymbol{x}(t)^{\mathrm{H}} \right\rangle_t, \tag{5}$$

where $m_s(t)$ and $m_n(t)$ denote TF masks for the target and interferences, respectively, and $\langle \cdot \rangle_t$ computes the average over t. Each mask comprises nonnegative real values. We

refer to these matrices as observation, target, and interference covariance matrices, respectively. Unlike $\boldsymbol{\Phi}_x$, both $\hat{\boldsymbol{\Phi}}_s$ and $\hat{\boldsymbol{\Phi}}_n$ are estimated matrices computed from the masks and observations without using $\boldsymbol{s}(t)$ and $\boldsymbol{n}(t)$.

Moreover, consider $\mathrm{GEV}_{\max}(\boldsymbol{A}, \boldsymbol{B})$ and $\mathrm{GEV}_{\min}(\boldsymbol{A}, \boldsymbol{B})$ to be the eigenvectors corresponding to the maximum and minimum eigenvalues in the following GEV problem, respectively:

$$\boldsymbol{A}\boldsymbol{w} = \lambda \boldsymbol{B}\boldsymbol{w}. \tag{6}$$

B. Mask-based and ideal MWF BFs

The MWF BF is formulated as a problem of minimizing the mean square error (MSE) between the BF output and the corresponding reference $p(t)$ [14]:

$$\begin{aligned} \boldsymbol{w} &= \arg\min_{\boldsymbol{w}} \left\langle \left| p(t) - \boldsymbol{w}^{\mathrm{H}} \boldsymbol{x}(t) \right|^2 \right\rangle_t & (7) \\ &= \boldsymbol{\Phi}_x^{-1} \left\langle \boldsymbol{x}(t) \overline{p(t)} \right\rangle_t, & (8) \end{aligned}$$

where $\overline{p(t)}$ denotes the conjugate of $p(t)$. The mask-based MWF BF employs the masked observation as the reference, and thus, corresponds to the case $p(t) = m_s(t) x_k(t)$ as

$$\begin{aligned} \boldsymbol{w}_{\mathrm{mwf}} &= \arg\min_{\boldsymbol{w}} \left\langle \left| m_s(t) x_k(t) - \boldsymbol{w}^{\mathrm{H}} \boldsymbol{x}(t) \right|^2 \right\rangle_t & (9) \\ &= \boldsymbol{\Phi}_x^{-1} \left\langle m_s(t) \boldsymbol{x}(t) \overline{x_k(t)} \right\rangle_t, & (10) \end{aligned}$$

where $x_k(t)$ denotes the observation obtained with the kth microphone.

Another significant variant is the ideal MWF BF, which provides the upper-bound extraction performance for all BFs [24]. When $\boldsymbol{s}(t)$ in (1) is known, the upper-bound extraction performance can be achieved using the MWF with $p(t) = \boldsymbol{s}_k(t)$. The corresponding filter is obtained as

$$\begin{aligned} \boldsymbol{w}_{\mathrm{ideal}} &= \arg\min_{\boldsymbol{w}} \left\langle \left| s_k(t) - \boldsymbol{w}^{\mathrm{H}} \boldsymbol{x}(t) \right|^2 \right\rangle_t & (11) \\ &= \boldsymbol{\Phi}_x^{-1} \left\langle \boldsymbol{x}(t) \overline{s_k(t)} \right\rangle_t. & (12) \end{aligned}$$

Note that the ideal MWF BF is not a particular case of the mask-based one. This is because a mask value $m_s(t)$ constrained to be real-valued and nonnegative cannot render (9) equivalent to (11), whereas $m_s(t)$ that can take any complex values can. Therefore, it is not evident whether the mask-based MWF BF can achieve the same extraction performance as the ideal alternative.

C. Max-SNR BF and its variants

The mask-based max-SNR BF is formulated as the following maximization problem [4], [5]:

$$\begin{aligned} \boldsymbol{w}_{\mathrm{snr}} &= \arg\max_{\boldsymbol{w}} \frac{\boldsymbol{w}^{\mathrm{H}} \hat{\boldsymbol{\Phi}}_s \boldsymbol{w}}{\boldsymbol{w}^{\mathrm{H}} \hat{\boldsymbol{\Phi}}_n \boldsymbol{w}} & (13) \\ &= \mathrm{GEV}_{\max}\left(\hat{\boldsymbol{\Phi}}_s, \hat{\boldsymbol{\Phi}}_n \right). & (14) \end{aligned}$$

Although this method originally utilizes two masks, we can derive two different variants that adopt a single mask by assuming the following relationship:

$$\hat{\boldsymbol{\Phi}}_s + \hat{\boldsymbol{\Phi}}_n = \boldsymbol{\Phi}_x. \tag{15}$$

One variant utilizes a mask for the interferences [17], [25]:

$$\begin{aligned} \boldsymbol{w}_{\mathrm{nor}} &= \arg\min_{\boldsymbol{w}} \frac{\boldsymbol{w}^{\mathrm{H}} \hat{\boldsymbol{\Phi}}_n \boldsymbol{w}}{\boldsymbol{w}^{\mathrm{H}} \boldsymbol{\Phi}_x \boldsymbol{w}} & (16) \\ &= \mathrm{GEV}_{\min}\left(\hat{\boldsymbol{\Phi}}_n, \boldsymbol{\Phi}_x \right). & (17) \end{aligned}$$

We refer to this as the minimum noise-to-observation ratio (min-NOR) BF. Similarly, we can derive the other, which employs a mask for the target and is expressed as

$$\begin{aligned} \boldsymbol{w}_{\mathrm{sor}} &= \arg\max_{\boldsymbol{w}} \frac{\boldsymbol{w}^{\mathrm{H}} \hat{\boldsymbol{\Phi}}_s \boldsymbol{w}}{\boldsymbol{w}^{\mathrm{H}} \boldsymbol{\Phi}_x \boldsymbol{w}} & (18) \\ &= \mathrm{GEV}_{\max}\left(\hat{\boldsymbol{\Phi}}_s, \boldsymbol{\Phi}_x \right). & (19) \end{aligned}$$

We refer to this as the maximum signal-to-observation ratio (max-SOR) BF.

Furthermore, even without assuming (15), the min-NOR and max-SOR BFs can be equivalent to each other in terms of the filter estimation if one mask is computed from the other using (20).

$$m_s(t) + m_n(t) = \alpha, \tag{20}$$

where α is a nonnegative value, such that all the mask values are nonnegative. For example, assigninig $m_s(t) = \alpha - m_n(t)$ to (18) and (4) results in the problem represented by (16) if $m_n(t)$ is nonnegative for all t.

For the max-SNR BF and its variants, the scales of the filter and BF outputs are uncertain, unlike the MWF BF. Hence, a post-process for determining the proper scales is required [16], [17]. Considering that the formulation of these BFs differs from that of the MWF BF, it is not evident whether these BFs can achieve the same extraction performance as the ideal MWF BF.

IV. Obtaining the optimal mask

To explore the peak performance for each BF method, this study employs a bottom-up approach that obtains the optimal mask for each mixture of the target and interferences, instead of a priori deciding whether a particular mask type is optimal.

Let $\mathcal{M}$ be a set of mask values adopted in a BF. This set comprises $m_s(t)$, $m_n(t)$, or both for all t, depending on the BF method employed. We can formulate $\mathcal{M}$ as the solution to the problem of minimizing the following MSE:

$$\mathcal{M} = \arg\min_{\mathcal{M}} \left\langle \left| s_k(t) - y(t) \right|^2 \right\rangle_t, \tag{21}$$

where $s_k(t)$ and $y(t)$ denote the target included in the observation of the kth microphone and BF output, respectively. To render the mask values nonnegative and to avoid both diverging the mask values and converging them to zero, we impose the following constraints on (21):

$$\begin{aligned} m(t) &\geq 0 \quad \text{for all } t, & (22) \\ \left\langle m(t)^2 \right\rangle_t &= 1, & (23) \end{aligned}$$

where $m(t)$ denotes $m_s(t)$ or $m_n(t)$. In (21), $y(t)$ is computed as follows. First, the BF filter $\boldsymbol{w}(t)$ is computed depending on the adopted BF method, then the $y(t)$ is computed using (2).

To determine the ideal scale of $y(t)$ independent of the BF method, we apply the following post-filtering process, referred to as the *ideal scaling*:

$$\gamma = \frac{\left\langle s_k(t)\overline{y(t)}\right\rangle_t}{\langle |y(t)|^2\rangle_t}, \tag{24}$$

$$y(t) \leftarrow \gamma y(t). \tag{25}$$

Owing to the ideal scaling, the constraint represented as (23) does not affect the scale of $y(t)$.

Because $\mathcal{M}$, $\boldsymbol{w}(t)$, and $y(t)$ depend on each other, $\mathcal{M}$ cannot be obtained explicitly. In contrast, we employ the iterative algorithm based on gradient descent. Given that the mask estimation process adopts no explicit association between the masks and sources, the obtained masks such as $m_s(t)$ and $m_n(t)$ do not necessarily correspond to the sources such as the target and interferences.

Equations (21), (22), and (23) might seem to solve the same problem as the ideal MWF BF, which is represented as (11), based on the iterative algorithm and consequently achieve the same extraction performance as the ideal MWF BF. However, such a perspective is incorrect, as mentioned in Sections III-B and III-C. Rather, the objective of this study is to examine to what extent the output of the mask-based BF can approach that of the ideal MWF BF if the mask best fits (21).

V. Experiments

To clarify Issues 1–3 mentioned in Section III, we conducted the following experiments:

1) Exploring the peak performance for each BF method
2) Verifying whether the optimal mask is common for all the BF methods
3) Examining whether the IRM can achieve the peak performance

The following subsections first mention the dataset and system for these experiments, and then demonstrate the experimental results in order.

A. Dataset and experimental system

We employed the CHiME-3 simulated test set [26], which comprises both 330 utterances from four speakers and four background (BG) noises. In this dataset, sound data were recorded at 16 kHz with six microphones attached to a tablet device. We generated the TF domain signals using the short-time Fourier transform with window and shift lengths of 1024 and 256, respectively.

Fig. 3 illustrates the experimental system. The modules labeled *Absolute value*, *Normalization*, and *Ideal scaling* correspond to (22), (23), and (25), respectively. The observation data were generated by mixing clean speech and BG noise. To represent multiple scenarios in different SNRs, three multipliers such as 1, 2, and 4 were applied to the BG noise. We refer to these values as *BG multipliers*. The BF output $y(t)$ was generated as explained in Section IV; one or two masks were employed and the BF filter was estimated depending on the BF method, such as (10), (14), (17), and (19). Given that

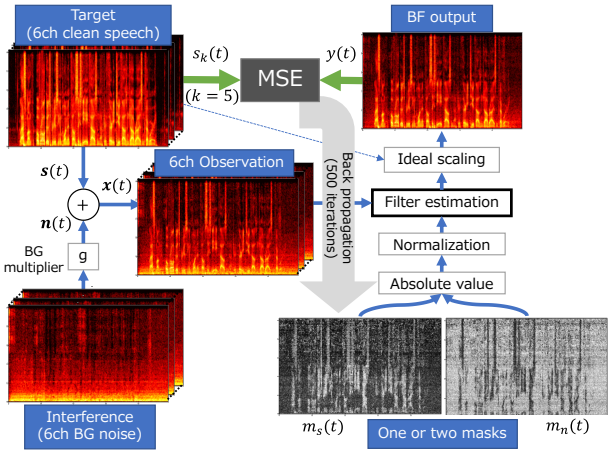

Fig. 3. Configuration of the system obtaining or employing the optimal mask(s) for each utterance

microphone #5 is the closest to the speaker, we set k to 5 in (21) and (24). The backpropagation based on the gradient descent algorithm was utilized only in the first experiment to obtain the optimal mask for each utterance. The estimation of the BF filter and output was implemented in PyTorch [27], which supports the backpropagation of matrix operations in the complex number domain.

Table II presents average SNR scores of the observation of microphone #5 for each BG multiplier.

For the evaluation score, we adopted the source-to-distortion ratio (SDR) [28], which is provided as a performance score in this dataset, considering that this score basically represents the closeness of the BF output to the target.

B. Experiment 1: Exploring the peak performance for each BF method

First, to explore the peak performance of each BF method, we obtained the optimal mask for each utterance, which is the solution to (21) under the constraints represented as (22) and (23), using the backpropagation of 500 iterations. Table III presents SDR scores of the mask-based BFs, including those of the ideal MWF BF using $k = 5$ in (12). All the mask-based BFs practically demonstrated identical scores comparable to the ideal MWF BF. These are remarkable results, given that they were not theoretically evident, as mentioned in Sections III-B and III-C.

C. Experiment 2: Verifying whether the optimal mask is common for all the BF methods

Furthermore, to verify whether the optimal mask is common for all the BF methods, we applied the optimal mask obtained

TABLE II
SNR scores [dB] of the observation of microphone #5

BG multiplier		
×1	×2	×4
7.540	1.536	-4.421

in a BF method to another one. If the same score is achieved after applying the mask, we can claim that the optimal mask is the same between these two BF methods. Although 12 permutations are possible from four methods, we examined six considered to be nontrivial. In the cases that $m_s(t)$ was applied to a BF method using $m_n(t)$, and vice versa, we converted the mask values using the following rules to satisfy (20):

$$m_s(t) = \max_t \{m_n(t)\} - m_n(t), \quad (26)$$

$$m_n(t) = \max_t \{m_s(t)\} - m_s(t), \quad (27)$$

where $\max_t \{\cdot\}$ denotes the maximum value over t.

The obtained results are presented in Table IV. The first and second rows indicate that the optimal masks obtained in the max-SNR BF were applied to the max-SOR and min-NOR BFs, respectively. These two rows present lower scores than Experiment 1. This suggests that the optimal mask obtained in the max-SNR BF is not necessarily optimal for the max-SOR or min-NOR BFs.

The third row indicates that the optimal mask $m_s(t)$ obtained in the max-SOR BF was applied to the min-NOR BF using (27), and the fourth row indicates that the mask $m_n(t)$ obtained in the min-NOR BF was applied to the max-SOR BF using (26). The two rows practically demonstrated the same scores as the max-SOR and min-NOR BFs in Table III. This suggests that the optimal mask can be converted between the max-SOR and min-NOR BFs, despite the fact that the two masks are not the same.

The fifth and sixth rows indicate that the optimal mask $m_s(t)$ obtained in a method was applied to the other for the max-SOR and MWF BFs. These two rows demonstrated considerably lower scores than the results of the max-SOR and MWF BFs in Table III. These results suggest that the optimal mask is not common between these two BF methods.

TABLE III
PEAK PERFORMANCE FOR EACH METHOD AND SCENARIO IN SDR [dB] COMPARED WITH THAT OF THE IDEAL MWF.

BF Method	Mask(s) used	BG multiplier ×1	×2	×4
Max-SNR	m_s, m_n	19.430	**14.276**	**9.451**
Max-SOR	m_s	19.426	**14.276**	**9.451**
Min-NOR	m_n	19.434	**14.276**	**9.451**
MWF	m_s	19.438	14.268	9.430
Ideal MWF		**19.441**	**14.276**	**9.451**

TABLE IV
EXTRACTION PERFORMANCE IN SDR [dB] AFTER APPLYING THE OPTIMAL MASK TO ANOTHER BF METHOD

BF for mask estimation	Applied to	Mask used	BG multiplier ×1	×2	×4
Max-SNR	Max-SOR	m_s	17.084	13.493	9.165
	Min-NOR	m_n	18.399	14.032	9.381
Max-SOR	Min-NOR	m_s & (27)	19.426	**14.276**	**9.451**
Min-NOR	Max-SOR	m_n & (26)	**19.434**	14.274	**9.451**
Max-SOR	MWF	m_s	15.465	10.259	5.337
MWF	Max-SOR	m_s	14.230	12.092	8.458

D. Experiment 3: Examining whether the IRM can achieve the peak performance

The third experiment is for examining if the IRM can achieve the peak performance for each BF method. Considering that the term IRM was ambiguously employed in the related studies [6], [12], [20]–[22], we define several masks that utilize the ratios of the target and interferences based on [12].

The IRMs for the target and interferences are defined as

$$m_s(t) = \left(\frac{|s_k(t)|^2}{|s_k(t)|^2 + |n_k(t)|^2} \right)^{\beta}, \quad (28)$$

$$m_n(t) = \left(\frac{|n_k(t)|^2}{|s_k(t)|^2 + |n_k(t)|^2} \right)^{\beta}, \quad (29)$$

where $k = 5$ and $\beta = 1$ or 0.5. As another type of ratio mask, we employed the spectral magnitude masks (SMMs) defined as

$$m_s(t) = \frac{|s_k(t)|}{|s_k(t) + n_k(t)|}, \quad (30)$$

$$m_n(t) = \frac{|n_k(t)|}{|s_k(t) + n_k(t)|}. \quad (31)$$

In the single-channel TF masking, these masks are ideal in terms of the magnitudes of the target and interferences [12].

The obtained results are presented in Table V. In this table, the combination of the max-SOR and IRM with $\beta = 0.5$ demonstrated the best score for all the scenarios. However, these scores were lower than that in Experiment 1. The results suggest that the IRM does not achieve the peak performance for any BF method examined in this study; hence, it differs from the optimal mask for each method.

In addition, Table V indicates that the max-SNR, max-SOR, and min-NOR BFs present the same scores for the IRM with $\beta = 1$. This is because this mask type evidently satisfies both (15) and (20). Hence, these three BFs are equivalent in this case, as mentioned in Section III-C.

TABLE V
EXTRACTION PERFORMANCE IN SDR [dB] WHEN THE IRM ($\beta = 1, 0.5$) AND SMM WERE EMPLOYED FOR EACH BF METHOD.

BF method	Type of ideal mask	Mask(s) used	BG multiplier ×1	×2	×4
Max-SNR	IRM ($\beta = 1$)	m_s, m_n	18.642	13.889	9.226

VI. Discussion

In this section, we discuss the experimental results for each issue mentioned in Section III.

A. Discussion on Issue 1

The results of Experiment 1 provide the answer to Issue 1. The peak performance of each BF method is practically identical and comparable to the upper bound given by the ideal MWF BF. These findings differ from the conventional idea presented in Fig. 2 and may deprive the meaning of the discussion on the BF that can achieve the best extraction performance. However, it is an open question whether these findings are applicable to any BF method and dataset. Therefore, further investigation is required.

B. Discussion on Issue 2

The results of Experiment 2 provide the answer to Issue 2. Although the optimal mask is not common, it depends on the BF method adopted. This finding differs from the conventional concept presented in Fig. 2, similar to the discussion on Issue 1. However, we consider this to be natural because the optimal mask is formulated as the solution to a different problem for each BF method, as explained in Section IV.

In addition, Table IV indicates several remarkable points. Although both the max-SOR and min-NOR BFs are derived from the max-SNR BF, as mentioned in Section III-C, the top two rows suggest that $m_s(t)$ and $m_n(t)$ are optimal for the max-SNR BF, while not for the max-SOR or min-NOR BFs. We consider that the reason for this is that the optimal masks obtained in the max-SNR BF do not satisfy (15) or (20). Hence, the max-SNR BF is not equivalent to the other two BFs in this case. In contrast, the third and fourth rows in this table suggest that the max-SOR and min-NOR BFs are equivalent if both $m_s(t)$ and $m_n(t)$ satisfy (20). Moreover, the bottom two rows exhibited lower scores than the other rows. Although $m_s(t)$ has commonly been interpreted as the mask for the target, the facts suggest that the optimal mask $m_s(t)$ for the max-SOR BF differs significantly from that of the MWF BF and vice versa.

From the discussion on Issues 1 and 2, we have obtained a novel idea for the peak performance and optimal mask among multiple BF methods, as illustrated in Fig. 4. This indicates that the optimal mask depends on the BF method adopted, while the peak performance is the same among multiple BF methods and comparable to the upper bound achieved by the ideal MWF.

C. Discussion on Issue 3

The results of Experiment 3 provide the answer to Issue 3. Although these masks have been considered to be optimal for any BF method, Table V suggests that the IRM and SMM do not achieve the upper-bound performance and differ from the optimal mask for any BF method. These findings can explain why the studies presented in Table I mentioned a different BF method as the best. Table V indicates that the BF method that appears the best depends on the mask type employed. For example, focusing on the IRM with $\beta = 0.5$ in this table, we can determine that the max-SOR BF performs the best. However, this result only suggests that this mask type is the closest to the optimal mask for the max-SOR in this dataset.

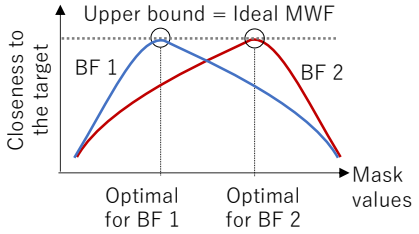

Fig. 4. Obtained concept of the peak performance and optimal mask among multiple BF methods

Furthermore, the fact that the IRM is not optimal imposes another issue on us. This is how the optimal mask is interpreted and represented as a formula. However, this is also an open question.

VII. Conclusions

In this study, we investigated mask-based BFs such as the max-SNR, max-SOR, min-NOR, and MWF BFs. To explore the peak performance for each BF method, we obtained the optimal mask for each utterance by minimizing the MSE between the BF output and target. We experimentally verified that these four methods have the same peak performance as the upper bound provided by the ideal MWF BF. Via additional experiments that applied the optimal mask across BF methods, we determined that the optimal mask differed for the BF method used. However, the mask values can be converted between the max-SOR and min-NOR BFs. These findings differed from the conventional idea that the optimal mask would be common and the peak performance would depend on the BF method. We verified that the IRM did not achieve the peak performance for these four BFs. Hence, this mask type was not optimal. We expect that these findings will contribute to the improvement of mask-based BFs.

Given that these findings are currently experimental, in the future, we would attempt to establish their theoretical background and investigate whether these apply to other BF methods and datasets.

The experimental system has been shared in https://github.com/hreshare/optimal_beamformers/.

***Abstract*—Disfluencies in spontaneous speech such as fillers and hesitations are major causes of automatic speech recognition (ASR) errors. In our previous work, we proposed a "disfluency labeling" method allows an end-to-end (E2E) ASR model to recognize such disfluencies as symbolized recognition targets. This study proposes a method of further improving spontaneous speech recognition by integrating a language model (LM) that can predict disfluencies as pre-defined symbols. First, we fine-tuned a pre-trained Bidirectional Encoder Representations from Transformers (BERT) to predict word boundaries where disfluency symbols ("#" for a filler and "@" for a hesitation) should be inserted within a corpus of normal written text. We then used it to generated a large corpus of disfluent text. Finally, we trained an LM to predict the disfluency symbols with the BERT-generated corpus, and integrated the LM into an E2E ASR model using Shallow Fusion. Our experimental results show that the LM trained using the generated disfluent text corpus improved disfluency prediction and, as a result, spontaneous speech recognition performance.**

I. Introduction

Automatic speech recognition (ASR) is a technology that has become well-known to the public through applications such as voice search services on smartphones and smart speakers, and through instant speech transcription. Thanks to significant progress in neural network (NN) modeling, the performance of end-to-end (E2E) ASR models, which are fully neural models that directly map input speech to the corresponding token sequence, has greatly improved. However, the recognition performance of these models when processing spontaneous speech remains unsatisfactory level. This is because spontaneous speech usually contains fillers such as "uh" and "um", and hesitations such as reparandum, repetition, or stuttering, and these disfluent acoustic phenomena are major causes of ASR errors [1]. In addition, since these disfluencies are generally unnecessary for downstream natural language processing (NLP) tasks, they should be removed from ASR results [2]. Several approaches have been proposed to alleviate this problem [3]–[7]. For example, in [6], the authors identified disfluencies based on fundamental frequency, and removed them before recognition.

Studies have also been conducted using E2E ASR approaches to cope with the disfluency problem. Lou and Johnson [8] developed a speech recognizer that generates fluent transcriptions directly from disfluent speech by training the ASR model with speech transcriptions which have had the disfluencies removed. Mendelev *et al.* [9] and we [10] replaced hesitations with hesitation labels, then trained an ASR with text containing hesitation labels and other regular tokens, in order to recognize hesitations. To target both fillers and hesitations, our previous study [11] also proposed a method called *disfluency labeling*, which replaces fillers and hesitations within transcriptions of spontaneous speech with symbols ("#" for fillers and "@" for hesitations). They then trained an ASR model using a corpus containing these disfluency symbols. Although spontaneous speech can include a theoretically unlimited variety of disfluencies, during decoding the ASR model treats all of these disfluencies as one of the two types of disfluencies represented by symbols, and thus the ASR robustly recognizes (detects) them, as it does with other tokens. Finally, by removing the two disfluency symbols from the ASR results we can obtain a transcription without unneeded information, i.e., one suitable for downstream tasks.

In [11], investigators performed inference using an ASR model without using a language model (LM). However, many studies have reported that using a method called *Shallow Fusion* to integrate an external LM into the main ASR model during inference is effective for improving recognition performance [12]–[14]. Shallow Fusion performs log-linear interpolation of the scores obtained by an ASR model and by a separately trained LM at each step of a beam search. By using an external LM and Shallow Fusion, it is possible to consider a larger amount of contextual information during inference.

In this study, we aim to improve the performance of the ASR model through disfluency labeling, and by using an external LM and Shallow Fusion. However, normal written text corpora do not contain fillers and hesitations, and thus LMs trained with these corpora are unsuitable for use with ASR models that employ disfluency labeling. Furthermore, manually building a large corpus of disfluent text would involve considerable costs in time and resources. To overcome this problem, we generated disfluent text by inserting disfluency symbols into written text using Bidirectional Encoder Representations from Transformers (BERT) [15]. The generated disfluent text is then

used to train an LM suitable for ASR of spontaneous speech. The BERT model can perform fill-in-the-blank tasks, in which, given a sentence with blanks, the model will complete the sentence by filling the blanks with suitable words. We treat written texts as disfluent texts, in which disfluency symbols are omitted. Then, using the BERT model with the fill-in-the-blank framework, we insert disfluencies to the written texts to generate disfluent texts. We then integrating it with the ASR through Shallow Fusion, we could improve the accuracy of the ASR system when it encounters spontaneous speech. Even though our method is simple, we experimentally show that it is very effective.

II. Related work

A. Insertion of disfluent acoustic events into text

Researchers have tried inserting disfluent events into text to increase the naturalness of text-to-speech (TTS) synthesis. In [16], a subject questionnaire was used to evaluate manual filler insertion during TTS. Then fillers were automatically inserted using various models. Recurrent neural network (RNN) and 4-gram LMs accurately inserted the fillers, and many of the subjects indicated that the inserted fillers were natural. In [17], high filler insertion accuracy was achieved by combining an LM and a decision tree using binary classification to determine whether or not to insert fillers between word boundaries. In [18], a Planner-Generator based disfluency generation model was created to augment the data used to train the disfluency detector, improving detection accuracy.

Other studies on phrase boundary prediction in text have inserted acoustic events (such as phrase boundaries) into the text instead of disfluencies, to improve speech articulation during TTS and readability of the ASR results. Models that predict time series data, such as RNNs [19], [20] and bidirectional long short-term memory based RNNs (BLSTMs) [21], [22], have been successful in this task. In [23], a self-attention-based model was used for punctuation prediction. Experiments on predicting the position and type of punctuation to be inserted were conducted using English IWSLT2011 datasets. Their results showed that the self-attention based model outperformed a state-of-the-art BLSTM-CRF (conditional random field) model. In this study, we employed BERT [15], a Transformer encoder model that can consider bidirectional context when inserting fillers and hesitations into written text, to generate the disfluent text needed to train an LM for spontaneous speech recognition.

B. Disfluency labeling

Our previous study [11] proposed a disfluency labeling method to improve the accuracy of ASR for spontaneous speech. Since the sentence that the speaker intended to say does not contain disfluencies, they need to be removed from the recognition results in order to interpret the target sentence. The box below shows an example of their disfluency labeling scheme:

Before	:	**Well...** the presentation is **all, uh,** almost over.
After	:	**#** the presentation is **@ #** almost over.
Target	:	The presentation is almost over.

This method replaces fillers and hesitations with the disfluency symbols "#" and "@", respectively. This approach makes the disfluency detection task easier for the ASR model as multiple types of fillers and hesitations can be represented with a single symbol, respectively, since the exact contents of these disfluencies do not need to be considered. Thus, a single symbol can be used to represent an entire class of disfluent phenomena. Fillers and hesitations have different features, so by using two different symbols they can be treated separately.

C. Shallow fusion

In this study, we used the Shallow Fusion method to integrate the external LM, trained with the generated disfluent text, with the ASR model. Shallow Fusion integrates the external LM only at the time of inference, performing log-linear interpolation using the LM at each step of the beam search [14]. Given acoustic feature vector sequence x, an E2E ASR model using an external LM through Shallow Fusion can predict the most probable output token sequence y^* as follows:

$$y^* = \underset{y}{\operatorname{argmax}}\{\log p(y|x) + \lambda \log p_{\mathrm{LM}}(y)\}, \tag{1}$$

where y is a possible output token sequence, $\log p(y|x)$ is the score of y given x obtained by the E2E ASR model, $\log p_{\mathrm{LM}}(y)$ is the score of y obtained by the external LM, and λ is an LM weight.

This method is very cost-effective because integration is performed only during inference. Applying the LM using Shallow Fusion makes it possible to consider a wider range of contextual expressions.

D. BERT

BERT is a Transformer encoder model that solves NLP tasks by considering context bidirectionally. Many open-source BERT models, pre-trained with large amounts of text data, are available. By fine-tuning such a pre-trained model using a small amount of data for the target task (such as sentence classification [24], question answering [15], or sentence tagging [25]), task-adapted models can easily be obtained, and their effectiveness has been experimentally confirmed.

In this study, we fine-tune our pre-trained BERT with a masked language modeling (MLM) task, using transcripts of labeled spontaneous speech. MLM is a self-supervised learning task in which the BERT automatically masks the sentences and then predicts the masked tokens. Tokens in the input sentences are randomly masked, then their content is predicted, allowing deep, bidirectional representation learning [15]. We hypothesized that taking additional context into consideration would allow us to more accurately insert the disfluency symbols.

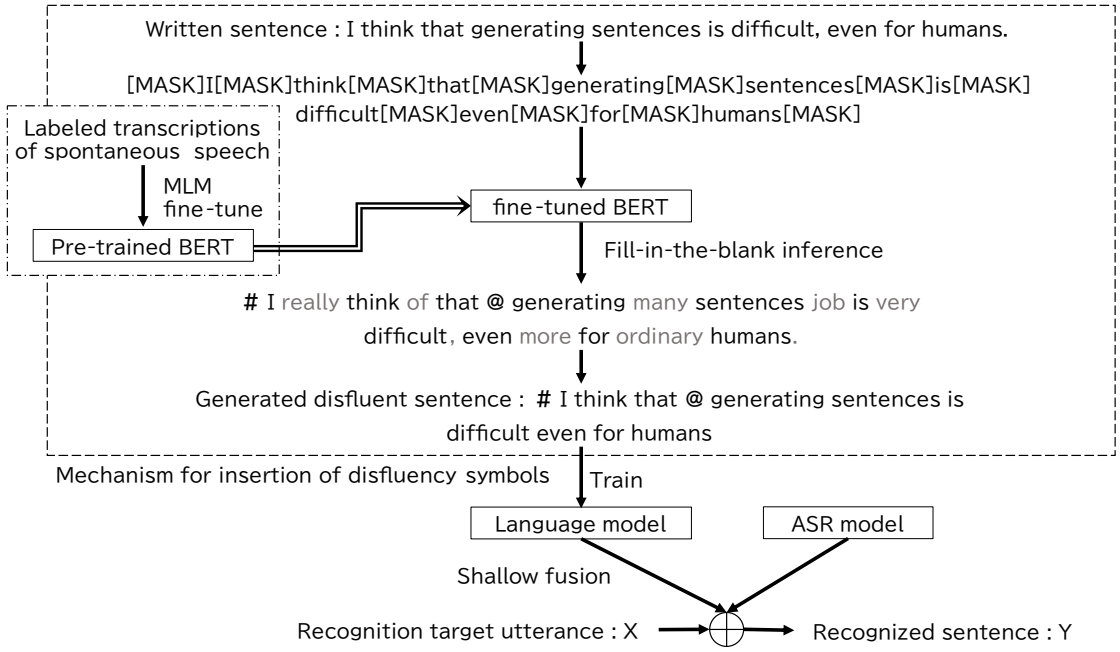

Fig. 1. Overview of disfluent sentence generation.

III. Disfluent sentence generation

To achieve further improvement in spontaneous speech ASR, we can train the LM using a large text dataset and then apply it during inference, however language models trained with written text are unsuitable for this task. Therefore, in this study we generated disfluent text by inserting disfluency symbols into written text using BERT [15]. The pre-trained BERT model was fine-tuned using the same spontaneous speech transcriptions used to train the ASR model, which were labeled in the manner described in Section II-B. Disfluency symbols were then inserted into the input sentences, and the generated text was then used to perform language modeling suitable for spontaneous speech. An overview of this approach is shown in Figure 1.

Fine-tuning was performed through the MLM task described above in II-D , during which 15% of the tokens in each sentence were randomly selected. Then 80% of the selected tokens were then replaced with "[MASK]" tokens, 10% were replaced with other random tokens, and the remaining 10% of the tokens were left unchanged [15]. This fine-tuning allows BERT to insert symbols into sentences based on the context on either side of a word. The BERT model can then make the inferences necessary to convert written text into disfluent text.

Suppose there is a written sentence such as, "I think that generating sentences is difficult, even for humans." First, "[MASK]" is inserted between each word and at the beginning and end of the sentence, as a preprocessing step to allow the insertion of symbols. Next, the masked sentence is entered into the fine-tuned BERT model, and the model performs inference for each masked word in the sentence, as to whether it is a filler (#), a hesitation (@), or some other word. An example is shown in Fig. 1, where inference is performed for all of the 11 masked words in the sentence. If a word inserted during fill-in-the-blank inference is not a symbol, it is discarded. In the example in Fig. 1, the words "really", "of", "many", etc. are all discarded. This discarding allows only disfluency symbols to be inserted into the sentences. Predicting all the masked elements using words, and then discarding them, prevents disfluency symbols from being inserted in positions where they are inappropriate (i.e., in a location where a word other than a disfluency symbol is predicted). Thus, disfluency symbols can only be inserted in positions where they are likely to be correct. This sequence of events generates disfluent text from written text. By applying this method to create a disfluent speech training corpus, the LM can be adapted to recognize disfluent spontaneous speech

The higher the BERT score (log-likelihood), the more likely the "[MASK]" element is a valid word. When generating disfluent text, a disfluency symbol is inserted even when the probability of a disfluency is low, but still higher than other words, regardless of its likelihood score. However, since the accuracy of symbol insertion is uncertain, a threshold p can be set. Symbols and words with likelihoods below p can be discarded to reduce the number of faulty disfluency symbol insertions, allowing more accurate generation of disfluent sentences.

IV. Evaluation experiments

A. Corpus

In order to evaluate the proposed method, we conducted experiments using the Corpus of Spontaneous Japanese (CSJ) [26], a dataset of spontaneous Japanese speech, as well as the Balanced Corpus of Contemporary Written Japanese (BCCWJ) [27], a dataset of written Japanese text. The CSJ contains 700 hours of spontaneous speech and approximately 7 million morphemes. It consists of monologues, such as academic

TABLE I
TRAINING DATA FOR EACH LANGUAGE MODEL.

LM ID	Training data	Symbols inserted by	Sentences	Characters	Fillers (#)	Hesitations (@)
1	original BCCWJ	-	4,220,470	147,654,449	0	0
2	CSJ disfluency removed	-	398,578	11,021,130	0	0
3	Training data for 1 + 2	-	4,619,048	158,675,579	0	0
4	CSJ with disfluency labeled [11]	Actual disfluencies	413,408	11,553,641	441,729	90,782
5	BCCWJ with # inserted at BOS	Automatically	4,220,470	151,874,919	4,220,470	0
6	BCCWJ with disfluency symbols randomly inserted	Randomly	4,220,470	149,519,873	1,534,087	331,337
7	BCCWJ with disfluency symbols inserted by BERT	BERT-based (proposed)	4,220,470	211,025,390	28,076,932	1,530,249
8	BCCWJ with disfluency symbols inserted by BERT ($p = -10$)	BERT-based w/p limit (proposed)	4,220,470	185,143,059	3,443,116	281,734
9	Training data for 4 + 8	Actual and BERT-based w/p limit (proposed)	4,633,878	196,696,700	3,884,845	372,516

presentation speech (APS) and simulated public speech (SPS), as well as dialogues [26]. We used 413,377 CSJ utterances to train the ASR model and fine-tune the BERT. 4,000 utterances were used as development data to validate the LM and ASR model during training. CSJ dialogue speech, which included 23,263 utterances, was used as the recognition target. The dialogs consisted of interviews with the presenters of the APS and SPS monologues, task-oriented dialogues, and free dialogues. The BCCWJ corpus, which is currently the most extensive corpus of written Japanese, was used to train the LM. It contains 100 million words and 4,557,815 sentences, covering a wide range of documents, including books in general, magazines, newspapers, governmental white papers, internet bulletin boards, a blog, etc. [27].

B. Experimental settings

We used 'cl-tohoku/bert-base[2]', which was pre-trained with Japanese Wikipedia, as our pre-trained BERT model. Fine-tuning was then performed with the MLM task, using a transcription of the CSJ training data. The loss was converged in 3 epochs. Word-wise segmentation of the sentences was performed using MeCab with IPAdic 1.0.0[3] as the dictionary, and "[MASK]" tokens were inserted between the words. MeCab is a morphological analyzer for Japanese (a language in which written sentences are not segmented into separate words, i.e., there are no spaces between words). IPAdic is a dictionary used by Japanese morphological analyzers. To conserve memory, sentences longer than 512 words were excluded during mask insertion, since the maximum input length for the BERT is 512 words. We used the *BertForMaskedLM* class from Huggingface transformers[4] for inference. We conducted our ASR experiments using ESPnet2 (version: v.0.9.9). Processing in the BERT was word-based, while that in ESPnet was character-based. We used the joint CTC-attention Transformer ASR model trained with disfluency-labeled transcriptions, as in [11].

Nine identical LSTM language models were trained differently, using the data shown in Table I. LMs 1, 2, and 3 are the baseline LMs. LM1 was trained with original BCCWJ text, so this LM cannot predict sentences containing disfluency symbols, since there are no disfluencies in the BCCWJ text. LM2 was trained by using "CSJ disfluencies removed", which is close to a written style data set. LM2 does not predict disfluent sentences too. LM3 was trained by using a data set that combines those for training LM1 and LM2. LM4 was trained with transcriptions of the CSJ utterances with disfluency labeling. Since the CSJ contains transcriptions of spontaneous speech, including all of the fillers and hesitations actually uttered by the speakers, the training data used for LM4 always had the disfluency symbols inserted in the correct positions. LMs 5 and 6 were trained with BCCWJ text containing disfluency symbols that were automatically inserted without using BERT, for comparison with the proposed model. LM5 was obtained by inserting the filler symbol "#" at the beginning of sentences (BOS) as a pseudo rule-based method, based on the tendency of fillers to appear before utterances [28], [29]. LM6 was obtained by randomly inserting disfluency symbols into the masked BCCWJ text at the same rate as CSJ Eval1 (1.67% for "#," and 0.36% for "@").

LMs 7 and 8 are LMs trained on texts generated by our BERT-based disfluent sentence generation method, however LM8 was trained with text that had disfluency tags inserted using a p value of $p = -10$. The BERT score usually ranges from -20 to 0, and therefore, -10 is about the median value. LM9 was trained by combining the training data used to train LM8 with the 'ground truth' CSJ data used to train LM4, providing data augmentation for the accurately labeled CSJ data, and domain adaptation for the BCCWJ data with BERT-applied disfluency labels. Training of the language models was repeated for 40 epochs, and the model with the lowest validation loss for each training data category was selected. Test set perplexity (PPL) of each LM was also calculated.

The ESPnet2 default hyperparameter settings were used for ASR training and recognition. The CSJ character list was used as the token list (3,263 tokens), with the addition of disfluency symbols "#" and "@". Integration of the ASR model and the LMs during inference was performed using Shallow Fusion, with Shallow Fusion weights for all of the LMs set to 0.3 since this value brought the lowest error rate when using an LM in our preliminary experiments. We also compared the results of inference for each model with the results when the LM was not

used. The reference sentences were obtained by labeling them in the same manner as the training data. We used character error rate (CER) and sentence error rate (SER) to evaluate ASR performance. These calculations were performed after the symbols were removed from both the recognition results and the reference sentences. To measure the symbol detection rate during recognition, recall, precision, and F-measure were used.

C. Experimental results

Table II shows the results of our ASR experiments when using different LMs. Note that LM4, trained with only labeled CSJ data, had the best perplexity. This must be because the recognition target included interviews related to the contents of the APS and SPS monologues in the training data, therefore the distribution of the vocabulary is close to the target.

Based on the results of baseline LMs 1-3, using LMs trained on written sentences that do not contain disfluent symbols does not even overcome the accuracy of not using LMs. This suggests that the nature of disfluent spoken sentences is very different from that of written sentences, and that it is effective to use LMs trained on sentences in which disfluent symbols are inserted, rather than simply fusing LMs. Comparing the LMs trained with the labeled BCCWJ text, LM7, which used variations of our proposed method, performed better than both LM5 with labeling at BOS and LM6 with random labeling, suggesting the effectiveness of the proposed method. The accuracy of LM8, using parameter p to limit disfluency symbol insertions, was better than that of LM5 without parameter p, indicating that using p as a limit when performing symbol insertion, for greater certainty, is effective for improving ASR accuracy. In addition, although LMs 7 and 8 improved ASR accuracy in comparison to not using an LM (ID 0), and to low accuracy labeling (LMs 5 and 6), their performance was slightly lower than that of LM4, which was trained with the accurately labeled CSJ data. This may be because the symbols in LM4 represent actual disfluencies, whereas those inserted by LMs 7 and 8 were BERT-based, simulated symbols.

TABLE III
DISFLUENCY SYMBOL DETECTION RATE [%] DURING ASR.

LM ID	Symbol	Recall	Precision	F-measure
0	#	70.2	81.7	75.5

These results indicate that a certain degree of accuracy in labeling is required when training LMs to handle disfluencies. However, our proposed method is still effective, especially when manually labeled or accurately transcribed spontaneous speech are unavailable.

The best performing language model was LM9, which was trained with both the CSJ data used to train LM4 and the training data used to train LM8, which had the highest accuracy of the LMs trained with only BCCWJ text. ASR accuracy was improved when using LM9, without degrading the PPL of LM4, indicating that the proposed method's augmentation of the LM's knowledge was effective. Additionally, result of the LM3 baseline shows that simply combining BCCWJ and CSJ does not yield higher accuracy than the ASR without LMs. So, it is effective to generate disfluent text and combine this data for the language model, not simply train the LM with additional normal written text data.

Compared to the performance of the ASR without LM integration (ID0), the relative CER and SER were reduced by 6.8% and 7.0%, respectively, when using LM9, a steady improvement in accuracy. Considering the difficulty of performing ASR on spoken dialogue, and the good baseline accuracy achieved without LM integration, the proposed method provides satisfactory results.

Table III shows the disfluency symbol detection rate during ASR without LM integration (ID0) and with LM9 integration. While the detection rate for filler symbol (#) increased when the LM was integrated, the detection rate for hesitation symbol (@) decreased. This may be because low insertion accuracy for the hesitation disfluency symbol negatively affected hesitation detection during ASR.

V. CONCLUSION

In this study, a language model for spontaneous speech was created by training it with disfluent text data, generated by inserting disfluency symbols into a large amount of text. The LM was then integrated with an E2E ASR model using Shallow Fusion. Our evaluation experiment showed that ASR accuracy when processing disfluent speech was significantly improved when using the LMs trained with the proposed method. In addition, the importance of disfluency labeling was shown in the area of LM training.

In the future, we would like to develop a better method of generating training data, and to devise a new method of integrating the LM with the ASR. We would also like to try changing the LM network from an LSTM to a Transformer-based method, to further improve the accuracy of ASR for spontaneous speech.

***Abstract*—Automatic speech recognition (ASR) of simultaneous interpretation is challenging due to disfluencies such as hesitations, filled pauses, interruptions, and self-repairs. Meanwhile, the simultaneous interpretation sometimes accompanies source language text. In particular, training materials for simultaneous interpreters have the source language text. The source language text can also be considered an ideal transcription of source language speech. Previously, we proposed a Transformer-based ASR with auxiliary input of source language text for transcribing simultaneous interpretation and verified the effectiveness of the model structure by using large-scale corpora of speech translation (ST). In this study, we fine-tuned and evaluated the proposed model using a corpus of simultaneous interpretation with transcription of the source language speech as the auxiliary input. We also added a filled pause model to the ASR and compared the effect on the reduction of a word error rate (WER) with the auxiliary input. The experimental results showed significant WER reductions by both the auxiliary input and the filled pause model, though the reduction made by the filled pause model was greater than that made by the auxiliary input.**

I. Introduction

Trainees of simultaneous interpreters take various interpretation tests in the course of the training program. Trainers score the quality of the trainees' interpretation with its transcribed text so that their subjective impression of the speech does not affect the score. Introduction of today's fast-evolving ASR is anticipated to transcribe the interpreters' speech automatically. However, the ASR of simultaneous interpretation is a challenging task due to disfluencies such as hesitations, filled pauses, interruptions, and self-repairs. Meanwhile, the ASR for the training programs of simultaneous interpreters has an advantage of having access to source language text because the test materials are prepared in advance. We aim to improve the accuracy of the ASR by using the source language text as an auxiliary input. We can consider the source language text a perfect transcription of the source language speech. If an accurate ASR of the source language speech is available, the proposed method can also be applied to general situations of simultaneous interpretation.

We have proposed a Transformer-based ASR model with auxiliary input of source language text toward transcribing simultaneous interpretation [1]. Since there is no corpus of simultaneous interpretation with source language text large enough to train the model, we simulated simultaneous interpretation data by changing the inputs and outputs of a large-scale corpus for developing end-to-end speech translation (ST), namely MuST-C corpus [2] for the initial evaluation of the model. The proposed model was trained and evaluated by using MuST-C corpus, with optimization of the model structure, specifically arrangement of Transformer blocks that have a source-target attention from the decoder and the audio encoder to the source language text encoder. The simulation showed that the proposed model significantly reduced WERs for four ST datasets.

In this study, we fine-tune and evaluate the proposed model using a simultaneous interpretation corpus. Since the speech of simultaneous interpretation contains many filled pauses, we added a filled pause model to the ASR [3]. We compared the effects on reduction of the WERs between the auxiliary input of the source language text and the filled pause model.

II. Related Studies

The proposed model is considered a new type of multimodal ASR. Having access to multiple modalities makes inference robust and provides complementary information [4]. In the field of ASR, audiovisual speech recognition (AV-ASR), which incorporates visual information from facial videos into ASR, has long been studied, and many studies have shown that the visual information contributes to noise robustness [5], [6]. AV-ASR now renews attention on how to incorporate two modalities effectively in an end-to-end manner [7], [8].

Textual input is more commonly used in combination with visual tasks such as visual question answering [9], [10] than audio tasks. Joint learning of visual and textual information with Transformer [11] flexibly captures the alignment between elements of an input text and regions in an image input with its attention mechanism, and it is even sensitive to syntactic relations such as associations between verbs and image regions that correspond to their arguments. Transformer-based vision-and-language models are extended to a unified Transformer encoder-decoder model that handles multiple tasks and domains in a single model [12].

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

In recent years, ASR with textual input has been studied in the context of low-resource settings [13]–[15]. To augment low-resource transcribed speech with much larger textual resources, multi-modal data augmentation [16] and pseudo-speech data augmentation architectures were proposed [14]. Pre-training an attention-based encoder-decoder ASR with the architectures showed significant improvement over a text-based augmentation without pre-training. Speech in low-resource languages sometimes accompanies translated speech in a high-resource language. Assuming an accurate transcription of the translated speech is available, ASR of the low-resource language with auxiliary input of the translation has been investigated. The auxiliary input of translation was studied in ASR on the basis of an encoder-decoder recurrent neural network with attention mechanisms [13], and that based on two Transformer encoders for audio and translation inputs and a decoder [15]. The Transformer-based model [15] has a similar architecture to our proposed model in a different context.

III. Transformer-based Multimodal ASR with Auxiliary Input of Source Language Text [1]

A. Model Structure

The proposed model consists of two Transformer encoders for inputting audio in the target language and source language text and one Transformer decoder for outputting recognized words. Figure 1 illustrates the model architecture. The blocks aligned in three vertical lines represent, from left to right, a source language text encoder, an acoustic encoder, and a decoder. The colors shading the blocks represent the types of Transformer blocks. The light gray blocks have a multi-head self-attention and a feed-forward network followed by a residual connection, layer normalization, and dropout with no source-target attention. The orange and green blocks have one and two multi-head source-target attentions, respectively, in between the multi-head self-attention and the feed-forward network. All Transformer blocks in the decoder have a source-target attention to the output of the audio encoder. Additionally, one Transformer block (the green one) in the decoder and one Transformer block (the orange one) in the audio encoder have a source-target attention to the output of the source language text encoder. The optimal arrangement of the two Transformer blocks was experimentally obtained through simulation using the ST corpus. The detailed process in the encoders and the decoder is described in [1].

B. Pre-training and Fine-tuning

The model is trained with two inputs of audio and source language text and an output of a correct transcription in an end-to-end manner. The training is conducted in teacher forcing, minimizing the cross-entropy error.

Since there is no corpus of simultaneous interpretation with source language text large enough to train the model, a large-scale ST corpus is used for pre-training instead. Then, a smaller corpus of simultaneous interpretation is used for fine-tuning the model.

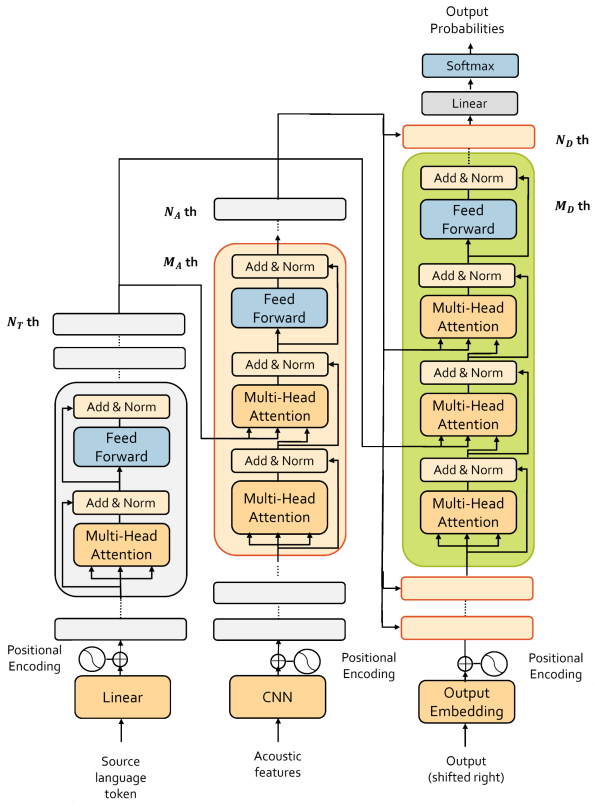

Fig. 1. Model structure.

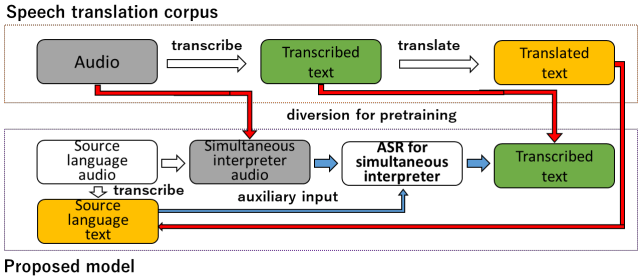

Fig. 2. Correspondence between components of speech translation (ST) corpus and input/output data of for training proposed model. Source language text (yellow block in bottom left) is substituted by translated text of ST corpus.

Figure 2 shows the correspondence between the components of the ST corpus and the input/output data for training the proposed model. The upper part shows three parts consisting of the ST corpus: audio, transcribed text, and translated text. The lower part shows the input/output data for training the proposed model: audio of simultaneous interpretation, transcribed text, and source language text. While the audio and the transcribed text are used as an input and an output of the model, the source language text (the yellow block in the bottom left) that does not exist is substituted by the translated text in the ST corpus.

The pre-trained model is further fine-tuned with a simultaneous interpretation corpus. The simultaneous interpretation

TABLE I
EXAMPLE OF PROCESSING FILLED PAUSES IN TRANSCRIPTION. WORDS WITH TAG OF FILLED PAUSE (IN RED FONTS) ARE SUBSTITUTED WITH LABEL '#' FOR TRAINING. RECOGNIZED LABELS '#' ARE REMOVED IN EVALUATION.

Stage	Transcription
Original	so uh depending on the uh depending on what uh this at uh modifies uh there are different ways of uh uh modification when understanding
Training	so # depending on the # depending on what # this at # modifies # there are different ways of # # modification when understanding
Evaluation	so depending on the depending on what this at modifies there are different ways of modification when understanding

corpus consists of source language speech, its simultaneous interpretation, and transcriptions of the two speech data.

C. Modeling Filled Pauses

Simultaneous interpretation contains many filled pauses and disfluencies. We extracted filled pauses in the transcription of the simultaneous interpretation corpus and added a filled pause model. Specifically, we introduced a filled pause model proposed in [3]. We substituted words tagged "filled pause" with a symbol '#' and trained the filled pause model.

IV. EXPERIMENTS

We conducted a comparative evaluation of the baseline model without the auxiliary input and the proposed model with the auxiliary input in two steps. First, we evaluated the two models with simulated data using the ST corpus and then evaluated them with the simultaneous interpretation corpus. We tested the filled pause model in the second step. We compared the effects of the auxiliary input and the filled pause model on the reduction of the WER.

A. Datasets

1) MuST-C Multilingual Speech Translation Corpus [2]: MuST-C is a large-scale speech corpus with translation in multiple languages for developing end-to-end ST models. The data consist of audio of English TED talks, transcribed text (i.e., subtitles), and manually translated text in multiple languages (i.e., translated subtitles). More than 500 hours of English TED talks were transcribed and translated into 15 languages. The dataset of the translated subtitles is maintained for each language, where 430 hours were transcribed per language on average and 237 hours at least. We used English speech as audio input and Dutch (MuST-C En-Nl), German (MuST-C En-De), and Japanese (MuST-C Ver.2 En-Ja) translations as the source language text. Must-C En-Nl, En-De, and En-Ja had 434.2, 400.0, and 540.9 hours of speech, respectively, as training sets, and they all had 4.1 hours of speech as a common test set.

2) CIAIR Simultaneous Interpretation Database [17]: CIAIR simultaneous interpretation database is a collection of simultaneous interpretations of monologue and dialogue speech between Japanese and English. The data consist of stereo audio of source language speech and its simultaneous interpretation in L and R channels, respectively, and transcriptions of both the source language and interpretation speech. We used monologue data consisting of lecture speech in Japanese and simultaneous interpretation in English. The Japanese-English monologue data contain 84 lectures that cover topics such as politics, history, culture, natural language processing, and spoken dialogue systems each lasting 10-30 minutes.

TABLE II
WERS OF BASELINE AND PROPOSED MODELS FOR THREE ST DATASETS: MUST-C EN-NL, MUST-C EN-DE, AND MUST-C VER.2 EN-JA.

	MuST-C		
	En-Nl	En-De	En-Ja
Baseline	14.4%	14.6%	11.4%
Proposed	9.5%	10.6%	10.4%

TABLE III
WERS OF BASELINE AND PROPOSED MODELS FOR CIAIR SIMULTANEOUS INTERPRETATION CORPUS. LEFT FIGURES ARE WERS INCLUDING FILLED PAUSES, WHEREAS RIGHT FIGURES IN PARENTHESES ARE WERS EXCLUDING FILLED PAUSES.

	W/o filled pause model	With filled pause model
Baseline	21.4% (19.7%)	18.5% (18.1%)
Proposed	20.5% (18.7%)	17.8% (17.3%)

The simultaneous interpretation data were processed in a sentence unit. Since the data were transcribed with time stamps and sentence boundary tags, the English speech data could be segmented into sentences. Then, the Japanese sentences corresponding to the segments of English speech were manually aligned after pre-processing of automatic alignment by Vecalign [18]. When a corresponding Japanese sentence was not found, the segment of English speech was removed from the dataset. As a result, a total of 6,019 utterances with 120,757 words, which amounted to 21 hours of simultaneous interpretation, were prepared with the source language text. We partitioned the sentence-segmented data into ten sets for cross-validation. In the data partitioning, we assigned all utterances from one interpreter into a specific set so that the cross-validation became an interpreter-open evaluation.

The transcription has various tags, such as a filled pause, repair, unclear voice, and general disfluency. We substituted tokens tagged "filled pause" with a symbol '#' for training the filled pause model. The total counts of '#' in the 6,019 utterances were 7,775, which occupied 6.4% of all tokens.

B. Experimental Setup

In the first step, we trained a baseline model and three types of the proposed model with the three language datasets of the MuST-C corpus. In the second step, we fine-tuned the baseline model and the proposed model with an auxiliary input of Japanese text, and evaluated them in cross-validation

TABLE IV

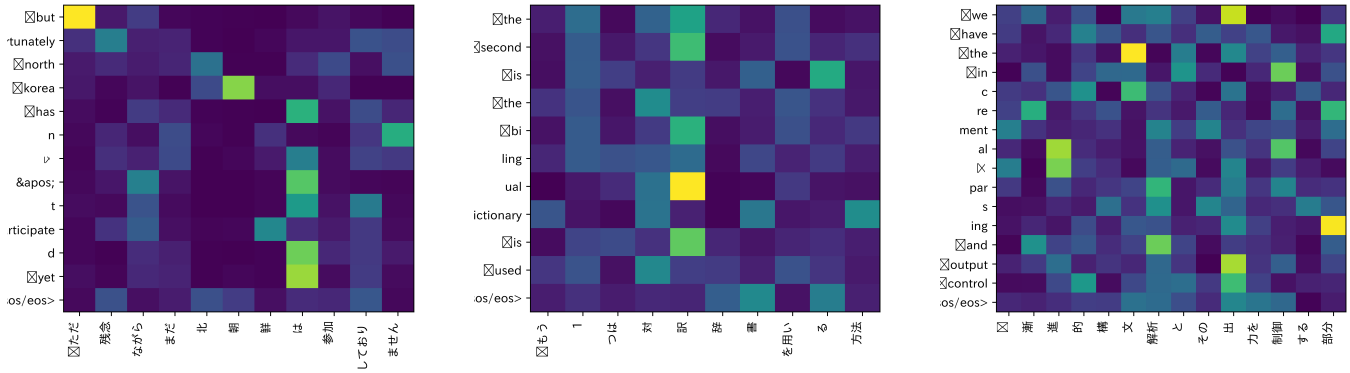

Fig. 3. Attention weights from decoder to source language text encoder in proposed model for samples listed in Table IV. Horizontal and vertical axes list source language tokens and recognized tokens, respectively. Yellow cells represent higher attention weights close to 1, while navy ones represent lower weights close to 0. Corresponding source language tokens or tokens close to those are attended to for corrected output tokens with proposed model.

with the CIAIR database. The two models were pre-trained with the MuST-C Ver.2 En-Ja dataset and fine-tuned with the CIAIR Japanese-English monologue dataset. This experiment examined the filled pause model, too.

We set model parameters as follows. The numbers of Transformer blocks in the source language text encoder, the audio encoder, and the decoder were 6, 12, and 6, respectively. The eleventh block in the audio encoder and the fourth block in the decoder had a source-target attention to the output of the source language text encoder, respectively. The dimension d_M of the embedding vectors in the source language text encoder, the audio encoder, and the decoder was 256. The number of heads in the multi-head attention was 4, and the dimension d_F of the vector in the feed-forward network in each Transformer encoder/decoder block was 2,048. The input acoustic features were 80-dimensional log Mel filterbank outputs sampled at 10 ms intervals and their temporal resolution was reduced to one-fourth by using a 2D-convolutional network.

The baseline model had the same model structure and parameters except that it had no source language text encoder.

English transcription and Japanese source language text were tokenized into 5,000 and 8,000 subwords, respectively, using SentencePiece unigram model [19]. The models were trained with a batch size of 64. The learning rate was set to 2.0e-4 with 20k warm-up steps. The training was conducted with early stopping with patience of five epochs at a maximum of 70 epochs. SpecAugment [20] was applied with parameters (m_F,m_T,f,t)=(2, 2, 15, 20). We used Espnet2 toolkit [21].

C. Experimental Results with MuST-C Corpus

Table II shows the WERs of the baseline and proposed model for three source language texts in the evaluation using the MuST-C corpus. The WERs were significantly reduced by the proposed model for all three source language texts. The reductions were greater for Dutch and German, which are from the same language family, than for Japanese, which is from a different language family.

D. Experimental Results with CIAIR Corpus

Table III shows the WERs of the baseline and proposed models with an option of the filled pause model for the CIAIR corpus. Percentage figures on the left and the right (in parentheses) are WERs, including and excluding filled pauses in the calculation, respectively. We will discuss the results on the basis of the WERs excluding the filled pauses here. To begin with, the baseline WER for CIAIR corpus was nearly double that for MuST-C corpus (11.4% vs. 19.7%). The auxiliary input of the source language text reduced the WER of the baseline by 1.0% (18.7%), whereas the filled pause model reduced it by 1.6% (18.1%). The auxiliary input reduced the WER of the baseline with the filled pause model by 0.8% (18.1% vs. 17.3%), whereas the filled pause model reduced the WER of the proposed model by 1.4% (18.7% vs. 17.3%). We conducted an ANOVA test on the WERs that were the mean of 84 interpreters' WERs with the model structure

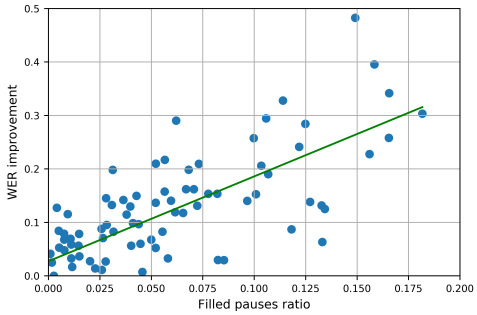

Fig. 4. Scatter plot of 84 interpreters' filled pause ratio and WER improvement for CIAIR corpus. Dot represents 10-30 minute long session. Straight green line represents regression line, and Pearson's correlation coefficient is 0.726.

and the filled pause model being within-subject factors. There was no significant interaction of the model structure and the filled pause model ($F_{(1,83)} = 1.5, p = 0.232$). There was a significant difference between the baseline and proposed models ($F_{(1,83)} = 15.6, p < 0.001$). There was a significant difference between with and without the filled pause model ($F_{(1,83)} = 102.6, p < 0.001$).

Table IV and Figure 3 show examples of recognized texts improved by the proposed model and the attention weights of a source-target attention from the decoder to the source language text encoder, respectively. The examples show that mis-recognitions of nouns and adjectives to similar-sounding words were corrected by the auxiliary input of the source language text. The attention maps show that the corresponding source language tokens or tokens close to those were attended from the corrected output tokens.

Figure 4 shows a scatter plot of the filled pause ratio and WER improvement by introducing the filled pause model into the proposed model for 84 sessions of simultaneous interpretation in CIAIR corpus. Blue dots represent 10-30 minute long sessions played by simultaneous interpreters. The green straight line represents a regression line. The ratio of filled pauses and the improvement of WER had a positive correlation. Pearson's correlation coefficient was 0.726.

V. Conclusions

We evaluated the Transformer-based end-to-end ASR that has an auxiliary input of source language text using a corpus of Japanese-English simultaneous interpretation. We also modeled filled pauses contained in the simultaneous interpretation and compared the effect on the reduction of WER to that made by the auxiliary input. The experimental results showed that both the auxiliary input of source language text and the filled pause model significantly reduced WERs though the reduction made by the filled pause model was greater than that made by the auxiliary input.

An Analysis of Personalized Speech Recognition System Development for the Deaf and Hard-of-Hearing

Lester Phillip Violeta and Tomoki Toda
Nagoya University, Japan
E-mail: violeta.lesterphillip@g.sp.m.is.nagoya-u.ac.jp

***Abstract*—Deaf or hard-of-hearing (DHH) speakers typically have atypical speech caused by deafness. With the growing support of speech-based devices and software applications, more work needs to be done to make these devices inclusive to everyone. To do so, we analyze the use of openly-available automatic speech recognition (ASR) tools with a DHH Japanese speaker dataset. As these out-of-the-box ASR models typically do not perform well on DHH speech, we provide a thorough analysis of creating personalized ASR systems. We collected a large DHH speaker dataset of four speakers totaling around 28.05 hours and thoroughly analyzed the performance of different training frameworks by varying the training data sizes. Our findings show that 1000 utterances (or 1-2 hours) from a target speaker can already significantly improve the model performance with minimal amount of work needed, thus we recommend researchers to collect at least 1000 utterances to make an efficient personalized ASR system. In cases where 1000 utterances is difficult to collect, we also discover significant improvements in using previously proposed data augmentation techniques such as intermediate fine-tuning when only 200 utterances are available.**

I. Introduction

Deaf or hard of hearing (DHH) people typically have their development of speech stunted due to hearing impairedness. This results in difficult-to-understand speech [1], commonly referred to as atypical speech, which makes daily conversations a tedious task for them. As communication is one of the essential aspects of being human, there is a need to develop more systems to support DHH speakers and provide them with more communication alternatives.

Recent advancements in artificial intelligence (AI) has given way for computers to assist humans in their everyday life. One particular field with substantial improvements in the past decade is automatic speech recognition (ASR) [2], [3], [4], the conversion of speech into its corresponding text labels. Owing to neural network-based approaches and the availability of large-scale datasets, several systems have been proposed that could transcribe text at an astounding accuracy rate. Smart devices, in particular voice assistants, have used this technology as a means of communication between users' speech and a control system to execute the said command, enabling several conveniences such as controlling appliances around the house. Thus, with the growing popularity of ASR, several devices and software applications now support using speech to navigate through the device or an application. For DHH users, using ASR to transcribe their spoken speech into text becomes available as an alternative communication option. With the huge benefits and conveniences that ASR-based smart devices bring, improving and developing personalized ASR systems for DHH speakers can allow them a communication alternative and be able to use these devices as an assistant in everyday life.

Although ASR systems have been successful with typical speech, it has struggled with transcribing DHH speech due to the difference and high variability in the DHH speech patterns compared to typical speech. The deaf speaker usually cannot control the high-frequency components of speech [5] due to their hearing conditions, making how other humans and ASR models perceive their speech entirely different from typical speakers. Consequently, this means that although ASR models are usually trained on large-scale typical speech (usually a minimum of 1000 hours), the success of these ASR models is also limited to just typical speech. Replicating the same success on DHH speech would require training the ASR model on a large-scale DHH speaker dataset; however, recording at a large scale, due to strict ethics regulations and the effort it takes to setup recordings, makes this a difficult task to resolve. Thus, speakers with atypical speech have found these devices rather difficult to use [6], [7]. However, as mentioned, DHH users would be the ones who could benefit the most from ASR-based devices.

In this research, we provide an analysis of how to create personalized ASR systems for DHH speakers. Our goal is to provide a thorough analysis such that researchers would be able to understand the training size/performance tradeoff when collecting speech data, and how to make use of methodologies used in the literature to properly develop personalized ASR systems. Our previous work has shown the effectiveness of large-scale pretraining and using imperfect synthetic data to improve recognition accuracy in electrolaryngeal speech recognition [8]; however, there is still some doubt on whether the previously proposed method works on different types of atypical speech or on larger dataset sizes. Thus, this extension of the analysis provides information on the effects of varying the training data sizes and how it affects the performance of each ASR method. Moreover, compared to other atypical datasets used in the literature, we collected a large dataset of

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

four DHH speakers with 28.05 hours in total, allowing us a thorough examination of the dataset.

Our main findings are as follows:

- We perform a thorough analysis with publicly available ASR resources on four different DHH Japanese speakers to make a personalized ASR system. We train personalized models and analyze different scenarios with different training data sizes and data augmentation techniques to give researchers an idea of what requirements are needed to train high-performing personalized ASR systems.
- Through our findings, we confirm that our previously proposed speech synthesis-based data augmentations indeed improve ASR performance in low-resourced scenarios (200 utterances) even on DHH speech datasets. However, using at least 1000 utterances of real recordings to fine-tune pretrained models already shows huge performance boosts in ASR performance, and thus recommend researchers collect around this number of utterances as it is the best cost/performance tradeoff point.
- Finally, we emphasize the effectiveness of creating personalized ASR systems, as when conducting data augmentation, using the synthesized speech of the target speaker was always better than using real recordings from other speakers.

II. Related Literature

Since the number of devices and software applications that support the use of speech as an input grows more and more each day, using ASR as a communication alternative is becoming more available as an option. However, research such as [6], [7] has investigated that for DHH and atypical speech, currently productionized or open-sourced ASR models have up to 60% increase in word error rates (WER) compared to typical speech. Thus, although ASR-based technology has been gaining popularity and more support on devices, current models are still far from being inclusive to all people, and more investigations need to be done to resolve this issue.

Although not focused on DHH speech, several research works have investigated improving ASR performance for atypical speakers. The most common method to resolve this is by pretraining the model with large-scale typical speech data, and subsequently fine-tuning on the target low-resourced atypical speech data [9], [10], [11], [12]. Through large-scale pretraining, the model can generalize to the target better by using these as the initialization model parameters, rather than training the model from randomized initialization model parameters. The larger the pretraining dataset used, the more generalized the model could be and thus more robust to different types of speech during fine-tuning.

Research such as [11], [13] has shown that personalized ASR models will always outperform ASR models trained on other speakers' data. Although this work has shown that simply fine-tuning a pretrained model with target speakers can massively improve ASR performance, our previous research in [8] shows that naively fine-tuning the pretrained model on the target speaker is not very effective in a low-resourced scenario, such as when there are only 200 utterances available for each speaker. To further improve performance, we proposed using an intermediate fine-tuning approach using imperfect synthetic speech by using text-to-speech (TTS) [8]. The main point made here was that even low-quality synthetic speech of the target speaker (in this case, the electrolaryngeal speaker) could be utilized to improve ASR performance, contrary to the common intuition that data augmentations should always be of high quality. This has opened doors in improving low-resourced ASR, by requiring looser requirements to train ASR models of a target atypical speaker. However, more work has yet to be done to verify the effectiveness of this method on other types of atypical speakers (such as DHH) or if it would still work well in scenarios with a larger training data size as the experiments were only conducted using a small-scale electrolaryngeal speaker dataset.

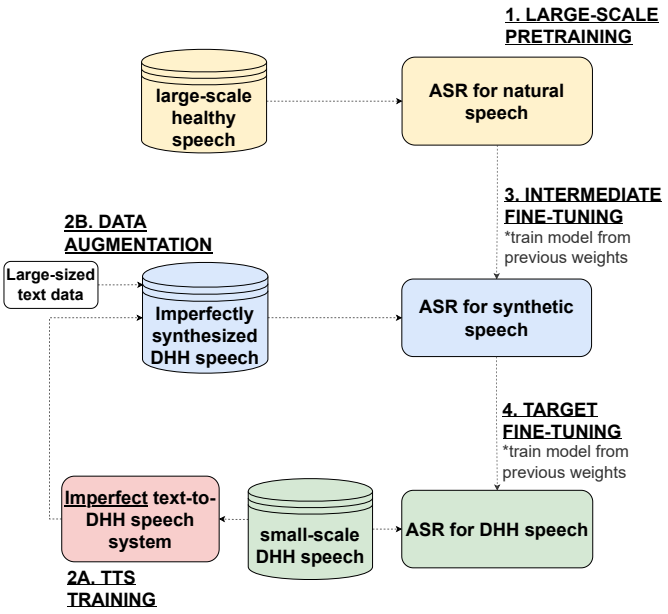

Fig. 1. An overview of the ASR training process. We follow the setup described in [8] and expand on the investigations of this work on deaf and hard-of-hearing speakers.

III. Methodology

A. Development of ASR model

We expand on our previous work shown in [8], to verify the effectiveness of the intermediate fine-tuning task on other atypical speech datasets and with different training data sizes. Following this experiment, we primarily used setups based on pretraining on a large-scale typical speech dataset and subsequently fine-tuning the model on each target speaker. We then perform a thorough analysis of their behavior to understand how to develop efficient ASR models. To generate synthetic speech used for data augmentation, we used the same TTS setup used in that experiment. The TTS setup involves using a pretrained model and fine-tuning it on each of the

TABLE I
AN OVERVIEW OF THE DHH SPEAKER DATASET COLLECTED.

Speaker ID	Gender	No. of utterances	Total length (Hours)
S1	Male	5000	11.41
S2	Male	4982	10.69
S3	Female	902	1.64
S4	Female	2493	4.31
Total	-	13377	28.05

speakers to create a larger training data. Then, text from a separate speech dataset is used to generate the larger speech dataset of each speaker. An overview of the ASR model training procedure is shown in Figure 1.

B. DHH dataset overview

The dataset we used was collected from four different DHH Japanese speakers in the comfort of their homes. To record the dataset, we asked them to utter the phrases from the Japanese speech corpus of Saruwatari Lab of the University of Tokyo (JSUT) dataset [14], a dataset spoken by a native female Japanese speaker. The dataset contains 7696 utterances and is commonly used for speech synthesis tasks. However, speakers were allowed to record only a subset of the dataset or skip some utterances if they felt uncomfortable saying some of the phrases. All datasets were recorded at a 44.1kHz sampling rate. A detailed look at the dataset can be found in Table I. Compared to commonly used atypical speech datasets such as UASpeech [15] and TORGO [16], our dataset is larger in total and contains a large number of utterances per speaker, making personalized ASR more possible. Moreover, compared to UASpeech [15] which only contains word-level utterances, our dataset contains sentence-level utterances, making it a more realistic scenario for certain personalized ASR scenarios. With a larger dataset, we aim to analyze the behavior of the network when varying the training data sizes.

IV. EXPERIMENTS

A. Experimental conditions

To conduct the experiments, we used ESPnet [17], [18], an open-sourced speech processing toolkit. For the ASR model architecture, we used a Conformer [19] encoder and a Transformer [20] decoder due to their proven strength in ASR tasks [21]. As for the TTS models, we used a Transformer [20] encoder and decoder. Since the TTS models only convert the text to a mel-spectrogram, we used a pretrained model based on HiFiGAN [22] as the vocoder to convert mel-spectrograms to waveforms. The ASR and TTS pretrained models are made openly-available by ESPNet, while we also used a pretrained HiFiGAN model[1] on the JSUT [14] dataset. To pretrain the ASR model, we used the large-scale LaboroTV [23] dataset, which contains around 2000 hours of Japanese speech collected from various TV recordings. On the other hand, to pretrain the TTS model, we used the entire JSUT [14] dataset.

To vary the training data sizes, we subset the datasets into different groups depending on the number of utterances available. More details on the number of utterances used are shown in Fig. 1 as they differ for each speaker due to the total dataset size. We evaluated the trained model using a test set with 250 utterances for speakers S1, S2, and S4, and 50 utterances for speaker S3. Although the TTS models were trained and synthesized the utterances in 24 kHz, the synthesized audio would be downsampled to 16 kHz when used to train the ASR model. Thus, all audio used in the ASR models were in a 16 kHz sampling rate.

B. Data augmentation setups

We describe the different setups used in our experiment. We follow the intermediate fine-tuning (IF) setup detailed in [8] and extend upon their findings.

- **Direct**: Directly using the out-of-the-box pretrained model and evaluating the performance without performing any fine-tuning.
- **Direct - speaker-independent**: Fine-tuning the dataset with the other DHH speakers' audio data. This means that we do not use the target DHH speaker's audio data to fine-tune the model.
- **Naive fine-tuning**: Simply fine-tuning the pretrained model on the target speaker without any extra procedures.
- **IF - TTS**: Based on the intermediate fine-tuning setup in [8]. We generate a larger dataset of the target DHH speaker using TTS, and use these during intermediate fine-tuning.
- **IF - TTS with text-swapping**: Similar to the TTS setup, but randomly swapping the text labels within the dataset. Note that the text labels are only swapped during the intermediate fine-tuning stage. We further investigate this setup due to its reported success in [8] but non-intuitive setup.
- **IF - speaker-independent**: Instead of using synthetic speech, we use the real speech recordings from other DHH speakers during intermediate fine-tuning. This allows us to assess if the improvements in intermediate fine-tuning come from the speaker-dependent or speaker-independent characteristics of the data.

C. Evaluation metric

To evaluate the ASR models, we use the character error rate (CER), as seen in Equation 1, a commonly used metric for Japanese ASR. Given the number of characters (N), and the number of wrongly predicted characters, which are categorized into three types, insertions (I), deletions (D), and substitutions (S), the CER can be calculated as the sum of the insertions, deletions, and substitutions divided by the number of characters, multiplied by 100. Thus, the lower the CER value, the better the performance of the ASR model.

$$\mathrm{CER} = \frac{\mathrm{I}+\mathrm{D}+\mathrm{S}}{\mathrm{N}} \,\mathrm{x}\, 100 \tag{1}$$

[1] https://github.com/kan-bayashi/ParallelWaveGAN

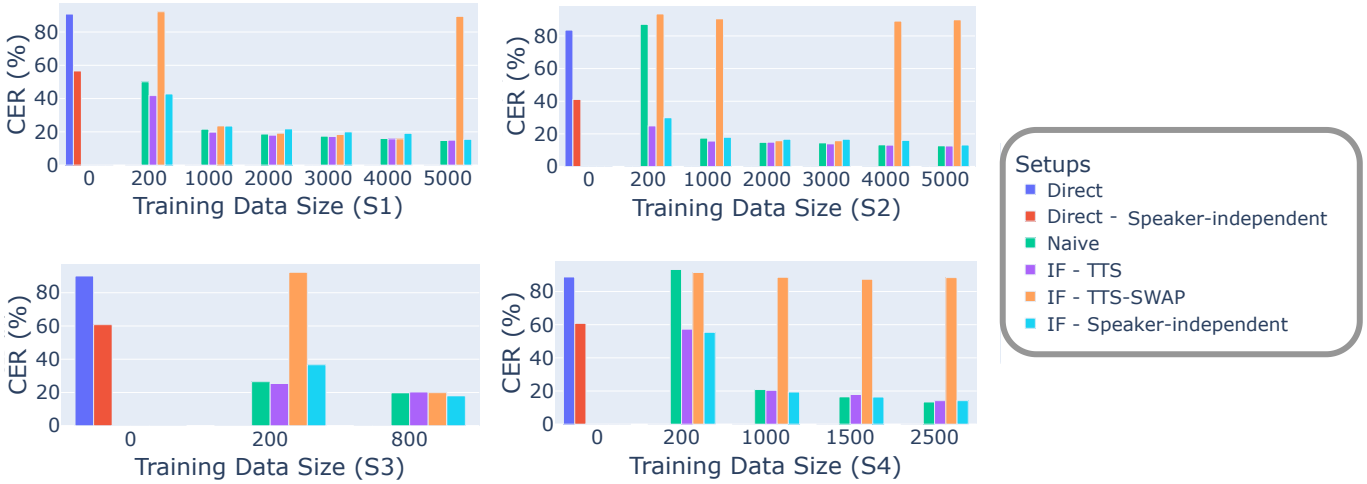

Fig. 2. Character error rate (CER) of the different developed ASR systems for all speakers (S1, S2, S3, and S4). The x-axis indicates the amount of data used in the training and development sets.

V. Results and Analysis

A. ASR model performance using out-of-the-box pretrained models

We present the summary of our results in Figure 2. As displayed, in all cases where fine-tuning is not used, the ASR model always performed above 80% CER as shown by the results of using the Direct setup. Thus, despite the ASR model being pretrained on a large-scale dataset, it still has difficulties adapting to the DHH speech, showing the difficulties faced by deaf speakers using out-of-the-box speech recognition devices. Aside from this, fine-tuning on speech data of other DHH speakers improves performance, but is still not effective enough as shown in the Direct - speaker-independent setup, proving the need for personalized ASR models due to the high variance in atypical speech. On the other hand, when fine-tuning the model on the available utterances (as shown by the Naive setup), the model's performance almost always improves, where the only exception is when using 200 utterances, similar to the findings in [8]. However, using a larger dataset of the target speaker should be sufficient enough for the model to generalize. In all speakers, we find improvements of between 5% to 30% CER by increasing the number of utterances to 1000 from 200. Thus, we recommend researchers collect at least 1000 utterances as the ASR models can be already be effectively fine-tuned using this amount of data.

B. Extending investigations on intermediate fine-tuning

We investigate whether our previously proposed data augmentation techniques for improving electrolaryngeal speech recognition also perform well on DHH speech. Using data augmentation techniques such as TTS to create a larger dataset of the target speaker and using intermediate fine-tuning, we see that this fine-tuning method can significantly improve performance in this low-resourced scenario, verifying that our

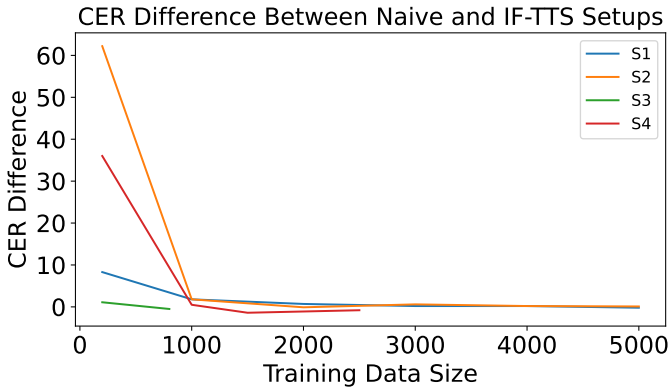

Fig. 3. Difference of the character error rate (CER) of the Naive and IF-TTS setups across different training data sizes.

method proposed in [8] can also be transferred to DHH speech data. However, we observed that using intermediate fine-tuning became less effective as the training data size increased. Amongst the different setups, we find that the IF-TTS setup was the most stable and showed the most improvements in the low-resourced scenarios. Although the IF-TTS text-swapping setup was reported to be successful in [8], we do not see the same trend in our experiments as we observe its instability. Specifically, in cases where the training data is too low or too high, we observed a collapse and the ASR model fails. One hypothesis on why this is the case is because of the difference in speech features between electrolaryngeal speech and DHH speech. For electrolaryngeal speech, the speaker identity is disrupted, but the intelligibility is still there, as several phonemes can still be pronounced almost the same as a typical speaker. On the other hand, DHH speech contains the speaker identity but has unintelligible speech. Thus, since the intelligibility information between the pretraining data

(LaboroTV) and the target data (electrolaryngeal speech) could be transferred and shared, the intermediate fine-tuning worked better on the electrolaryngeal dataset. On the other hand, in the case of our experiments, since the intelligibility information between the pretraining data (LaboroTV) and the target data (DHH speech) vastly differed, the information was not effectively shared. ASR models typically focus on the intelligibility information and disregard speaker identity information, which also explains why the text-swapping was not as effective in the case of DHH speakers. Finally, we observe that using data augmentations of the target speaker, even when the quality is low, was still always better than using real recordings of other DHH speakers as shown by the IF - speaker-independent setup results.

As a final observation, although we verified the validity of the intermediate fine-tuning in the low-resource scenario, we still found that it cannot beat the performance when using real recordings of the target speaker as the training data. A detailed look at the comparison of the Naive and IF-TTS setups is shown in Fig 3. As seen in the figure, using imperfect synthetic speech only became successful in the 200 utterance setup as there was a larger CER difference between using the two setups; however, as more real data was collected and used during training, the effects of using imperfect synthetic speech became close to none. Thus, although we acknowledge the difficulty of obtaining training data from the target speaker, we urge researchers to collect at least 1000 utterances to easily develop efficient personalized ASR systems, and such that they would not need to do any additional procedures such as intermediate fine-tuning and speech synthesis to improve the ASR models. On the other hand, in cases where collecting data is difficult, researchers can still opt to use the intermediate fine-tuning procedure as an alternative, as it has been verified to work even on other types of atypical speech.

VI. Conclusion

We presented a thorough analysis of developing personalized ASR systems for DHH Japanese speakers. We provided a thorough extension of our previous work to verify its effectiveness by analyzing its behavior when varying the number of utterances in the training data and with a different atypical speech dataset. We collected a large-scale DHH dataset, totaling around 28.05 hours of four speakers. Our findings show the following observations: 1) the most efficient setup is to collect 1000 utterances from the target speaker, as we see the most performance boost compared to using just 200 utterances, 2) in cases where 1000 utterances are challenging to collect, data augmentation techniques such as using intermediate fine-tuning with synthetic speech is still an available option to improve performance, and finally, 3) we emphasized the importance of using personalized models, as using real recordings from the target speaker as training data greatly outperforms using synthetic speech or recordings from other speakers. Future work would be to improve the speech intelligibility of atypical speakers using voice conversion techniques such that they can easily use out-of-the-box ASR models.

Classification of Vocal Cord Disorders: Comparison Across Voice Datasets, Speech Tasks, and Machine Learning Methods

Ching-Chieh Chen*, Wei-Cheng Hsu†, Tzu-Han Lin*, Kuan-Dar Chen*, Yung-An Tsou† and Yi-Wen Liu*

† Dept. Otorhinolaryngology, Head and Neck Surgery, China Medical University Hospital, Taiwan

***Abstract*—Dysphonia may originate from various vocal cord disorders (VCDs), and determination of its etiology usually requires image-based examination. However, such examination is invasive and not available in rural areas. Therefore, we aim to evaluate whether the voice of VCD patients may provide cues that could be utilized for screening purposes. Presently, a voice dataset containing entries of vocal fold atrophy, paralysis, benign organic lesions, and laryngeal cancer was prepared and support vector machine and neural network models were trained for VCD classification. Features were first extracted from /a/, and performance on the present dataset was compared against the Saarbruecken voice database. Next, the utterances of counting from 1 to 5 were processed, and "4", pronounced as /si/ in Mandarin, was found most suitable for classifying non-cancer VCDs. Finally, we demonstrated that inclusion of the subjective GRBAS scale consistently raised the classification accuracy.**

I. Introduction

Dysphonia, or having troubles with voice when one attempts to talk, may be a consequence of various vocal cord disorders (VCDs), including laryngeal cancer. Since dysphonia is common, the underlying VCDs are often overlooked and could therefore miss the best time for treatment. Accurate clinical diagnosis of VCDs requires video stroboscopic examination. However, the examination may not be available in rural or other medically under-staffed areas. To help clinicians identify the etiology of VCDs in a timely fashion and promote the welfare of residents in these areas, it is desirable to deploy a voice disorder screening tool that is easy to use by patients remotely.

Recordings of the patients' own voice may be a good starting point. Thanks to advances in speech and voice processing by machine-learning algorithms, one can envision that different VCDs possibly exhibit distinct spectrotemporal cues to be discovered and utilized by machines automatically. Indeed, pioneering work was conducted by Al-Nasheri *et al.* to detect and classify VCDs using feature vectors extracted from patients' sustained vowel /a/; the feature vectors could be derived from auto-correlation and entropy [1], or simply from the *Multidimensional Voice Program* (MDVP) [2]. In these studies, the efficacy of support vector machine (SVM) models were evaluated across German, English, and Arabic databases. More recently, Fang *et al.* thoroughly compared the performance of SVM, Gaussian mixture models, and deep neural networks (DNNs) for pathological voice detection [3], while others transformed voice data into images and applied convolutional neural networks (CNNs) to assess the health of the vocal cord [4]–[7].

The above studies commonly used the Saarbruecken Voice Database (SVD) [8] and the Massachusetts Eye and Ear Infirmary (MEEI) [9] database to validate performance of the models, but several limitations were noticed. According to Al-Nasheri *et al*. [1], [2], the performance that could be achieved by any model depended on (1) variation in the severity of pathological voice in a database, (2) differences in the recording environment and recording rules between databases, (3) mismatch in the demographic distributions between different types of pathology within the same database, and (4) imbalance between the number of samples for different disorders within a database. In addition, differences in the ethnic and linguistic background of patients might also be a factor to consider for VCD detection and classification purposes.

Though these challenges exist, nevertheless, accuracy of $> 90\%$ on the binary classification of pathological against normal voice has been achieved in previous studies (e.g., [3]). Therefore, in this study, we chose to focus on discriminating VCDs that might differ in subtle ways. Based on prevalence of the disorder and the importance of early detection to minimize the need for surgical intervention, we selected four categories of VCDs: vocal cord atrophy, vocal cord paralysis, benign organic lesions, and cancer lesions. We endeavored to establish a dataset that is well-balanced and age-matched between different disorders. The dataset contains voice recordings of the sustained /a/, counting from 1 to 10 (in Mandarin), and reading a short text. In terms of machine learning methods, we evaluated SVM and various pre-trained CNNs. The rest of this paper is organized as follows. Sec. II describes the present dataset and its counter-part that was sampled from the Saarbruecken database. Sec. III describes machine learning methods for VCD classification. Sec. IV presents the performance of models in terms of their accuracy on various classification tasks. Finally, discussion and conclusions are given in Sec. V and Sec. VI, respectively.

II. Dataset preparation

As mentioned in Sec. 1, the following four categories were chosen as the targets for classification: vocal cord atrophy, vocal cord paralysis, benign organic lesions (BOL), and cancer lesions. Laryngitis, though common, was not included because of its relatively short time from symptom onset to recovery.

Each of the four categories may contain several subtypes of disorders – the atrophy class (atrophy and sulcus), the paralysis class (palsy), the benign organic lesions (polyps, nodules, cysts,and edema) and the cancer lesions (leukoplakia and laryngeal cancer). To investigate the feasibility of machine classification, we trained SVM models and various CNNs and tested them on two datasets (namely, Saarbruecken and *the present*) that contain sufficient samples of the VCDs listed above. The datasets are introduced next.

A. The Saarbruecken voice database

The Saarbruecken voice database [8] is a German vocal cord disease database which contains more than 2,000 records. Among the available records, 1,356 records are pathological voice, and 687 records are healthy voice. The collection includes vowels /a/, /i/, /u/ with 4 types of intonation (low, normal, high, low-high-low), along with a spoken sentence "Guten Morgen, wie geht es Ihnen?" To facilitate the comparison across datasets, we selected the voice files of normal intonation sustained vowel /a/. The phonation time in the Saarbruecken dataset ranges between 1-4 seconds, and the sampling rate of the recording is 50 kHz with 16 bit resolution. The original database includes 71 disease types. After excluding the data with multiple diseases, the number of records in many categories became fewer than 10. We selected atrophy, palsy, polyp, and cancer for comparison purposes, and there were 35, 198, 36, and 20 records, respectively.

B. The present dataset

The voice data used in this research were retrospectively collected from a larger database that was established by the Voice and Swallowing Center of China Medical University Hospital (CMUH) in Taichung, Taiwan since 2017. Voice and electroglottography (EGG) signals were recorded by speech therapists for patients with laryngeal lesions who needed a diagnosis. The electroglottography instrument Model 6103 (KayPENTAX, Lincoln Park, NJ) was utilized, and an external microphone was connected to the EGG hardware interface (Computerized Speech Lab, model 4500). The signals were synchronously sent to the an analysis software (Real-Time EGG Analysis software, model 5138). The software computed the patients' MDVP, which helped the doctor to assess the patients' condition. In total, about 2300 entries were recorded.

The larger database contains a variety of VCDs; however, some disorders are quite rare, and in some cases the vocal cords were indirectly affected by lesions in other body parts of the patient. Some patients had concurrent VCDs, such as left vocal cord paralysis with right vocal cord atrophy. To avoid complications, we excluded the cases of multiple disorders in this study. The original database also included some data from the same patients before and after treatment, and we selected the ones before treatment. Thus, a total of 459 data entries would be studied in the present research, including 138 of atrophy (65M, 73F), 118 of palsy (56M, 62F), 142 of polyp and other BOL (31M, 111F), and 40 of cancer (36M, 4F). Statistics for their ages at the time of voice recording were as follows: atrophy = 58 ± 13, palsy = 59 ± 14, BOL = 54 ± 12, and cancer = 61 ± 13 years. This research was approved by the IRB of CMUH.

The database contains voice samples for the following speech tasks: (1) sustaining the vowel /a/, (2) counting from 1 to 10 in Mandarin, and (3) reciting a fixed passage from an article in Mandarin which contains 9 phrases and 71 Chinese characters. In this paper, only the /a/ task and the counting from 1 to 5 were analyzed. Table I summarizes the total number of data entries by different categories and speech tasks, as compared against those of the Saarbruecken dataset. For the present dataset, the counting task contributes to slightly fewer entries than /a/ because some patients had difficulties completing the task.

TABLE I
TOTAL NUMBER OF DATA ENTRIES IN THIS STUDY. THE SYMBOLS $/a/_1$ AND $/a/_2$ STAND FOR THE /a/ VOICE IN OUR PRESENT DATASET AND THE SAARBRUECKEN DATASET, RESPECTIVELY; "1-5" STANDS FOR THE MANDARIN COUNTING FROM ONE TO FIVE IN OUR PRESENT DATASET.

Disorder Type	$/a/_1$	"1-5"	$/a/_2$
Atrophy	138	135	35
Paralysis	118	106	198
Benign organic lesions	142	138	36
Cancer	40	34	20

To enhance the data, we also rated the voice quality of 459 patients in the GRBAS scale (*grade, roughness, breathiness, asthenia*, and *strain*) [10]. The GRBAS scale is commonly used in laryngology for voice quality evaluation. A score of 0, 1, 2, or 3 was given for each of the five scales to represent severity (normal = 0, and the most severe = 3). Existing research suggested that these five indicators can be useful for specifying VCDs [10]. In our study, two different versions of the GRBAS scale were collected. The first version was rated by the first author of this paper while focusing on the voice quality of the sustained vowel /a/, and the second one was rated by a speech therapist based on the overall voice quality in performing the sustained /a/ task, the counting task, and the reciting task.

III. Vocal cord disorder classification

In this section, we disclose details in the signal processing and machine learning methods that were used in this research.

A. Signal processing and feature extraction

First, the voice recordings in both the present and the Saarbruecken datasets were down-sampled to 16 kHz. A 512-point (or 32 ms, equivalently) Hann window was applied to calculate the short-time Fourier transform with 50% overlap. Then, the magnitude spectrogram was subject to triangular

filtering to compute 128 Mel energies. For training SVM models, we derived 20 Mel-frequency cepstral coefficients (MFCC); for training neural networks, 12-bins chroma vectors [11], which are typically adopted for music analysis and recognition purposes, were also extracted using *librosa* [12]. We also defined several aggregated features by stacking Mel-spectrogram, MFCC, and the chroma vector vertically, which was shown to improve classification performance empirically in existing research [13].

B. Support vector machine (SVM) configurations

The length of each person's phonation of /a/ is different. To reduce the dimension for training SVM, we computed the statistical functionals (mean, variance, median, and first and third quartile) of MFCC along the time axis as the features. After concatenation, the dimension of the feature space became $5 \times 20 = 100$.

Among various commonly used kernel functions, we selected the linear kernel and the radial basis function (RBF) for the experiments. In its simplest form, SVM was developed for binary classification. To classify data into three or more categories, multiple binary SVM models should be first constructed. In this research, we adopted the *one vs. rest* [14] strategy, which predicts data labels by considering the distance of a datapoint to the separation hyperplane in every binary model.

The penalty parameter C, the kernel type, and the RBF shape parameter γ were jointly determined by grid search within a reasonable range (Table II). In Sec. IV, results achieved by the best hyperparameter combination in terms of classification accuracy will be reported.

TABLE II
THE RANGE OF GRID SEARCH FOR SVM PARAMETERS

Parameter	Values
Kernel type	'linear','rbf'
C	0.8, 1, 1.2, 1.5, 2, 3, 4, 5, 6, 7, 8, 9, 10
γ	0.1, 0.01, 0.001, 0.0001

C. Neural network configurations

We tested various off-the-shelf ImageNet pre-trained convolutional neural networks from Tensorflow-Keras framework, including ResNet50 [15], DenseNet121 [16], InceptionV3 [17], Xception [18], MobileNet [19] and EfficientNetV2M [20]. Each network model was provided with various input features and performance of all feature-model combinations was evaluated. To modify and fine-tune the models, we loaded the models with ImageNet pre-trained weights and set all hyperparameters trainable. The input layer was modified to fit the shape of each feature, and softmax activation was utilized in the output layer. Each model was fine-tuned by 20 epochs with a batch size of 16, using the Adam optimizer with an initial learning rate of 1×10^{-4} and a weight decay of 1×10^{-5} after every epoch. All the training and validation were conducted on a single NVIDIA RTX-3060-12G GPU and AMD 5600x CPU with 16GB of RAM.

D. Cross validation settings

To evaluate the SVM and CNNs, we applied 5-fold cross validation to avoid overfitting. Note that the outcome depended on how data were assigned into five folds; therefore, we performed 10 rounds of random assignment, conducted all the experiments for each round, and will report the mean and standard deviation of accuracy across the 10 rounds in Sec. IV.

IV. RESULTS

In this section, we report the accuracy of vocal cord disorder classification.

A. Performance on different datasets

Table III shows the SVM classification accuracy for different tasks and compares the results across the two datasets. In the first two rows of the table, the "cancer/non-cancer" task refers to binary classification of cancer vs. the three other categories, and "3-class" refers to classifying the three benign cateogories (atrophy, paralysis, and BOL).

Generally, we observe that the rates of accurate classification on the Saarbruecken dataset exceed that of the present dataset. However, this is probably due to the fact that the former is less balanced than the latter in terms distribution of VCDs. For the present dataset, the accuracy of classifying the three types of benign disorders is merely 46.12% on average. Based on physicians' subjectively experiences, this task is also quite difficult for human ears. Therefore, it is not surprising that Table III did not clearly indicate the potential of using MFCCs to discriminate the three benign disorders.

Next, we examine if there was a clear difference between any two categories of the benign disorders. It is noteworthy that the average classification accuracy between BOL and atrophy is only 52.32%. From a pathological point of view, vocal cord atrophy can lead to incomplete closure, and the BOLs may also cause gaps in the closure of the vocal cords. When the gaps caused by the two diseases are similar, the voices may be difficult to distinguish. In contrast, patients with palsy generally had more severe voice abnormalities in the present dataset. Consequently, a higher accuracy could be achieved between paralysis/atrophy or paralysis/BOL than between BOL/atrophy. The same trend is also observed with the Saarbruecken dataset.

In the last column of Table III, we report the results of mixing the two datasets and training a single model to perform classification. The rates of accurate classification by mixed modeling consistently fall between what were obtained on individual datasets.

B. Vocal cord disorder classification by neural networks

In this part of the experiments, we tested the neural networks with the 3-class task. The rates of accurate classification for all feature-model combinations are listed in Table IV. Because the sizes of MFCC and the aggregated MFCC+Chroma feature

TABLE III
PERFORMANCE OF DISORDER CLASSIFICATION (%) BY THE SUPPORT VECTOR MACHINE MODEL

Classification task	/a/$_1$	/a/$_2$	Mixed
Cancer/non-cancer	75.14±4.96	85.00±6.44	78.07±4.10
3-class	46.12±7.17	67.22±7.59	56.57±3.02
Atrophy/Paralysis	66.15±3.77	82.77±3.86	76.94±3.82
Paralysis/BOL	65.58±7.37	79.79±4.78	70.20±5.10
BOL/Atrophy	52.32±5.59	61.33±4.00	53.94±6.73

were below the minimal requirement of InceptionV3, the corresponding evaluations are absent. Otherwise, it appears that the aggregated feature Mel+Chroma yielded better results than other features on most of the models, while Xception produced the highest accuracy among all the models regardless of the features being used. When used jointly, the combination of the Mel+Chroma feature and Xception (with 49.52% accuracy) outperformed the baseline SVM (46.12%, Table III) by approximately 3.4%.

C. Comparing the sustained /a/ and the counting task

The Mandarin numbers 1 to 10 have the unique property in that every number has exactly one syllable. This simple fact provides a research opportunity to investigate whether utterances of the numbers could contain useful cues for different vocal disorder classification tasks. In this research, we first performed forced alignment to the counting task voice data using AISHELL [21] on the Kaldi platform [22]. The utterances were thus parsed automatically, so that we could subsequently apply the same feature extraction and SVM training settings that were used for sustained /a/ data to the voice recordings in the counting task. Presently, we focus on "1" (yi1), "2" (er4), "3" (san1), "4" (si4), and "5" (wu3). Here, the pronunciation of each character is transcribed in Pinyin with the tone number. Note that "1" and "5" happen to contain sustained vowels /i/ and /u/, respectively. Therefore, we expected that they might provide information that is complementary to /a/ for the purpose of voice disorder classification.

Performance of the SVM model is summarized in Table V. From the first row, it appears that /a/ and "1" were most effective for cancer detection. Quite peculiarly, the model trained on utterances of "4" achieved the highest accuracy in many of the classification tasks. For classifying Paralysis vs. BOL in particular, the performance using "4" was approximately 17% higher than using /a/. Implications of these observations will be further discussed in Sec. V.

D. The potential value of adding GRBAS

We combined GRBAS and MFCC and conducted another set of experiments. When combined with MFCC functionals, the feature space extended by 5 dimensions because G, R, B, A, and S each provided a numeric score. SVM models were trained in this extended space. In Table VI, the label $+$GRBAS^1 refers to the results of adding the GRBAS scale that was evaluated on the sustained vowel /a/, while $+$GRBAS^2 refers to the results of adding the overall speech sound quality evaluation. Apparently, adding the subjective GRBAS scores improved the performance in all classification tasks. The improvement appears greatest in cancer detection (from approximately 75% to 83%) and in Atrophy vs. BOL (from approximately 52% to 63%). Implications will be discussed in Sec. V.

V. DISCUSSION

A noteworthy finding from Table IV would be the performance boost produced by adding the chroma vectors. Since chroma is a pitch-related feature, its usefulness might imply that benign VCDs had tendencies to alter the pitch of patients' voice differently while they delivered the sustained /a/. If so, these tendencies probably were not captured explicitly by Mel energies or MFCC. Therefore, the chroma feature might have provided information that was complementary to Mel-based features so as to raise the classification accuracy in our experiments.

The most surprising finding in this research is probably the efficacy of "4" for classification between paralysis, atrophy, and BOLs (Table V). While the Mandarin "4" is transcribed as *si4* in Pinyin, the vowel is not the front vowel /i/; it has been either considered as the central vowel /ɨ/ or a denti-alveolar approximant /ɹ/ which follows /s/ [23]. The promising findings with Mandarin "4" suggest that it might be beneficial to explore continuous speech data for VCD classification purposes [24]. As long as the short text is phonetically balanced, rich information in all the phonemes could be analyzed either separately or sequentially to assess vocal cord conditions.

Finally, GRBAS required subjective evaluation in the present research and this may seem to defy the purpose of serving medically under-staffed areas. Nevertheless, the GRBAS scoring process could also be automated [25]. Since results in Table VI clearly indicate the benefit of including GRBAS, in the future, it would be worthwhile to develop a separate GRBAS prediction module and integrate it with the current systems. Until then, however, the results listed in Table VI should be viewed as a performance upperbound that is not yet achieved by the present methods.

VI. CONCLUSIONS

This research focused on distinguishing the voice of vocal cord atrophy, paralysis, BOLs, and cancers. The first three categories are benign but atrophy and BOLs are difficult to differentiate automatically by voice. Automatic classification of cancer/non-cancer voice, nevertheless, produced promising results especially if GRBAS could be jointly considered. The fact that a model that was developed based on /sɨ/ outperformed /a/ in many tasks may point toward further research directions as to process continuous speech data for voice-based classification of VCDs.

VII. ACKNOWLEDGEMENTS

We would like to thank the National Science and Technology Council of Taiwan for supporting this research under grant No. 109-2221-E-007-094-MY3.

Detecting the Underwater Distance and Swimming Direction of Tilapia using YOLO

Yi-Zeng Hsieh*, Chia-Hsuan Wu and Cheng-Hou Chou
Department of Electrical Engineering, National Taiwan University of Science and Technology Taipei City, Taiwan

yzhsieh@mail.ntust.edu.tw

Abstract— **The article introduces a groundbreaking system designed to revolutionize underwater operations involving the recognition of tilapia fish by underwater unmanned vehicles (UUVs). This innovative technology aims to replace the traditional method of employing human divers, offering a safer and more cost-effective approach to underwater tasks. By harnessing the capabilities of YOLOv3, this system achieves real-time image recognition, enabling the determination of both the distance and direction of tilapia fish with remarkable speed and accuracy.**

Keywords—machine learning, deep learning, underwater technology

I. INTRODUCTION

According to statistics from the Fisheries Agency, the number of people employed in Taiwan's fishing industry in 2018 was 325,940, accounting for approximately 2.86% of the total employed population in Taiwan. The number of employees in Taiwan's fishing industry has been decreasing year by year, and there has already been a shortage of front-line fishing workers. In addition, with the global population increasing and per capita consumption of aquatic products on the rise, the fishing industry is facing serious challenges. Taiwan's total catch has only reached 1 million tons. Despite continuous technological advancements in fishing, production levels have not been able to increase, leading to the vicious cycle of overfishing in global fishing industries. Therefore, many countries have turned to aquaculture as a source of seafood, and Taiwan's aquaculture is largely based on manual methods. To address these problems, the academic and industrial sectors of various countries have begun to develop various intelligent aquaculture systems. For example, the Internet of Things (IoT) can be applied to environmental monitoring in aquaculture, with sensors collecting environmental data and transmitting it to servers to provide users with real-time information.

Automatic feeding can also be achieved through algorithms, reducing inter-fish competition and food waste. This not only lowers costs but also helps to improve water quality and avoid turbidity. With the rapid growth of hardware, high-performance GPUs can be used to execute complex calculations in real-time, driving the further development of machine learning. Therefore, some researchers have proposed using Recurrent Neural Networks (RNN) to identify abnormal behavior in fish. Currently, research on intelligent aquaculture mainly focuses on environmental monitoring and automatic feeding, with little related to underwater operations. In Taiwan, underwater operations are mostly carried out by divers, so this paper proposes using a Remotely Operated Vehicle (ROV) to replace divers for underwater work. The focus of this paper is on identifying the distance and swimming direction of the Tilapia fish based on YOLO recognition. Tilapia is an important cultured fish species in Taiwan, with a production of 63,329 tons in 2017, ranking first in Taiwan's aquaculture and covering an area of approximately 4,052 hectares, second only to sea bass.

Underwater operations have long relied on human divers to perform essential tasks such as fish monitoring, maintenance, and data collection. However, these operations come with inherent risks and significant costs associated with deploying divers and vessels. This article addresses these challenges by introducing a novel system that employs advanced computer vision technology to recognize tilapia fish, one of Taiwan's most important cultured fish species, and their precise locations. The primary objective is to develop a cost-effective and safe alternative to traditional underwater personnel and vessels.

The research highlights several key points regarding Taiwan's fishing industry and the challenges it faces. Here are five potential contributions that can be made based on the information provided:

1.Development of Intelligent Aquaculture Systems: One significant contribution can be the development and implementation of intelligent aquaculture systems in Taiwan. Drawing inspiration from global efforts, Taiwan can invest in research and technology to create advanced systems that incorporate IoT, algorithms for automatic feeding, and real-time data analysis. These systems can help optimize production, reduce costs, and promote sustainable aquaculture practices.

2.Sustainable Aquaculture Practices: Given the dwindling number of front-line fishing workers and concerns about overfishing, Taiwan can focus on sustainable aquaculture practices. By embracing technological advancements, Taiwan can contribute to global efforts in responsible seafood production, ensuring that its aquatic resources are utilized efficiently and with minimal environmental impact.

3. Application of Machine Learning in Aquaculture: Taiwan can make strides in the application of machine learning, such as Recurrent Neural Networks (RNN), to identify abnormal behavior in fish. By developing and deploying AI-powered systems for fish behavior analysis, Taiwan can enhance fish health monitoring and management, ultimately leading to improved production and resource conservation.

4. ROV-Based Underwater Operations: Introducing Remotely Operated Vehicles (ROVs) for underwater operations in Taiwan's aquaculture industry can be a significant advancement. ROVs can replace human divers for tasks such as fish monitoring and maintenance, making underwater operations safer, more efficient, and cost-effective. This transition can contribute to the safety and well-being of workers in the industry.

5. Tilapia Fish Farming Enhancement: Focusing on the specific case of Tilapia fish, Taiwan can lead research and innovation to optimize its production. By utilizing YOLO

XXX-X-XXXX-XXXX-X/XX/$XX.00 ©20XX IEEE

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

recognition technology to identify the distance and swimming direction of Tilapia fish, the industry can improve farming techniques, reduce waste, and enhance the overall quality of Tilapia production. This approach can serve as a model for other fish species in Taiwan's aquaculture sector.

In summary, Taiwan has the opportunity to play a pivotal role in the development of intelligent and sustainable aquaculture practices, benefiting both its economy and the global seafood industry. By embracing cutting-edge technology and innovative approaches, Taiwan can contribute to the long-term health and viability of its fishing and aquaculture sectors.

II. Related works

With the advent of the deep learning era, deep image analysis has become a popular topic of discussion. Since 1949, the first step towards machine learning was opened by the mechanism of neural psychology-based learning, but machine learning algorithms require a large number of iterations to produce training results, require a lot of computing power, and have a high dependence on hardware devices. In the early stages of machine learning development, the efficiency was relatively high in cost.

However, with the rapid growth of computer hardware in recent years, the computing power of computers has significantly improved, which has led to the flourishing development of neural network technology and has been once again promoted by many scholars. The architecture of computer vision systems has become increasingly sophisticated, and with the improvement of deep perception capabilities, images can further enhance recognition accuracy, making it a key technology for deep image analysis in recent years. With the improvement of hardware, many scholars have applied deep learning to an important issue in computer vision, object recognition.

[1] Using the Selective Search algorithm, the input image generates 2,000 to 3,000 candidate regions, then extracts the features of the candidate regions through Convolutional neural network (CNN), inputs the features into SVM (Support Vector Machine) for classification, and finally adjusts the bounding box through a linear regression model. [2] Improved R-CNN, in which traditional R-CNN extracts features for each candidate region, while fast R-CNN produces a feature map after passing through Convolution layer and Max Pooling. Then, it extracts the feature vector from the feature map through RoI Pooling, and finally sends the feature vector into the fully connected layer, and is divided into two outputs, one for classification using softmax and the other for adjusting the bounding box using a regression model. Both R-CNN and fast R-CNN need to generate candidate regions through the Selective Search algorithm, while [3] proposes faster R-CNN, which does not need to generate candidate regions in advance. Instead, the image is input and passed through the Convolution layer to generate a feature map. Then, the feature map is input into RPN (Region Proposal Network), whose output is the bounding box and the probability of the bounding box containing an object, and then through RoI Pooling similar to fast R-CNN, each region is classified, and the precise bounding box is found.

The key research problem highlighted in these sentences revolves around the efficiency and accuracy of object detection algorithms, particularly in the context of computer vision and image processing. Specifically, the sentences discuss various approaches to object detection, and the problem can be summarized as follows:

Improving Object Detection Efficiency and Accuracy: The central research problem is to enhance the efficiency and accuracy of object detection in images. Traditional methods like Selective Search generate a large number of candidate regions, which can be computationally expensive and may lead to inefficiencies. The challenge is to develop methods that can accurately detect objects while minimizing the number of candidate regions generated, thus improving computational efficiency.

The evolution of object detection algorithms, from R-CNN to fast R-CNN and finally to faster R-CNN, highlights the ongoing effort to address this problem. The goal is to extract meaningful features from images and efficiently classify and locate objects within them, ultimately reducing the reliance on time-consuming candidate region generation processes like Selective Search. Faster R-CNN, in particular, represents an attempt to eliminate the need for pre-generated candidate regions altogether, which is a significant step towards more efficient and accurate object detection.

III. Method

This article develops a system that recognizes the distance and direction of tilapia fish captured by underwater unmanned vehicles (UUVs) to replace divers for underwater operations, thus avoiding danger and reducing the cost of employing underwater personnel and vessels. YOLOv3 is

used for the development of the model, and its fast characteristics enable real-time recognition of images captured by the UUV and the determination of the distance and direction of the tilapia fish. The main research methods are divided into: (1) UUV device body; (2) data set collection; and (3) tilapia fish direction and distance model training.

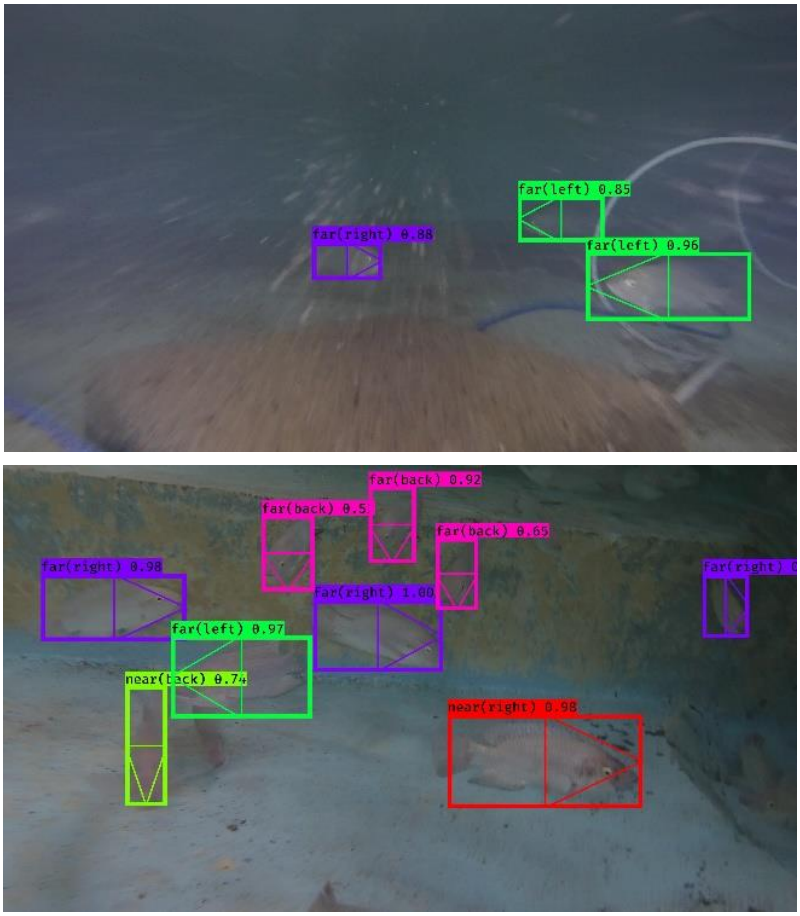

Fig.1 Experiment results

- UUV Device Body Development: The first phase involves the creation and optimization of the UUV device itself. This encompasses the selection of appropriate hardware and software components, ensuring that the UUV is equipped to capture high-quality underwater images and transmit data in real-time.
- Data Set Collection: To train the recognition model effectively, a comprehensive dataset of underwater images containing tilapia fish in various orientations and distances is collected. This dataset forms the foundation for the system's machine learning capabilities, allowing it to recognize and differentiate between different fish positions and distances.
- Tilapia Fish Direction and Distance Model Training: The core of the system's functionality lies in its ability to accurately determine the direction and distance of tilapia fish. This is achieved through the training of a sophisticated machine learning model, powered by YOLOv3. YOLOv3's speed and accuracy make it an ideal choice for real-time image recognition. The model is trained to identify tilapia fish within the collected dataset and provide precise information about their locations relative to the UUV.

A. UUV Device Body

To be able to move quickly and flexibly in the water, a flexible ROV, the Power Ray from Power Vision, was chosen as it has excellent maneuverability and low power consumption, with a working time of up to 4 hours underwater. It can completely replace underwater workers for long-term underwater work, making it the most suitable UUV for this system.

B. Data Set Collection

The dataset used in this article is composed of tilapia fish images captured by the ROV, in the breeding grounds of tilapia fish at the Gongliao Aquatic Research and Conservation Center shown in Fig.1. The video captured by the ROV was cut into photos, and some of the photos were either blurry or without fish, making them unsuitable. Therefore, there are about 5000 tilapia fish images, and labeling was used to mark the distance and direction of the fish in the images.

C. Tilapia Fish Direction and Distance Model Training

To be able to recognize the direction and distance of tilapia fish in real time, YOLOv3 was chosen as the prediction algorithm, which has top performance in terms of accuracy and time. This deep learning network can be divided into two parts: Darknet-53, which is the main architecture for feature extraction, and the YOLO layer architecture, which allows YOLOv3 to predict at multiple scales.

1) Darknet-53

This is the first to seventy-fifth layer of the entire YOLOv3 architecture, with a total of 53 convolution layers and the rest are residual layers shown in Fig.2. The network is mainly composed of a series of 11 and 33 convolutional layers, and its performance is better than resnet-101 and its efficiency is 1.5 times that of resnet-101. Compared with resnet-152, the effect is not much different, but the efficiency is twice as much.

2) YOLO Layer Architecture

It is divided into three scales: small YOLO layer (13*13), medium YOLO layer (26*26), and large YOLO layer (52*52), which produce different feature maps at each scale. Then, the feature maps of different scales are merged with filters of different sizes (3*3 and 1*1), and the final output feature map has a depth of 39 shown in Fig.3. [4] Mentions that the use of anchor boxes can effectively help with object detection, and they used K-Means to obtain 9 sets of anchor boxes. However, these 9 sets of anchor boxes such as (137,163), (192,294), (250,118), (329,148), (342,355), (437,200), (568,592), (594,258), (905,363), are not suitable for our own dataset, so we used K-Means for our dataset to obtain anchor boxes that are more suitable for our purposes.

IV. Experiment Result

At the beginning of the experiment, the video or photo of tilapia captured by the ROV can be inputted into the YOLO model that has completed training, and the final output judgment results can be obtained as shown in the figure 1. It can be seen from the figure 1 that the recognition ability of the model trained in this article is good and the accuracy is high when the object being recognized is not obstructed. However, if the object is obstructed, the model will not be able to recognize its swimming direction smoothly. In terms of recognition of distance, there is a problem of simultaneously recognizing both far and close objects in the middle distance. In order to quickly and intuitively determine the swimming direction, we also added arrows pointing to the direction of movement in the recognition results. Applying this system to aquaculture systems can reduce the cost of underwater personnel and avoid dangerous situations. With this system, tilapia swimming direction can be quickly determined from shore.

The developed system represents a significant advancement in underwater operations and aquaculture management. By replacing human divers with UUVs equipped with YOLOv3-based recognition capabilities, the system enhances safety by eliminating the risks associated with underwater personnel. Additionally, it offers substantial cost savings by reducing the need for expensive vessels and diver employment.

V. Conclusion:

This paper introduces an innovative system that leverages YOLOv3 technology to revolutionize underwater operations, particularly in the context of tilapia fish recognition. The combination of advanced hardware, comprehensive dataset collection, and machine learning model training yields a solution that significantly enhances safety and reduces costs in underwater tasks. The potential applications extend beyond tilapia fish recognition, offering a versatile approach to various underwater operations and aquatic resource management challenges. This technology represents a pivotal step towards the future of efficient and cost-effective underwater operations.

Acknowledgment

Abstract — **Thermal imaging has gained significant use in recent years, particularly during the epidemic, including its application in architecture for damage detection on archaeological monuments through high-temperature analysis. The non-invasive nature of thermal imaging, along with its ability to visualize temperature levels, allows for problem identification while preserving the building's structure. The integration of artificial intelligence further enhances its potential applications. This study aims to propose an automated inspection system using a convolutional neural network (CNN) for analyzing materials in high-temperature floor blocks. Data for this study are provided by the Bureau of Cultural Heritage, Ministry of Culture (BOCH), Republic of China (Taiwan). In addition, a professor with more than seven years of experience in monument maintenance is responsible for assisting in the identification of overheated data and collecting thermal images of the floor. Analyzing materials at elevated temperatures for restoration purposes offers several benefits: efficient identification of problematic materials, identification of materials suitable for specific environmental conditions through high-temperature analysis, and determining the sequence of temperature variations among different materials to aid in restoration planning. The identification accuracy rate of this study is as high as 92.1%. Compared with the speed of 3600s for professionals to identify 100, this research only needs 3s. The efficiency is increased by about 99.91, which is an amazing improvement. These functions increase the practicality of restoration efforts, improve restoration quality and efficiency, and contribute to academic research on ancient monument preservation.**

I. INTRODUCTION

Thermal imaging has emerged as a crucial tool in various fields, including architecture and archaeological research. By capturing the thermal radiation energy emitted by objects, thermal images provide valuable insights into temperature distributions and thermal properties. These images convert thermal energy into two-dimensional temperature data, with colors representing different temperature levels. The non-invasive nature of thermal imaging makes it particularly suitable for architectural inspections, allowing for the identification of potential issues while preserving the integrity of the structure. Similarly, in archaeological research, thermal imaging aids in locating damage and understanding the thermal characteristics of ancient monuments.

In a related study highlighted in [3], a similar approach was employed to assess and repair bridge concrete using thermal images. Abnormal temperature distributions detected in the thermal images were indicative of damaged areas, leading to successful bridge repair. With an accuracy of 80% as reported in the literature, the technique demonstrated the potential of abnormal temperature distribution analysis in thermal images for guiding repairs. Applying a similar approach to identify potential damage and mark out vulnerable areas in ancient site sheet metal can greatly contribute to restoration efforts by

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

providing valuable insights into the condition of the site. To specifically address the analysis of floor materials, the project focuses on processing the thermal images to remove non-objective objects that could interfere with an accurate analysis. Drawing inspiration from the powerful CNN technique mentioned in [4], which has proven successful in various applications such as medicine and face recognition, the project leverages CNN's capabilities in image recognition and target identification through feature extraction. The CNN architecture allows for the extraction of relevant features from thermal images, enabling the identification and classification of materials based on their thermal characteristics.

However, retraining the CNN model from scratch can be time-consuming. To enhance execution efficiency, the project adopts a strategy known as migration learning, as outlined in [5]. This approach involves training the AlexNet CNN model, a widely used architecture, by adapting the pre-trained model to the specific requirements of the project. By modifying specific link layers, adjusting the number of recognition types, and providing extensive training and validation datasets, the project achieves optimal performance while reducing the training time and computational resources required. The results reported in the literature further validate the effectiveness of migration learning, with recognition accuracy reaching an impressive 99% and demonstrating the versatility of the approach in creating different models with varying training sets and parameter configurations. In this research, the trained AlexNet CNN model is employed to identify materials on demand. By accurately identifying and quantifying the percentage of vulnerable materials, maintenance methods can be appropriately planned and executed, ensuring the longevity and preservation of the architectural elements. Furthermore, the analysis of suitable materials based on their thermal characteristics adds valuable insights to the restoration process, enabling informed decisions regarding material selection and facilitating the restoration of ancient monuments to their original splendor.

In summary, thermal imaging offers unparalleled visibility and non-invasiveness, making it an invaluable tool for architectural inspections and archaeological research. By adopting a similar approach to the assessment of bridge concrete, the project aims to explore the potential damage in ancient site sheet metal using thermal imaging techniques. Leveraging the power of CNN and migration learning, the project seeks to develop an automated system capable of accurately identifying and quantifying vulnerable materials. This information will assist in the planning of restoration methods and the analysis of suitable materials, ultimately enhancing the quality and efficiency of restoration efforts.

II. Methods

This research aims to leverage artificial intelligence to rapidly detect high-temperature areas in thermal images of historic sites, enabling professionals to promptly assess the condition of the sites and identify areas in need of repair. Furthermore, this technology can serve as a preventive measure by identifying excessively smooth areas that may pose safety risks. The research encompasses three main components: image processing, image segmentation, and CNN recognition. The flow chart illustrating the research process is depicted in Fig. 1.

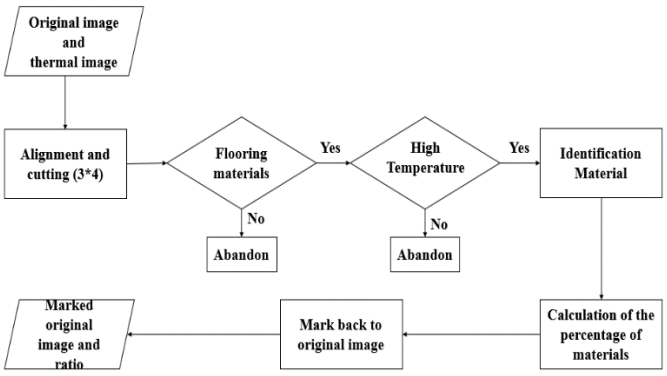

Fig. 1 This research process.

A. Image proofreading

To ensure a seamless alignment between the vulnerable regions identified in the thermal image and the corresponding areas in the original image, it is crucial to crop both images to the same dimensions. This process involves centering the images and removing any excess portions, as illustrated in Fig. 2 and Fig. 3.

In the first step, shown in Fig. 2, the centers of the thermal image and the original image are aligned. This alignment establishes a common reference point for subsequent analysis and marking of the vulnerable areas. By centering the images, we ensure accurate mapping and facilitate the integration of the thermal image's findings with the original image. Once the centers are aligned, the excess parts of both images are cropped, as depicted in Fig. 3. This cropping procedure ensures that both images share the same size and removes any unnecessary areas. The resulting images can then be seamlessly combined, enabling a smooth and accurate representation of the vulnerable regions within the context of the original image.

By implementing this cropping technique, the research aims to enhance the visual coherence and precision in marking the vulnerable parts of the thermal image onto the corresponding areas in the original image, aiding in the assessment and evaluation of the site's condition.

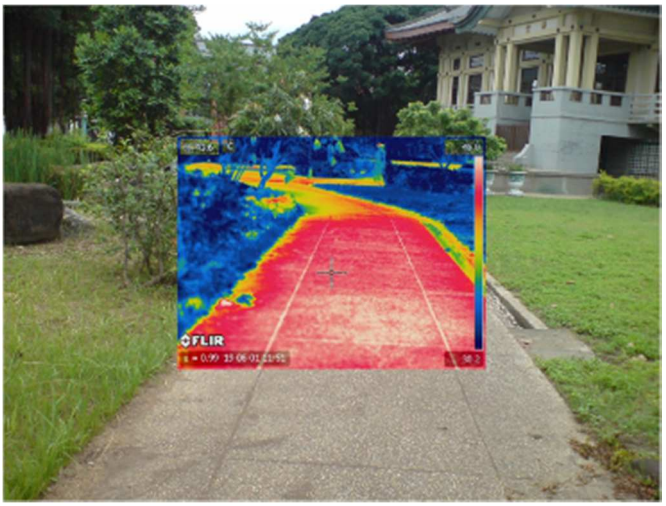

Fig. 2 Center Point Alignment

Fig. 3 Cutting results.

B. Image cutting

Since the floor block street is located in the lower half of the image, this study decided to divide the raw and thermal images into 12 smaller images to form a grid of 3 rows and 4 columns, which can effectively help to identify the high temperature status of the floor area later.

In addition to this by splitting the images into smaller ones, a more detailed and comprehensive dataset can be generated to train the model and improve the drawback of the study itself which has not many sources of images. And the increased amount of data enables more robust and accurate thermal pattern analysis and helps to identify weak regions. Fig. 4 and Fig. 5 visually show the 12 small images resulting from the segmentation of the original and thermal images. Each image represents a different region of interest in the whole image, enabling a more refined analysis.

The aim of the total study is to improve the accuracy of the analysis by utilizing the enhanced dataset obtained from the segmented images. This will improve the ability to identify and assess vulnerable areas within historic sites based on thermal imaging data.

Fig. 4 The original picture is cut into 3*4 sheets.

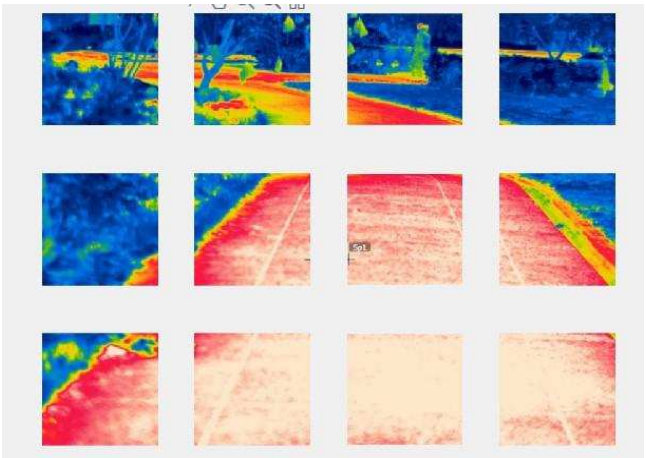

Fig. 5 Thermal image cut into 3*4 sheets.

C. Defining model recognition objects and training sets.

The CNNs for material identification are designed based on the functional requirements, specifically targeting four materials: standard brick, asphalt, red brick, and concrete. RGB images of these materials are classified and organized into a training set.

Fig. 6 visually presents the arrangement of the training set, where the identified materials are categorized and stored for training the CNNs. This process enables the networks to learn the distinctive features and characteristics of each material, facilitating accurate material identification in subsequent analysis. By tailoring the CNNs to address these specific materials and leveraging a well-structured training set, this research aims to enhance the precision and reliability of material recognition. This approach contributes to the

advancement of robust techniques for material identification and analysis within the context of historic sites, providing valuable insights for conservation and restoration efforts.

standard brick | asphalt | red brick | concrete

Fig.6 Four types of identification materials.

D. CNN Object Recognition Training

The training process for the AlexNet model is conducted using MATLAB's integrated deep learning network program. The material-aware floor model is represented by four distinct types, which are inputted into the program's Data section after completion. To augment the dataset and enhance training accuracy, various techniques are employed, such as rotating the images within the training set and adjusting the parameters in the training block. Through several iterations and experimentation, the optimal training parameters have been determined, as outlined in Table I and Table II. These parameter adjustments play a crucial role in fine-tuning the training process and improving the overall accuracy of the model. By systematically refining the training parameters, the research endeavors to optimize the performance of the AlexNet model and ensure its effectiveness in material recognition and analysis. The utilization of MATLAB's deep learning network program and the systematic parameter adjustments contribute to the robustness and reliability of the training process, enhancing the model's ability to accurately identify materials in the context of the floor analysis.

Table I. Rotation parameters of x-axis

	Min	Max
Random rotation	-90	90
Random rescaling	1	2

Table II. Training Parameters

InitialLearnRate	0.0001
ValidationFrequency	4
MaxEpochs	8
MiniBatchSize	10

E. Mark back to the original image

(i). Calculation method and encoding

The corrected image will be saved as 640*480 pixels and then each small piece of the image will be cut equally into 160*160 pixels. The method is described as follows, take the coordinates x=0 and y=0 of the upper left corner of the image as the starting point, increase x to the right, increase y to the bottom, divide the length (x direction) into four equal parts, divide the width (y direction) into three equal parts, and the cutting points in the x direction are x=160, x=320, and x=480, and the cutting points in the y direction are y=160, and y=320. In order to find the cutting images that are the same symptom as that in the original image, it is necessary to number the cutting images. of the cut pictures, the cut pictures need to be numbered. Based on the number of images entered, the cuts are named alphabetically, and then cut into 3*4 images, numbered from top left to bottom right as 1 to 12. Finally, the code can be used to retrieve the location from the thermal image that corresponds to the original image.

(ii). Matching the thermal image to the original map

By applying the established coding methodology, the blocks identified in the thermal image are accurately matched back to their corresponding locations on the original map. The matching process enables the precise localization of high-temperature symptomatic areas. These identified blocks are visually highlighted by encircling them with bounding boxes, providing a clear visual representation of the regions exhibiting elevated temperature symptoms. This visual marking aids in distinguishing and analyzing the areas that require attention and potential restoration interventions. The systematic matching of the thermal image to the original map, along with the prominent highlighting of selected blocks, facilitates effective analysis and assessment of high-temperature phenomena within the floor structure.

F. Calculated Material Share

In this study, the material composition analysis involves calculating the percentage of each material within the high-temperature area. This calculation is performed by considering the total number of sheets identified as high temperature as the denominator. The numerator represents the number of sheets of each material detected within the high temperature area using the material Convolutional Neural Network (CNN). To obtain the percentage of each material, the numerator is divided by the denominator and then multiplied by 100, as shown in

$$\frac{(Total\ number\ of\ sheets\ of\ material)}{(Total\ number\ of\ sheets\ of\ high\ temperature\ material)} * 100\%. \quad (1)$$

This approach allows for a quantitative analysis of the distribution and prevalence of different materials within the regions exhibiting elevated temperatures. By calculating the percentage of each material, valuable insights can be derived regarding the material makeup and its relative contribution to the high-temperature areas. Such information is crucial for understanding the composition of the structure, identifying potential material-related issues, and facilitating appropriate maintenance and preservation strategies.

III. Result

A. CNN Accuracy

For the training phase of the material identification model, a comprehensive dataset comprising 1531 material images was employed. This dataset was divided into a training set, consisting of 1072 images, and a validation set, consisting of 459 images. The distribution of training sessions for each item is outlined in Table III, highlighting the number of iterations dedicated to each material during the training process.

In order to assess the performance of the trained models, confusion matrix analysis was used to measure the final accuracy, the confusion matrix will provide a detailed breakdown of the predictive accuracy of the models, enabling a comprehensive assessment of the effectiveness of the various models applied in this study. The four functions that make up the confusion matrix are TP (correctly predicted successful samples), TN (correctly predicted successful negative samples), FP (incorrectly predicted negative samples), and FN (incorrectly predicted negative samples), and the accuracy rate is calculated from these four elements, as shown in

$$Accuracy = \frac{TP + TN}{TP + FP + FN + TN}. \quad (2)$$

As shown in Tables IV and V, the accuracy of the model in recognizing various categories calculated by (2) reaches more than 89%, where the overall accuracy of the model as a whole, also calculated by (2), reaches an impressive 92.1%.The confusion matrix provides a detailed breakdown of the model's predictive accuracy, enabling a comprehensive assessment of its effectiveness in correctly identifying different materials within the thermal images. The high accuracy rate obtained by the model demonstrates its robustness and reliability in accurately recognizing and classifying materials based on their thermal signatures. This result signifies the effectiveness of the training process and the successful adaptation of the Convolutional Neural Network model to the specific requirements of material identification in the context of this study.

B. Research Results

The output of the analysis produces two images: the first image overlays boxes on the original image to highlight areas exhibiting high temperature symptoms, while the second image presents the corresponding thermal image. Fig.7. showcases the corresponding thermal image obtained from the analysis.

The analysis also provides information regarding the distribution of materials within the high temperature areas. The upper column of the output image displays the percentage of each material present in the identified high temperature region.

Notably, the results depicted in Fig.7 indicate that red brick displays the highest vulnerability in the given environment. Following red brick, standard brick exhibits a lesser degree of vulnerability, and finally, the concrete material demonstrates the least susceptibility to high temperature effects. By identifying the most vulnerable materials, such as red brick, appropriate maintenance and preservation strategies can be developed to mitigate potential risks and ensure the longevity of historic sites. The findings the significance of utilizing thermal imaging and material identification techniques to prioritize areas in need of attention and implement targeted interventions to safeguard vulnerable materials.

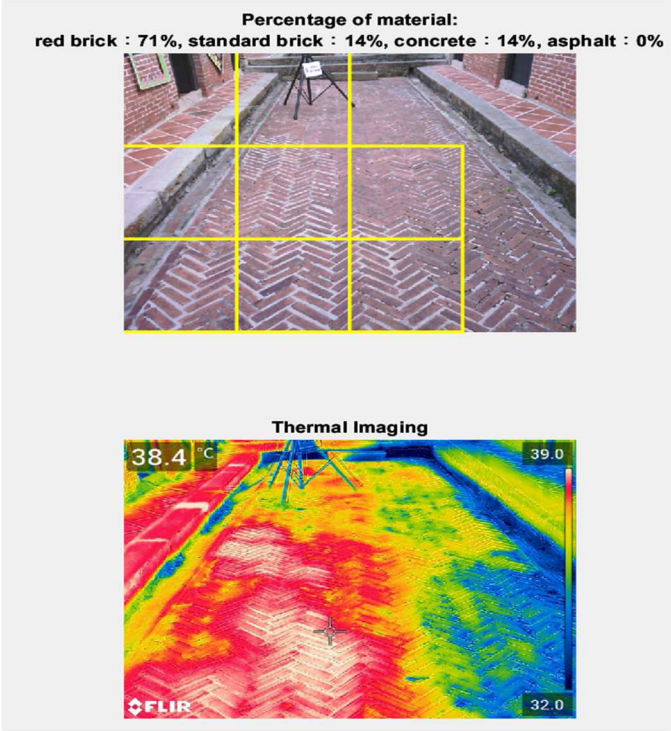

Fig.7 The actual use of the results of this study

In addition, the results of this study were compared with the results of human identification in terms of time and accuracy in recognizing 100 images, with the assistance of a professor with more than seven years of experience in monument maintenance. The results revealed that while manual recognition achieved a slightly higher accuracy rate of approximately 3%, the proposed method demonstrated a remarkable improvement in speed, requiring only 3 seconds to recognize the entire set of images. This represents an impressive enhancement of approximately 99.16%. The experimental findings indicate that the proposed approach significantly contributes to time-saving and enhances overall work efficiency, as illustrated in Table VI.

IV. CONCLUSIONS

This research has highlighted the impact of rising temperatures on historical sites and emphasized the importance of proactive measures to mitigate damage. The study focused on detecting high-temperature areas within floor materials, specifically red bricks, concrete floor tiles, asphalt, and square bricks. The research also underscored the significance of efficient material identification and analysis for selecting suitable materials in varying environmental conditions, aiding restoration efforts. Additionally, it is worth noting that the research achieved a remarkable recognition accuracy rate of 92.1%. This high level of accuracy signifies significant success in accurately identifying and classifying materials based on their response to high temperatures. The achieved accuracy rate demonstrates the effectiveness of the developed methodology and the reliability of the material recognition system. It is worth noting that the amount of training data varies greatly, and it is easy to make mistakes in judgment. To enhance the research's comprehensiveness and reliability, future collaborations with the Cultural Affairs Bureau are planned to obtain additional samples.

Furthermore, this research extends its implications beyond historical sites. The methodology employed can be applied to other material types used in road construction, contributing to the development of resilient infrastructure. Expanding the research's scope has the potential to benefit broader contexts by addressing the challenges posed by increasing temperatures and promoting sustainable practices in construction and maintenance. Through further collaborations and research, these findings can be applied to preserve cultural heritage and foster the development of sustainable infrastructure.

ACKNOWLEDGMENT

The authors gratefully thank the Bureau of Cultural Heritage, Ministry of Culture of Taiwan for its funding and equipment support.

***Abstract* — The problem of road potholes caused by vehicle pressure, plate movement, and thermal expansion and contraction must be overcome for road safety and comfortable driving. Many experts have proposed solutions to this problem, including image analysis, sensors that can detect vibrations caused by potholes, and other tactics. Deep learning (DL) has been utilized widely in several sectors in recent years, including object identification, which can be used to find potholes in the road. In order to preprocess the information and remove less important features, which will increase average precision (AP), this study suggests using the you only look once (YOLO) series of models in combination with data augmentation (DA) and discrete wavelet transform (DWT) features. According to experimental results, when combined with DWT and Cutout-based DA, trained using two different publicly available pothole datasets, and then objectively compared, our suggested method outperforms several other model designs in the task of pothole detection, with an improvement of 2.5% in AP. This illustrates the study's effective improvement in detection accuracy and real-time performance.**

I. INTRODUCTION

In today's society, people rely on transportation for convenience, and the traffic burden on roads is increasing. Due to the weight of moving cars and the influence of the outside climate, asphalt pavement on roadways is susceptible to developing potholes. However, the size and depth of potholes are important indications that affect drivers' safety. Severe cases might result in traffic accidents, while moderate ones can cause passengers' discomfort. When a pothole detection system is placed in a car, it can assist drivers in assessing road conditions. This enables them to slow down or change lanes ahead of time to avoid potholes, enhancing passenger safety and comfort. Drivers must concentrate on driving while on the road, thus this study will focus on detecting potholes on the road, which informs drivers about potholes ahead.

Many research projects have proposed pothole detection solutions in recent years. Kim *et al*. [1] classified three approaches to road pothole detection: vibration-based systems, 3D reconstruction, and computer vision (CV). The authors' first method, vibration-based systems, uses sensors [2] they designed to determine whether a vehicle has driven over a pothole. Its benefits include the fact that it does not require a big quantity of data storage and is cost-effective. However, there are three major disadvantages. For instance, because the sensors are attached to the vehicle, they can only detect potholes when the tires contact them, limiting the detection range. Second, the large vibrations that trigger the sensors can be generated by anything from potholes to road gaps or manhole covers, resulting in false positives. The second method relies on 3D reconstruction. According to [3], the authors employed a 3D laser scanning system to detect the state of road potholes. The device emits and absorbs reflections from an invisible light spectrum in order to reconstruct a 3D image known as a point cloud. In Fig. 1, the point cloud contains information such as distances on the *x*, *y*, and *z* axes, and the scanning speed is 5000 points per second with a 360° x 60° field of view. Drivers can use the point cloud data to detect road potholes through analysis and aggregation. Although this method gives excellent accuracy, high-precision laser scanning equipment can be quite expensive. The third method is to detect potholes using CV. For pothole identification, Rahman *et al*. [4] proposed utilizing the single shot multibox detector (SSD) [5], a deep learning (DL) technique. To achieve lightweight implementation, they replaced the VGG16 design in the front end with the MobileNet architecture [6], as shown in Fig. 2.

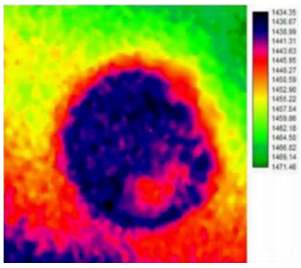

Figure 1. Pothole heatmap [3].

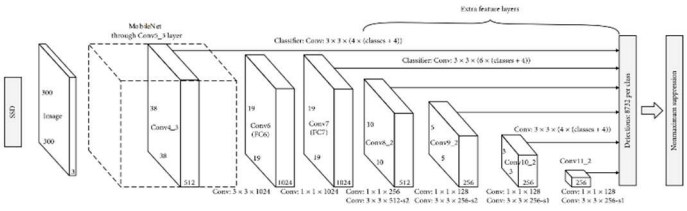

Figure 2. SSD MobileNet model architecture [5].

According to Bochkovskiy *et al*. [7] on you only look once (YOLO)v4, as shown in Fig. 3, the backbone portion is used for feature extraction. The neck portion is utilized to collect features from several scales, while the head portion is used for localization and categorization. Object identification algorithms can be classified as two-stage (such as R-CNN) or one-stage (such as YOLO and SSD). The primary distinction between the two is that two-stage algorithms select region proposals and then perform feature extraction and classification on those regions. One-stage approaches, on the other hand, perform both localization and classification at the same time. Girshick *et al.* [8] suggested a region-convolutional neural network (R-CNN) object detector. First, the selective search algorithm selects 2000 candidate regions in an image. Then, on each potential region, feature extraction is conducted, and support vector machines (SVM) are utilized for classification, along with bounding box (BBox), which refine the target's position. However, R-CNN requires feature extraction for each candidate region, resulting in a longer calculation time. To address this issue, Girshick *et al*. [9] established fast R-CNN, which performs feature extraction on the input picture only once to obtain a feature map, to improve on R-CNN. Then, using fully connected layers, the candidate regions are mapped onto the feature map. The regions of interest (ROIs) in fast R-CNN are the same as those in R-CNN. The authors used ROI pooling to convert each ROI's image into a fixed-scale feature map, and Softmax was used instead of SVM for classification. Ren *et al*. [10] later combined the region proposal network (RPN) with the fast R-CNN design, resulting in faster R-CNN.

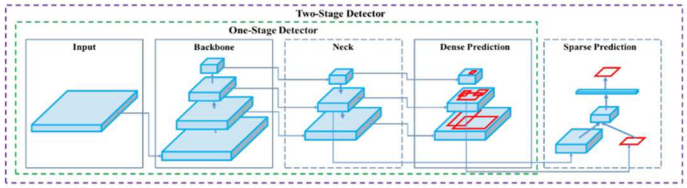

Figure 3. Object detection architecture [7].

YOLOv4 [7] promoted integrating the original backbone network with the cross stage partial network (CSPNet) [11] to form CSPDarknet53. YOLOv4 replaced the feature pyramid network (FPN) in the neck region with the path aggregation network (PAN). This combination improves network speed and accuracy while lowering hardware requirements. In contrast, YOLOv5 [13] added the focus structure to the backbone, which splits the incoming image. It employs two distinct CSPNets in the backbone and head. YOLOv5 does not require the explicit definition of anchor boxes; instead, the model learns them based on the training data. Its key advantage is that it offers four alternative sizes of training models for customers to pick from, letting them customize the network depth to their unique requirements. The smallest model, YOLOv5s, has only 27 MB of parameters, a 90% reduction in parameter count over YOLOv4. In [13], on the other hand, presented YOLOR, which describes human learning and comprehension in terms of the auditory, visual, and tactile senses, as well as learning from previous experiences. Visual and auditory information, which constitute explicit knowledge, can be grasped through regular learning. Conversely, the ability to draw conclusions and learn from the past depends on implicit knowledge or subconscious understanding. YOLOR combines explicit and implicit knowledge encoding, as seen in Fig. 4.

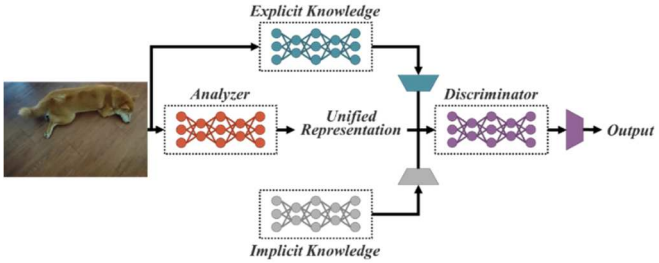

Figure 4. The integration of implicit and explicit knowledge processing [13].

SSD [5] network structures come in two sizes: SSD 300 and SSD 512. The primary distinction is the size of the input image (300x300 *vs*. 512x512), with both variants employing the VGG16 neural network for feature extraction. SSD is capable of handling multiple scales and sized feature maps. The feature maps are larger in the early shallow layers of the CNN, and pool with a stride of 2 is used in the succeeding convolutional layers to lower their size. For detection, both shallow and deep feature maps are used. It can be used to find tiny item targets

in the shallow levels of the network. When dealing with larger targets, the bounding box becomes too narrow to effectively encompass the target. As a result, in the network's deep layers, the feature maps are pooled, lowering their size while increasing the receptive field. As a result, the network can identify larger targets with more accuracy.

According to [7], YOLOv4 falls behind SSD in terms of real-time speed, although having a higher AP. YOLOv5, on the other hand, provides AP similar to YOLOv4 [14], but with improved real-time performance. Furthermore, YOLOR [15] achieves an AP of about 58% when trained on the publicly available MSCOCO dataset [16]. As a result, this study will examine the performance of YOLOv4, YOLOv5, and YOLOR as object detection algorithms in road pothole detection. The above-mentioned road pothole detection aims to address the issue of high cost. As a result, we decided to use a combination of CV and DL techniques. This research will focus on road pothole identification in this direction. Furthermore, the following issues must be addressed in this research: *1)* A real-time object detection algorithm, *2)* Image preprocessing prior to training to improve detection accuracy, and *3)* DA techniques to increase data diversity because the dataset may not cover all real-world circumstances.

II. Proposed Method

This work presents a YOLO-based object identification technique for training road potholes. The dataset is provided to DWT before training the model, and its results of applying alternative YOLO structures to the training model for road pothole identification are compared. The YOLO structure and DWT are investigated in order to improve average precision (AP). Figure 5 depicts the structure of the road pothole detecting model used in this study.

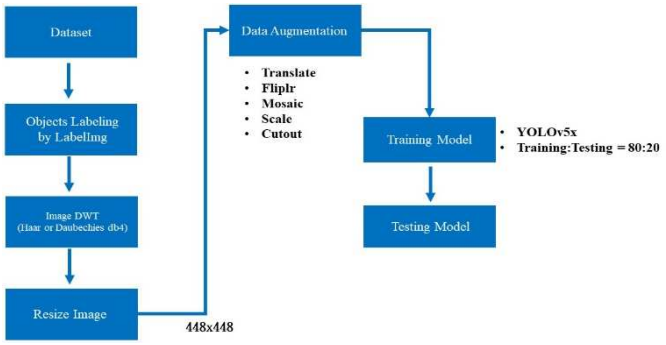

Figure 5. Road pothole detection model system.

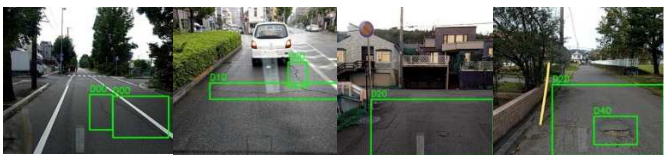

A. Data Preprocessing

We labeled the dataset using the open-source software application LabelImg [17], which allows us to save the labeled data in YOLO format to analyze the annotations. In this research, we used two public datasets: Rahman *et al*. [4] pothole dataset and Arya *et al*. [18] RDD2020 pothole dataset. The usage of these two datasets aims to highlight the model's generalization capacity. Regarding the variety of potholes, the dataset given in [4] is wide. The authors compiled it using smartphone photographs or Google searches. Figure 6 depicts the dataset distribution, which includes 532 photos for training and 133 images for validation. The RDD2020 dataset [18], on the other hand, was obtained by placing a smartphone inside a car to capture photographs from the inside looking out. Road damage is classified into four types: vertical cracks, alligator cracks, diagonal cracks, and potholes. The training set, however, is labeled, while the test set is not. As a result, we utilized only the training set in this study, which was further separated into training, validation, and test sets. In addition, we excluded all other characteristics from the dataset because our focus was on pothole detection. After organizing the dataset, the distribution is as follows: 2275 photos for training, 578 images for validation, and 218 images for testing. The training to testing data ratio is about 80:20, as shown in Fig. 7. The RDD2020 dataset excludes potholes with collected water under rainy weather. However, it contains more image examples than [6]. These two datasets' constraints complement each other, making them acceptable for comparing our model's training experiments.

Figure 7. RDD2020 Pothole Dataset [18]: (a) D00 vertical cracks; (b) D10 diagonal cracks; (c) D20 alligator cracks; (d) D40 potholes.

B. Wavelet Transform

DWT is widely used in image analysis [20-21], where the transformation separates the original image into four sub-band frequency domains: low low-band (LL-band), low high-band (LH-band), high low-band (HL-band), and high high-band

(HH-band). When CNN extract features from an image, certain regions of the image can cause a drop in recall, resulting in prediction errors in the trained model. As a result, DWT is applied to the dataset images in this study, and multiple frequency domains are kept for training the model. We conduct tests to determine which frequency domain enhances the trained models' AP. Before training or testing the object detection algorithm, the dataset is processed using DWT preprocessing to eliminate unnecessary information from the images.

DWT provides a variety of mother wavelet functions, such as Haar, Daubechies, Symlets, Coiflets, PyWavelets, and so on. For this study, we use PyWavelets, which supports 38 Daubechies functions (db1 through db38). As a result, we use Daubechies db4 [22] and Haar as wavelet functions. Different wavelet functions are applied to the dataset for DWT under the same parameter settings for the object detection technique, and the models are trained. We examine the influence of wavelet transform as a data preparation strategy on road pothole detection by comparing the AP differences between datasets without wavelet and those processed with different mother wavelet functions.

C. Data Augmentation

Road potholes have variable shapes and are influenced by external influences, making it difficult to compile a comprehensive dataset that includes all sorts or variations of potholes. To improve the learning effectiveness of DL models, DA approaches can change the picture features in the dataset. The object identification methods employed in this study, such as YOLOv4, YOLOv5, YOLOR, and others [12,15,23], often incorporate DA by modifying parameters or disabling certain augmentation strategies. Image attributes that are effective for detecting road potholes include edges, colors, orientations, locations, textures, and more. However, capturing all of these differences in the obtained dataset is difficult. In this study, various strategies are used to enrich the gathered data [24-25] and increase the complexity of the dataset due to the irregular shape, angle-dependent changes, and influence of external influences on road potholes:

1) Scale: Image resizing while retaining original resolution. *2)* Translate: Perform horizontal or vertical image translations. *3)* Rotation: Rotate the images clockwise or counterclockwise around their axis. *4)* Mosaic: The process of creating a new image by merging four separate images. *5)* Cutout: Using a fixed-size rectangular mask to obstruct portions of an image. The first three strategies are standard DA methods that emphasize and improve the presence of useful information in a dataset. In a study [26], it was demonstrated that conducting translation or mirroring DA on training data resulted in lower error rates across multiple algorithm models tested on CIFAR-10 and CIFAR-100 datasets. This study recommends the usage of Cutout [27], a technique that randomly eliminates pixels from the original image and fills them with surrounding pixels. This strategy has been shown to be effective in lowering mistake rates. The Mosaic approach is based on Cutmix [28], as updated by the authors of the YOLOv4 [7]. Cutmix picks a section from one image at random and replaces it with the same region in another image, whereas the Mosaic approach takes four images at random from the dataset, performs region cropping, and merges them into a single image. When compared to Cutmix, using the Mosaic approach can result in improved model correctness.

D. System Design

We compare three object detection methods in this study: YOLOv4 [12], YOLOv5x [23], and YOLOR with version YOLOR-D6 [15]. We use these approaches to train models with the experimental data from [4]. For model training, the TensorFlow version of SSD MobileNetv2 is used. We compare the AP of YOLOv4, YOLOv5, and YOLOR with the YOLOR-D6 variation based on the above. Table 1 displays the model structures. After training the models with a 50% intersection over union (IoU) criterion (Table 2), the performance of all three object detection algorithms exceeds the strategy provided in [4]. Furthermore, the difference in AP between the three approaches is minor. To provide a more precise comparison, we train the models using the dataset from [18], as shown in Table 3, where YOLOv5x has higher AP values for both public datasets. As a result, we use YOLOv5x as the fundamental method for detecting road potholes in this study.

Table 1. Object detection model structure.

Models	YOLOv4	YOLOv5x	YOLOR-D6
Backbone	CSPDarknet53	CSPDarknet53	CSPDarknet53
Neck	PAN, SPP	PAN, SPPF	PAN, SPPCSP
Head	YOLOv3	YOLOv3	YOLOv4
Activation	Leaky, Linear, Mish	Leaky ReLU	Mish, Linear
Optimization	SGD	SGD	SGD
Image size	448x448	448x448	448x448
Batch size	8	8	8
Epochs	300	300	300

Table 2. Comparison of training results on dataset [4].

Detection Methods	AP50
SSD MobileNetv2	65.0%
YOLOv4	78.5%
YOLOv5x	**78.8%**

YOLOR-D6	78.7%

Table 3. Comparison of training results on dataset [18].

Detection Methods	AP50
YOLOv4	54.8%
YOLOv5x	**55.6%**
YOLOR-D6	53.0%

III. EXPERIMENTAL RESULTS

This part conducts experiments based on the research method given in Section II. The experimental findings suggest that YOLOv5x outperforms alternative object detection algorithms on two public datasets, as shown in Tables 2 and 3. The two datasets are merged and combined with DWT and DA to increase the model's generalization and AP.

A. Research Environment

To verify whether the proposed algorithm is effective when applied to two public datasets, the work utilized variant road environment data that were captured from public datasets. The experimental environment is established using an Intel Core i11-11400 CPU@2.6GHz, 32GB RAM, Microsoft Windows 10, Nvidia GeForce RTX3060 12GB for display card, SSD is 1TB, and Anaconda3-5.2.0 + Python3.6, Pytorch 1.10.1, CUDA 11.3 + CuDNN8.4.0 are chosen as the software development platform. The two datasets were combined based on the description in Section 2. Since the dataset proposed in [4] lacks a distinct test set, 67 photos with their associated annotation files were removed from the training set to produce a test set. The structure is as follows: The training set contained 465 photos, the validation set contained 133 images, and the test set contained 67 images. Lastly, the two datasets were combined, yielding the following distribution after organization: 2740 photos in the training set, 711 images in the validation set, and 285 images in the test set.

B. Research Analysis

This section discusses numerous aspects of the research analysis. Specifically, the comparison of several wavelet functions, frequency domains, and levels is shown, as well as the training results of mixed datasets employing DWT. In the experiment, Haar and Daubechies db4 wavelet functions were compared. The frequency domains taken into account include LL, HL, LH, and HH. In Table 4, the experimental results show that training the model with a first-order wavelet utilizing a two-dimensional technique gives higher detection rates than training with a second-order DWT. Furthermore, when the two DWT wavelet functions are compared, the Haar wavelet function performs better in terms of preserving the LL and LH bands in the frequency domain, resulting in a 1.2% improvement. This demonstrates that DWT can improve the learning effectiveness of the YOLOv5x model.

Table 4. Training results using a two-dimensional multi-level DWT.

Methods	Precision	Recall	AP50
YOLOv5x	68.5%	56.5%	60.3%
YOLOv5x + Haar-Based LL1、LH1	68.5%	56.2%	61.5%
YOLOv5x + Haar-Based LL1、HL1	64.8%	57.1%	59.8%
YOLOv5x + Haar-Based LL1、HH1	73.6%	53.1%	60.9%
YOLOv5x + Haar-Based LL2、LH2	69.8%	50.5%	57.4%
YOLOv5x + Haar-Based LL2、HL2	63.6%	50.9%	55.3%
YOLOv5x + Haar-Based LL2、HH2	69.8%	50.5%	57.4%
YOLOv5x + Daubechies-Based LL1、LH1	68.5%	54.9%	60.2%
YOLOv5x + Daubechies-Based LL1、HL1	62.7%	57.1%	59.4%
YOLOv5x + Daubechies-Based LL1、HH1	69.5%	54.8%	60.4%
YOLOv5x + Daubechies-Based LL2、LH2	68.1%	52.6%	58.4%
YOLOv5x + Daubechies-Based LL2、HL2	67.4%	50.3%	56.4%
YOLOv5x + Daubechies-Based LL2、HH2	67.0%	51.0%	56.7%

Table 5. Training results using a two-dimensional first-order DWT combined with DA.

Method	Precision	Recall	AP50
YOLOv5x + Cutout	68%	58.5%	62.4%
YOLOv5x + Haar-Based LL、LH + DA	71.6%	54.8%	62.8%
YOLOv5x + Haar-Based LL、HL + DA	69.7%	55.2%	60.1%
YOLOv5x + Haar-Based LL、HH + DA	63.6%	57.0%	59.6%
YOLOv5x + Daubechies-Based LL、LH + DA	70.1%	55.7%	61.7%
YOLOv5x + Daubechies-Based LL、HL + DA	70.8%	56.1%	61.9%
YOLOv5x + Daubechies-Based LL、HH + DA	68.3%	57.0%	61.2%

After conducting experiments and demonstrating that DWT processing of datasets improves the learning of the YOLOv5x model, it was observed that the model gets better learning outcomes when employing a two-dimensional first-order DWT rather than a second-order DWT. Based on the results of this experiment, the previously mentioned Cutout-based DA was implemented in YOLOv5x. Table 5 displays the outcomes produced when the two-dimensional first-order DWT was combined with Cutout. When Cutout is employed without the two-dimensional first-order DWT, the training results show a 2.1% improvement over when the Cutout is not used. The Haar wavelet function surpasses the Daubechies db4 wavelet function in retaining the LL and LH bands in the frequency domain when the two-dimensional first-order DWT and DA techniques are used. Combining Haar DWT and LH + Cutout yields a 0.4% improvement over not utilizing DWT and a 1.3% improvement over using only Haar DWT with LL and LH

bands. Based on these findings, combining DWT and DA improves the learning effectiveness of the YOLOv5x model.

IV. Conclusion

Various YOLO detection algorithms were used to detect road potholes in this study. Based on training results with two separate publicly available datasets, YOLOv5 revealed higher average precision (AP) in detection. This article is based on YOLOv5, which is a single-class classification job for detecting road potholes. It also includes the image pre-processing step, which enhances the focus structure. In addition to YOLO detection models, this study used the DA of Cutout approach and the Haar-based DWT to pre-process the dataset by maintaining the low-low and low-high bands. The experimental findings demonstrated that the proposed model in this study improved AP for road pothole identification. The suggested method has the highest AP, with a 2.5% increase over the model trained without data preprocessing, making it appropriate for road pothole identification tasks.

***Abstract*—Most of the studies on one-class learning for voice spoofing detection have poor generalization ability for unknown attacks and lack flexibility for different tasks. To address these problems, we propose an improved one-class softmax (IOC-Softmax) by reformulating the scale factor of one-class softmax (OC-Softmax) into two parts such that it down-weights the loss assigned to bona fide samples. Our IOC-Softmax is a novel dynamically scaled OC-Softmax, which can select different scale factors for different tasks, so that it can prevent a large number of bona fide samples from overwhelming the anti-spoofing model during training. To verify the effectiveness of the proposed IOC-Softmax, we perform numerous experiments on the ASVspoof 2019 dataset. The results show that our IOC-Softmax achieves better performance when compared with OC-Softmax.**

I. Introduction

Automatic speaker verification (ASV) is a technique that verifies the identity of the speaker by the speech information [1], which has been applied successfully to various practical scenarios, such as remote authentication. However, spoofing attacks created by text-to-speech (TTS), voice conversion (VC) and replay bring big threats to the ASV system.

To enhance the anti-spoofing ability of the ASV system, voice spoofing detection methods are investigated to detect spoofing attacks. Four ASVspoof challenges [2]–[5] have been successfully organized, which provide datasets, evaluation metrics and baselines for research on anti-deception tasks. The common anti-spoofing research centers on features and classifiers. Well-designed acoustic features have achieved good performance, such as Linear Frequency Cepstral Coefficients (LFCC) [6], constant Q transform (CQT) [7], etc. Gaussian Mixture Model (GMM) [8]–[10] and deep neural network-based classifiers [11]–[14] are the mainstream back-end classifiers. Other efforts have investigated the data augmentation [15], feature fusion [16] and other training strategies to improve the detectability of the anti-spoofing model. Ge et al. [17] employed the LFCC as the front-end feature, and explored a differentiable architecture search method to detect spoofing attacks. Li et al. [18] introduced channel-wise gating into Res2Net to reduce the redundant information.

Although great progress has been achieved, the generalization ability of existing efforts to unknown attacks is not satisfactory. One possible reason is that most anti-spoofing efforts are considered to be the binary classification problem, which assumes that test data and training data have similar data distributions for the same class. However, in the actual application, with the rapid development of TTS and VC technologies, the data distribution of the training set is difficult to catch up with the expansion of test data.

To this end, a potential direction for improving generalization ability is one-class learning. Villalba et al. [19] presented a one-class SVM to fit the distribution of bona fide speech, but the feature space is still obtained by the form of binary classification. Zhang et al. [13] proposed the OC-Softmax for synthetic voice spoofing detection, which builds the feature space by employing two margins for genuine and spoofed speech. Lou et al. [20] used OC-Softmax to model the bona fide samples for replay attack detection, and designed the residual variability block to reduce the variance of bona fide embedding space.

Although OC-Softmax has improved the detection ability of the anti-spoofing model, it still has the following two problems: first, the generalization ability is still unsatisfactory, and second, the flexibility to different tasks is insufficient. We discover that the scale factor in OC-Softmax is the central cause, which causes genuine samples to overwhelm the training of the model. Specifically, when real speech and fake speech are classified correctly, the loss value contributed by genuine speech is much greater than that of spoofed speech. And the genuine speech is compact enough around the weight center, it is difficult to further reduce its loss. Therefore, in the process of training, the model can only further force the spoofing speech to converge in the opposite direction of the weight vector to reduce the total loss. However, the aggregation of spoofing speech will lead to poor generalization ability. To overcome the above problems, this paper proposes an improved OC-Softmax, named IOC-Softmax. Our method reformulates the scale factor of OC-Softmax into two parts, one tailored for genuine speech and the other tailored for spoofing speech. These two scale factors enhance the generalization ability of the anti-spoofing model and the flexibility of one-class learning by adjusting the loss values contributed by genuine samples

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

and spoofed samples.

The main contributions are as follows:

- We empirically investigate and analyze the effects of the scale factor.
- We propose an improved one-class softmax (IOC-Softmax) by reshaping the scale factor into two parts to improve generalization ability of anti-spoofing model and flexibility for different tasks.
- Comprehensive experiments are carried out on both the LA and PA scenarios of the ASVspoof 2019 dataset to demonstrate the advantage of the proposed IOC-Softmax.

II. Method

A. Preliminary: One-class learning loss function

The original one-class learning loss function [13] can be defined as

$$L_{OC} = \frac{1}{M}\sum_{i=1}^{M}\log(1+e^{s(m_{y_i}-\hat{w}_0\cdot\hat{x}_i)(-1)^{y_i}}), \qquad (1)$$

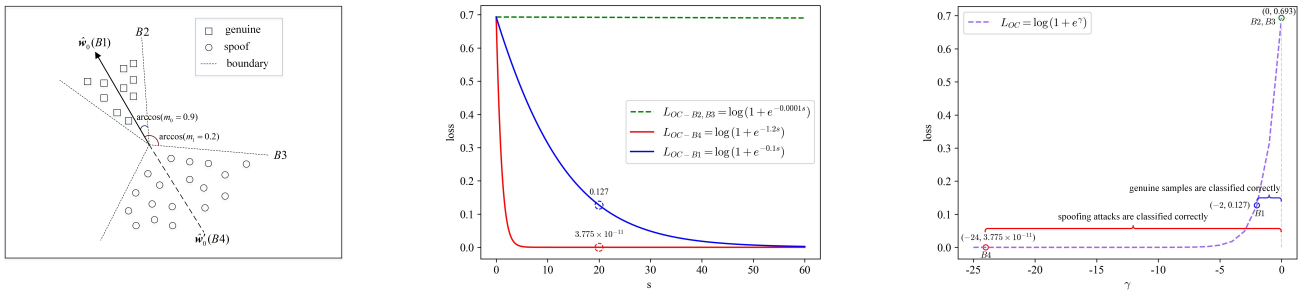
where M is batch size. s is the scale factor. $\hat{w}_0$ is a normalized weight vector, and it represents the optimization direction of real samples. $\hat{x}_i \in R^D$ is the normalized feature embedding, where D is the dimension of feature embedding. In this paper, we take D as 256. y_i is the label. m_0 and m_1 are two margins used to constrain the angle α_i between $\hat{w}_0$ and $\hat{x}_i$. The range of values for m_0 and m_1 is -1 to 1, and the value of m_0 is greater than that of m_1. When the input is the genuine speech ($y_i = 0$), m_0 is used to make α_i less than $\arccos(m_0)$, and a small $\arccos(m_0)$ can make the genuine samples more compact around $\hat{w}_0$. m_1 is employed to force α_i larger than $\arccos(m_1)$ when $y_i = 1$, and a relatively large $\arccos(m_1)$ can keep the spoofing samples away from the $\hat{w}_0$.

B. Improved one-class learning

In this subsection, we first delve into the mechanism of OC-Softmax. Table I elaborates four cases described in Fig. 1(a), Fig. 1(b) and Fig. 1(c), i.e., $B1$, $B2$, $B3$ and $B4$. $\hat{w}_0\cdot\hat{x}_i$ represents the similarity of center vector $\hat{w}_0$ and speech samples $\hat{x}_i$. Fig. 1(a) is the schematic of OC-Softmax, where $B1$, $B2$, $B3$ and $B4$ are four cases discussed in Fig. 1(b) and Fig. 1(c). Fig. 1(b) describes that the value of OC-Softmax ($m_0 = 0.9, m_1 = 0.2$) varies with the scale factor s under four cases. The corresponding loss functions of these cases are L_{OC-B1}, L_{OC-B2}, L_{OC-B3} and L_{OC-B4}. We rethink OC-Softmax based on these four cases. As shown in Fig. 1(b), compared with $L_{OC-B2,B3}$, the loss values of L_{OC-B1} and L_{OC-B4} are much smaller, so the genuine samples will converge to $B1$, and the spoofed samples will converge to $B4$. For $B1$ and $B4$, when the genuine samples and the spoofed samples share the same scale factor, the loss values contributed by these two types of samples are either almost zero or very different. The former makes the embedding space of both genuine speech and spoofed speech more compact, resulting in the poor generalization ability of the model. For the latter, taking the setting $s = 20$ in OC-Softmax as an example, the loss value contributed by the genuine sample is 0.127, while the loss value contributed by the spoofed sample is 3.775×10^{-11}, which is quite different, resulting in the genuine samples overwhelming the training of the model. Further, Fig. 1(c) illustrates the loss range of OC-Softmax when genuine samples and spoofing attacks are classified correctly, where $\gamma = s(m_{y_i} - \hat{w}_0\cdot\hat{x}_i)(-1)^{y_i}$. For genuine samples, the range of γ is $[-2, 0]$ and the corresponding range of loss value is $[0.127, 0.639]$. For spoofing attacks, the range of γ is $[-24, 0]$ and the corresponding range of loss value is $[3.775 \times 10^{-11}, 0.639]$. When the genuine speech converges to $B1$, its loss value reaches the minimum, that is, 0.127. To further reduce the total loss value, the spoofing speech can only be compressed to $B4$ during the training of the model. This leads to a compact spoofing embedding space and then results in poor generalization ability of the anti-spoofing model.

In addition, genuine speech and spoofing attacks share the same scale factor, which limits the flexibility to balance two classes. For example, replay attacks on the PA scenario are produced by different acoustic and replay configurations, and the training data and testing data still have similar data distribution in essence. Synthetic samples are produced by different TTS and VC technologies, which results in the different distribution of testing data and training data. Because of the above, it is difficult to use only one scale factor to achieve universality.

To solve these problems, we reformulate the formula of OC-Softmax, called IOC-Softmax. The definition of IOC-Softmax is given as follows:



$$L_{IOC} = \frac{1}{M}\sum_{i=1}^{M}\log(1+e^{s_{y_i}(m_{y_i}-\hat{w}_0\cdot\hat{x}_i)(-1)^{y_i}}), \qquad (2)$$

where s_{y_i} is the scale factor, including two parts, i.e. s_0 tailored for genuine samples and s_1 customized for spoofing attacks. These factors control the loss values contributed by speech samples.

III. Experiments

A. Datasets

We perform all experiments on the ASVspoof 2019 dataset [21], which includes two subsets, i.e. LA scenario and PA scenario. Each scenario consists of three partitions, i.e. training set, development set and evaluation set. For brevity, we abbreviate these partitions to Train, Dev and Eval. Both LA and PA scenarios contain bona fide speech and spoofed speech. On the LA scenario, the spoofed speech is generated by representative TTS and VC algorithms. The spoofing attacks of the Trian set and the Dev set are both A01-A06 attacks, while the attack types of the Eval set are different from those of the Train and Dev sets. This results in the spoofing samples of the Eval set being unknown attacks to the model trained with the Train set. On the PA scenario, the spoofed samples are produced by 27 acoustic configurations and 9 replay configurations, and all sets share the same spoofing attack types, namely AA-CC. Table II describes this dataset in detail.

(a) (b) (c)

Fig. 1. The rethinking of OC-Softmax. (a) The schematic of OC-Softmax. (b) The loss value of OC-Softmax varies with scale factor under $B1$, $B2$, $B3$ and $B4$. (c) The loss range of OC-Softmax when genuine samples and spoofing attacks are correctly classified.

TABLE I
FOUR CASES SHOWN IN FIG. 1.

	Case	Description
$B1$	$\hat{w}_0 \cdot \hat{x}_i = 1$	genuine samples $\hat{x}_i$ converge to the weight vector $\hat{w}_0$.
$B2$	$\hat{w}_0 \cdot \hat{x}_i = 0.9001$	$\hat{w}_0 \cdot \hat{x}_i = 0.9$ is the critical condition for the correct classification of genuine samples.
$B3$	$\hat{w}_0 \cdot \hat{x}_i = 0.1999$	$\hat{w}_0 \cdot \hat{x}_i = 0.2$ is the critical condition for the correct classification of spoofed samples.
$B4$	$\hat{w}_0 \cdot \hat{x}_i = -1$	spoofed samples $\hat{x}_i$ are forced to the opposite direction of weight vector $\hat{w}_0$.

Loss	Dev		Eval	
	EER	t-DCF	EER	t-DCF
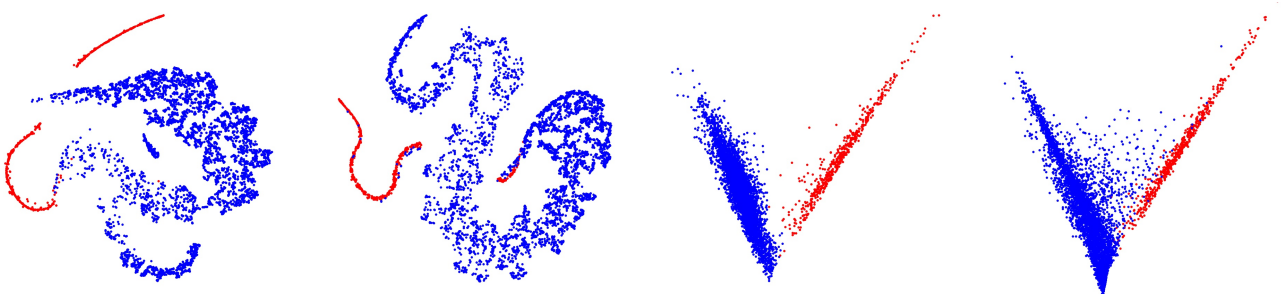
Softmax	1.34	0.037	1.90	0.055
AM-Softmax	1.71	0.039	1.89	0.051
OC-Softmax	1.33	0.040	1.99	0.058
IOC-Softmax	**1.18**	**0.028**	**1.34**	**0.038**

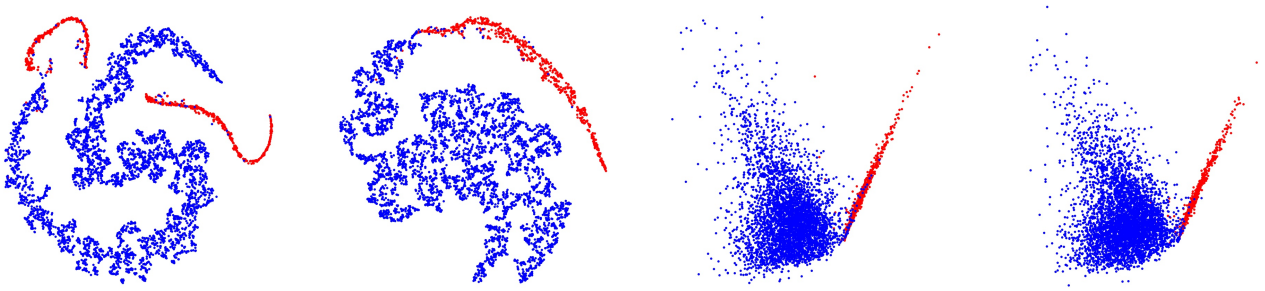
B. Evaluation metrics and implementation details



We use equal error rate (EER) and the tandem detection cost function (t-DCF) [22] to assess the proposed IOC-Softmax, the former measures the capability of the voice spoofing detection model and the latter appraises the reliability of the voice spoofing detection model to the ASV system. The lower the two indicators are, the stronger the system performance is.

For a fair comparison with OC-Softmax, we employ the network structure from [13]. The input of the network is extracted 60-dimensional LFCC features, and the 750 frames are set as the fixed length. The output of the network is 256-dimensional feature embedding. The feature embedding is then fed into IOC-Softmax to get the score that indicates the classification result. For AM-Softmax, s and m are set to 20 and 0.9, respectively. For OC-Softmax, s, m_0 and m_1 are 20, 0.9 and 0.2, respectively. And for IOC-Softmx, m_0 and m_1 are same as those of OC-Softmax, and s_0 and s_1 are 40 and 20 on the LA scenario, respectively. On the PA scenario, s_0 and s_1 are set to 60 and 40, respectively.

We train all the models using Pytorch on a single NVIDIA RTX 2080 Ti GPU. The Adam optimizer and Stochastic Gradient Descent (SGD) optimizer are employed to update the weights of the backbone and the loss function respectively, and the β_1 and β_2 in the Adam optimizer are 0.9 and 0.999 respectively. The epoch and batch size are set to 100 and 64 for all models. The initial learning rate is 0.0003, which decreases by 50% every 10 epochs. The model with a minimum EER on the Dev set was chosen as the final model for evaluation.



C. Results

1) Comparison with other loss functions: To validate the effectiveness of the proposed method, we conduct comparative tests with Softmax, AM-Softmax and OC-Softmax on the Dev and Eval sets of the ASVpoof 2019 dataset. Experimental re-

A10	1.18*	1.14*	0.63	0.50
A11	0.34*	0.12	0.02	0.04
A12	0.43*	0.46*	0.52*	1.01
A13	0.69*	0.22	0.26	0.28
A14	4.98*	0.69	0.50*	0.52
A15	5.43*	1.40	0.69*	1.12
A16	0.22	0.32	0.50*	0.28
A17	23.48*	9.21*	13.47*	7.77
A18	0.20*	0.89*	4.23*	1.44
A19	1.34*	0.89	0.85	0.83

TABLE VI
COMPARISON WITH SOFTMAX VARIANTS ON INDIVIDUAL ATTACKS OF THE PA SCENARIO.

Attack	Softmax	OC-Softmax	AM-Softmax	IOC-Softmax
AA	2.68*	2.67*	2.62*	1.87
AB	1.37	1.48*	1.36	1.01
AC	1.38*	1.75*	1.52 *	0.88
BA	2.38 *	2.34*	2.31	1.83
BB	1.41*	1.32	1.35	1.00
BC	1.41*	1.82*	1.44*	0.86
CA	2.34*	2.54*	2.23*	1.70
CB	1.66*	1.50*	1.52*	1.10
CC	1.62*	1.89*	1.71*	0.96

sults in Tables III and IV show that the proposed IOC-Softmax outperforms other loss functions. Specifically, compared with OC-Softmax, our IOC-Softmax improves EER by 21.91% and t-DCF by 22.03% on the Eval set of the LA scenario. And on the Eval set of the PA scenario, our method achieves an EER improvement of 33.66% and a t-DCF improvement of 34.48% when compared with OC-Softmax.

2) Performance comparison on individual attacks: For four different loss functions, we calculate their detection capabilities for each attack on the Eval set, and the comparison results are presented in Tables V and VI. In order to evaluate performance differences more clearly, we use the method in [23] to conduct the statistical significance test. "*" indicates a statistically significant difference in EER performance of individual attacks between other loss functions and IOC-Softmax, with a confidence interval of 99%. Table V shows that our IOC-softmax outperforms other loss functions on individual attacks, especially on A17. As shown in Table VI, our IOC-softmax achieves significantly superior performance on individual attacks.

3) Visualizations: We perform feature embedding visualizations using Principal Component Analysis (PCA) [28] and t-distributed Stochastic Neighbor Embedding (t-SNE) [29]. In Fig. 2 and Fig. 3, (a) and (b) are the results of t-SNE, and (c) and (d) are visualization results using PCA. The (a) and (c) in both Fig. 2 and Fig. 3 are embedding visualizations on the Dev set, and the (b) and (d) are embedding visualizations on the Eval set. Red dots represent genuine speech and blue dots are spoofed speech. As can be seen from Fig. 2, on the LA scenario, the data distribution of spoofing attacks on the Dev is different from that of spoofing attacks on the Eval.

TABLE VII
PERFORMANCE COMPARISON WITH SOME OF EXISTING SINGLE SYSTEMS

Single System	LA		PA	
	EER	t-DCF	EER	t-DCF
Baseline CQCC+GMM [4]	9.57	0.237	11.04	0.245
Baseline LFCC+GMM [4]	8.09	0.212	13.54	0.302
CQMOC+LCNN [12]	8.59	0.26	1.32	0.036
CQMOC+GMM [12]	7.10	0.199	6.95	0.135
CQT-MMPS+LCNN [12]	5.99	0.176	**0.90**	0.024
CQT-MMPS+ResNet [12]	3.72	0.119	1.08	0.031
CQCC+NF-ResNeXt [24]	6.72	0.160	-	-
MFCC+NF-ResNeXt [24]	5.13	0.132	-	-
sm-ALTP+Asymmetric Bagging [25]	5.22	0.132	1.10	0.034
STFT+LCGRNN+GKDE-Triplet [26]	3.03	0.078	0.92	**0.020**
Spec+scDenseNet [27]	4.45	0.131	-	-
LFCC+scDenseNet [27]	1.89	0.047	-	-
ResNet+IOC-Softmax	**1.71**	**0.046**	**1.34**	**0.038**

However, on the PA scenario of Fig. 3, the data distributions of spoofing attacks on the Dev and Eval sets are basically the same. This indicates that it is necessary to customize scale factors for different scenarios. As can be seen in Fig. 2 and Fig. 3, our IOC-Softmax can separate genuine speech from spoofing speech very well, showing good detection capability.

4) Comparison with other single systems: In order to further verify the advantage of the proposed IOC-Softmax, we compare our method to advanced single systems on the ASVspoof 2019 Eval set, and Table VII describes EER(%) and t-DCF results. These results are from reports in the [4], [12], [24]–[27], and "-" indicates that the LA scenario or PA scenario is not investigated in the corresponding paper. As can be seen from Table VII, our method achieves comparable or better results than other advanced single systems.

IV. CONCLUSIONS

In this paper, we study and analyze the effect of scale factor on OC-Softmax, and find that setting the same scale factor for real speech and spoofing speech reduces the detectability of the model and limits its flexibility for different tasks. For this purpose, this paper presents an improved one-class learning loss, called IOC-Softmax. We reformulate the scale factor of OC-Softmax into two parts, one tailored for genuine speech, and the other customized for spoofing speech, to balance the impact of two class samples on the loss value. We perform comprehensive experiments on the ASVspoof 2019 dataset, and the experimental results show that the proposed IOC-Softmax is effective. Compared with OC-Softmax, our approach achieves better performance. In future work, we will apply the proposed IOC-Softmax to other fields.

***Abstract* — Information safety is becoming increasingly important in modern society, and biometric recognition technologies have become a key to achieve information security due to its universality, permanence, distinctiveness, and collectability. This research proposed a palm vein verification system based on CNN (convolution neural network). In preprocessing step, we first perform ROI localization and image contrast adjustment, and then proceed to feature extraction through lightweight convolutional neural network. Finally, we validated our method on the CASIA palm vein dataset. As a result, the system achieved an Equal Error Rate (EER) of 0.529%, which is superior compared to other renowned architectures, and it also possesses the minimal parameter count and the fastest execution speed.**

I. INTRODUCTION

As advances in modern society continue, the importance of information security has been raised to an unprecedented height. A system that is highly secured and convenient at the same time is in the society's need. Traditionally information safety has been protected by passwords, identity card, smart card, and etc., but these systems have risks like forgetting the passwords and losing the card. Moreover, traditional methods are also vulnerable to people with bad intentions who may attempt decoding or stealing, which is clearly a sign to its shortcoming in not meeting the society's need for a well-developed information security technology. Under such circumstances, research and studies have shown that biometric recognition is a great solution to the rising issue mainly because of its following four characteristics: Universality: feature that every human being possesses naturally, such as DNA, facial features, fingerprints, veins, iris, and etc., Permanence: Biological traits do not undergo significant changes over time; any variations are minor and exhibit a linear pattern of observation. Distinctiveness: Every individual's biological characteristics is different and identifiable. Not even the left and right palm veins of the same person nor the palm veins of a pair of twins would be the same [1]. Collectability: biological characteristics can be obtained quickly and conveniently through special instrument [6].

Apart from being efficient and accurate in verifying the user's identity, utilizing human biological characteristics also reduces the risks with forgetting passwords and losing an ID card, making it much safer, more reliable, and convenient compared to the traditional methods of identity cards and passwords.

In the scheme of human biological characteristics, there are generally two categories: external biological characteristics and internal biological characteristics. External biological characteristics are the qualities of the human body that can be directly recorded and further recognized, such as facial feature [2], fingerprints [3], palm prints [4], while internal biological characteristics are the qualities that reside inside the human body and requires more sophisticated machinery to detect or collect data, such as DNA, finger veins [5], palm veins. However, external biological characteristics can be easily stolen and used by unauthorized individuals [6], For instance, facial feature can be frequently captured in unknown circumstances, while fingerprints leave traces every time objects are touched, making them exploitable by malicious actors. Therefore, systems that are based on external biological characteristics are more susceptible to attacks, lowering the overall safety of the system [7].

Compared to external biological characteristics, palm vein and other internal biological characteristics are hidden within the human body, which makes them more difficult to obtain. Slight stains and injuries would also have little to no effect on the systems' functionalities [6], and vein is a relatively consistent characteristic that does not change significantly through time [8]. It is by these qualities that vein recognition has stood out amongst human biological characteristics, having

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

the potential to satisfy all the needs for a well-developed biometric system.

Vein images are mainly composed of the vein networks underneath the human skin. Under visible light, it is almost impossible for the naked eye to recognize a complete vein network. Under near-infrared light, hemoglobin (Hb) in the human blood would absorb the spectrum within 750 nm to 1050 nm of wavelength while human muscle would reflect it [9]. The vein images only can be captured using a camera with near-infrared light, it's ensuring that this biological characteristics can only be obtained from a living human being [10].

Despite its benefits, palm vein recognition still has some issues. For instance, collecting palm vein images requires the use of near-infrared light, which makes it more difficult compared to other biological databases. This limitation results in a smaller dataset, which in turn increases the difficulty of training Convolution Neural Network (CNN) models. Furthermore, biometric recognition systems are commonly used in edge devices, which often have limitations in terms of network computation and system complexity.

In the field of biometric recognition, depending on the different application scenarios, there are primarily two modes: identification and verification. The identification mode aims to identify a user's identity from a large database, following a 1:N matching method. The objective of the verification mode is to verify whether the current biological characteristic matches the specific identity previously stored in the database, adhering to a 1:1 matching method. In this research, we will focus on the verification mode.

II. RELATED WORK

In recent years, there has been rising attention to vein-based recognition systems, which includes palm vein [7], finger vein [11]. Due to its convenience in extraction and complexity in feature textures compared to other vein features in the human body, palm vein and its related studies are the focuses of this research. Typically palm vein recognition system primarily captures images using near-infrared cameras. The captured images are then processed for region of interest (ROI) localization and vein feature extraction. Finally, compares the extracted features with the enrolled feature and outputs the recognition result. Currently, palm vein recognition algorithm field can be separated into two types:

A. Handcrafted Feature:

Handcrafted features are an early and common method in the field of vein recognition. This type of method mainly defines vein images and extracts features with human identification significance. It can be further categorized into these three methods:

a. Geometry-based methods [12]: This method mainly utilizes the linear structures presented on the palm vein images and extracts data of such segments, curves, and points, which are supposedly close to the shape of the vein texture. It highly on the processed image, which requires a ROI localization; however, features obtained from this method sometimes have blurs and only few feature points, so it is more difficult to overcome sample rotation, zoom, and displacement [13]. Among these methods, radon transform [10] and Gabor feature [13] have been commonly used in the palm vein recognition field. Despite this, a clear limitation to these methods is that their performance highly relies on the artificially selected features. Consequently, these handcrafted methods may face difficulties when handling different lightings, changes in hand gesture, blockings, and other complex obstacles.

b. Statistical-based methods [11]: These methods use statistics from data to perform feature recognition, including through local binary histograms and image invariant moments, and can be distinguished as global or local statistics. However, these methods are equivalently sensitive to rotation, zoom, and displacement.

c. Local invariant-based methods [14]: Inspired by scale-invariant feature transform (SIFT), these methods directly extract local invariant data from the palm vein image feature. Although they effectively contend feature displacement and rotation, they are susceptible to small changes in the surrounding lightings and the device lightings, resulting in lesser extracted invariant feature points.

B. CNN based:

CNN based method have demonstrated its strength in feature extraction and have been successfully applied to several computer visual tasks, such as image classification [15]. It has also been used in the field of vein recognition, as it is

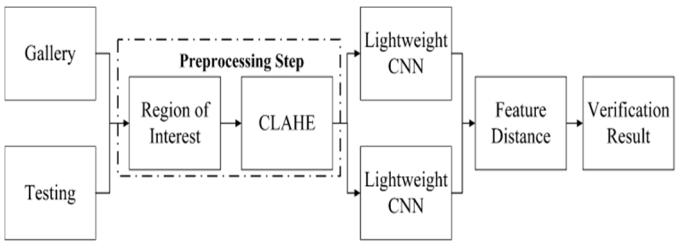

Fig. 1, System operation flowchart

applied to vein image quality assessment by Qin et al. [16] and also to vein pattern segmentation [17]. Additionally, Chen et al. [6] proposed a lightweight neural network for palm vein, using Gabor filter and Weight Selection Mechanism to enhance system safety, and Qin et al. [18] proposed a novel palm vein defensive framework, reducing the negative effects caused by low image qualities. Eladlani et al. [25] proposed a method that utilizes model merging, and ensemble network techniques to achieve commendable recognition results. These previous working examples have proved that CNN based algorithms have decent recognition ability in the vein recognition field, but they mostly overlooked the calculation inabilities of typical edge devices. Therefore, this research introduced lightweight system architecture, implementing CLAHE and lightweight CNN to lower the error rate of the system.

III. METHOD

A. System flowchart

Fig. 1 illustrates the workflow of the palm vein verification system proposal in this research. To reduce system load, the system mainly consists of the preprocessing stage and the feature extraction stage.

Initially, after obtaining the palm vein image, the system performs region of interest (ROI) localization enhances its contrast by applying Contrast Limited Adaptive Histogram Equalization (CLAHE). The adjusted image is then fed into a CNN for feature extraction. This compresses the original two-dimensional palm vein image into one-dimensional feature. During the verification step, the extracted features will calculate the feature distance with the enrolled features. If the distance is smaller than the threshold, the system will classify them as the same user.

B. Preprocessing – ROI

In the image captured through a near-infrared camera, background information is unnecessary to the system apart from the main portion that contains the palm veins. A great

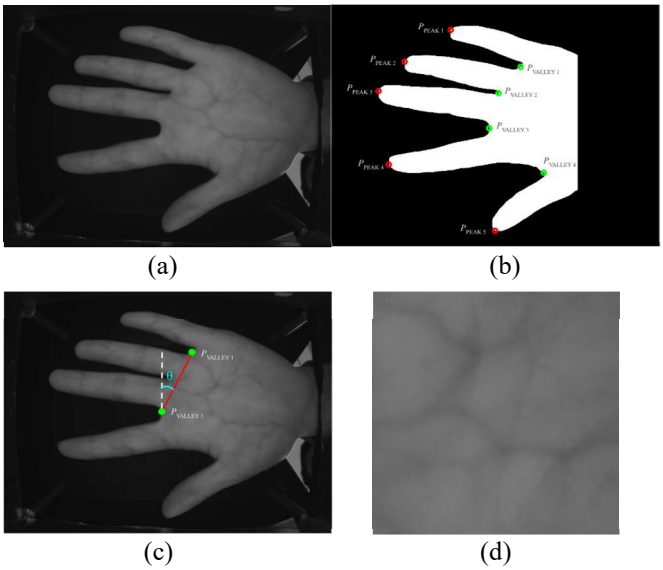

Fig. 2, Palm vein extraction and ROI process diagram (a) Original palm vein image, (b) Locating finger peaks and valleys, (c) Rotation angle θ, (d) Palm vein ROI image.

image localization method can effectively improve the system's effectiveness. The palm-vein capturing device on the current market can be separated into two types: contact and contactless devices. Even though contact-required devices can limit and reduce inconsistencies in hand placement, most systems employ contactless devices due to their superiority in terms of hygiene, allowance for unrestrained hand placement, and higher acceptance from users [13]. However, this inevitably causes more noise and varieties in size ratio, displacement, and rotation due to inconsistent camera angles and hand placements from different images that are captured at a different occasion. Consequently, several algorithms, such as ROI contouring, angle correction, scale correction, and other algorithms, are needed to ensure that the extracted palm vein data would not be heavily influenced by the aforementioned variables.

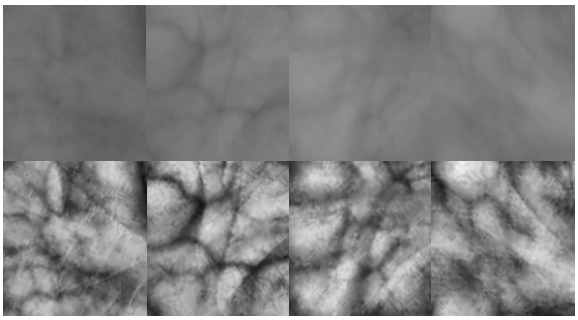

Fig. 3, CLAHE Sample Comparison. The first row shows the original image, the second row shows the image after applying CLAHE.

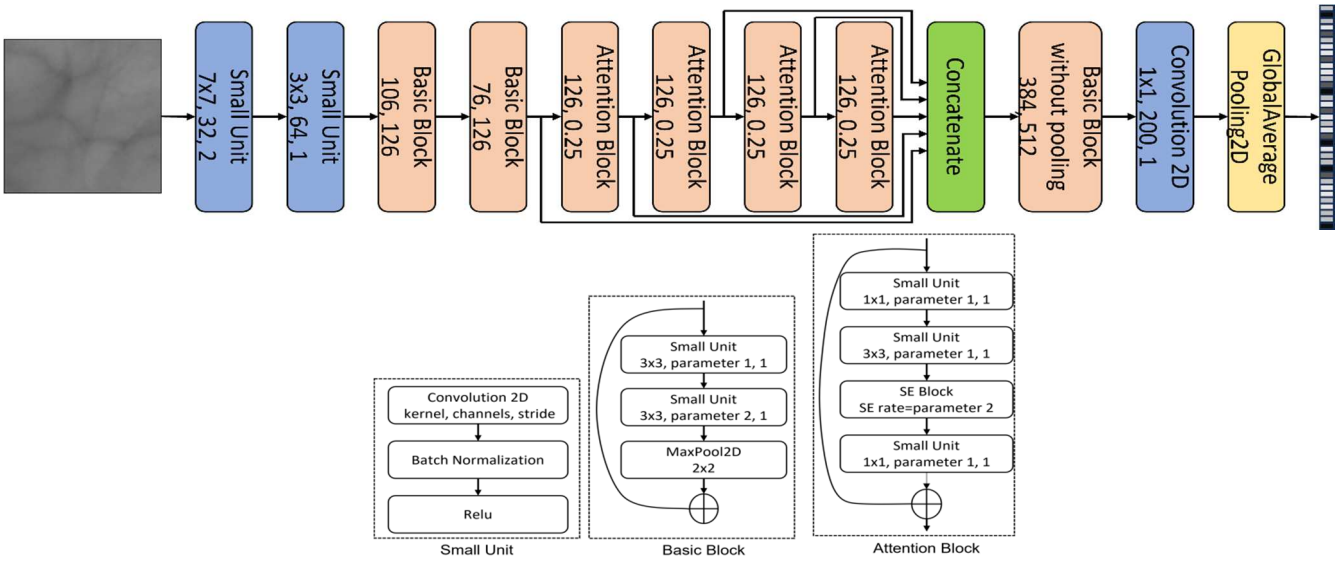

Fig. 4, Proposal architecture of the Lightweight CNN model.

The proposal ROI localization algorithm in this research, as shown in Fig. 2, involves filtering the foreground and background using OTSU's method [19]. Next, the radial distance function (RDF) is used to calculate the distance between the palm centroid and the palm contour, allowing for the localization of fingertip and finger valley positions. By identifying the finger valleys between the index finger and middle finger, as well as between the ring finger and little finger, the hand rotation angle is determined, and the ROI region size is defined. Finally, the palm vein information is extracted.

C. Preprocessing - contrast adjustment

Although the addition of an external near-infrared light source improves the contrast to some extent during palm vein extraction, the contrast in vein images still lack adequacy. After reference [18], we found that adding the CLAHE method would noticeably increase the contrast between veins and muscle tissues in palm vein images.

In CLAHE, there are two parameters, Clip-Limit and Tile-Size. The Clip-Limit primarily serves as a cap, redistributing excess histogram values evenly to lower values. This method effectively prevents the loss of image detail due to excessively enhanced contrast. The Tile-Size determines the number of sections into which the image will be divided for processing. More subdivisions can enhance the image's local contrast, balancing brightness and contrast within each block, but it can also introduce conspicuous block effects. Fig. 3 displays images of the veins before and after implementing the CLAHE algorithm. When compared to images processed without the use of CLAHE, it is observed that the image processed with CLAHE has an enhanced contrast between the veins and muscle tissues.

D. Lightweight Convolution Neural Network

To operate palm vein image verification, the processed image would go through a refined CNN structure that is adaptable to vein images to perform feature extraction. Most of the CNNs architectures are not specifically designed for palm vein verification and may face challenges such as inadequate recognition accuracy or excessively large network parameters when confronting palm vein images.

To address this problem, we came up with an improved version of the CNN structure, in which the main structure is illustrated in Fig. 4. This architecture is made up of multiple convolution layers with batch normalization layer (BN) and Relu after each of the convolution layers. Additionally, in order to reduce the number of network parameters, we employed separable convolutions [16] for all convolution layers except the first two convolutions. This choice enhances processing speed and reduces the overall number of model parameters. Residual connections [17] are also used on Basic Block and Attention Block. Finally, a Dropout layer is added before the output layer to mitigate overfitting.

In Loss function, we hired the Triplet loss function to enhance the network's ability to separate feature distance from different samples. The Triplet loss aims to minimize the feature distance between the same user's samples and maximize the distance between the different user's samples. In the training step, the calculated value is utilized to optimize the lightweight CNN.

IV. EXPERIMENT RESULT

A. Database

To assess our proposal method's performance, we chose to use the database Multi-Spectral Palmprint Image Database 1.0 from CASIA (Institute of Automation of the Chinese Academy of Sciences) as experimental dataset, which was collected through contactless devices and consists of the right and left hand images of a hundred people. This dataset was created with two sessions, with at least a month spanning in between each session, in order to simulate real-life circumstances. Each collection will add six different light spectra, including 460nm, 630nm, 700nm, 850nm, 940nm, and white. For each session, three images were captured for each type of spectrum. The entire dataset consists of 7200 images, 2400 of which used near-infrared spectra and are suitable to perform palm vein recognition. To simulate real-life situations, we separated the images collected from those two sessions into categories called gallery and test, each having 1200 images. Apart from serving as training samples for deep learning, gallery images also represent registered users and are used in the EER experiments.

B. Evaluation Metrics

In biometric recognition technologies, there are typically two indexes used to evaluate its performance: Accuracy and Equal Error Rate (EER). Each of these two indexes corresponds to two major fields of biometric recognition: Identification and Verification.

Identification is the process of comparing the input biometric characteristic with the registered biometric characteristic to identify the identity. In this scenario, Accuracy is an important index. It is comparably simpler and more straightforward, representing the ability of the system to distinguish and identify individual samples. In an ideal situation, a perfectly accurate system would have an Accuracy of 100%, meaning that it has classified every input correctly.

On the other hand, Verification's goal is to confirm whether the user is the identity of which they claimed to be, so we only have to compare the input data with the said identity's known data. EER is often used to evaluate the security of a system. EER is composed of the two parameters False Accept Rate (FAR) and False Reject Rate (FRR). During evaluation, by adjusting the threshold, FAR and FRR will change correspondingly; when their values are the same, this specific point represents the system's EER. A lower EER indicates higher recognition performance and better security of the system.

Table 1, The impact of adjusting Tile Size on the EER, with Clip-Limit of 1, 9 and 17.

Tile Size	*Clip-Limit (EER %)*		
	1	*9*	*17*
4	0.547	**0.529**	0.646
8	1.6	0.963	1.162
16	2.146	4.111	1.724
20	2.281	2.946	1.996
32	0.592	2.312	2.424
40	2.969	3.413	3.268
80	3.444	5.380	2.632
160	3.464	2.487	3.291

C. Contrast Adjustment

To evaluate the effectiveness of the CLAHE algorithm in adjusting image contrast, we compared the original image with the processed one. In addition, to find out their effects on the palm vein recognition system, we performed the following experiment based on the two parameters Clip-Limit and Tile Size of the CLAHE algorithm. Firstly, we hold Clip-Limit constant at 1, 9 and 17 while adjusting Tile Size. As shown in Table 1, there are variations in EER with the increase of Tile Size. In the end, we selected a Tile Size of 4 and a Clip-Limit of 9 as the final parameter values.

D. Lightweight Convolution Neural Network

In this research, we designed a lightweight convolution neural network specifically for palm vein verification. This architecture's intention is to improve the precision and efficiency of biometric verification and offer opportunities for future applications to edge devices. To thoroughly assess the architectures designed, we compared our design with various common convolutional neural networks.

As shown in Table 2, our network architecture performs excellently in terms of EER and has the lowest processing-time and parameter count among all the comparison subjects. This demonstrates that the proposal network architecture is the most applicable to be implemented in edge devices, because while promising a decent accuracy, it effectively lowers the processing time and parameters, which is a significant advantage as a system operating in an edge device that requires specific capabilities.

Table 2, Comparison among different network structures

Method	*Parameter*	*Processing -time*	*EER (%)*
Xception[20]	21.31M	0.0709s	0.882
VGG16[21]	14.85M	0.0673s	2.274
MobileNetV2[22]	2.27M	0.0287s	6.260
NASNetMobile[23]	4.52M	0.0680s	5.251
ResNet50 V2[24]	24.03M	0.0570s	4.293
Proposal	**1.12M**	**0.0285s**	**0.529**

V. CONCLUSION

This research proposes a lightweight palm vein verification system. During the image preprocessing stage, the Region of Interest is utilized to filter out background information, and CLAHE is applied to enhance the vein information. Lightweight CNN is then used for feature extraction. The extracted features are then compared with the features of enrolled users, and the feature distance is calculated. If the distance is below a threshold, it is recognized as the same user. The experiment was validated using the CASIA multispectral palm vein database, achieving an EER of 0.529%. The experimental results also demonstrate that our proposed network has an excellent verification rate and the potential for deployment on edge devices.

Breast Cancer Detection Auxiliary System

Leveraging Deep Learning and Mixed Reality

Szu-Yin Lin*, Ming-Chun Chien, Edwin Tiong Kwong Meng, Yu-Chien Wang, Yu-Yi Kuo, Che-Hsuan Lin

E-mail: szuyin@niu.edu.tw

Abstract — **According to the World Health Organization (WHO), in 2022, breast cancer is the most diagnosed cancer among women worldwide, irrespective of age. In Taiwan, it is the most prevalent cancer among women and has the fourth-highest mortality rate. Additionally, diagnosing breast cancer often takes a long time searching for symptoms. In this study, we propose utilizing artificial intelligence image analysis methods and mixed reality interfaces to track and compare breast cancer images. We employed a deep learning convolutional neural network to analyze and classify acquired images of benign or malignant cases. Thus, establishing breast cancer tracking and a diagnostic decision support system for physicians to reference would benefit the future medical field. By incorporating mixed reality technology, doctors can save time and reduce labor costs without being constrained by geographic limitations.**

I. INTRODUCTION

This study aims to integrate various technologies, including deep learning, image processing, and mixed reality, to develop a specialized breast cancer diagnostic system that helps address physicians' challenges in diagnosing this disease. Breast cancer is one of the most prevalent cancers among women worldwide, and early diagnosis and treatment are crucial for improving patients' survival rates and quality of life. However, the current diagnostic process for breast cancer often relies on subjective assessments, leading to reduced diagnostic accuracy. Therefore, there is a pressing need to develop an accurate, reliable, and visualized breast cancer diagnostic system to enhance diagnostic precision and alleviate the burden on medical staff.

This research aims to apply deep learning techniques to analyze and predict calcification-related features in breast cancer diagnosis. The Efficient Net B7 model enhances the accuracy of predicting benign and malignant breast cancer radiographs. Techniques such as histogram equalization and data augmentation, are used during the training phase. Furthermore, we have developed a case comparison and marking feature that facilitates the identification of discrepancies and abnormal areas between different reports. This provides physicians with more comprehensive diagnostic information. To ensure a seamless user experience, we utilize mixed reality devices as the user interface for the breast cancer diagnostic system. These devices offer portability and enable hands-free operation, empowering doctors to access data and diagnose without being limited to a specific location. The system operates seamlessly, with only a wireless network connection being required.

II. LITERATURE REVIEW

Breast cancer diagnosis is a critical area of medical research, with numerous studies dedicated to enhancing the accuracy and efficiency of diagnostic methods. This section reviews prior studies and relevant literature to gain insights into the current knowledge and approach to breast cancer diagnosis. In recent years, the application of artificial neural networks in medical image processing has garnered significant attention. For instance, Wessam et al. [1] developed a breast cancer diagnosis model based on convolutional neural networks, achieving remarkable accuracy. Furthermore, image processing techniques have found extensive use in breast cancer diagnosis. Petrick et al. [2] utilized image processing techniques to extract features from mammography images, improving diagnostic accuracy.

Despite the progress made in research thus far, there remain challenges and limitations in breast cancer diagnosis. The accuracy of existing models in predicting benign and malignant cases necessitates further improvement. Additionally, more research is required to enhance preprocessing techniques and image segmentation methods. Furthermore, applying adjunctive diagnostic systems in real clinical settings requires further investigation and validation.

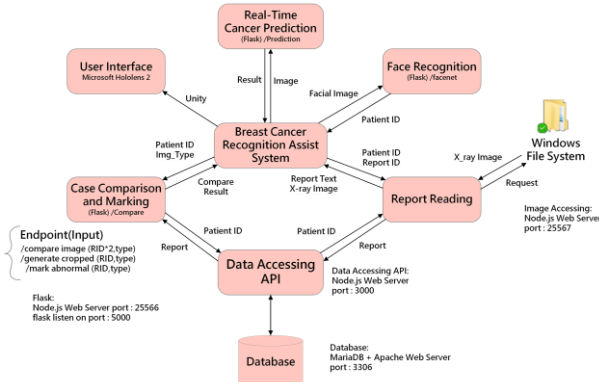
This study employs the CBIS-DDSM dataset [3] for experimentation and analysis. CBIS-DDSM is a publicly available medical image dataset comprising thousands of mammography images. This dataset provides valuable resources to validate the effectiveness of the developed adjunct diagnostic system in real-world scenarios. Integrating various technologies, such as deep learning, image processing, and mixed reality, would develop a specialized assistive diagnostic system for breast cancer that enhances the accuracy and efficiency of diagnosis.

III. METHODOLOGY

Fig. 1 shows the system architecture. The system in this study has two main functions: cancer prediction and X-ray image comparison. All image data used in this study are from the CBIS-DDSM dataset.



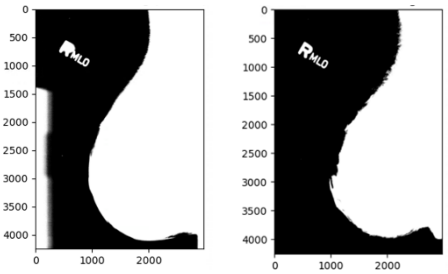


Fig. 1 System Architecture

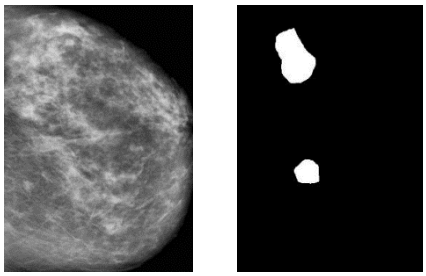
A. Image Masking



The Opening and Closing operations in morphology enable us to denoise [4], fill holes, and refine the edges of images. Opening and Closing require the assignment of a structural element and the specification of the number of iterations. Structural factors, such as square, oval, and more, can vary in size and shape. The number of iterations determines the strength and impact of the operation. The Opening operation removes small items, reduces noise, and smoothes out the edges, while the Closing operation fills holes and connects fragmented edges. In this study, we utilize OpenCV's function, cv2.morphologyEx(), to implement these operations. Image masking is a common technique for edge processing, image segmentation, and object detection. It significantly improves image quality and enhances readability.

We utilized OpenCV's cv2.morphologyEx() function to perform the Opening operation. This function requires specifying the structural element's shape, size, and number of iterations. Additionally, because the text in the corners of the X-ray image can affect subsequent processes, we used cv2.contourArea to locate and remove smaller contours representing the text. Subsequently, we employed cv2.drawContours to obtain the most significant contour, the image mask. This mask then creates an X-ray image that includes only the patient's breast. We can improve the quality and clarity of X-ray images in this study by employing these techniques and utilizing OpenCV's functions.

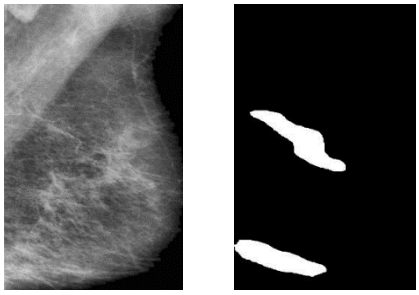
Fig. 3 Image Data (a) Original Image (b) Corresponding ROI



B. Cropped Image Generation

To facilitate physicians in observing the lesion area in detail and conducting subsequent benign and malignant classification, we use the contour of the ROI image to get the crop area. When the original image is appropriately positioned, the corresponding section is cropped and saved as a separate image to assist physicians in diagnosing. To accomplish this, we first employed the cv2.findContours function to identify the contours within the ROI. Then, using the cv2.boundingRect function, we obtained the boundary frame of the contour. With these coordinates, we could precisely crop only the abnormal portion of the X-ray image. The resulting output includes two cropped images: one from the original image and another from the corresponding ROI image. These cropped images aid in subsequent observation and diagnosis by medical professionals.

(a) (b)

Fig. 4 Cropped Image (a) cropped from the first contour (b) cropped from the second contour

(a) (b)

Fig. 5 Image Data (a) Original Image (b) Corresponding ROI

C. *Calculation of Contour Information of the Lesion Area*

We utilized the patient ROI in the dataset and employed OpenCV to calculate the lesion area information. This information was then added to the original image, allowing doctors to access additional reference information while observing the X-ray film, aiding in subsequent diagnosis. The following images display the original images and their corresponding ROIs to demonstrate the functionality. For each contour within the ROI, we drew a contour line and framed the boundary of the contour using the coordinates obtained from cv2.boundingRect on the original image. Subsequently, we utilized OpenCV's functions to calculate the contour length, width, area, and perimeter. Finally, we displayed this information on the original image. It is important to note that the values obtained from the drawing are in pixel units.

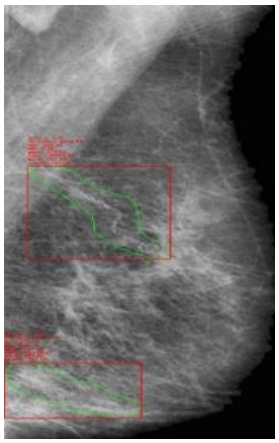


Fig. 6 Mammography image with the information marked.

D. *Comparison of Mammography Images*

To enable physicians to compare mammograms of the same patient at different times and identify any differences (lesion areas), we simulated the differences between the two images. We highlighted them in rectangular boxes in the second image. The following images display the original mammograms and our simulated difference maps. We calculated the differences between the two images using a metric subtraction approach, and the areas with variations were marked with red boxes. While this method works well with our simulated data, we have concerns about its effectiveness with real-world data. Therefore, we plan to develop a series of processes to deal with potential issues such as misalignment. For now, here are the results of the image comparison.

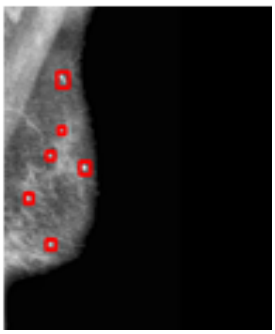

Fig. 7 Mammography image with differences marked.

IV. EXPERIMENTAL RESULTS

We have successfully developed a Breast Cancer Prediction model with a 70% accuracy rate for calcification data. Additionally, we have created a user interface for AR devices and a corresponding server for data access and computing service. We used the CBIS-DDSM dataset's crop images as our model training data. The data ratios for the training sets were as follows: Calc training set - 1002 benign cases and 544 malignant cases; Mass training set - 678 benign and 636 malignant cases. To solve the data imbalance problem, we employed downsampling, reducing benign data to match the number of malignant cases. To improve the image's visual quality to make it clearer and more distinctive for model training, we used histogram equalization to enhance the images [5]. Due to the limited number of samples available for training data relevant to medical applications, it becomes necessary to increase the data through data augmentation. This helps alleviate the issues caused by insufficient data. The data scaling process involves several steps. First, an image is taken as input. Then, the image is subjected to horizontal and vertical flipping, which creates mirror images. Next, the image is rotated 30 degrees clockwise while simultaneously flipping it. Subsequently, the image is rotated 60 degrees clockwise and flipped again. At this point, the resulting images from the first few steps are written or saved. At last, the data scaling process

concludes and produces the transformed images with various flips and rotations.

We chose six common CNN models used in medical imaging for prediction models: ResNet50, VGG16, DenseNet121, InceptionV3, EfficientNetB7, and MobileNet [6]. We took these models as a foundation and trained all of them using transfer learning techniques by incorporating customizable, fully connected layers. To quantify the models' performance and efficiency, we evaluated them using various metrics, including Precision, F1-Score, AUC, FPR, Accuracy, and Recall. These metrics helped us determine the most suitable models. Below are some of the training results:

Table 1 Calcified Histogram Equalization Model Training Data

Model	EfficientNetB7	ResNet50	MobileNet	VGG16	DenseNet121	InceptionV2
Sensitivity (%)	71.3564	75.9748	61.7605	68.6147	68.2539	59.8124
Precision (%)	70.2914	62.4552	65.0951	63.3155	63.4473	58.5038
F1-Score (%)	70.8199	68.5547	63.3839	65.8587	65.7629	59.1509
AUC	0.7721	0.7278	0.6840	0.7081	0.7071	0.6001
FRP	0.3015	0.4567	0.3311	0.3975	0.3932	0.4242
Accuracy	0.7092	0.6645	0.6616	0.6529	0.6500	0.5966
Recall	0.7135	0.7597	0.6176	0.6861	0.6825	0.5981

Table 2 Mass Histogram Equalization Model Training Data

Model	EfficientNetB7	ResNet50	MobileNet	VGG16	DenseNet121	InceptionV2
Sensitivity (%)	60.8311	61.3616	65.7382	64.3678	43.1476	65.2077
Precision (%)	74.9455	64.3486	61.2186	60.4149	62.2052	58.0480
F1-Score (%)	67.1547	68.5547	63.3839	62.3287	50.9527	61.4199
AUC	0.7768	0.6869	0.6824	0.6655	0.6353	0.6311
FRP	0.2033	0.3399	0.4164	0.4217	0.2621	0.4712
Accuracy	0.7285	0.6441	0.6273	0.6242	0.6109	0.5923
Recall	0.6083	0.6136	0.6573	0.6436	0.4314	0.652

The above results show that the best result of both is EfficientNetB7, which achieves 70% accuracy for quality and calcification data. Since this study focuses on proposing a complete diagnostic system, the current calcification accuracy rate of 70% is believed to be able to assist doctors in their diagnostic work to a certain extent.

V. Conclusion and Discussion

This study integrates technologies such as deep learning, image processing, and mixed reality to develop a breast cancer-specific assistive diagnostic system addressing the challenges doctors face in diagnosing breast cancer. Firstly, in terms of functionality, we employed artificial neural networks to predict breast cancer's benign or malignant nature from X-ray images. Through discussions with medical professionals, it became evident that existing research primarily focuses on cases involving the masses. Therefore, our system is primarily designed to identify calcifications. By utilizing the EfficientNet B7 model and employing techniques such as histogram equalization and data augmentation during training, we achieved an accuracy rate of 70%. Secondly, we have developed a case comparison and marking feature that enables the comparison of two reports, highlighting differences and abnormal regions. However, this feature requires the inclusion of region of interest (ROI) images in addition to the patient's breast radiographs. Since this study did not encompass the generation of ROI images, we hope future studies can fill this gap by developing accurate image segmentation models to provide reliable ROI data. Finally, we have successfully implemented the HoloLens 2 mixed reality device as a user interface for the Breast Cancer Assistive Diagnostic System. The mobility of the HoloLens 2 allows users to access data and make diagnoses regardless of their location, only requiring a wireless network connection.

***Abstract*— Reversible data hiding (RDH) technology can hide secret data in multimedia to realize the purpose of secret communication, copyright and content protection. However, the current RDH methods for 3D models are challenging to balance embedding capacity and carrier distortion. This paper proposes an RDH method for 3D mesh models with high embedding capacity and low model distortion based on multiple least significant bit (multi-LSB) substitution and ring-prediction. The coordinates of the vertices are converted into specific format by preprocessing. The secret data are embedded in multi-LSB of converted coordinates by multi-LSB substitution. The cover 3D mesh model is reconstructed by correlation of 1-ring of neighborhood vertices. Experimental results show that the proposed method achieves higher embedding capacity and lower distortion than the state-of-the-art methods.**

***Index Terms*—3D mesh model, Reversible data hiding, Multiple least significant bits, Ring prediction**

I. Introduction

Reversible data hiding (RDH) technology can hide secret data in multimedia to realize secret communication, copyright, and content protection and recover the carrier after extracting secret data [1], [2]. This technology studies how to reversibly embed data into the carrier without introducing permanent distortion. The early RDH technology mainly uses the digital image as the carrier. RDH technology based on digital images has matured, and theoretical optimal solutions have been achieved. However, mature RDH technology of digital images cannot be directly applied to other carriers (such as video, audio, and 3D model). The 3D model is an emerging digital media after image, audio, and video, widely used in video game production, building structure display, and other fields. Research on RDH techniques for 3D models meets the urgent need for multimedia data security in complex and diverse social environments. According to different application scenarios, current RDH methods for 3D models can be divided into encryption domain and plaintext domain. RDH in encrypted domain (RDH-ED) method for 3D models [3]–[10] is proposed to protect carrier content from disclosure. This kind of method encrypts the carrier before embedding the data. Jiang et al. [3] first extended the RDH method on encrypted images to encrypted 3D mesh models. Yin et al. [5] proposed an RDH method for 3D mesh models based on multiple most significant bit (multi-MSB) prediction for the first time, which effectively improved the embedding capacity of 3D mesh models, and there are no corresponding attacks as there may be with digital images [11]. Embedding information in encrypted domain usually does not consider the deformation of the carrier caused by data embedding, and the average embedding rate of current reversible data hiding methods in encrypted domain of 3D models is as high as 33.15 bit per vertex (bpv) [10].

Different from the RDH-ED method for 3D models, the common method to protect privacy is encryption, but the special form of ciphertext encoding is messy and easy to attract the attention of attackers. RDH in plaintext domain pays more attention to the invisibility of the method. It is clear that covert storage requires both properties, namely, undetectability and reversibility. That is to say, this algorithm also focuses more on how to improve the embedding capacity while maintaining low distortion. The typical RDH method for images [12]–[26] can be divided into three categories: (1) histogram shifting [12], [19]–[23], (2) difference expansion [13], [14], [24]–[26], and (3) lossless compression [15]–[18]. Many ideas of RDH for multimedia are based on the classic method of RDH for digital images. In [27], DCT transformation is performed on the vertices cluster to embed the data by changing the high-frequency component coefficients. However, this method uses multiple vertices to embed 1-bit data, and the utilization rate of vertices is low. [28]–[30] uses compression algorithms to compress and encode 3D models and then embeds the secret data. In [31]–[36], secret data is embedded by modifying the difference between the predicted vertex coordinates and the actual vertex coordinates. However, controlling the cover model distortion is difficult when improving the embedding capacity by modifying the prediction error directly.

The performance of the RDH method for 3D models in

plaintext domain is evaluated by embedding capacity and carrier distortion. In most studies, researchers strike balance between these two indicators. To embed multi-bit data into vertices, the multi-MSB prediction method of [5] is applied to our method. Compared with [5], to control the distortion of the model, instead of embedding the data into the multi-MSB of the vertex coordinates, the proposed method embeds the secret data into the multiple least significant bit (multi-LSB) that has the least impact on the vertex through vertex transformation. Different from the existing work of RDH in plaintext domain for 3D models, this paper does not directly calculate the difference between the coordinates of adjacent vertices, but first normalized to a 32-bit binary form, which provides more embeddeable room for secret data embedding. We propose a new method to effectively improve the embedding capacity and reduce the introduced distortion. The main contributions of this paper are summarized as follows:

(1) The data embedding room is obtained by using the correlation of local regions of 3D mesh model, and multi-bit data can be embedded in each embeddable vertex by multi-LSB substitution to improve embedding capacity.

(2) The vertex coordinates are converted to a specific format, and the carrier distortion is controlled by modifying the position that has the least impact on the vertex to embed the secret data.

(3) The cover 3D mesh model is restored by predicting the modified vertices through the multi-LSB of the vertices of 1-ring neighborhood and realizing the separation of data extraction and model reconstruction.

The rest of this paper is organized as follows. Section II introduces the related works. An efficient RDH method for 3D mesh model is designed in Section III. The experimental results are discussed in Section IV, and finally we conclude this paper in Section V.

II. Related Works

To embed the secret data into the plaintext domain, it is necessary to better balance the distortion caused by the data embedding and the embedding capacity. Most works are based on difference expansion to hide secret data into unencrypted 3D mesh models. This kind of method can effectively embed secret data with low distortion by using the spatial correlation of adjacent vertices.

An RDH method for 3D mesh models based on prediction error expansion is proposed in [31]. The method predicts the position of the vertex by traversing the center of mass of the adjacent vertices, and the secret data is embedded in the difference between the predicted and actual position. In addition, too large prediction errors will not be enlarged to control the distortion introduced by selecting the threshold adaptively. This method extends the prediction error extension method to 3D mesh models for the first time, but its embedding capacity and model loss still have a lot of room for improvement. At the maximum embedding capacity, the SNR of the 3D mesh models tested by this method is all less than 35 dB. The three-dimensional model is spatially distributed, so the x, y, and z axis coordinates of each vertex can be used to embed secret data. To make full use of the high-dimensional characteristics of the 3D mesh model, Jiang et al [34] proposed to divide vertices according to odd-even property and obtained the prediction error by using the geometric similarity of adjacent vertices, combined every three neighboring prediction errors into a triplet of prediction errors, and constructed a three-dimensional prediction error histogram with lower entropy than the one-dimensional prediction error histogram by using the correlation between the prediction errors. According to the estimated optimal probability transfer matrix, the prediction error histogram is modified to embed the data to achieve the minimum distortion. This method can observe the obvious deformation of the model when the embedding capacity reaches 0.13bpv. In 2019, Zhang et al. [32] proposed to define the smoothness of the local area by using local average curvature, and priority is given to embedding data in smooth cells. The twice-layered strategy uses candidate vertices and reference vertices interchangeably to improve embedding capacity. This method effectively improves the embedding capacity, but the model still produces distortion visible to human eyes when the embedding capacity reaches 1.4 bpv. To further improve the embedding performance, Girdhar et al. [36] embedded data by selecting the average difference of appropriate vertex pairs, and logical mappings are introduced to randomly embed data into vertex coordinates. The secret data is distributed among the three coordinates of all vertices to control the distortion of the cover model, which effectively controls the distortion and greatly improves the embedding capacity. In 2022, Bhardwaj[30] proposed a more effective RDH method in the plaintext domain for 3D models, this method first uses hierarchical absolute moment block truncation coding compression model, and binary secret data is embedded in a particular block through interchanged operations. The model distortion is effectively controlled by embedding data according to the characteristics of each block, and the embedding capacity is higher than the existing RDH methods for 3D mesh model in plaintext domain.

III. Proposed Method

This paper proposes an RDH method for 3D mesh models based on multi-LSB substitution and ring-prediction. Figure. 1 is a sketch describing the proposed method. The proposed method is mainly divided into three parts. (1) The cover model M is first preprocessed by the sender. (2) The senders embed the secret data into the model through prediction error detection, generating data-embedded model M'. (3) The receiver with different permissions can extract secret data and reconstructed cover model $\widetilde{M}$, respectively.

A. Preprocessing

1) Vertex coordinates transformation: This paper studies the most popular triangular 3D meshes. The 3D mesh model is a carrier distributed in space, and the vertex coordinates of an uncompressed 3D mesh model are represented as valid 6-bit floating-point numbers. For example,

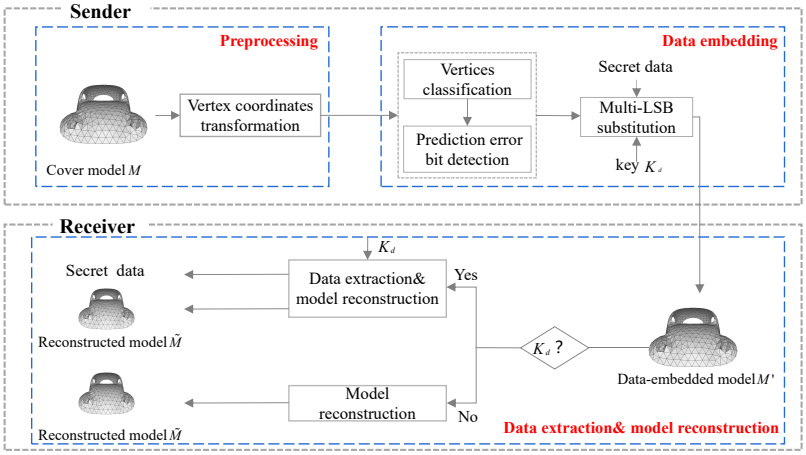

Fig. 1. Framework of the proposed method.

$v = \{0.295122, 0.338337, 0.103678\}$. Most applications of 3D models should be carried out at an acceptable level of accuracy, without the need to operate on every bit of floating-point [37]. So we do not directly modify vertex coordinates and then embed secret data. All vertices position coordinates are normalized to the accuracy of u bits and represented as integers between 0 and $2^u - 1$, where $u \in [1, 33]$. Vertex $v_{i,j}$ is normalized to $v'_{i,j}$,

$$v'_{i,j} = \lfloor v_{i,j} \times 10^u \rfloor, \quad j = x, y, z, \tag{1}$$

where i represents i_{th}th vertex, u is truncation coefficient.

To simplify data embedding operations, vertex coordinates are first converted into 32-bit binary stream form according to IEEE754 standards [38]. In modifying such a format the coordinates of the multi-LSB have little effect on the vertices according to the characteristics of the IEEE754 standard. Figure. 2 shows the transformed vertex coordinate and is calculated by

$$v'_{i,j} = (-1)^s \times \text{mant} \times 2^{e-127}, \tag{2}$$

where s represents the positive (0) or negative (1) of vertex coordinate, e is exponent (8 bits), and mant is mantissa (23 bits).

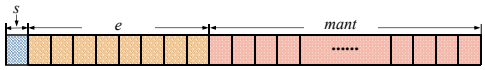

Fig. 2. IEEE754 format for vertex coordinates.

B. Data embedding

1) Vertices classification: The sender modifies part of the coordinates of the 3D mesh model to embed data. Since the neighborhood of a vertex contains multiple triangles, if the vertex is modified, the neighborhood vertex should remain unchanged to reconstruct the vertex coordinates reversibly. Therefore, vertices are divided into "embedded set" S_e for embedding data and "reference set" S_r for recovering modified vertices. Note that vertices in "reference set" are not modified during data embedding, and vertices are traversed in ascending order according to the topological structure of the triangle face. The triangle face list is denoted as $F = (f_1, f_2, \cdots, f_v)$, where $f_i = (v_{i,x}, v_{i,y}, v_{i,z})$ is any triangle face, $f_t = (v_{t,x}, v_{t,y}, v_{t,z})$ is next triangle face to be traversed. The initial states of S_e and S_r are both empty sets. If the vertices in f_t are neither in S_e nor in S_r, add $v_{t,x}$ to S_e and add $v_{t,y}$, $v_{t,z}$ to S_r. If there is a vertex $v_{t,j}$ is contained in S_e but not in S_r, add other vertices to S_r. If there are at least one vertex $v_{t,j}$ is not contained in S_e but contained in S_r, add the first vertex in f_t except $v_{t,j}$ to S_e, and add other vertices to the S_r. Figure. 3 shows the "Beetle" model and its magnified local area. The vertices marked red, blue, and yellow represent vertices in "embedded set", vertices in "reference set", and the vertices to be traversed.

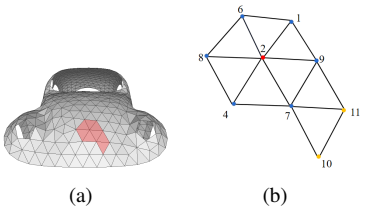

Fig. 3. Local vertex distribution of "Beetle" 3D mesh model.

2) Prediction error bit detection: The data encryption key K_d is used to generate a random bitstream to encrypt secret data by XOR operation to improve data security. Based on the characteristics of the IEEE754 standard, modifying the multi-LSB of the transformed vertex coordinates has the least impact on the vertex coordinates, so secret data is embedded in the multi-LSB of coordinates to control the distortion of the cover mesh model. The vertices in "embedded set" are predicted by multiple vertices in "reference set" of 1-ring of neighbors. The

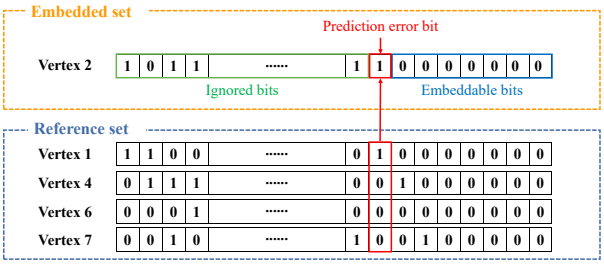

Fig. 4. Prediction error bit detection.

ring-prediction results can be obtained by

$$p_{i,j}^{k}=\begin{cases}1, & N_{1,k}\geq N_{0,k}\\ 0, & N_{0,k}>N_{1,k}\end{cases}\qquad k=1,2,\ldots,23, \tag{3}$$

where $p_{i,j}^{k}$ is the k_{th} LSB predicted value of vertex coordinate. $N_{1,k}$ denotes the number of '1' in the k_{th} LSB of vertices in S_r. $N_{0,k}$ denotes the number of '0' in the k_{th} LSB of vertices in S_r. If the number of '1' is greater than or equal to the number of '0' bit, then the predicted value the LSB of the current vertex coordinate in S_e is 1, otherwise, predicted value is 0. Compare ${v_{i,j}}'^{rLSB}$ and $p_{i,j}^{rLSB}$ sequentially from LSB to MSB until a certain bit is different,

$$\arg\max_{r}\ {v_{i,j}}'^{rLSB}=p_{i,j}^{rLSB},\quad r=1,2,\ldots,23, \tag{4}$$

where $v'_{i,j}$ is integer coordinate, ${v_{i,j}}'^{rLSB}$ and $p_{i,j}^{rLSB}$ are represent the r_{th}LSB of the 32-bit IEEE754 form coordinates and its predicted value $p_{i,j}$.

3) Multi-LSB substitution: Through the above operation, the embeddable length of each vertex can be obtained, and the multi-LSB that are correctly predicted are substituted by the secret data. For example, vertex 2 is the vertex in "embedded set", and vertices numbered 1, 4, 6, and 7 are the vertices of the 1-ring neighborhood of vertex 2. Figure. 4 describes the process of prediction error detection. The 8_{th} LSB of vertex 2 is inconsistent with the predicted result. The secret data is embedded in 7-LSB of the vertex coordinates of the "embedded set" by multi-LSB substitution. A 3D mesh model is a carrier in space, and each vertex is composed of x, y, and z coordinates. Assuming that r_1, r_2, and r_3 represent the embeddable lengths of the x-, y-, and z-axis coordinate, respectively, the embeddable length of the vertex is $r=\min\{r_1,r_2,r_3\}$.

C. Data extraction and model reconstruction

The sender classifies vertices into "embedded set" and "reference set" by ascending traversal according to the topological relation of neighborhood vertices. Similarly, the receiver also classifies the vertices into "embedded set" and "reference set" in the above way. As shown in Figure. 5, the receivers with different permissions implement data extraction and model recovery, respectively, in the following two cases:

Case 1: the receiver with the encryption key K_d can extract and decrypt secret data directly. The vertex coordinates in "embedded set" can be reconstructed using the ring-prediction rules of Eq.(3). Then the model $\widetilde{M}$ can be reconstructed by inverse coordinate transformation.

Case 2: legitimate receivers without the encryption key K_d can recover the cover model by predicting the modified vertices in "embedded set" using multi-LSB of the vertices in "reference set" of the 1-ring neighborhood. Then, the cover model can be reconstructed by inverse coordinate transformation. The secret data cannot be decrypted because there is no encryption key, so the original data cannot be extracted.

As the above analysis, both the secret data and the cover model at the receiver end are successfully retrieved in a separable manner.

IV. Experiment

The commonly-used princeton shape benchmark [39] which consists of 380 different 3D objects, and we selected four common 3D mesh objects: Cow, Beetle, Elephant, and Mushroom are adopted to test the validity of the proposed method. To demonstrate the performance of the proposed method, the corresponding analysis and discussions are given in this section in terms of analysis of embedding capacity, imperceptibility, choice of truncation coefficient u, and comparison with the state-of-the-art works.

A. Embedding capacity

In the Cartesian coordinate system, multi-dimensional embedding is realized by modifying the coordinate values of the x-, y-, and z-axis. To minimize the distortion of the cover model caused during data embedding, we choose the mantissa of vertices to embed the secret data; that is, the maximum embeddable length of each direction coordinate of each vertex is 23. The embeddable length of each vertex can be obtained by prediction error detection. In this paper, the embedding threshold l is set , $l\in[1,23]$, to mark the embeddable length of vertices. Vertices with embeddable length less than l are judged to be predictive errors and therefore not used for embedding data. The embedding rate can be calculated as

$$ER=\frac{3l\left(n_e-n_{error}\right)}{n}, \tag{5}$$

where n_e represents the number of embeddable vertices, n_{error} is the number of vertices with embeddable length less than l, and n is the total number of vertices of 3D mesh model.

B. Imperceptibility

The vertex coordinates are modified when data is embedded, making the difference between the data-embedded and the cover models. We measure the imperceptibility of the difference by subjective evaluation of human eye evaluation and objective evaluation of statistical analysis. The less easily the data embedding operation is perceived, the lower the distortion caused by the data embedding to the carrier. Experiments are conducted on four models. Figure. 6 shows the appearance of

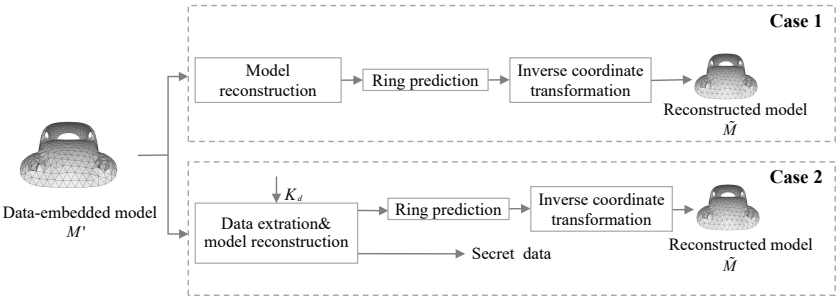

Fig. 5. Two cases of data extraction and model reconstruction for the receiver.

four 3D mesh models of each phase. The first row contains four original 3D mesh models for testing, and the second row contains the data-embedded 3D mesh models. 30 observers are invited to evaluate the difference among the data-embedded and the cover models. According to the feedback, 30 observers cannot distinguish the difference between the cover, data-embedded. Signal noise ratio (SNR), Hausdorff distance, the maximum moving distance, and average moving distance were introduced as objective evaluation indicators of difference. Statistical results under the maximum embedding rate are listed in Table I. SNR measures geometric distortion due to added noise and Hausdorff distance to measure the degree of deviation of 3D mesh models vertices after embedding secret data. The closer the SNR value is to ∞, the more similar the structure of the two models. The closer the Hausdorff distance is to 0, the smaller the difference between the two models. SNR is calculated as

$$\text{SNR} = 10\lg\frac{\sum_{i=1}^{N}\left[(v_{i,x}-\bar{v}_x)^2+(v_{i,y}-\bar{v}_y)^2+(v_{i,z}-\bar{v}_z)^2\right]}{\sum_{i=1}^{N}\left[(\hat{v}_{i,x}-v_{i,x})^2+(\hat{v}_{i,y}-v_{i,y})^2+(\hat{v}_{i,z}-v_{i,z})^2\right]}, \tag{6}$$

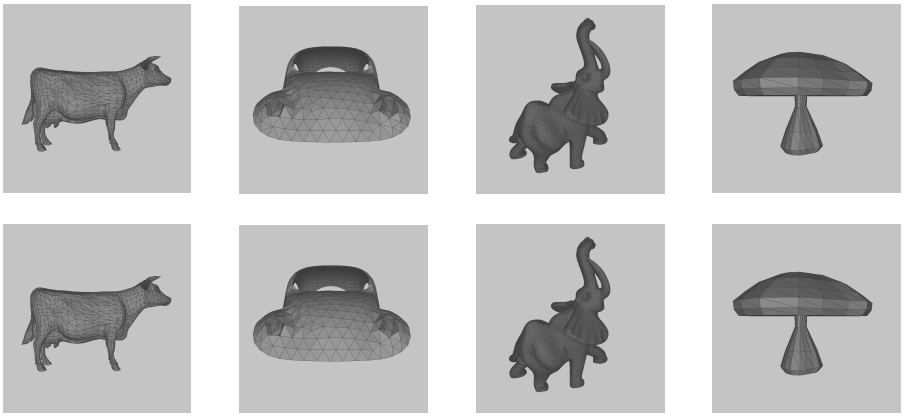
where $\bar{v}_x$, $\bar{v}_y$, $\bar{v}_z$ are the mean coordinates of the models; $v_{i,x}$, $v_{i,y}$, $v_{i,z}$ are the original coordinates of v_i; and $\hat{v}_{i,x}$, $\hat{v}_{i,y}$, $\hat{v}_{i,z}$ are the modified coordinates of v_i, and N is the total number of vertices. Hausdorff distance is the distance between two subsets of a metric space. It can be represented by

$$HD(W,V)=\max_{w\in W}\left\{\min_{v\in V}\{d(w,v)\}\right\}, \tag{7}$$

where W and V are any two sets in Euclidean space, and w and v are two arbitrary vertices in these two sets respective. $d(\cdot)$ is the distance between two vertices. In addition, the maximum moving distance $MaxD$ of the vertices in cover mesh model and the average moving distance $AvgD$ are calculated by

$$MaxD=\max\left(\sqrt{(v_{ix}-v'_{ix})^2+(v_{iy}-v'_{iy})^2+(v_{iz}-v'_{iz})^2}\right), \tag{8}$$

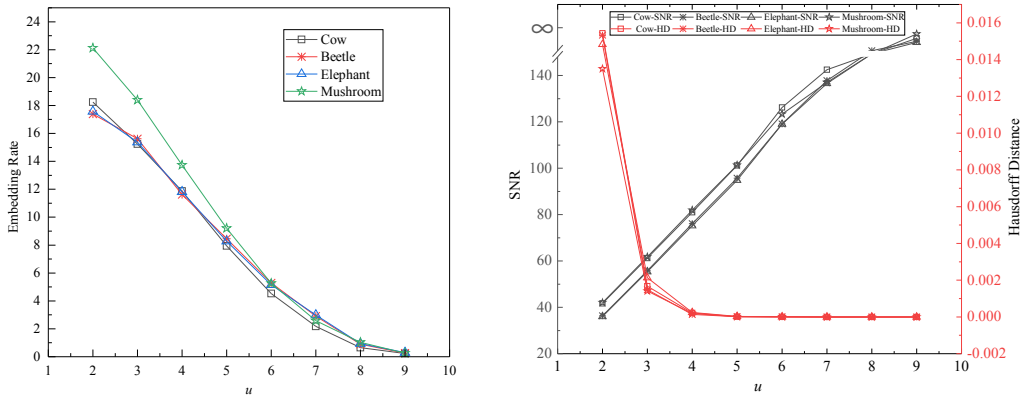
$$AvgD=\frac{1}{N}\sum_{i=0}^{N-1}\sqrt{(v_{ix}-v'_{ix})^2+(v_{iy}-v'_{iy})^2+(v_{iz}-v'_{iz})^2}, \tag{9}$$



where v_{ix}, v_{iy}, and v_{iz} represent the coordinates of the cover 3D mesh model, v'_{ix}, v'_{iy}, and v'_{iz} are the coordinates of the data-embedded 3D mesh model, and N is the total number of vertices. As shown in Table I, the statistical analysis results show that the difference between the cover mesh model and the data-embedded mesh model is only a small order of magnitude. The above experimental results and analysis effectively demonstrate that our method introduces lower distortion.

TABLE I
STATISTICAL ANALYSIS OF DISTORTION INTRODUCED BY DATA EMBEDDING FOR TEST MODELS

Models	Embedding Rate	Hausdorff Distance	SNR	MaxD	AvgD
Cow	7.93	1.60e-05	100.39	3.18e-04	1.10e-07
Beetle	8.45	1.51e-05	95.07	1.82e-04	1.84e-07
Elephant	8.28	2.80e-05	93.60	10.50e-04	41.90e-07
Mushroom	9.19	1.50e-05	100.50	0.94e-04	4.16e-07



C. Choice of truncation coefficient u

In the proposed method, u is an important parameter that determines the precision of vertex coordinates. The embedding capacity and the quality of the data-embedded model are affected by u. In general, when u is 1, the decimal reservation precision is too low to apply to most application scenarios and has no practical significance. Therefore, the proposed method takes the common precision of u for paper. The correlation between u and embedding rate is explored, as shown in Figure. 7(a). With the change of u, the embedding rate also changes to different degrees. The spatial distribution of 3D mesh models with different shapes is disorganized. As u increases, the vertex coordinates become more disordered, so the correlation of the LSBs of vertex coordinates in the 1-ring neighborhood decreases accordingly. Figure. 7(b) show the Hausdorff distance and SNR of the cover and data-embedded mesh model on different u under maximum embedding rate on four test models. As u increases, the Hausdorff distance approaches 0, and SNR approaches ∞. As u increases, the embedding rate gradually decreases, and less distortion is introduced. To better balance the embedding capacity with the introduced distortion, the truncation coefficient u = 5 is selected. According to the different application scenarios, the sender can choose the appropriate truncation coefficient according to the actual requirements.

Fig. 7. Influence of truncation coefficient u on embedding rate and imperceptibility.

D. Comparison with the state-of-the-art works

To better highlight the effectiveness of our method, the performance of the proposed method is compared with several similar methods. Table II shows the experimental results of our method and other methods on the dataset. Jiang et al. [34] constructed prediction error histogram with lower entropy and obtained the prediction error triplet. The coding optimization embedded data is constructed to achieve the optimal prediction error histogram modification, however, the method is embedding capacity less than 1.5 bpv. Zhang et al. [32], [35] proposed two RDH methods successively. The first emthod is a hybrid prediction method based on the uniformity factor, which produces a small prediction error. The embeddable space can be obtained by using overlapping segmentation and adaptive embedding in the multi-layer embedding process. The second method is an improved RDH based on prediction error expansion and ordering. However, both methods produce significant distortion when the embedding capacity exceeds 1.5 bpv. Girdhar et al. [36] embedded secret data using the difference between the coordinates of the vertex pairs on the selected coordinate axis. Their method introduces chaotic logical mapping to select vertex coordinates embedded in secret data and extract secret data. The secret data can be extracted using the logical map without restoring the model, thus realizing the separability of the method. The embedding rate of this method is affected by the number of adjacent embeddable vertices and threshold parameters. The embedding rate of their method still has much room to improve. In [30], hierarchical absolute moment block truncation coding is used to compress the mesh blocks and then embed secret data in the compressed domain. The method proposed by Bhardwaj [30] greatly improves the embedding rate of secret data in plaintext domain of the 3D model. The receiver can reconstruct the cover model using the designed embedding rules without extracting secret data. However, the method will generate auxiliary data in the process of data embedding. In our method, vertices are divided into two spatially adjacent sets. Data embedding modifies the coordinates of the vertices in "embedded set" and recovers the modified vertices by the vertices in "reference set" without extracting secret data. After the vertex coordinates in "embedded set" are converted into 32-bit IEEE754 format,

the embeddable length of the vertices in "embedded set" is obtained by comparing the consistency of the coordinates of the embeddable vertices with their reference vertices. Each vertex coordinate can embed multi-bit data to effectively improve each vertex's embedding capacity. These modified bits have minimal impact on the coordinates and effectively control the distortion of the cover model. Receivers with different permissions can extract secret data and reconstruct the cover model. So the separability of data extraction and model reconstruction of our method is satisfied. As shown in Table II, our method achieves higher embedding rate and better imperceptibility than other methods.

TABLE II
COMPARISON OF FEATURES WITH THE STATE-OF-THE-ART METHODS

Methods	Features				
	Embedding Rate	Hausdorff Distance	Data Error(%)	SNR(dB)	Separable
Jiang et al.[34]	1.29	-	0	46.78	No
Zhang et al.[32]	1.40	-	0	48.00	No
Zhang et al.[35]	1.50	-	0	40.00	No
Girdhar et al.(k=1)[36]	1.50	0.2610	0	98.74	Yes
Girdhar et al.(k=2)[36]	3.00	0.3360	0	97.50	Yes
Girdhar et al.(k=3)[36]	4.50	0.4829	0	95.08	Yes
Bhardwaj[30]	6.94	0.2358	0	96.40	Yes
Proposed method	**8.08**	**0.000017**	0	**99.81**	Yes

V. CONCLUSIONS

In the paper, an RDH method for 3D mesh model with higher embedding rate and lower distortion is proposed based on multi-LSB substitution and ring-prediction. The vertex coordinates are converted to a specific format, and the multi-LSB with the least impact on the vertices is selected to embed the data by bit substitution. Each embeddable vertex can embed multi-bit data without significant distortion to the cover model. 3D mesh model can be reconstructed without extracting secret data by exploring the correlation of vertices in the local region. Experimental results show the proposed method outperforms state-of-the-art methods in embedding rate and model distortion. However, the proposed method is not yet against malicious attacks. In follow-up research, it is urgent to enhance the robustness of the method against external attacks. We also consider using genetic algorithm to find the optimal vertex embeddable set to make full use of the vertex topological relationship of 3D model.

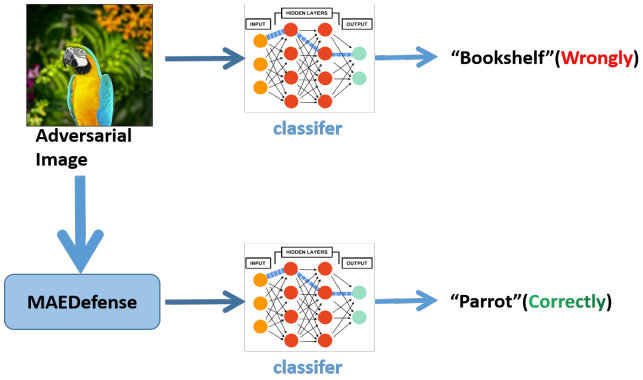
***Abstract*— Recent studies have demonstrated that deep neural networks (DNNs) are vulnerable to attacks when adversarial perturbations are added to the clean samples. Reconstructing clean samples under the premise of inputting adversarial perturbations is a challenging task. To address this issue, this paper proposes a Mask AutoEncoder Defense (MAEDefense) framework to counter adversarial attacks. Firstly, the adversarial sample is divided into two complementary masked images. Secondly, the two masked images with carefully crafted adversarial noise locations are reassigned to non-adversarial noise locations. Finally, the two reconstructed images are pixel-wise fused (weighted average) to obtain a "clean image". The proposed method requires no external training and is easy to implement. Experimental results show that the proposed method significantly defends against white-box attacks and black-box transferable attacks compared with state-of-the-art methods.**

I. Introduction

Due to their success in vision tasks such as image classification[1], target detection [2], target tracking [3], and image segmentation[4], deep neural networks (DNNs) have been widely used in critical areas such as autonomous driving [5]and face recognition[6]. However, recent studies have shown that deep neural networks are vulnerable to adversarial attacks and can be easily fooled [7]. These attacks are difficult for the human visual system to detect. Adversarial samples are generated by deliberately introducing imperceptible perturbations to clean samples, causing the model to produce false results with a high level of confidence. Furthermore, research has shown that adversarial samples can also exist in the physical world[6], posing significant security risks. Therefore, considering the security of deep neural networks has become a necessity rather than an option.

Numerous defense methods have been proposed to counter adversarial attacks. These defense mechanisms can be broadly categorized into two main types: robustness-based defense and input transformation-based defense. Robustness-based defense aims to improve the performance of deep convolutional neural network (DCNN) classifiers by retraining them and utilizing augmented datasets that include adversarial examples.[7]–[10]. These defense methods demonstrate a strong resistance against specific attacks that generate adversarial examples. However, these defense methods are typically time-consuming and computationally expensive when dealing with large-scale, high-dimensional image datasets (such as ImageNet[11]). Additionally, robust defense methods, when faced with unknown attacks, require retraining of the classifier, which can lead to a decrease in the accuracy of recognizing clean examples[7], [10]. Unlike robust defense methods, input transformation-based defense methods [12]–[15] are more practical. However, most existing methods heavily rely on external priors learned from training datasets, while overlooking the rich intrinsic priors inherent in the input data. For instance, methods like PixelDefend[16] and ComDefend [12]transform adversarial examples into "clean samples" and train models using adversarial examples as input. Similarly, DefenseGAN[17] utilizes generative adversarial networks (GANs) to mitigate the impact of adversarial perturbations. Defense methods that rely on learning external priors suffer from the issue of significantly reducing the defensive capabilities of the model when the counter-attack method changes or when the attack method is unknown.



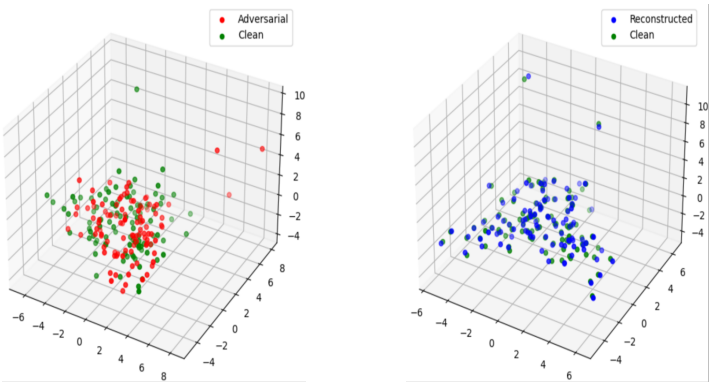


Fig. 1. An example of the proposed MAEDefense.

Adversarial perturbations are carefully designed noises, and disrupting their structure is a natural defense mechanism. A straightforward idea is to directly mask the pixels in order to eliminate the structure of the noise. While this method may eliminate the noise structure, it also damages the structural

information of the original image, resulting in a decline in the neural network's performance. However, this naive idea presents an intriguing suggestion: By utilizing random masking, the meticulously designed structure can be disrupted, while an image reconstruction model can be employed to restore the overall structure of objects in the image. If the reconstruction successfully preserves the underlying global structure, the pixel masking and image reconstruction can effectively redistribute the carefully designed adversarial noise into non-adversarial structures. Recently, He et al[18] proposed a simple and efficient unsupervised training model called MAE. This model leverages the abundant redundancy in image data and employs an asymmetric codec to restore partially obscured information. Inspired by their work, we have incorporated the MAE model as the reconstruction component in our defense approach.

(a) (b)

Fig. 2. (a) The left image shows a 3D map illustrating adversarial image features (highlighted in red) and corresponding clean image features (highlighted in green). (b) On the right side, we depict the features of the corresponding defense image (highlighted in blue). This visual representation clearly demonstrates how the masked reconstruction model effectively redistributes the carefully crafted adversarial noise into non-adversarial structures.

This paper presents a model-agnostic defense (MAEDefense) that effectively restores adversarially perturbed images to their original class labels. As shown in Fig**??**, an image of a "parrot" with adversarial perturbation is initially misclassified as a "bookshelf," but it is correctly classified after undergoing the MAEDefense process. The defense is based on the MAE model, which randomly masks image pixel blocks and reconstructs the masked pixels. This paper explores the feature structures of clean samples, adversarial samples, and reconstructed samples. Fig2 displays 100 randomly selected features projected onto a 3D space using principal component analysis. This figure clearly demonstrates how the masking and reconstruction model reallocates carefully crafted adversarial noise into non-adversarial structures, thereby disrupting the structure of the adversarial noise. The main contributions of our paper are as follows:

- The paper proposes a simple and effective defense method called MAEDefense. The carefully crafted adversarial noise locations are reassigned to non-adversarial noise locations, which effectively breaks the inherent structure of the adversarial noise. By utilizing the class activation map visualization, the MAEDefense method successfully redirects the classifier's attention away from the noise region and towards the main structure region of the image.
- The prior information embedded in the image and Mask AutoEncoder model is utilized to reconstruct the adversarial examples, resulting in a significant reduction in computational time. Through extensive experimentation, it has been demonstrated that MAEDefense is an effective countermeasure against various attack strategies.

II. Relate Work

A. Adversarial Attacks

Existing adversarial attack methods can be broadly categorized into two types: black-box attacks and white-box attacks. In a white-box setting, the attacker has knowledge of the model's structure and specific parameters, enabling them to launch adversarial attacks against the victim model with ease. In black-box attacks, the attacker has no knowledge of the internal structure, training parameters, etc., of the target model. The attacker can generate a large number of adversarial samples by querying or training substitute models, and then use these examples to attack the victim model.

Several attack methods have been proposed to effectively work in the white-box environment. Goodfellow et al[7] proposed a single-step attack called the Fast Gradient Symbolic Method (FGSM). Unlike FGSM,BIM[6] perturbs small multi-step perturbations along increasing gradients in an iterative manner.The projected gradient descent(PGD)[8] attack is BIM with random starts.The C&W attack[19] is an efficient optimization method used to find the smallest perturbation.

In the "arms race" between attackers and defenders, classifier owners may employ defensive measures to protect the targeted classifier. The effectiveness of many attack methods is compromised, but black-box attacks, such as transfer-based attacks, are more powerful. Momentum FGSM (MIM) [20] introduces momentum into gradient accumulation at each iteration, enhancing both robustness and transferability. DIM[21] further improves MIM by applying random transformations to the input image. TIM utilizes a set of images to compute gradients, which is particularly useful for black-box models with defensive mechanisms. To reduce the computation of gradients, Dong et al[22] propose shifting the image within a small range and approximating the gradient by convolving the gradients of untransformed images with a kernel matrix. Wang et al. [23] propose a method based on variance tuning to enhance transferability (VMI).

B. Adversarial Defenses

The goal of adversarial defense is to protect victim classifiers from adversarial attacks. Among the existing defense methods, reconstruction-based defense methods are becoming increasingly popular. These methods aim to reconstruct a "clean sample" by disrupting the fixed structure of the adversarial perturbation.

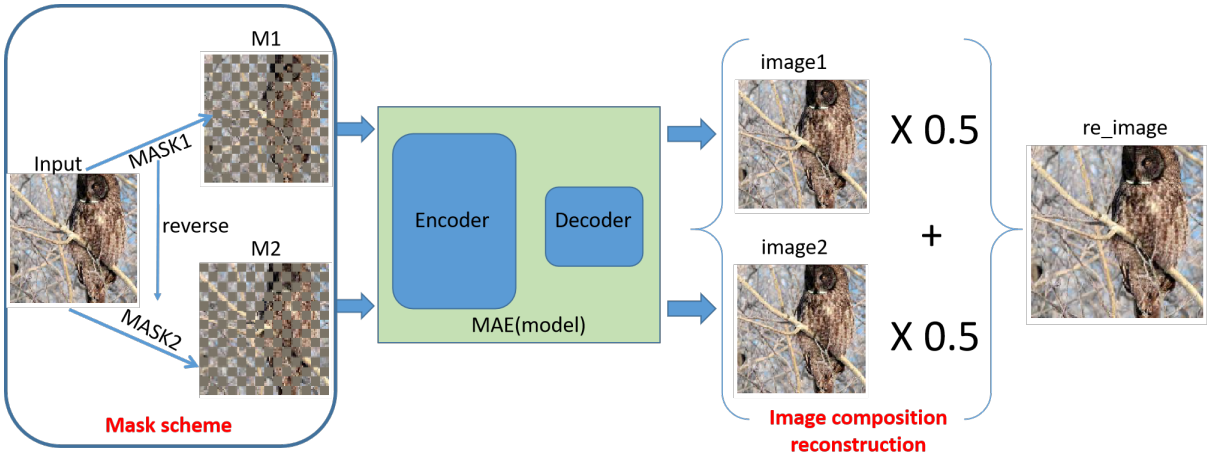

Fig. 3. Framework diagram of the MAEdefense.

Recently, a new approach called ComDefend[12] was proposed to remove adversarial noise from images while preserving their structural information. This approach is an end-to-end compression model. In addition, Mustafa et al[14] proposed a method that combines wavelet denoising and pre-trained super-resolution (SR) networks to reconstruct clean images. To address the issue of adversarial perturbations in the feature space, Naseer et al[15] developed a neural representation purifier (NRP). Such defenses require training on external datasets or pre-trained models, although they are effective in defending against certain attacks. Unlike previous methods, DIPdefend[13] exploits the internal priors of a target image to reconstruct clean images, achieving state-of-the-art performance in adversarial defense. However, DIPDefend can only operate on a single image and requires multiple iterations, which is not only time-consuming but also susceptible to overfitting.

C. Masked AutoEncoder

Masked Autoencoder[18] is a specialized neural network that is extensively used in image processing tasks. It is designed to reconstruct input data while simultaneously learning to mask or remove specific regions. This approach effectively removes noise, occlusions, and perturbations from images while preserving essential visual information. MAE consists of two main components: an encoder, which compresses input data (such as images) into a potential encoding, and a decoder, which utilizes this code to reconstruct the original input. During the training phase, MAE introduces masks that are applied to the input data, blocking certain portions. The network learns to reconstruct the original input data from these masked inputs, filling in missing or obscured regions with information from unmasked areas. This strategy allows MAE to focus on specific areas of interest, making it particularly valuable for tasks such as inpainting, denoising, and image completion. In summary, the Masked Autoencoder serves as a potent tool for image reconstruction and restoration. It effectively eliminates unwanted perturbations while preserving the visual quality of the original input data.

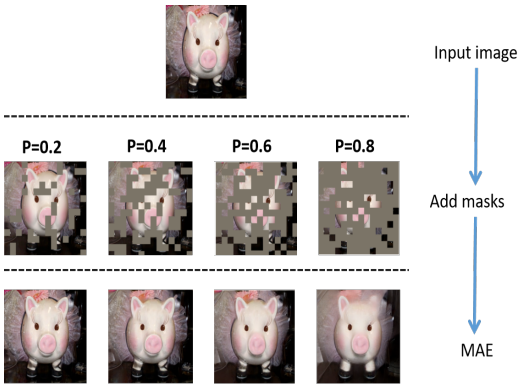

Fig. 4. An example of how a Masked AutoEncoder (MAE) affects input images. We apply various masks and display the reconstructed images using MAE

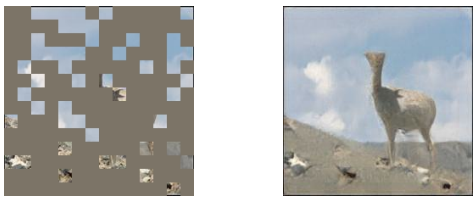
III. METHODOLOGY

A. Design Motivation

Typically, the ”clean images” obtained also contain white noise present in the environment, which is considered as part of the image. While modern deep neural networks perform at a human-level when dealing with unstructured small noise, the situation is different when it comes to carefully crafted structured adversarial noise, known as adversarial examples. This type of adversarial noise can easily disrupt the output of neural networks, leading to predictions that are inconsistent with human perception. To enhance the robustness of neural networks against adversarial noise, we need to carefully eliminate or reduce adversarial structures that are specifically crafted, while still preserving the intrinsic structure within the image to ensure accurate classification.

Through previous studies, we have learned that adversarial perturbations are highly unstable and can be eliminated using simple input transformation methods. Our approach involves initially neutralizing a significant portion of the structure



created by the adversarial noise through pixel masking (zeroing out blocks of pixels) in the image. However, this process also introduces non-adversarial noise to the image, which negatively affects the global structure of the image. Fortunately, we can use the MAE model to effectively recover the global structure of an image using information from the unmasked portion. the MAE model recovers the intrinsic structure of a clean image, such as the primary structure of a dog in a dog image.

Next, we present the reconstruction results based on the MAE model with different masking ratios, as shown in Fig4. It is worth noting that the global structure is maintained even when the image has a masking rate of 0.6. This indicates that the model is able to reconstruct the underlying global image structure from the masked adversarial image, despite the fact that a large amount of pixel block information has been removed. By applying a mask with a specific ratio, we can preserve the overall structure while reducing the impact of other potential adversarial structures.

B. MAEDefense as a defense mechanism

The analysis above demonstrates that the MAE reconstruction model is capable of restoring the visual information of an image. Even when some pixel block information is omitted, the remaining pixel information can still be utilized to reconstruct the global structure of the image. In this paper, we first reconstruct two adversarial images using the uniform mask and MAE model. Then, we fuse the two reconstructed images pixel by pixel to obtain the final clean image. The framework of the method is shown in Fig3. Firstly, the adversarial sample is divided into two complementary masked images. Secondly, the two masked images with carefully crafted adversarial noise locations are reassigned to non-adversarial noise locations. Finally, the two reconstructed images are pixel-wise fused (weighted average) to obtain a ”clean image”.

C. Mask scheme

(a) Random Mask

(b)Uniform Mask

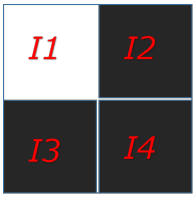


Fig. 5. Reconstructed images under different masking schemes. (a) random mask reconstructed at 75% ratio, and (b) uniform mask reconstructed at 75% ratio.

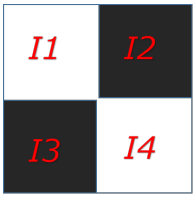
The MAE reconstructs the complete image after randomly masking 75% of the image in the current self-supervised learning task. Unlike the task of MAE itself, our goal is to restore the visual information of the image while disrupting the adversarial perturbation.



It has been found that when the pixels of an image are widely and randomly discarded, the MAE model is unable to predict the discarded pixel information based on the remaining pixel information. This leads to incomplete recovery of the global structure of the image. As shown in Fig5(a), features such as the antelope head and antelope horns could not be recovered, resulting in incorrect classification of the reconstructed images. This ultimately led to a decrease in the accuracy of image classification. This is because the visible elements within each local window are completely obscured, making it difficult to recover structural features within that window. To address this issue, a uniform masking scheme is proposed in this paper, as illustrated in Fig5(b). The specific operation is as follows: the image is divided into 49 pixel blocks, each measuring 32x32 in size. Again, the pixel blocks I are uniformly refined into four 16×16 pixel blocks, as shown in Fig 6(a). These four regions are named I1, I2, I3, and I4. We use the generated mask to discard all pixel information of regions I2, I3, and I4, and only keep the pixel information from the I1 region. Finally, we chose the mask scheme shown in Fig6(b) to balance the classification accuracy after reconstructing the adversarial and clean samples.

D. reconstruction scheme

When the perturbation is small and the attack intensity is low, reconstructing the recovery after discarding only a few pixels can provide effective defense. However, as the intensity of the attack increases, the structure against noise becomes more robust, and the defense performance of reconstructing clean samples by discarding only some blocks of pixels is greatly reduced. Therefore, the key to solving the problem lies in disrupting the structure of the antidisturbance by discarding more pixel information. In this paper, we propose a method to mitigate full-image adversarial perturbations using two masks. We reconstruct two similar images by MAE model, and then enhance the global structure of the reconstructed image by fusing the two images (weighted average) to achieve better defense performance.

(a)75% Ratio

(b)50% Ratio

IV. EXPERIMENTS

A. Experimental Settings

Dataset: We randomly pick 1,000 clean images pertaining to the 1,000 categories from the ILSVRC 2012 validation set. **Attacks and Defense Methods:** To verify the effectiveness of the defense framework, five classical methods,FGSM[7],BIM[6],PGD[8],MIM[20] and C&W[19] are chosen to generate different types of adversarial samples for defense testing. In this attack setup, the model owner evaluates the effectiveness of the defense methods in protecting the victim model. The defense methods include three methods that require external prior information training,ComDefend[12],SR[14],NRP[15] and DIPDefend[13], which does not require any external training. These methods are evaluated and compared with the proposed method. Additionally, with the development of adversarial attack and defense techniques, more and more advanced attacks are proposed. Black-box attack methods, such as transferable attacks, are more robust, and many defense mechanisms fail under advanced transferable attacks, such as DIM[21],TIM[22],VMI and VNI[23],etc. We have also conducted experiments to evaluate the performance of our defenses against transferable attack methods.

B. Assessment under White-Box Attack

In this experiment, ResNet-50[25] is used as the victim model and achieves an accuracy of 94.7% for clean image samples without any defense mechanism. However, under classical adversarial attacks, the classification accuracy of the adversarial samples decreases rapidly, and it is difficult to disrupt the fixed structure of the adversarial perturbation. As a preprocessing method that does not require external training data, this method still achieves a high average classification accuracy (ACC) of 69.2% under various classical adversarial attacks, as shown in Table I. In comparison to previous defense methods, our proposed method not only achieves higher classification accuracy after reconstruction but also does not require any additional training. When compared to the advanced defense method DIPDefend, which does not require multiple iterations, our method is simpler and more efficient to implement. Our defense method achieves a significant improvement not only on the adversarial examples but also on the clean examples.

Although the proposed defenses achieve good performance against classical attack methods, many of them fail to withstand the emergence of various attack techniques. The most notable among these are black-box attacks, which are based on tranferrable attacks. These attacks generate more robust adversarial examples and perturbations that are more difficult to eliminate. We selected three classifier models ResNet50[25],VGG16[26] and DenseNet-121[27] as our victim models to generate adversarial examples under four robust transferable attack methods. We present the classification accuracy of the models before and after the adversarial samples are defended by our defense methods, as shown in Table II. Maintain more than 40% model classification accuracy in the face of advanced attack methods.Comparing different attack methods, we find that the performance of our defense method is degraded by image pre-processing based data enhancement attacks DIM and TIM attacks, while the gradient obfuscation-based adversarial attack methods have relatively little impact on our defense methods.

In addition to comparing defense capabilities, we also compared the image quality generated by different defense methods. In Table III, we quantitatively compared the ImageNet dataset using the SSIM[24] metric. We conducted a visual comparison of image quality among different defense methods under five different types of adversarial attacks. Our observations indicate that the proposed method generally outperforms the baseline methods in terms of visual quality. The superiority of the reconstructed images further confirms the effectiveness of our proposed strategy for mask reconstruction denoising in improving image quality.

C. Assessment under Black-box Attack

In this section, we assess different defense methods counter cross-model black-box attacks. In such attacks, the adversary does not have access to the parameters of the target classifier or defense model. Instead, a substitute model (referred to as the source model) with a distinct architecture is trained. The adversarial examples generated from the source model can deceive the target classifier. Black-box attacks can easily be transferred between different models.

Our method is compared to the DIPDefend approach, as it has demonstrated superiority over several previous defense methods in similar settings. To evaluate the robustness of our method against black-box attacks, we utilize the ResNet-50 model as the substitute model to generate adversarial samples using various attack methods. The Inception-v3 and VGG16 models have been chosen as our target models. The overall accuracy results are presented in Table IV. We observed a significant decrease in accuracy for the target models when they were tested on the adversarial samples generated from the substitute model. This confirms the transferability of adversarial examples. However, by implementing various defense strategies, the precision of the target models significantly enhances across different attack scenarios. Comparatively, our method demonstrates superior performance in the majority of black-box attack scenarios.

D. Analysis of the Proposed Method

Why is the mask ratio 50%?We investigated the relationship between the classification accuracy of reconstructed images and the masking rate. Different masking rates were applied to both the original and adversarial samples, and then these images were reconstructed. The reconstructed images were inputted into the ResNet-50 network for classification. Fig8 illustrates the classification accuracy and the corresponding masking rates.From the figure, it can be observed that the recognition accuracy of reconstructed clean samples gradually decreases as the masking rate increases. However, for highly perturbed adversarial samples, the classification accuracy of

	70.2	49.7	61.8
VNI[23]	1.0	0.8	0.1
	69.6	49.8	60.8

the reconstructed samples is highest when the masking rate of 50%. This could be attributed to the fact that preserving a certain proportion of the image information enables the reconstructed samples to retain some similarity to the original samples, thereby enhancing the classification accuracy. However, as the masking rate increases further, more information is lost in the reconstructed images, leading to a decrease in classification accuracy. Therefore, in this experiment, a masking rate of 50% was found to be the threshold for achieving optimal classification accuracy.

In order to analyze the performance of the proposed method, we compare it with the direct reconstruction method using MAE[18], analyze the proposed method. As shown in Table V, the proposed method not only outperforms MAE in reconstructing clean samples but also surpasses MAE in countering adversarial attacks.The effectiveness of our proposed method is fully demonstrated by the analysis of experimental results. To validate the shorter runtime of our method, we compared its runtime with that of DIPDefend on a single image. The Table VI shows that our method has a significantly shorter runtime compared to DIPDefend. This is because DIPDefend requires multiple iterations, typically around 1000 iterations, to generate normal samples, whereas our proposed method does not require any iterative computation. Therefore, compared to other methods, our approach has an advantage in terms of defense accuracy and computational cost.

In the final part of this paper, we utilized Class Activation

Mapping (CAM) to interpret the predictions made by the Convolutional Neural Network (CNN) model. CAM generates heatmaps by replacing the last fully connected layer with a Global Average Pooling (GAP) layer. By applying a class-weighted average to the feature maps, the Class Activation Map (CAM) algorithm highlights the regions in the image that are relevant to the predicted class label. The Fig7 illustrates the results of the CAM analysis for the top-1 predictions of the model on clean samples, adversarial samples, and recovered samples. It can be observed that the masked reconstruction disrupts most of the noise structure, resulting in CAM results that resemble those of clean images. The MAE-based masked reconstruction helps restore the model's attention to distinctive regions that correspond to the correct class label.

TABLE VI

DIPDefend	600.038
Ours	5.316

V. CONCLUSION

The paper presents a novel and simple defense method against adversarial examples. Unlike previous work, the scheme disrupts the fixation structure of adversarial perturbations by masking blocks of pixels and reconstructing the global structure of classified images using a Masked AutoEncoder (MAE). Extensive experiments on a public image dataset demonstrate that the proposed approach surpasses numerous existing defense methods in terms of defense performance and visual quality. In addition, our defense method is independent of the type of attack, does not require additional training, and is equally effective against both black-box and white-box attacks.

***Abstract*—Image steganography plays a vital role in the realm of information hiding, involving the discreet embedding of confidential data within an image. However, the misuse of this technology by malicious actors on social media platforms poses a significant threat to public security. Presently, the primary defense against image steganography is steganalysis technology, which effectively distinguishes steganographic images from regular ones by detecting subtle modifications. Nevertheless, there is considerable room for improvement in existing steganalysis techniques, especially when dealing with small payloads. In this paper, we propose a proactive strategy to enhance the detection of steganographic images with small payloads. Specifically, as the image is captured, we apply a meticulous-designed and imperceptible mask to it. This mask is aimed at increasing the success rate of detection. We have developed three convolutional neural networks (CNNs) to facilitate this proactive image processing: preemptive-CNN, steganography network (Stego-CNN), and steganalysis discriminator. During the training process, Stego-CNN remains unaltered, while preemptive-CNN and the discriminator are jointly trained to ensure that the applied mask enhances the detection accuracy. Experimental results demonstrate the effectiveness of our proposed approach in enhancing the detection accuracy, all without compromising the visual quality of the images.**

I. Introduction

Thousands of images are transmitted on social networks every day. With communication technology rapidly developing and photography equipment becoming increasingly portable, people can record and share images almost anytime and anywhere. However, while this brings great convenience to social communication, it also poses some security risks. Image steganography enables an image to carry secret information with minimal modification, typically less than 1 per pixel. Due to the minimal amplitude of modification per pixel, the human visual system finds it difficult to detect the difference between the original and steganography-altered images. Criminals can exploit steganography to embed criminal information in seemingly normal images, making it appear no different from regular image transmission. Therefore, studying the technology of resisting steganography holds great practical significance in maintaining social security and fighting crime.

Image steganography [1]–[5] is a technology that enables the embedding of secret information into an image using an imperceptible method. Steganography typically introduces only slight pixel value distortions to an image to maintain its invisibility. Moreover, image steganography prefers to modify the textured and complex regions of the image [6]–[9] to preserve statistical characteristics and avoid visible artifacts. This process is similar to conventional image processing techniques, such as JPEG compression. However, steganography introduces even subtler changes to the images compared to JPEG compression. Fig. 1 illustrates the influence of steganography and JPEG compression on an image. For the sake of simplicity, the original image is referred to as the cover, and the steganographic image is referred to as the stego in the subsequent content of this paper.

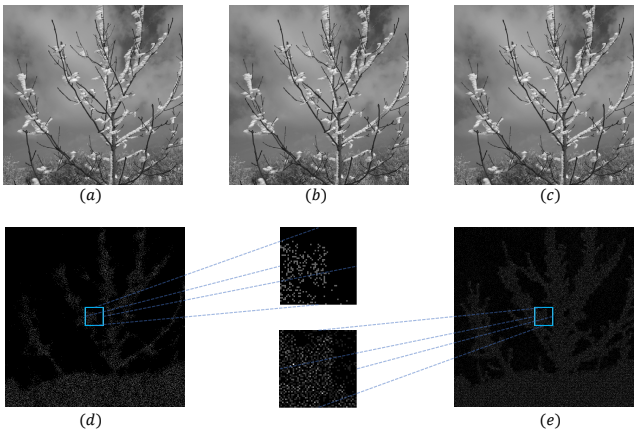

Fig. 1. (a): Original image. (b): Steganographic image, where the embedding algorithm is HILL with payload $= 0.2$. (c): Compressed image with the quality factor of 95. (d): The residual image between steganographic image and the original image (magnified 100 times). (e): The residual image between compressed image and the original image (magnified 30 times).

In order to mitigate the potential security risks linked to image steganography, a plethora of countermeasures have been put forth. Among these countermeasures, steganalysis technology emerges as the predominant and highly efficient approach. Steganalysis typically comprises three key steps: initially, computing the residuals of both cover images and stego images; next, extracting high-dimensional statistical features from these residuals; and ultimately, employing these features to identify stego images through the use of a discriminator.

Classical steganalysis primarily focuses on the disparity of hand-crafted statistical features during the feature extraction

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

stage. These features exhibit strong mathematical interpretability between cover and steganographic images [10]–[16]. The detection accuracy of steganalysis discriminators heavily relies on the dimensionality of the extracted features. Higher-dimensional features result in better detection performance. In primary steganalysis, discriminators often employ nonlinear Support Vector Machines (SVMs) to classify the extracted features [17]–[21]. However, the computational complexity of SVMs increases significantly with the feature dimension, which limits the timeliness of the discriminator. In current steganalysis practices, Fisher Linear Discriminant (FLD) ensemble classifiers are commonly employed to handle high-dimensional features [22]. Specifically, FLD serves as the fundamental classifier, and the final decision result is obtained through voting aggregation based on the decisions of multiple basic classifiers, such as the Spatial Rich Model (SRM) [23] and the selection-channel-aware rich model (maxSRM) [24].

On the other hand, all three modules of steganalysis can be simulated and implemented using convolutional neural networks (CNNs). The steganalysis technology based on CNN is gradually emerging [25]. The performance of CNN has even surpassed that of classical steganography since the advent of YeNet [26], which is the first CNN-based steganography that made a breakthrough in performance. Steganalysis Residual Network (SRNet) [27] overcomes the constraints of YeNet on the database and prior knowledge, making network training an end-to-end process. SiameseNet breaks the constraints of steganography on image size and can detect images of multiple sizes without degrading performance.

However, both traditional steganalysis methods and modern neural network-based steganalysis techniques have shown suboptimal performance when dealing with small steganographic payloads. In this research, we introduce an innovative CNN-based approach to combat image steganography. Our method involves superimposing an imperceptible mask on the image during its creation, which we call the ”masked cover.” Detecting steganography in the masked cover is more achievable compared to the original cover, even when the masked cover undergoes standard image processing before steganography. To implement our approach, we offer a discriminator to social network operators, empowering them to identify images containing concealed information. By identifying steganographic images, they can prevent them from being uploaded to social networks.

The main contributions of the proposed strategy are summarized as follows:

- We implemented an approximation to image steganography using convolutional neural networks.
- The proposed scheme enhances the complexity of image steganography while preserving the visual quality of the image..
- Our scheme improves the detection accuracy of stego images and is compatible with existing steganalysis techniques.

The remaining structure of this paper is as follows. The second section II is the related work of steganography and steganalysis. The implementation details of our scheme are in section III. The fourth section IV presents our experimental results. Finally, the conclusion of this study are presented in section V.

II. Related work

A. Steganography

Image steganography represents a fundamental method for covert communication. It involves concealing information within an ordinary, unaltered image, effectively shrouding the secrecy of transmission. The key differentiation between steganography and encrypted communication lies in the visibility of the communication process: the latter is observable, while the former adeptly disguises it. Historically, steganography can be broadly classified into three categories: naive steganography, adaptive steganography, and CNN-based steganography.

Naive steganography includes Least Significant Bit (LSB) substitution [24], Bit-Plane Complexity Segmentation (BPCS) [28], vector pixel randomly Plus or Minus 1 (PM1) [29], MMD [30] encoding and ZZW [31] encoding, among others. These algorithms, collectively known as non-adaptive steganography, solely prioritize the visual quality of stego without thoroughly considering image statistical features. Consequently, they are prone to detection by steganalysis.

Adaptive steganography is the prevailing steganography technique that assigns different distortion values to pixels in varying positions. It comprises two frameworks based on minimizing distortion and mathematical models. The minimization distortion steganography framework conceals secret information while minimizing overall distortion. Ever since Filler et al. introduced the convolution code-based Syndrome-Trellis Codes (STC) [32], which approximates the theoretical distortion limit, the focus of research in the minimization distortion steganography field has shifted towards defining better distortion value functions. Highly Undetectable steGO (HUGO) [33] defines the distortion value based on the deviation of features extracted from the cover and stego using the steganalysis algorithm SPAM [34]. A smaller deviation corresponds to a smaller distortion value. Wavelet Obtained Weights (WOW) [2] and UNIversal WAvelet Relative Distortion (UNIWIARD) [3] employ a set of multidirectional wavelet filters to predict the pixel residuals in the cover. Pixels that are difficult to predict in any direction are assigned a small distortion value. HIgh-pass, Low-pass, and Low-pass (HILL) [5] uses a high-pass filter to identify the hard-to-predict areas in the cover, while two low-pass filters concentrate pixels with low distortion costs. Steganography based on a mathematical model offers more theoretical support and interpretability compared to methods based on distortion value. Multivariate Gaussian (MG) [35] models the cover and stego using a multivariate Gaussian model, optimizing the KL-divergence of the probability distribution to achieve indistinguishability. Fridrich et al. [4] employ the Multivariate Generalized Gaussian model

(MVG), which incorporates optimization parameter measures to specify modifications to the carrier image, resulting in improved security compared to MG.

Currently, the rapid advancement of Convolutional Neural Networks (CNN) is forging a novel path within the realm of steganography. A series of CNN-based methodologies have been sequentially introduced to this field. Volkhonsiky et al. [36] have presented a steganographic approach rooted in Generative Adversarial Networks (GANs). In this paradigm, the generator handles the process of embedding confidential information, while the discriminator specializes in steganalysis. By leveraging GANs for continual optimization of the distortion function, Tang et al. have achieved a level of security performance equivalent to UNIWARD. In the HiDDeN framework [37], the encoder is entrusted with the task of generating an encoded image, referred to as stego, from a combination of secret information and a cover image. The resulting stego image is meticulously designed to be visually indistinguishable from the original cover image, while still allowing for the extraction of concealed information. Tang et al. [38] have introduced the ADV-EMB algorithm, which adapts the distortion function based on the gradient of the neural network, drawing inspiration from adversarial samples. Furthermore, UT-6HPF-GAN [39] is capable of crafting a modified probability graph to confound the discriminator by utilizing the cover image as input to the generator. This innovative approach showcases the ever-evolving landscape of steganography through CNN-driven techniques.

B. Steganalysis

Steganography is a countermeasure to steganalysis, which is used to detect whether an image has embedded secret information. Steganography requires changing the pixel values in the cover, which inevitably destroys the neighborhood correlation of pixels. Even if the correlation is difficult to be perceived by human eyes, steganalysis can distinguish cover from stego. Generally, steganalysis includes three modules: residual calculation, feature extraction, and discriminator. Obviously, the performance of steganalysis depends on the quality of extracted features and the discriminating ability of the discriminator, which also guides the direction of technical development.

The nonlinear Support Vector Machine (SVM) [40] is a commonly employed discriminator in naive steganalysis. However, since the introduction of SRM, the number of feature dimensions has surged to a staggering 34,671. Persisting with SVM as the discriminator in such circumstances would result in a substantial computational burden. Consequently, contemporary steganalysis approaches often opt for an ensemble discriminator based on Fisher's Linear Discriminant (FLD) to handle high-dimensional features. Fridrich et al. first introduced SRM [23], which leverages multiple submodels and high-pass filters to capture a wide range of steganographic features. This methodology strives to enhance the detection of potential damage to the neighborhood correlation of pixels. As an upgraded iteration of SRM, maxSRM [24] assigns varying statistical weights to the pixels in the cover image. It examines the maximum pixel modification probability in four positions to compute the co-occurrence matrix of the cover image.

The potent feature extraction and classification capabilities of Convolutional Neural Networks (CNNs) offer novel opportunities to enhance steganalysis detection accuracy. GNCNN [41] stands as the pioneering CNN-based scheme that can rival classical steganalysis in terms of performance. It comprises three integral components: a preprocessing layer (utilizing a non-random high-pass filter), a feature extractor (a convolution block), and a discriminator (a fully connected layer). YeNet [26] adopted an initial layer of thirty 5×5 SRM filters in their CNN architecture, achieving superior detection performance compared to previous classical approaches, marking a significant breakthrough in CNN-based steganalysis. Yedroudj et al. further refined the YeNet structure, introducing Yedroudj-net [42] to enhance detection performance. In pursuit of improved detection capabilities, Li et al. devised a broad structure featuring parallel subnets with several filter groups for preprocessing. This innovative structure goes by the name ReST-Net [43]. SRNet, introduced by Boroumand et al. [27], represents the first scheme that dispenses with manually designed filters for feature extraction. Instead, they initialized filters randomly and extracted ample noise residuals through multiple non-pooled convolutional blocks. Weike et al. expanded the horizons of steganalysis by leveraging the relationships between image sub-regions to distinguish whether an image contains steganographic content or not [44]. This approach broadens the applicability and versatility of steganalysis techniques.

III. METHOD

In this section, we will elucidate the intricate details of our innovative approach. As illustrated in Fig. 2, our proposed scheme is primarily composed of three essential core modules: the Preemptive-CNN, Stego-CNN, and Steganalysis Discriminator. Initially, the Preemptive-CNN generates the original cover and subsequently creates the masked cover. Following this, the masked cover is fed into the Stego-CNN, where it is utilized to embed confidential information and generate the stego image. Finally, both the stego image and the masked cover serve as inputs for the discriminator. To ensure that the first processed image can receive feedback from the subsequent discriminator, it is imperative that all three aforementioned modules be differentiable.

A. Preemptive-CNN

The purpose of the preemptive-CNN is to enhance the original covers prior to steganography, making it easier to detect steganography on the modified covers compared to the original ones. To accomplish this, an encoder-and-decoder neural network is employed to implement the preemptive-CNN. The input to the preemptive-CNN consists of the original covers, while the output is masked covers of the same size. Given that the covers are images used in a social network, the visual quality of the masked covers is crucial. Therefore, any arbitrary modification of pixels in the original covers is not allowed. In the proposed method, we impose restrictions

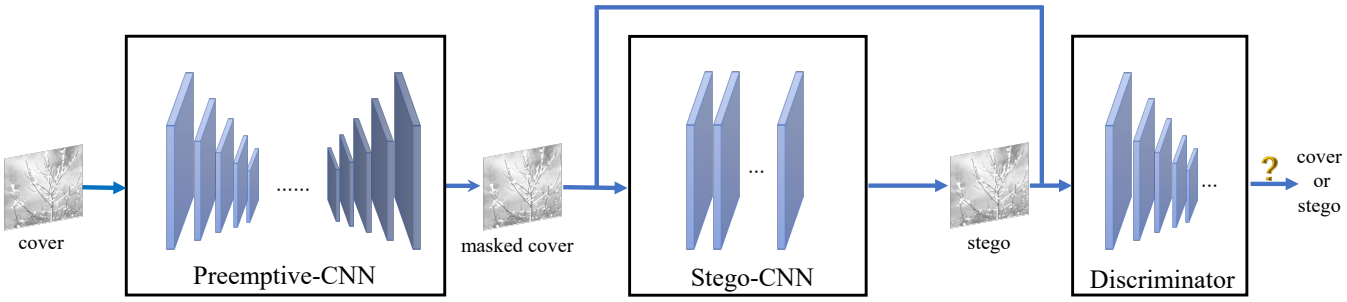

Fig. 2. Framework of proposed method

on the Structural SIMilarity (SSIM) [45] value of the original cover to ensure that the difference between the masked covers and the original covers is imperceptible to the human visual system.

Mathematically, this can be expressed as follows:

$$ssim(x_{ori}, Clip(f_P(x_{ori}))) > \mathcal{T}. \tag{1}$$

Where x_{ori} is an original cover, f_P is the preemptive-CNN, $Clip$ is used to force the value of pixels in the output in $[0, 255]$, and $\mathcal{T}$ is the constraint threshold. The SSIM is defined as follow:

$$ssim(x, y) = \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\mu_x^2 + \mu_y^2 + c_2)}. \tag{2}$$

where μ_x and σ_x^2 is the mean and variance of x, respectively. σ_{xy} is the covariance of x and y. $c_1 = (0.01L)^2$, $c_2 = (0.03L)^2$ where L is the fluctuation range of pixel values.

Considering the nature of the image data, it is important to note that the value of each pixel is an integer within the range of [0, 255]. Consequently, the value of each pixel in the masked cover should also be an integer. However, due to the characteristics of CNN, the generated masked cover, produced through encoding and decoding processes, often exist in a floating-point format. This poses a challenge, as the usage of the $Round()$ function for approximating the masked cover is non-differentiable, leading to the disappearance of gradients throughout the entire network.

To address the aforementioned issues, we propose a solution by employing the $Sigmoid()$ function to approximate the masked cover image. This approach allows us to maintain the integer representation of the pixels while ensuring the differentiability of the overall network. Mathematically:

$$\widetilde{X} = \lfloor X \rfloor + sigmoid\left(C \cdot (X - \lfloor X \rfloor)\right). \tag{3}$$

Where X is the output of preemptive-CNN, C is a constant and permitted to select in $[10, 50]$.

B. Stego-CNN

For reference [47], we design the Stego-CNN to simulate the embedding process of HILL [5], which is one of the most effective steganography. HILL is constituted by a highpass filter H and two low-pass filters L_1 and L_2, which are implemented by convolution in proposed method. The cost value ϱ of the cover X is defined as:

$$\varrho = \frac{1}{|X \otimes H| \otimes L_1} \otimes L_2. \tag{4}$$

Where the notation $\otimes$ stands for mirror-padded convolution. L_1 and L_2 are both average filter with sizes of 3×3 and 15×15 respectively, and the form H is as:

$$H = \begin{bmatrix} -1 & 2 & -1 \\ 2 & -4 & 2 \\ -1 & 2 & -1 \end{bmatrix}. \tag{5}$$

Employing STC [32] to embed secret information, the theoretical steganographic distortion can be noted as:

$$D = \sum_{i=1}^{M}\sum_{j=1}^{N}\left[p_+(i,j)\rho_+(i,j) + p_-(i,j)\rho_-(i,j)\right]. \tag{6}$$

Where $\rho_+(i,j)$ and $\rho_-(i,j)$ stand the cost values of modifying $x_{i,j}$ by $+1$ and -1, and $\rho_+(i,j) + \rho_-(i,j) = 2/3\varrho_{i,j}$. $p_+(i,j)$ and $p_-(i,j)$ are the corresponding modification probabilities, and further

$$p_+(i,j) = \frac{e^{-\alpha\rho_+(i,j)}}{1 + e^{-\alpha\rho_+(i,j)} + e^{-\alpha\rho_-(i,j)}}. \tag{7}$$

$$p_-(i,j) = \frac{e^{-\alpha\rho_+(i,j)}}{1 + e^{-\alpha\rho_+(i,j)} + e^{-\alpha\rho_-(i,j)}}. \tag{8}$$

Where α is the parameter to adjust the payload. The value of α for each cover is randomly selected between $[10, 150]$ to achieve various payload during training.

C. discriminator and loss function

The discriminator's inputs consist of two parts: masked covers and masked stegos. Its outputs determine whether the input images are covers or stegos. Masked covers refer to the original covers processed with a preemptive-CNN, while masked stegos are the stegos corresponding to the masked covers. Both the discriminator and the preemptive-CNN are updated synchronously during training, while the StegoCNN

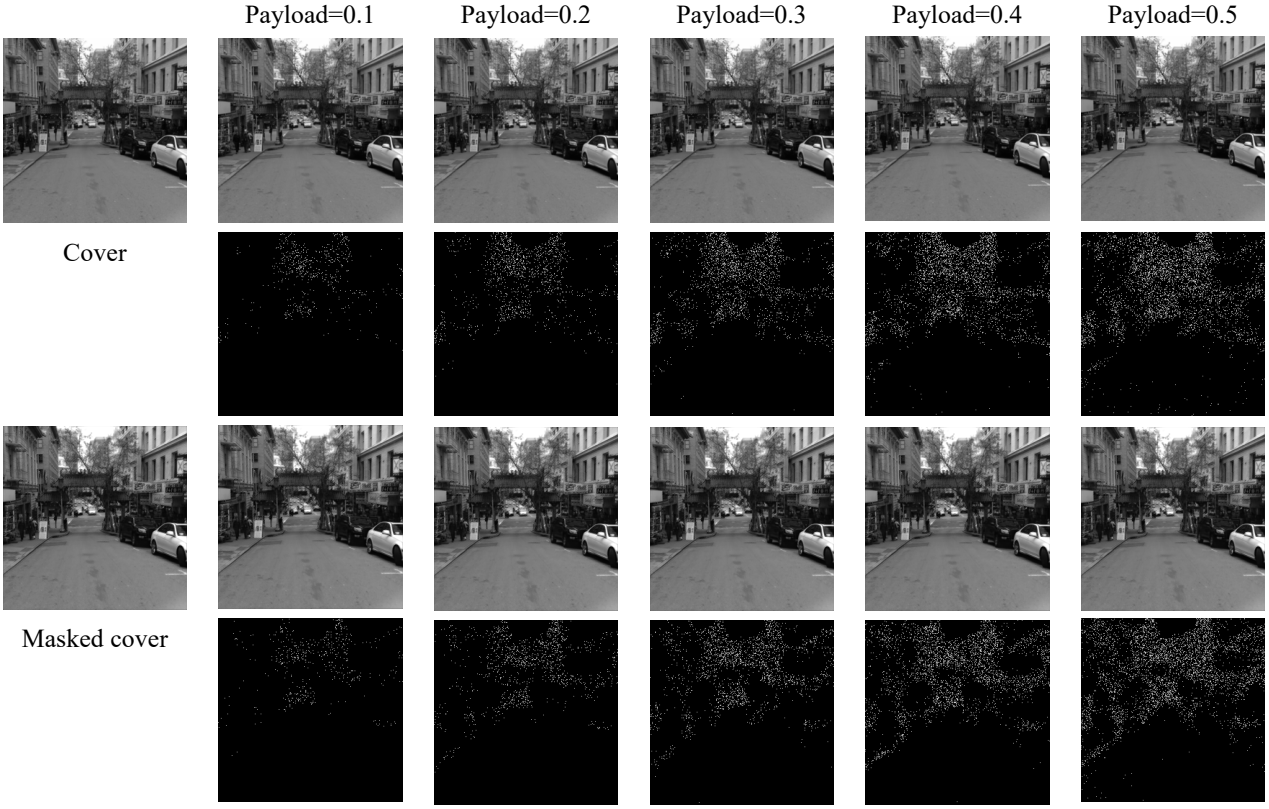

Fig. 3. Visual quality comparison of the original cover image, the masked cover image, and the stego images under various steganography payloads. The leftmost image of the first row displays the original cover, while the right side showcases the stego images corresponding to different payloads in sequence. The second row presents the residual image obtained by comparing the stego image with the original cover. The far left of the third row illustrates the masked cover, and the right side exhibits the stego images corresponding to different payloads in sequence. The fourth row showcases the residual image resulting from comparing the stego images with the masked cover.

remains unchanged. The loss function for the entire method is denoted as follow:

$$L = L_P + \lambda L_D. \tag{9}$$

Where the loss function of preemptive-CNN L_P is to ensure the visual similarity between the original covers and masked covers. We measure visual similarity with ssim as stated III-A.

$$L_P = ssim(X_{ori}, X_{masked}). \tag{10}$$

L_D denotes the loss function of discriminator and includes two components

$$L_D = L_{cls}. \tag{11}$$

Where L_{cls} is the cross-entropy loss to binary classification.

IV. Results

A. Setting

Unless otherwise specified, all experimental details and hyperparameters are set as follows. Select $\mathcal{T} = 0.95$ in equation (1), $C = 10$ in equation (3), $\alpha = 50$ in equations (7) and (8) To reduce the computation, we presume $\rho_+(i,j) = \rho_-(i,j) = 1/3\varrho_{i,j}$ in equation (6).

We select the Adam optimizer with learnning rate $lr = 1e-3$ to minimize L_P, and Adamax optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1e-8$ to minimize L_D. The balancing hyperparameter $\lambda = 1$ in equation (9).

The complete CNN model is implemented using PyTorch version 1.10.2, and the runtime results presented herein were achieved employing an Nvidia GeForce 2080Ti GPU. The batch size is configured to 6, necessitating approximately 10GB of GPU memory for training images of dimensions 256 × 256. We have conducted network training on diverse datasets, spanning 1000 epochs, a computational endeavor that consumes approximately 55 hours on our specific hardware configuration.

We selected 10,000 images from BOSSbase 1.01 as our original covers. These images were divided into three sets: the training set, the validation set, and the test set, with a ratio of 5:1:4 respectively. There was no overlap between these sets, and they were all resized to dimensions of 256 × 256. In all of our CNN experiments, we selected the model with the best performance on the validation set. Subsequently, we ran this model five times on the test set to calculate the mean and standard deviation of its performance.

B. Advantage of preemptive processing

Fig. 3 illustrates the visual distinctions among the original cover, the masked cover, and the stego images across different steganography payloads. It is evident that both the original cover and the masked cover undergo imperceptible modifications due to steganography, as perceived by the human visual system. It is important to note that the visual disparity between the original cover and the masked cover is exceedingly small, primarily because the SSIM threshold is set at 0.95. Consequently, it becomes arduous for the human visual system to discern any dissimilarities between them. Furthermore, in Fig. 3, the second and fourth rows reveal that the respective altered residuals of the masked cover exhibit a higher concentration compared to those of the original cover under the same payload. This characteristic contributes to facilitating the detection of the steganography within the mask cover.

TABLE I showcases a comprehensive comparison of detection performance between the original carrier and the mask carrier, both processed by a preemptive network, using various steganalysis algorithms across different embedding loads. The steganalysis techniques employed encompass SRM, SRMQ1, and maxSRMd2, which represent traditional, rich model-based methods. These experiments were executed within MATLAB R2022b. Each steganalysis experiment was repeated ten times, and the resulting average detection accuracy was deemed the ultimate detection outcome.

Additionally, YeNet and F-Net are steganalysis models based on convolutional neural networks. To implement these models, we utilized PyTorch 1.10.2, set the batch size to 32, selected ADAM as the optimizer, and established a learning rate of $1e-4$. Similar to the traditional steganalysis experiments, each trial for the neural network-based models was performed five times, and the average detection accuracy was used as the final detection result.

TABLE I illustrates the progressive increase in the detection success rate of various steganalysis algorithms as the steganographic payload rises. This phenomenon occurs due to the augmented steganography payload leading to a greater number of modified pixels within the overall image. Consequently, the detection of steganography becomes easier. Notably, different steganalysis algorithms exhibit varying levels of detection accuracy. Generally, CNN-based steganalysis outperforms traditional methods in terms of detection performance.

Regarding the original cover, the HILL algorithm demonstrates superior concealment compared to other algorithms. It proves to be the least easily detected under a range of detection algorithms. Moreover, the detection success rate for the masked cover consistently surpasses that of the original cover image. For traditional steganalysis algorithms, the preemptive strategy contributes significantly to performance improvement as the embedding load increases.

It is worth mentioning that the advantage of the HILL algorithm's invisibility becomes less pronounced, primarily because Stego-CNN only simulates the HILL algorithm during joint training. The proposed strategy greatly enhances CNN-based steganalysis algorithms since the joint training process incorporates a CNN architecture-based discriminator. When the load is set to 0.1, the preemptive strategy improves detection accuracy by an average of 8 percentage points. However, with a payload of 0.3, the preemptive strategy can boost accuracy by up to 20 percentage points. Moreover, when the load exceeds 0.3, the proposed method achieves a near 100% detection success rate, eliminating all stego images.

To summarize the discussion, we propose a preemptive strategy that significantly enhances the detection precision of steganographic analysis algorithms, regardless of whether the steganographic analysis algorithm is based on a sophisticated

model or CNN.

V. Conclusion

The current image steganalysis technology exhibits poor detection performance when the embedding payload is low. In light of this issue, this paper proposes a preemptive detection strategy. The strategy involves incorporating a carefully designed imperceptible mask into the original cover image, thereby facilitating the detection of steganography in the masked cover. The proposed method consists of three main modules: preemptive-CNN, Stego-CNN, and discriminator. Each module is implemented using a differentiable convolutional neural network. During the training phase, the Stego-CNN remains unchanged while the preemptive-CNN and discriminator are jointly trained. Experimental results demonstrate that the detection of steganography becomes easier when applied to the masked cover after processing the original cover using the preemptive-CNN. Moreover, the proposed method minimally impacts the visual quality of the image and remains compatible with existing steganalysis techniques.

***Abstract*—In this paper, we present a multi-speaker accent speech synthesis framework. It can generate accented speech of unseen speakers using only a limited amount of accent training data. Without relying on the accent lexicon, the proposed network is able to learn the accent phoneme embedding via a simple model adaptation. In specific, a standard multi-speaker speech synthesis is first trained with native speech. Then, an additional neural network module is appended for adaptation to map the native speech to the accented speech. In the experiments, we have synthesized English speech with Singapore and Hindi accents. Both objective and subjective evaluation results successfully confirm that our proposed technique with phoneme mapping is effective to generate high-quality accent speech for unseen speakers.**

I. Introduction

With an increasing demand for personalized speech synthesis, text-to-speech (TTS) synthesis systems need to generate speech not only in the target speaker's voice, but also the target accent. Accent speech synthesis is a task seeking to generate high-quality accent speech in the target speaker's voice. Accent speech synthesis has several significant real-world applications that make it an important area of research and development. Accent TTS can be used to create language learning tools that provide learners with exposure to different accents and dialects. In the entertainment industry, accent TTS can be used to create more immersive experiences in video games and movies. Accent TTS can be employed in virtual assistants and customer service applications to provide users with a personalized and culturally relevant experience. In some cases, accent TTS can play a role in preserving and documenting endangered languages and dialects, contributing to linguistic diversity and heritage conservation.

Accent refers to the variations in pronunciation, intonation, and individual speech habits associated with specific geographical regions or linguistic communities. These variations can include differences in vowel and consonant sounds, rhythm, stress patterns, and prosody. Accents may also encompass dialectical differences and linguistic features unique to certain cultural or regional groups. In the accent TTS, we are primarily addressing the pronunciation and prosodic aspects of speech associated with different regions or linguistic backgrounds.

Most of the previous studies on accent speech synthesis are based on the traditional speech synthesis system. By employing FestVox [1], a voice generation toolkit, the researchers obtained paired speech data between the accent phoneme representations and accent speech features. Therefore, accent speech can be generated directly from the accent phoneme representation. This approach has been adopted for Indian accent languages [2]–[4]. Another attempt utilizes the grapheme-to-phoneme (G2P) to construct the accent phoneme space and generate an accent phoneme representation [5]. These methods have demonstrated their effectiveness in accent speech synthesis, where phoneme plays a key role to characterize the accent pronunciation. However, their success rely on the accent language lexicon, which is difficult to obtain from limited accent data.

Alternatively, some works imitated the application of speaker embedding in speaker adaptation[6]–[8], and implemented an accent encoder to learn a fixed dimension vector to represent the accent identity, which is used for accent speech generation [9], [10]. However, learning speaker embedding usually requires thousands of multi-speaker data [11]. Consequently, the accuracy of accent embedding may not be ideal. Moreover, prior foreign accent studies have reported that both phonemic and prosodic qualities essential for identifying an accent [12], [13]. It might not be enough to fully express one accent with a single vector. Besides, the accent ID has been augmented to the input features [14] to learn the tone variance. Yet, these methods didn't account for the phoneme information change between accents and also trained in a data-driven manner requiring large training data.

With recent advances in deep learning, the performance of neural TTS systems have achieved great success. Many end-to-end speech synthesis systems can generate human-like voice with high quality [15]–[18], where sequence-to-sequence architecture is adopted. Generally, sequence-to-sequence models include an encoder to convert the input text sequence into a latent linguistic representation, an attention mechanism [19] or length regulator [20] to learn the alignment between the linguistic representation and Mel-spectral features, and a decoder to convert the aligned linguistic representation into Mel-spectral features. Such a complex network usually owns a huge parameter number, and the model training requires a large amount of data to generalize well. In the personalized TTS scenario, it learns to synthesize a new voice with few speech

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

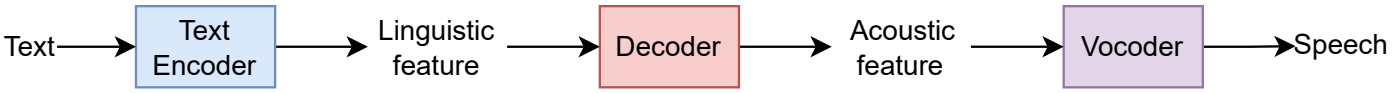

Fig. 1. The main modules in end-to-end TTS.

data from the target speaker [21]. Using limited data to train the large TTS model may result in under-fitting problem, thus leading to poor performance. Speaker adaptation successfully addresses the problem, which has been popularly adopted in personalized TTS [22], [23].

Inspired by the speaker adaptation technique, we propose an accent adaptation method for accent speech synthesis with limited data. The proposed method is able to learn the phoneme mapping between different accents. The TTS model leverages large-scale speech data by training a standard multi-speaker TTS. Then, a phoneme mapping neural network module is added for adaptation. In particular, only the phoneme mapping module and the attention will be updated during adaptation. The mapping module is carefully designed and the adaptation is dedicated for accent speech synthesis. By doing so, the mapping module is able to pick up the accent pronunciation whereas the decoder is still speaker-independent.

The rest of this paper is organized as: Section 2 introduces the proposed method; Section 3 presents the experiments and discusses the results; Section 4 concludes this work.

II. Related Work

A. End-to-end TTS

Neural TTS has experienced tremendous growth in recent years, leading to remarkable improvements in the quality of generated speech. End-to-end models (e.g., Tacotron 1/2 [15], [16], and FastSpeech 1/2 [18], [20]) drastically decrease the complexity of text analysis and allow direct input of characters or phonemes, while Mel-spectrograms simplify acoustic features. Fully end-to-end TTS systems, such as ClariNet[24] and EATS [25], are able to produce waveform directly from text, outperforming traditional concatenative and parametric synthesis in terms of both intelligibility and naturalness with minimal preprocessing and feature engineering.

A modern TTS system generally consists of three primary components, as shown in Figure 1: a text encoder module for translating text into linguistic features, a decoder module for learning alignment between linguistic and acoustic features and generating acoustic features from the output, and a neural vocoder for synthesizing waveform from the acoustic features. In this work, we focus on manipulating the linguistic aspect of TTS as it is closely related to accent-related information which will be explored further in the next section.

B. Identify of Foreign Accent

To understand what is meant by a "foreign accent," we must take into account the contact of two phonological systems, one being from a native language (L1) and the other from a non-native second language (L2). To identify a foreign accent we must be aware of the differences in cultural backgrounds, the environment of language acquisition, and any psychological and pragmatic factors that come into play. In other words, the imitation of a foreign accent involves the integration of multiple elements, so as to form an effective cognitive connection between the two different linguistic systems. But in the aspect of audio processing, both segmental and suprasegmental features are important when identifying a foreign accent, and there should be a reflection of both phonemic and prosodic aspects [13]. Therefore, when it comes to accent speech synthesis, the foremost components that need to be taken into consideration are phonemes and prosody. Phonemes are particularly essential, as the duration of each can be inferred from its representation.

The encoder part of a speech synthesis system plays an integral role in constructing the linguistic features of a synthesized speech. It generates phonemes and prosodic information, which then feed into the subsequent decode stages. In this work, we focus on transforming the linguistic features generated by the encoder to more accurately represent the desired accent. To do this, We take measures to modify the phoneme information and improve the accuracy of the prosodic characteristics. With this, we are able to constrain the generation of accent information that is better aligned to the desired outcome.

III. Methodology

Our proposed system is based on the Tacotraon2 framework [16] and the architecture of our system is illustrated in Fig. 2. The model consists of an encoder followed by a residual layer, an attention mechanism, and a decoder. The proposed accent speech synthesis approach is an accent adaption technique based on a pre-trained model.

A. TTS pre-training

First, we train a standard TTS model on a publicly accessible multi-speaker corpus. The pre-trained model has a similar architecture to Fig. 2, except that the residual layer after the encoder is absent. We follow the voice cloning technique to train the multi-speaker TTS system, as described in [8]. Instead of concatenating the speaker embedding to the encoder output, our TTS model concatenates it to the context vector that produced by the attention mechanism. In this way, the attention mechanism takes only the phoneme information as input, the alignment prediction between the phoneme representation and the Mel-spectral features should be speaker-independent.

We used a G2P module to convert the input text sequence into a standard phoneme sequence [26]. When trained with native speech data from multiple speakers, the encoder learns to transform the standard phoneme sequence to the average

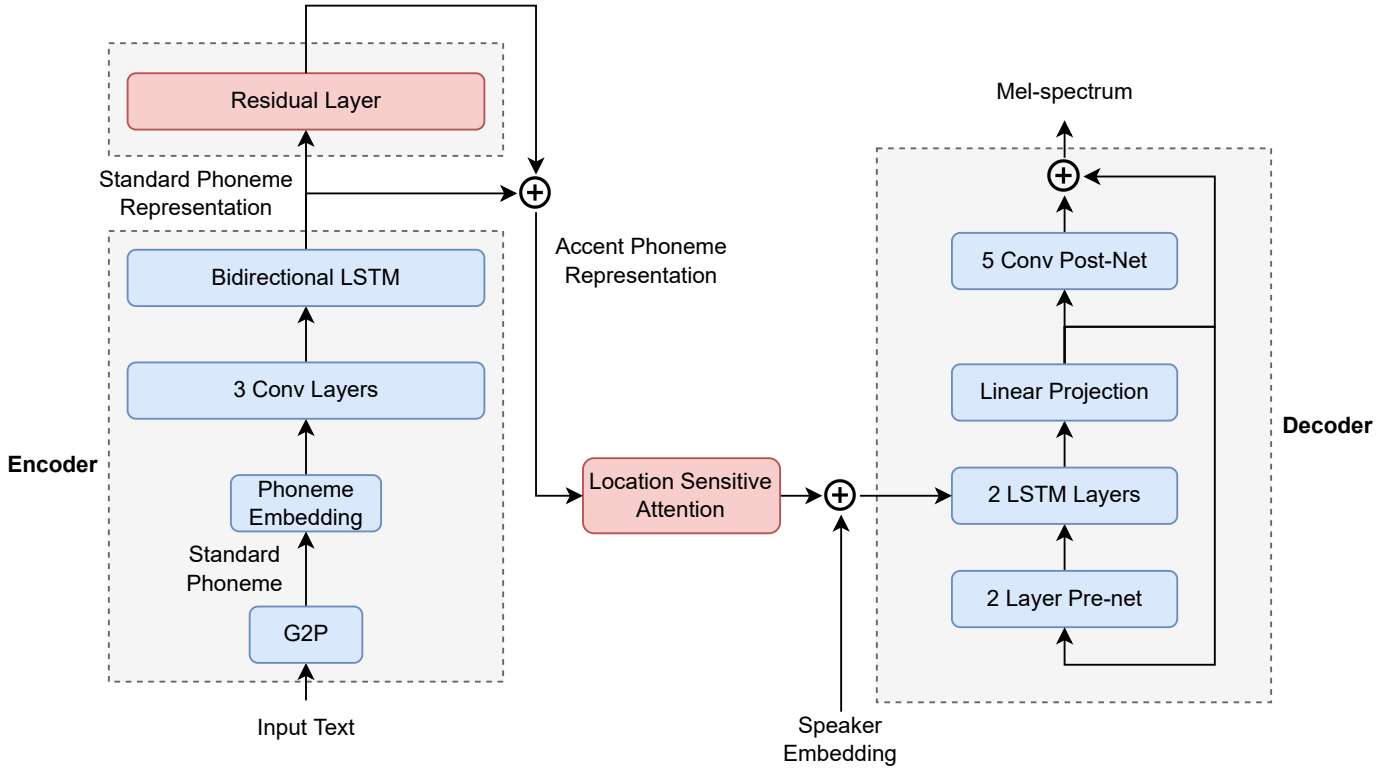

Fig. 2. Architecture of the proposed accent speech generation system

standard phoneme representation. Then the attention-based decoder will learn to convert the standard phoneme representation to the Mel-spectral features, conditioned on the speaker embedding.

The pre-trained TTS system is a well-trained zero-shot multi-speaker speech synthesis model that can generate high-quality speech with the voice of an unseen speaker.

B. Accent adaptation

According to the previous research on accent speech synthesis, the most critical step is to obtain accent-specific phoneme [2]–[5]. In the sequence-to-sequence speech synthesis system, the encoder module is primarily responsible for generating the phoneme information. If the encoder can generate an accent-specific phoneme representation from the standard phoneme sequence input, the decoder is able to generate accent sound speech accordingly by taking the accent information as input.

In many speaker adaptation works, the parameters of the entire model are updated during the adaptation stage. As a result, the model becomes speaker-dependent and can only produce the voice of one target speaker. To preserve the ability of the pre-trained model to generate multi-speaker voices during adaptation, we need to fix the decoder parameters.

It also can be risky to update all of the encoder parameters, especially with limited training data available. The distribution of phonemes in the adaptation training data is imbalanced. If all parameters of the encoder are updated, the encoder will be over-fitted to the sparse training data. This affects the accuracy of out of vocabulary phonemes generation. Therefore, we propose to use an additional module dedicated to the encoder to learn the mapping from the standard phoneme representation to the accent phoneme representation.

We have investigated the use of a standard convolutional or long-short term memory (LSTM) layer as the additional module in our work. However, the training process becomes challenging because the following attention module fails to learn how the phoneme representations and Mel-spectral features are aligned. Since the outputs of the newly added additional layer are completely new to the attention mechanism, it is difficult to infer alignment from such limited data. We propose to use the residual layer architecture to combine the output of the previous encoder output with the output of the additional layer. The residual layer does not discard the original information, but provides residual knowledge to learn the difference between the standard phoneme and the accented phoneme. In addition, this also helps in learning the phoneme variations. Since not all phonemes vary between accents, the residual layer only affects the residual information while maintaining the consistency of the remaining phonemes. Given that their functions are comparable, the residual layer is a 1D convolutional layer with ReLU activation that has the same architecture as the decoder Post-Net. The Post-Net is also provided as residual compensation for the generated Mel-spectral features.

The attention module is also essential to the accent learning.

TABLE I
HYPER-PARAMETERS AND MODEL ARCHITECTURE

Encoder	3-layer conv-5-512-RELU Bi-directional LSTM (512 units)
Residual Layer	1-layer conv-5-512-RELU
Accent Classifier	3-layer LSTM (786 units) Linear Projection (6 units)
Decoder	Pre-net: 2-layer fully connection (256 units) 2-layer LSTM (1,024 units) Linear Projection (80 units) Post-net: 4-layer conv-5-512-RELU + 1-layer conv-5-80-Linear

In addition to the phoneme variation, prosodic quantities are also necessary to form an accent [12], [13]. The attention mechanism provides the prosodic information by learning the duration from the accented phoneme representations. Therefore, only the additional residual layer and attention module are updated during adaptation, as illustrated in red color in Fig. 2. The encoder and decoder are frozen to preserve the ability to synthesize speech of different speakers. The training loss function in the adaptation stage is the same as the pre-trained model, i.e., the combination of the Mel-spectral feature loss and the stop token loss [16].

During inference, by conditioning on any speaker's speaker embedding, the model is capable of generate the target accent sound speech with any speaker's voice.

IV. EXPERIMENTS

A. Experimental Setup

To train the pre-trained TTS model, we use VCTK corpus [27]. It's a multi-speaker corpus that contains speech data uttered by 110 English speakers. For the accent speech data, we use two different accents Singapore and Hindi data to verify our proposed approach. And for each accent, we only use 300 utterances for training. Mel-spectral features are extracted using 12.5ms frame shaft with 50ms frame length. To convert the generate Mel-spectral features to waveform, we trained a ParallelWaveGAN neural vocoder [28]. The vocoder is trained with the same data of the pre-trained TTS model and the accent data is not used.

The details of model architecture are listed in table I. Where "conv-k-c-ReLU" denotes 1-D convolution with k filter size and c output channels with ReLU activation. For optimization, we use Adam optimizer with the learning rate of 0.001. The batch size is set to 64 in our experiments.

B. Objective Evaluation

To evaluate the generation accuracy of our proposed method, we calculated the objective evaluation metrics from two aspects: phoneme and pitch.

For the phoneme accuracy evaluation, we used Google Speech-to-Text API to convert the generated samples to text, then calculate the Word Error Rate (WER) to compare. The speech recognition model we were using is United States English model. We calculate the WER of both ground-truth speech and the generated speech. The results are shown in II. We can see from the results that our proposed system can generate speech with low distortion levels and high phoneme accuracy that is closed to the ground-truth for both accents.

TABLE II
WER RESULTS OF THE GROUND-TRUTH AND GENERATED ACCENT SPEECH

	Ground-truth	Generated
Singapore accent	20.09%	26.67%
Hindi accent	25.38%	29.63%

TABLE III
RMSE, CORRELATION AND DTW DISTANCE OF PITCH IN GENERATED AND TARGET SAMPLES

	RMSE	Corr	DTW
	Singapore		
Pre-trained	38.16	0.85	17.84
Proposed	**31.53**	**0.89**	**13.11**
	Hindi		
Pre-trained	32.68	0.87	13.95
Proposed	**28.64**	**0.91**	**11.67**

For the pitch accuracy evaluation, we compute the RMSE, correlation, and DTW distance of F0 between the model outputs and the ground truth speech. We compare the results between the pre-trained model and our proposed model. We use the pre-trained model to generate non-accent sound speech using the accent speaker's embedding. Evaluation results are shown in Table III. The F0 comparison demonstrates that our proposed method outperforms the pre-trained model in terms of the pitch accuracy.

C. Subjective Evaluation

We also conduct listening experiments to evaluate the similarity of accents and speakers, as well as speech quality, in addition to the objective evaluations. The objective evaluation only applies to the seen speaker because there is no ground-truth for the accented speech of unseen speakers. We evaluate the performance of unseen speaker generation in this section as well [1].

In the accent and speaker similarity test, we generate accented speech of both seen speaker and unseen speakers. Listener are required to compare the accent and speaker similarity between the generated speech and target speech, and select one of the four options for each sample: "Different, Sure", "Different, Not sure", "Same, Not sure" and "Same, Sure". The similarity test results are shown in Fig. 3 and Fig. 4. From both results, we can see that our proposed system can achieve high performance in terms of accent and speaker similarity for both seen and unseen speakers. The unseen speaker generation is slightly worse than the seen speaker generation, but still outperforms the pre-trained model.

To evaluate the overall speech quality of the proposed system, we conduct mean opinion score (MOS) test for each TTS system and the target. Listeners are required to listen to all samples one by one and rate the quality and naturalness of the

[1]Speech samples are at: https://arkhamimp.github.io/AccentTTS/

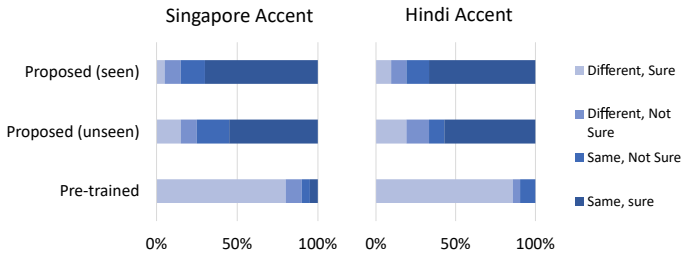

Fig. 3. Accent similarity test results between the generated speech and the target

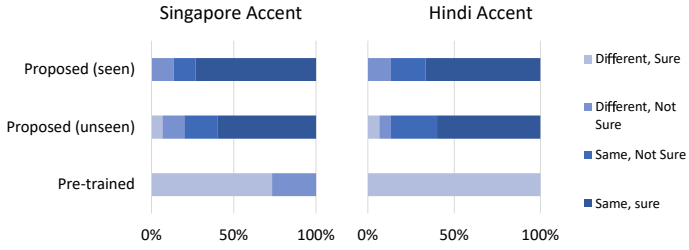

Fig. 4. Speaker similarity test results between the generated speech and the target

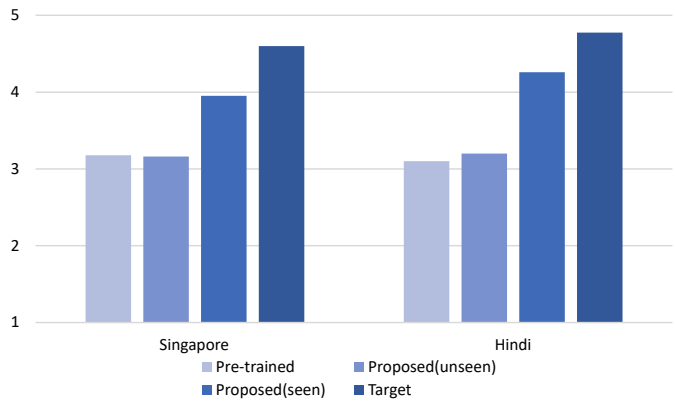

Fig. 5. MOS test results of different models and the ground-truth target

converted speech on a 5-point scale. The higher score indicates a better speech quality. Fig. 5 shows the MOS test results. Similar conclusions are also revealed by the MOS test that the unseen speaker generation achieves comparable performance with the pre-trained model, while the speech quality of the seen speaker generation is significantly improved.

V. Conclusion

This paper presents a multi-speaker accent speech synthesis system that capable of generate any speaker's voice with the target accent while only use a little amount of accent speech training data. Both the objective evaluation and subjective evaluation experiments demonstrate our proposed system outperform the pre-trained system in terms of both accent and speaker similarity and speech quality.

***Abstract*—Neural network based speech enhancement (SE) has developed rapidly in the last decade. Meanwhile, the self-supervised pre-trained model and vector quantization (VQ) has achieved excellent performance on many speech-related tasks, while they are less explored on SE. As it was shown that utilizing a VQ module to discretize noisy speech representation is beneficial for speech denoising, in this work we therefore study the impact of using VQ at different layers with different number of codebooks. Different VQ modules indeed enable to extract multiple-granularity speech features. Following an attention mechanism, the contextual features extracted by a pre-trained model are fused with the local features extracted by the encoder, such that both global and local information are preserved to reconstruct the enhanced speech. Experimental results on the Valentini dataset show that the proposed model can improve the SE performance, where the impact of choosing pre-trained models is also revealed.**

I. Introduction

Speech enhancement (SE) aims at mitigating background noises and reverberation contained in noisy speech recordings, which is widely configured as a front-end in, e.g., speech recognition [1], [2], assistive hearing [3], robust speaker recognition [4]. Traditional statistics-based SE methods usually depend on the stationarity assumption, which, however hardly holds in practice. Recently, the development of deep neural networks (DNNs) facilitates a new direction for performing SE, which even shows a superiority over conventional approaches, particularly in non-stationary scenarios. In general, DNN based SE models can be implemented in a generative [5], [6] or discriminative fashion [7], [8]. The generative models aim to learn the speech distribution, where noisy speech is fed into the model to generate the estimated speech signal subject to a consistency constraint on the distributions of enhanced and clean speech. The latter is based on directly minimizing the difference between enhanced and clean signals by training discriminative models, such that the impact of ambient noises on the spectrum can be removed. The discriminative model can be implemented in the frequency domain [9], [10] or time domain [7], [11], where the frequency- domain SE is achieved by estimating a mask matrix, while the time-domain counterpart is usually implemented following an encoder-decoder fashion.

Discrete representation learning has demonstrated an efficacy in many fields, especially for low-resource tasks, where vector quantization (VQ) is often used. For example, in [12], [13] VQ was used to learn discrete latent representations to generate high quality images. In [14], [15], VQ was used for speech synthesis to generate more natural speech by learning discrete representations. In [16], scalable VQ was applied to encode multi-scale features for speech coding. Considering that learning discrete representations can yield meaningful discrete units and diminish noise components, it was shown in [17] that VQ was also applicable to SE by reconstructing speech from discrete noisy representations. However, it was also shown that VQ with a single fixed codebook cannot adequately learn the clustering units at different granularities, which limits its applicability for SE.

In the speech domain, self-supervised pre-training models [18]–[22], e.g., wav2vec2.0 [18], HuBERT [20], data2vec [21], have been rapidly developed by exploiting large amounts of unlabeled data, which were shown to be helpful for various downstream tasks. The difference therein is that indeed wav2vec2.0, HUBERT and data2vec perform contrastive learning, masked prediction and regression tasks, respectively. The SE performance can also be boosted by using self-supervised pre-trained models. In [23], thirteen pre-trained models were applied to SE tasks, which are taken as feature extractors to estimate spectral masks to reconstruct the clean speech waveform. This implies that the high-level features extracted by self-supervised pre-trained models are applicable to SE, which can also be combined with traditional acoustic features [24]. These pre-trained features are all utilized in the estimation of time-frequency mask, but not validated in the U-Net based SE models.

In this paper, based on [17], which uses a single VQ module with a fixed codebook, we therefore explore how VQ in combination with pre-training models can be better leveraged for the SE task. Considering that different layers of the SE model learn different granularity of information, we first propose a multi-granularity VQ technique to model different levels of information by utilizing different VQ at different layers. Specifically, different VQ modules have different numbers of codebooks and learnable codevectors. Compared to [17], it is shown that the performance can be improved due to the use of multi-granularity VQ at the cost of a small increase in the model parameters. Secondly, to enable the model to

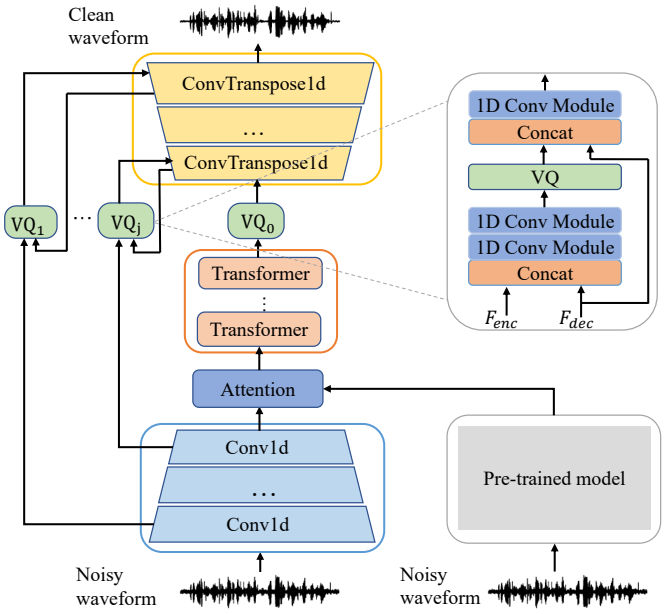

Fig. 1. An illustration of the proposed SE model with multi-granularity VQ modules and self-supervised pre-trained model. The feature fusion mechanism of the proposed multi-granularity VQ is shown at the upper right corner.

better make use of global and local information, we fuse the contextual features extracted by the pre-trained model with the local features extracted by the encoder of the SE model. Both the contextual and local features are input to the U-Net framework. This differs from the scheme in [23], [24], where only the features extracted by the pre-trained model are incorporated to estimate the time-frequency mask, as the considered features for the proposed method become much richer. In addition, it is shown that different pre-trained models have a different effect on the performance, where the data2vec model performs the best with nearly the same amount of parameters. Experimental results on the Valentini dataset demonstrate that utilizing the multi-granularity VQ in different layers is beneficial for SE. The rest of this paper is organized as follows. Section 2 presents the proposed SE method. Experimental setup and results are shown in Section 3 and Section 4, respectively. Finally, Section 5 concludes this work.

II. Method

To guide the reader, in this section we first briefly introduce the SE model in [17], which is the basis of the proposed method. The SE model follows the U-net structure, which contains convolution-based encoders and decoders and the Transformer encoder based bottleneck layer. This is similar to the DEMUCS network. The VQ module is used to discretize the representations output of the bottleneck layer, which is then fed to the decoder to reconstruct clean speech waveforms, and it is shown in Section 4 that both the VQ module and pre-trained models can be beneficial for the performance. However, we found that a single VQ cannot learn speech representations at different granularities. For more details, we refer to [17].

A. Model structure

The structure of our proposed model is shown in Fig. 1, which mainly contains encoder, bottleneck layer, multi-granularity VQ and decoder. The encoder and decoder contain D-layer one-dimensional (1D) convolution and D-layer 1D transposed convolution, respectively, and the bottleneck layer consists of N-layer Transformer encoder. A skip connection is utilized between the i-th encoder layer and the i-th decoder layer. The encoder adopts a convolutional module that can efficiently extract local features. To better utilize the pre-trained model to model long-time contextual information, we take the pre-trained model as a feature encoder. Local features and global features are fed into the attention network for fusion. The fused features are sent to the bottleneck layer, whose output is fed to the decoder after being discretized by quantizer VQ_0. In order to incorporate discrete units of different granularity, we utilize different vector quantizers. Specifically, the output of the i-th encoder layer and the output of the i-th decoder layer are fused into VQ_i to obtain the i-th discrete representation, which is then fused with the output of the i-th decoder layer.

B. Multi-granularity VQ

The proposed multi-granularity VQ mechanism is shown in the upper right corner of Figure. 1, which mainly contains the fusion VQ modules. We first concatenate the output of the i-th encoder layer and the output of the i-th decoder layer. The combined features are fed into the two-layer 1D convolution to obtain the fused features,which are input into the VQ module to obtain the discrete features. Then, the discrete features and the decoder output are concatenated and fed to the 1D convolution module to construct the final output. The VQ module is built on production quantization, where different number of codebooks and codewords for different layers are considered. Given G codebooks, each with V learnable d-dimensional codewords, we first map the input feature to $\boldsymbol{l} \in R^{G \times V}$ logits, and then select the discrete vectors by the Gumbel-softmax [25] operation in a differential way. The probability of choosing the v-th codeword from the g-th codebook is given by

$$\overline{p}_{g,v} = \frac{\exp(\bar{l}_{g,v} + n_v)/\tau}{\sum_{k=1}^{V} \exp(\bar{l}_{g,k} + n_k)/\tau}, \tag{1}$$

where $n_v = -\log(-\log(u))$ with u uniformly distributed over [0, 1] and τ is a non-negative temperature coefficient, In the forward stage, the code vector is selected by $argmax$ operation, and in the backward propagation stage the true gradient of the Gumbel-softmax output is utilized. As it is expected that more codewords can be used for quantization by maximizing the softmax distribution l, we consider the

diversity loss function L_d, which is given by

$$L_d = \frac{1}{GV} \sum_{g=1}^{G} \sum_{v=1}^{V} \overline{p}_{g,v} \log \overline{p}_{g,v}. \quad (2)$$

C. The total loss function

For each VQ module, a codebook diversity loss function is utilized. The overall loss function consists of the SE loss function and weighted codebook diversity loss functions, given by

$$L_{\text{total}} = L_{\text{se}} + \sum_{i=0}^{D} \lambda_i L_{d_i}, \quad (3)$$

where L_{d_i} is the codebook diversity loss of the i-th VQ and λ_i is the weighting parameter, and L_{se} is the SE loss function, which is given by [7], [17]

$$L_{\text{se}} = \frac{1}{T} \left(||\boldsymbol{y} - \hat{\boldsymbol{y}}||_1 + \sum_{i=1}^{M} L_{\text{stft}}^{(i)}(\boldsymbol{y}, \hat{\boldsymbol{y}}) \right), \quad (4)$$

where

$$L_{\text{stft}}(\boldsymbol{y}, \hat{\boldsymbol{y}}) = L_{\text{sc}}(\boldsymbol{y}, \hat{\boldsymbol{y}}) + L_{\text{mag}}(\boldsymbol{y}, \hat{\boldsymbol{y}}), \quad (5)$$

$$L_{\text{sc}}(\boldsymbol{y}, \hat{\boldsymbol{y}}) = \frac{|||\text{STFT}(\boldsymbol{y})| - |\text{STFT}(\hat{\boldsymbol{y}})|||_F}{||\text{STFT}(\boldsymbol{y})||_F}, \quad (6)$$

$$L_{\text{mag}}(\boldsymbol{y}, \hat{\boldsymbol{y}}) = \frac{1}{T} || \log |\text{STFT}(\boldsymbol{y})| - \log |\text{STFT}(\hat{\boldsymbol{y}})|||_1, \quad (7)$$

where T denotes the speech length, $\boldsymbol{y}$ and $\hat{\boldsymbol{y}}$ are the clean and enhanced speech signals, respectively, M denotes the number of multi-scale STFT loss functions, $||\cdot||_F$ the Frobenius norm and $||\cdot||_1$ the L_1 norm. The multi-resolution loss $L_{\text{stft}}^{(i)}$ utilizes the STFT loss with the number of FFT bins ranging from {512, 1024, 2048}, hop size from {50, 120, 240} and window length from {240, 600, 1200}, respectively.

III. Experimental setup

A. Data description

To evaluate the effectiveness of the proposed method, we utilize the Valentini [32] dataset, which contains 28.4 hours of clean-noisy speech pairs consisting of 34647 mono audio samples for training and 824 mono audio samples for testing at a sampling rate of 48 kHz. The duration of the audio ranges from 1 second to 15 seconds (the average duration is around 3 seconds). These data are collected from 84 speakers with 10 different types of noises added to the clean speech at 4 signal-to-noise ratios (SNRs) (i.e., 0, 5, 10 and 15 dB) in the training set and 5 types of noise added to the speech with 4 SNRs (2.5, 7.5, 12.5 and 17.5 dB) in the test set, and all speakers are native English. The raw speech waveforms are downsampled to 16kHz and then applied the remix and bandmask techniques for data augmentation as in [7].

The performance of the proposed method is evaluated using objective metrics, including 1) perceptual evaluation of speech quality (PESQ) [33], 2) short-time objective intelligibility (STOI) [34], 3) mean opinion score (MOS) prediction of distortion of speech signal (SIG) [35], 4) MOS prediction of intrusiveness of background noise (BAK) [35], 5) MOS prediction of overall quality (OVRL) [35].

B. Model configuration

Our network is built on the basis of the DEMUCS model [7], which is modified by replacing the LSTM with Transformer and using an attention module as feature fusion module. Both the encoder and decoder have D = 5 layers and the dimension is 512. We utilize 2 Transformer encoders in the bottleneck layer, where each has a dimension of 512, the feedforward neural network has a dimension of 2048, and the self-attention module has 12 heads. The 1D convolution in the encoder uses a kernel size of 8 and a stride size of 2. For the pre-trained models, we use the publicly available wav2vec2.0 base[1], HuBERT base[2] and data2vec base[3] models in experiments. All three models are obtained by self-supervised pre-training using the same unlabeled data and have similar parameters. These model parameters are not used for training, and we only use them to extract features. For the attention fusion module, we adopt a cross-attention layer with a dimension of 512. For VQ_0 and $VQ_i (i = 1, 2, 3, 4, 5)$ modules, we adopt G = 2 codebooks with V = 320 and $G = 1$ codebook with V = {320, 640, 960 2560, 5120} learnable 128-dimensional vectors, respectively. λ_i in (3) is set to be 0.01 due to the range of the diversity loss, since the amplitude of the codebook diversity loss function L_d is approximately 100 times larger than that of the SE loss function L_{se}. We use the Adam optimizer to train the SE model for 1M iterations, where the batch size is 30 and the maximum learning rate is 2×10^{-4}. All models are trained on 4 Tesla-V100-32G GPUs.

IV. Experimental results

Comparison methods: We first measure objective evaluation metrics on the noisy test set as a reference. The time-domain comparison methods include SEGAN [26], SEGAN-D [28] and MetricGAN [30], which are based on the generative adversarial network (GAN). The time-frequency domain comparison approaches include MMSE-GAN [29] and Deep-MMSE [31], which estimates the noise spectral density under the minimum mean square error (MMSE) criterion. Wave U-Net [27], DEMUCS [7] and CleanUNet [8] are also compared, which depend on the U-net network in the time domain.

Table I shows the experimental results of different models on the Valentini dataset. It can be seen that the proposed method using pre-trained model and multi-granularity VQ can achieve a PESQ of 3.18 and an STOI of 96.7, respectively, which is the best among all comparison methods and is better than the method in [17], which utilizes a fixed codebook and adopts a pre-trained model to initialize the encoder. This implies that using multi-granularity VQ modules and a pre-trained model as the feature extractor is more effective than the single-fixed counterpart. In addition, the deployment of multiple

codebooks only results in a small increment of the parameter amount. (The codebook has codevectors that are learnable, so the number of model parameters added can be calculated as $(320+640+960+2560+5120+320\times2)\times128/10^6 \approx 1.3M$.) In order to more clearly see the impact of each module, we present a comparison in Table II. The base model does not use VQ or pre-trained models, leading to a PESQ of 3.07 and an STOI of 95.2, which are similar to that of CleanUNet, because their model structures are rather similar. In case the multi-granularity VQ modules are included for the base model as shown in Figure 1, the SE performance in all metrics is clearly improved, showing the effectiveness of using multiple codebooks. By the inclusion of multiple VQs and using any pre-trained model (wav2vec2.0, HuBERT or data2vec) as the feature extractor (i.e., fusing the extracted contextual features with the local features extracted by the SE encoder), the performance can be further improved to some extent, while the features extracted from the data2vec model seem the best and the benefits from using wav2vec and HuBERT are almost the same.

Further, we experimentally analyze the impact of the VQ of different layers in Table III. It is clear that in case the VQ

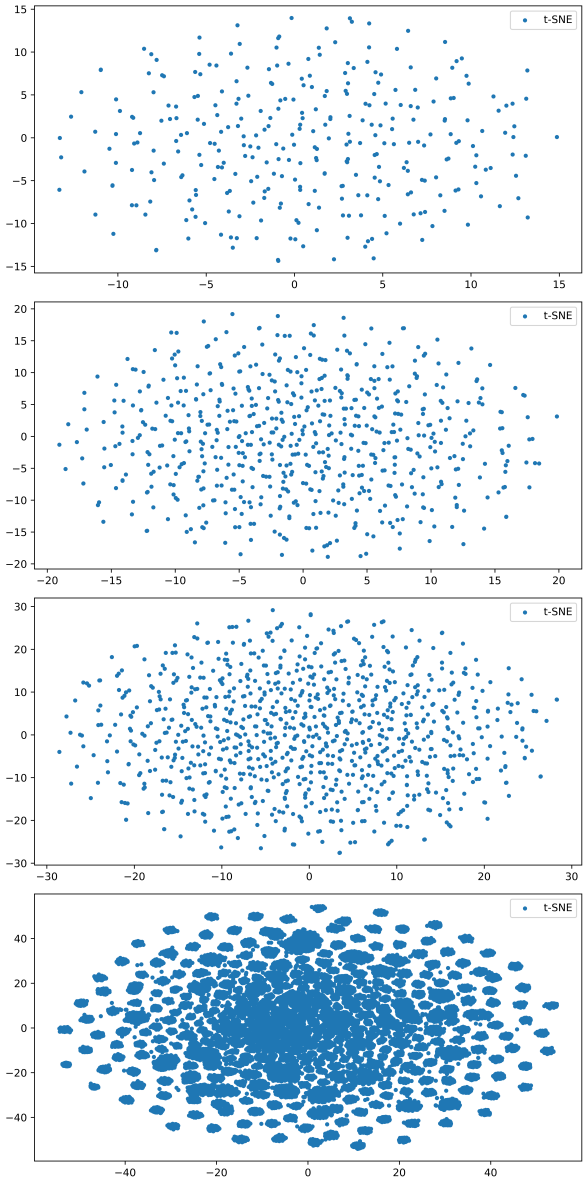

Fig. 2. Codebook visualization with different number of learnable vectors, where a single codebook with 320, 640 and 960 learnable vectors and two codebooks with 320 learnable vectors are included from top to bottom.

module is included for each layer, the best SE performance is achieved. The removal of the VQ at any layer leads to a performance decrease, meaning the necessity of the proposed multi-granularity VQ operations. It seems that the removal of VQ_0 has a more significant impact on the performance, indicating that the discretized contextual features are more beneficial for model denoising. VQ_1 has the smallest impact among all VQ modules, and a higher-layer VQ roughly affects the performance more. Due to the limited size of this dataset, these results might not reflect the analysis comprehensively, so in the future we will evaluate the proposed method in a larger-sized dataset.

Finally, we visualize the learned 128-dimensional codebooks using t-SNE, which are reduced to two dimensions and shown in Figure 2, where a single codebook with 320 (VQ_1), 640 (VQ_2) and 960 (VQ_3) learnable vectors and two codebooks with 320 learnable vectors (320×320 vectors in total, i.e., VQ_0) are included from top to bottom. It is clear that more learnable vectors used in the VQ codebook, more fine-grained speech embeddings can be extracted. From the perspective of t-SNE distributions, the speech embedding extracted by VQ_0 shows a clearer clustering property, which is useful for classification. On the other hand, the multiple embeddings are not spatially overlapped, resulting in the so-called multi-granularity speech features, they are somehow complementary to represent the speech domain. That is why the inclusion of each VQ module positively contributes to the performance in Table III.

V. Conclusion

In this paper, we investigated the application of multi-granularity VQ and pre-trained models to speech enhancement. It was shown that using different VQ modules at different layers can improve the SE performance compared to using a single-fixed VQ. The fusion of contextual features extracted by the pre-trained model and local features extracted by the encoder allows the model to better model global and local information. Compared with the self-supervised pre-trained wav2vec2.0 and HuBERT models that are dedicated to speech representation learning, data2vec seems more effective for SE as it can learn representations from general data (e.g., speech, images, video).

***Abstract*—Speaker-attributed automatic speech recognition (SA-ASR) in multi-party meeting scenarios is one of the most valuable and challenging ASR tasks. It was shown that Single-Channel Frame-level Diarization with Serialized Output Training (SC-FD-SOT), Single-Channel Word-level Diarization with SOT (SC-WD-SOT), and joint training of Single-Channel Target-Speaker separation and ASR (SC-TS-ASR) can be exploited to partially solve this problem, where the latter achieves the best performance. In this paper, we propose three corresponding MultiChannel (MC) SA-ASR approaches, namely MC-FD-SOT, MC-WD-SOT, and MC-TS-ASR. For different tasks/models, different multichannel data fusion strategies are considered, including channel-level cross-channel attention for MC-FD-SOT, frame-level cross-channel attention for MC-WD-SOT and neural beamforming for MC-TS-ASR. Experimental results on the AliMeeting corpus reveal that our proposed multichannel SA-ASR models can consistently outperform the corresponding single-channel counterparts in terms of the speaker-dependent character error rate (SD-CER).**

I. Introduction

Multi-talker speech modeling in real meeting scenarios (also known as the cocktail party problem) is one of the most valuable and challenging problems in speech signal processing [1], [2], where speaker-attributed automatic speech recognition (SA-ASR) is expected to correctly identify "who spoke what" [3]–[5]. Therefore, SA-ASR not only needs to recognize the possible overlapping speech sounds of different speakers [6]–[8], but also needs to identify the corresponding speaker for each recognized utterance.

Serialized **O**utput **T**raining (**SOT**) [8] was proposed for multi-talker ASR in order to avoid the limit of the maximum number of speakers and duplicated hypotheses [6], [9], which introduces a special symbol to represent the speaker change with only one output layer. To obtain the speaker attribute transcription, three **S**ingle-**C**hannel (SC) SA-ASR approaches were proposed by modular combination [10], namely **S**ingle-**C**hannel **F**rame-level **D**iarization with **SOT** (**SC-FD-SOT**), **S**ingle-**C**hannel **W**ord-level **D**iarization with **SOT** (**SC-WD-SOT**) and **S**ingle-**C**hannel **T**arget-**S**peaker separation and **ASR** (**SC-TS-ASR**). In SC-FD-SOT, the frame-level speaker diarization and SOT-based ASR are combined to obtain the speaker-attributed transcription. However, due to the modular independence, such an alignment strategy may suffer from erroneous timestamps, which severely hinder the speaker assignment performance. In order to alleviate this problem, SC-WD-SOT was proposed, which uses an attention mechanism to diarize the hypotheses of SOT-based ASR at the token level to obtain the corresponding speaker of each character. In order to further get rid of the dependence on SOT-based ASR hypotheses, SC-TS-ASR was proposed to train the joint model of target speaker separation and ASR, which achieves the best SA-ASR performance.

Although these approaches can work well on real-meeting corpora, they all use single-channel audio after beamforming as the input of the model. However, in real meeting scenarios, we usually have multichannel signals recorded using microphone arrays, which can be used more efficiently inside the model to learn richer temporal and spatial information. In this work, we therefore propose three **M**ulti**C**hannel SA-ASR approaches accordingly, called **MC-FD-SOT**, **MC-WD-SOT** and **MC-TS-ASR**, respectively.

In literature, **F**rame-**L**evel **C**ross-**C**hannel **A**ttention (**FLCCA**) [11], [12] and **C**hannel-**L**evel **C**ross-**C**hannel **A**ttention (**CLCCA**) [13], [14] were proposed in the context of ASR, speech separation and speaker diarization, where the former attends more on the time frames and the latter more on channels. **M**ulti-**F**rame **C**ross-**C**hannel **A**ttention (**MFCCA**) [15] reaches a tradeoff in-between by integrating cross-channel information between adjacent frames. As the MFCCA-based SOT works best for the multi-talker ASR and outperforms the best system in M2MeT challenge [16]–[18], we adopt the MFCCA-based SOT to replace SOT in SC-FD-SOT and SC-WD-SOT, namely MC-SOT. In track 1 of M2MeT, as the CLCCA was applied to **T**arget-**S**peaker **V**oice **A**ctivity **D**etection (**TS-VAD**) [19], [20] to fuse multichannel speech information and achieved the best performance (i.e., MC-TS-VAD [14]), we propose to combine MC-TS-VAD with MC-SOT, i.e., MC-FD-SOT. As for word-level diarization, the text and speech representations based attention is required, which means the importance of inter-frame speech context, we therefore adopt FLCCA in word-level diarization to fuse multichannel information. Combined with multichannel

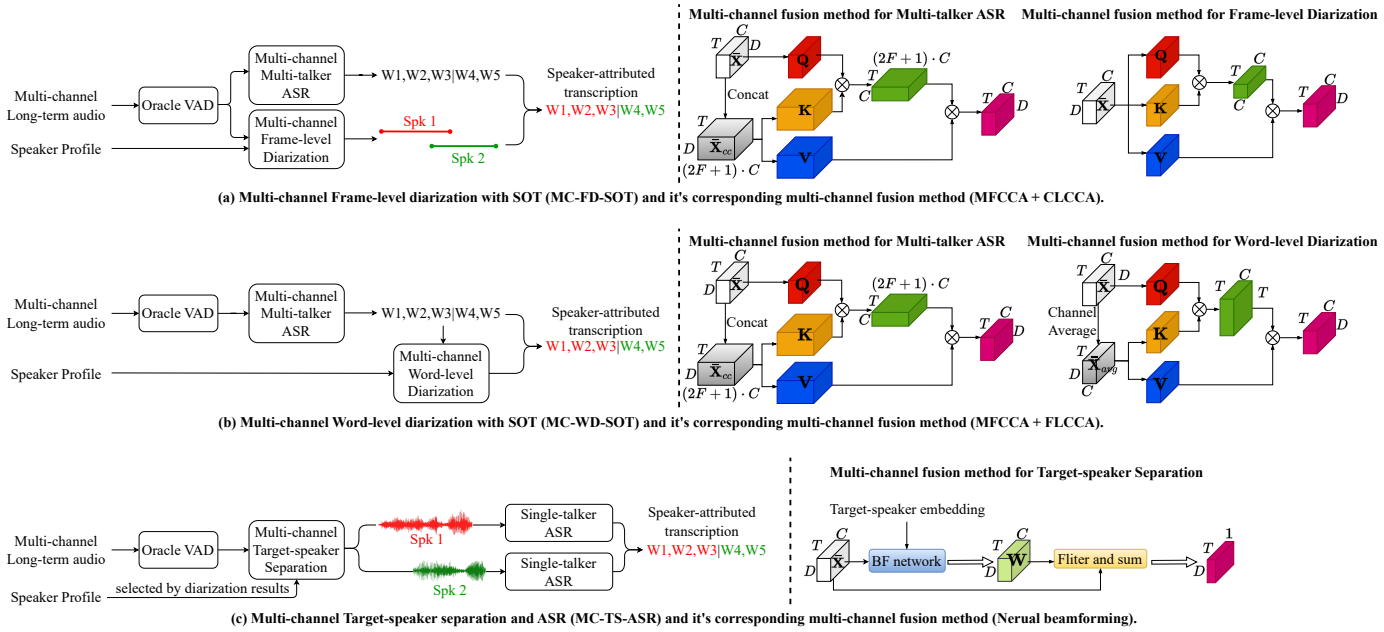

Fig. 1. The diagram of MC-FD-SOT, MC-WD-SOT and MC-TS-ASR and the corresponding simple diagram of multichannel fusion.

word-level diarization and MC-SOT, MC-WD-SOT is then obtained. Neural beamforming has been widely used for multichannel speech separation recently [21]–[24], where a trainable neural network is used to adapt the filter weights and the single-channel output speech spectrum is then given by the filter-and-sum operation. Considering the noise reduction capacity of neural beamforming techniques, we further propose the MC-TS-ASR method by jointly training the pre-trained neural beamforming based multichannel target speaker separation and ASR modules.

Experimental results on a real meeting scenario corpus, AliMeeting, show that the MC-FD-SOT approach achieves an average speaker-dependent character error rate (SD-CER) of 33.5%, which outperforms the SC-FD-SOT. The MC-WD-SOT approach achieves an average SD-CER of 30.7%, which is better than SC-WD-SOT. The MC-TS-ASR approach obtains the best performance with an average SD-CER of 28.3%, which is still better than SC-TS-ASR. The remainder of the paper is organized as follows. Section 2 presents the proposed MC-SA-ASR methods, including MC-FD-SOT, MC-WD-SOT, and MC-TS-ASR. Section 3 shows the experimental setup, followed by results in Section 4. Finally, Section 5 concludes this work.

II. MC-SA-ASR

A. MFCCA-based MC-SOT

The FLCCA attends more to the information between frames but simply averages the information between channels, while the CLCCA applies attention between channels but ignores the information between local frames. The MFCCA strategy can be regarded as a combination of FLCCA and CLCCA by attending to both the channel-level and frame-level information.

The i-th head of MFCCA is calculated as

$$\mathbf{Q}_i = \bar{\mathbf{X}}\mathbf{W}_i^q + (\mathbf{B}_i^q)^\top \in R^{T\times C\times D}, \quad (1)$$

$$\mathbf{K}_i = \bar{\mathbf{X}}_{cc}\mathbf{W}_i^k + (\mathbf{B}_i^k)^\top \in R^{T\times (2F+1)\cdot C\times D}, \quad (2)$$

$$\mathbf{V}_i = \bar{\mathbf{X}}_{cc}\mathbf{W}_i^v + (\mathbf{B}_i^v)^\top \in R^{T\times (2F+1)\cdot C\times D}, \quad (3)$$

$$\mathbf{H}_i = \text{softmax}\left(\frac{\mathbf{Q}_i\mathbf{K}_i^\top}{\sqrt{D}}\right)\mathbf{V}_i \in R^{T\times C\times D}, \quad (4)$$

where T, C, D stand for time, channel and feature dimension, respectively, $(\cdot)^\top$ denotes transpose operation, F is the number of local context frames at each time step, $\bar{\mathbf{X}}_{cc} = [\bar{\mathbf{X}}_{cc}^0, \cdots, \bar{\mathbf{X}}_{cc}^T]$ with $\bar{\mathbf{X}}_{cc}^t, \forall t \in \{0, \cdots, T\}$ being the concatenation of the context frames at time step t, which is constructed as $\bar{\mathbf{X}}_{cc}^t = [\bar{\mathbf{X}}^{t-F}, \cdots, \bar{\mathbf{X}}^t, \cdots, \bar{\mathbf{X}}^{t+F}] \in R^{(2F+1)\cdot C\times D}$, $\mathbf{W}^*$ and $\mathbf{B}^*$ are learnable parameters.

It can be clearly seen that the MFCCA can combine both channel-level and frame-level information, and it was shown in [15] that the combination with the attention based encoder-decoder (AED) to configure an MFCCA-based multichannel ASR model is beneficial for performance with a small increase in the computational cost. Considering the issues of overlapping speech and an unknown number of speakers in real-world meeting scenarios, the MFCCA was combined with SOT to tackle the multichannel multi-speaker ASR task, which is called MC-SOT. It was shown that since the SOT does not require a defined number of speakers and enables to model the transcribed dependencies of different speakers and transcripts from different speakers are concatenated in line with the corresponding starting time with a separator $\langle$sc$\rangle$ in-between, the SOT can thus work better than permutation invariant training (PIT) [6].

B. MC-FD-SOT

As the MC-TS-VAD method performs the best in the M2MeT Challenge Speaker Diarization Track [14], which utilizes a CLCCA-based TS-VAD to fuse multichannel features (e.g., the diarization error rates (DERs) are 2.26% and 2.98% on AliMeeting eval and test sets, respectively). As shown in Fig. 1(a), here we combine MC-TS-VAD and MC-SOT by aligning their timestamps to obtain the speaker-attributed transcription.

The detailed procedure of MC-FD-SOT is the same as SC-FD-SOT [10]. First, we estimate the utterance number $\hat{N}$ by diarization output of MC-TS-VAD and oracle sentence segmentation, and the utterance number of MC-SOT output is defined as N. In case $\hat{N} = N$, no further effort is required; if $\hat{N} > N$, we select the top-N longest utterances from the output of MC-TS-VAD and discard the rest; otherwise we select the $\hat{N}$ utterances with the longest text length from the MC-SOT output and discard the others. Finally, we align the utterances between MC-TS-VAD and MC-SOT in a chronological order.

C. MC-WD-SOT

In SC-WD-SOT, three independent encoders are used to encode the multi-talker hypotheses, speech features and speaker embeddings. The encoded hypotheses $H = \{\mathrm{h}_l | l = 1, \ldots, L\}$ and encoded features $X = \{\mathrm{x}_t | t = 1, \ldots, T\}$ are input into an attention layer, where H is viewed as query, X as key and value, and the output is the word-level representation $R = \{\mathbf{r}_l | l = 1, \ldots, L\}$. Next, the context-independent (CI) score $S_{l,n}^{CI}$ is calculated using the dot product between the encoded speaker embeddings $V = \{\mathrm{v}_n | n = 1, \ldots, N\}$ and the aggregated representations R. Meanwhile, the self-attention based network (SAN) [25] is also applied to H and V to compute the context-dependent (CD) score $S_{l,n}^{CD}$. Finally, the CI and CD scores are concatenated and fed to a post-processing network to predict the corresponding speaker for each character.

In MC-WD-SOT, the FLCCA is used in prior to the speech encoder to fuse multichannel speech information. As shown in Fig. 1(b), it can better extract the frame-level speech context information while fusing the cross-channel information. FLCCA is followed by 2D-convolution to obtain the single-channel representation required by the speech encoder. The speaker attribute transcription can then be obtained by merging the multichannel word-level diarization results with the MC-SOT hypotheses.

D. MC-TS-ASR

The multichannel target speaker separation module uses the given target speaker embedding to separate the multichannel mixed speech into single-channel target speaker representations, and the transcription of each speaker is then obtained by joint modeling through the ASR module, e.g., see Fig. 1(c). In general, multichannel speech separation can be achieved by neural beamforming techniques in e.g., [21]–[24].

In this work, we adopt the embedding and beamforming network (EaBNet) [24] for multichannel target speaker separation, which is an effective neural beamforming approach. The EaBNet mainly consists of an embedding module (EM) and beamforming module (BM), where the former follows an encoder-TCN-decoder structure. The encoder gradually extracts features with multiple downsampling operations, and the decoder is a mirror version of the encoder that recovers the features in the original dimensions. Temporal convolutional networks (TCNs) [26] are the bottleneck connecting the encoder and decoder, which functions as a separator. Unlike traditional beamformers [27], the BM directly uses the mapping capability of the network to estimate the beamformer weights, which consists of several LSTM layers. Finally, the desired spectrum and speech are obtained using the filtered spectrum and filter-and-sum operation. In order to better extract the target speaker, feature-wise linear modulation (FILM) [28] is used to integrate the speaker embedding into the feature before each TCN layer.

III. Experimental Setup

A. Dataset and evaluation metrics

In this work, the AliMeeting corpus [16], [17] is used to evaluate the proposed MC-SA-ASR systems. The AliMeeting corpus contains 104.75 hours data for training (Train), 4 hours for evaluation (Eval) and 10 hours for testing (Test). Each subset contains several meeting sessions and each consists of a 15 to 30-minutes discussion by 2 to 4 participants. The dataset includes 8-channel far-field audio recorded by microphone arrays (*Ali-far*) and single-channel near-field audio recorded by participants' headsets (*Ali-near*). For MC-TS-ASR, we further simulate 50 hours mixed training data (called *Train-Ali-simu*) from *Train-Ali-near* to train the front-end module as well as the corresponding eval *Eval-Ali-simu* and *Test-Ali-simu* sets.

For SA-ASR, the speaker-dependent character error rate (SD-CER) [29] is used for performance evaluation. SD-CER is calculated by matching the ASR hypothesis to the corresponding speaker reference transcription, which is a rigorous evaluation metric for meeting scenarios. Besides, we adopt the scale-invariant SNR (SI-SNR) [30] to measure the speech separation performance.

B. Model configuration

For MC-SOT, we employ a transformer model with MFCCA-based Conformer [31] encoder to construct MC-SOT, which includes 11 encoder layers and 6 decoder layers with 4-head multi-head self-attention (MHSA), where the dimensions of MHSA and feed-forward network (FFN) layer are set to be 256 and 2048, respectively. The obtained CERs on Eval and Test sets of AliMeeting corpus are 17.3% and 18.4%, respectively. For MC-WD-SOT, similarly to SC-WD-SOT, a four-layer self-attention based encoder is employed to encode the recognized text with 8 attention heads and 256 hidden units in each layer. For the speech encoder, a four-layer feed-forward sequential memory network (FSMN) [32] is adopted with 256 memory blocks and a kernel size of 31. We adopt a one-layer

of FLCCA with 8 attention heads and 560 hidden units in prior to the speech encoder. FLCCA is followed by three-layer 2D-convolutions, where the number of kernels is $\{16, 8, 1\}$ and the kernel size is (5, 7). For MC-TS-ASR, to reduce the computational burden, a squeezed version of TCNs (S-TCNs) is used, where three S-TCNs are stacked and each consists of 6 squeezed temporal convolutional modules with a kernel size of 5 and dilation rate of $\{1, 2, 4, 8, 16, 32\}$. The feature dimension in S-TCNs is 256, and 2 uni-directional LSTM layers with 64 hidden nodes are used as the BM. We employ a Res2Net-based d-vector extraction network trained on the VoxCeleb corpus [33], [34] as the speaker embedding model. For a fair comparison, the conformer with 8 layer encoder is used as the back-end ASR model, so that the amount of model parameters is 44M as close as that of MFCCA-based MC-SOT (45M).

C. Training details

The 80-dimensional log Mel-filter bank feature (Fbank) is calculated as the input feature using the ESPnet toolkit [35]. We use 4950 commonly-used Chinese characters as the modeling units. The MFCCA-based MC-SOT model is trained using *Train-Ali-far* and *Train-Ali-near* (i.e., around 210 hours of speech data in total). For MC-TS-ASR model, we first pretrain the front-end model with *Train-Ali-simu* and the ASR model with *Train-Ali-near*, respectively, which are then finetuned jointly using *Train-Ali-simu*. To maintain the front-end performance, we still adopt signal-level separation loss for pre-training, which is linearly combined with the ASR loss, such that the total loss function can be given by

$$Loss = \lambda L^{\text{SEP}}(\hat{\boldsymbol{w}}, \boldsymbol{w}) + (1-\lambda) L^{\text{ASR}}(\hat{\boldsymbol{y}}, \boldsymbol{y}), \qquad (5)$$

where $\boldsymbol{w}$ and $\boldsymbol{y}$ are the true speech and transcription, and $\hat{\boldsymbol{w}}$ and $\hat{\boldsymbol{y}}$ are corresponding hypothesizes, respectively. L^{SEP} and L^{ASR} are loss functions for separation and ASR, respectively. The negative SI-SNR is used as the separation loss, while joint attention-CTC loss is used for ASR, and λ is set to be 0.5. Finally, we use *Train-Ali-far* and *Train-Ali-simu* to jointly finetune the model with only the ASR loss being taken into account. The total amount of data used in the experiment is consistent with that in [10] to ensure a fair comparison. All models are trained with the Adam optimizer [36]. When pre-training the front-end model, the learning rate is initialized to be 1.5e-4, which will be halved if the loss does not decrease for consecutive two epochs. Besides, we use a learning rate of 1e-3 with 10000 warmup steps to jointly fine-tune the model.

IV. EXPERIMENTAL RESULTS

First of all, we show the performance of the proposed MC-SA-ASR methods in Table I in comparison with the SC-SA-ASR counterparts, which use the *Ali-far-bf* data generated by the CDDMA beamformer (bf) [37] for training and inference. In order to utilize multichannel information, both MFCCA and CLCCA are used in SOT and frame-level diarization module for MC-FD-SOT, which achieves an average relative SD-CER reduction of 18.8% in Eval and Test sets compared to SC-FD-SOT (from 41.2% to 33.5%). For MC-WD-SOT, MFCCA and FLCCA are used in SOT and word-level diarization module, an average relative SD-CER reduction of 16.6% is achieved compared to SC-WD-SOT (from 36.8% to 30.7%). It is clear that the proposed MC-TS-ASR method, which calculates the filter weights of a neural beamformer and then performs filter-and-sum to obtain the fused spectrum, results in the best performance among all MC-SA-ASR systems and an average relative SD-CER reduction of 17.7% compared to SC-TS-ASR (from 34.4% to 28.3%).

Second, we show the performance of the application of different multichannel information fusions to the proposed MC-WD-SOT method in Table II. To improve the performance, similarly to [10] we use the combination of ASR hypotheses and real transcriptions for training. It is clear that combining the single-channel word-level diarization (SD-WD) and MC-SOT results, the performance can be largely improved compared to SC-WD-SOT. Using the FLCCA before speech encoder to fuse the multichannel information can further improve the performance, which converges to the case when an oracle separator ($\langle$sc$\rangle$) is additionally exploited.

Since short utterances might cause interference and lead to too many insertion errors, we further show the impact of the minimum length of diarization utterances on the MC-TS-ASR performance in Table III. Compared with the original oracle speaker labels, the ones obtained from speaker diarization (MC-TS-VAD) obtain better results in most cases, due to the fact that there are some interfering utterances that are not recognized by the diarization model. A further improvement can be achieved by removing the very short diarization utterances, especially on the Eval set (e.g., from 30.4% to 28.2%).

Finally, we compare the performance of speech separation and ASR in different stages is shown in Table IV for the proposed MC-TS-ASR method. Specifically, after pre-training we first fine-tune the whole model jointly on *Train-Ali-simu*, such that the front-end separation module can adapt to the back-end ASR module. We then fine-tune the model using real data composed of *Train-Ali-far* and *Train-Ali-simu*. In this step, we use ASR-only and joint training strategies for comparison. The difference between them is whether to freeze the front-end module during training. It can be seen that the relative SD-CER of joint training decreases by 34.2% (from 46.2% to 30.4%) and 37.2% (from 43.8% to 27.5%) on the Eval and Test sets, respectively, compared to the ASR-only training. However, joint training also leads to a decrease in the SI-SNR. In other words, joint fine-tuning enforces the front-end module to be adaptive with the ASR module at a sacrifice in the separation performance. This implies that given a speaker embedding, the end-to-end ASR model directly recognizes the speaker's utterances rather than the separated speech in multi-talker scenarios. This also shows that a better front-end signal quality (e.g., in SI-SNR) does not necessarily mean a better back-end ASR performance in practice.

V. Conclusions

In this paper, we proposed three multichannel SA-ASR approaches in the context of multi-party meetings. The MC-FD-SOT corresponds to SC-FD-SOT, which introduces MFCCA and CLCCA into ASR and frame-level diarization. While the MFCCA is also used in the ASR module of MC-WD-SOT, merged with FLCCA-based word-level diarization. The MC-TS-ASR uses neural beamforming to fuse the multichannel information. It was shown that the proposed multichannel methods outperform the corresponding single-channel counterpart. The joint fine-tuning of MC-TS-ASR enables the front-end module to match the ASR module, but the separation performance drops, implying that a direct recognition of the target speaker's speech might be a more appropriate choice, particularly in multi-talker scenarios. To our knowledge, this work is the first attempt to the multichannel SA-ASR problem in real meeting scenarios. In the future, we will explore more effective multichannel multi-talker modeling methods in meeting scenarios and attempt to further take speaker localization (or direction-of-arrival estimation) into account, such that the considered SA-ASR can identify "who spoke what from where".

***Abstract*—With the development of deep learning, End-to-End (E2E) automatic speech recognition (ASR) based on Connectionist Temporal Classification (CTC) and attention has achieved great success and become the most popular method. In speech recognition, the selection of modeling units is critical. Most of the time, the modeling units of Mandarin are Chinese characters. However, the phenomenon of homophones and polyphonic characters in Chinese is very common, which degrades ASR performance. Pinyin can be regarded as the syllables of Chinese characters, which can reflect the pronunciation information of Chinese characters. In E2E ASR, due to the sequence-to-sequence form, Chinese characters directly correspond to the acoustic features and lack intermediate-level representations. In this paper, we introduce pinyin with tones as an auxiliary modeling unit to compensate for the mismatch between Chinese characters and acoustic features. On the basis of the hybrid modeling of syllables and Chinese characters, we propose a multi-task ASR model based on syllables and characters, which introduces a syllable CTC decoder and an attention decoder from syllables to Chinese characters to the joint CTC-attention model. Furthermore, a method of syllable auxiliary attention-rescoring method is proposed. Compared with the character-based ASR model, our method achieves a relative 8.6%/9.4% character error rate (CER) drop on Aishell-1 by greedy-search/attention-rescoring.**

I. Introduction

Automatic speech recognition (ASR) is the technology that converts speech into text. Traditionally, the entire ASR process is divided into multiple modules that are independent, including acoustic model, language model, and pronunciation lexicon, and then a decoder, such as weighted finite-state transducers (WFST) [1], is designed to search for the best path in search space according to the output of each module.

With the development of deep learning, End-to-End (E2E) ASR has become the mainstream speech recognition method. Unlike traditional speech recognition approaches that are generally divided into multiple modules, E2E ASR is trained using paired speech and text transcriptions, directly modeling the mapping of acoustic features to characters. In E2E ASR process, Connectionist Temporal Classification (CTC) can well solve the problem that acoustic features and text sequences have different lengths and cannot be aligned [2], and the attention mechanism of transformer can better capture context information [3]. At present, the model based on joint CTC and attention structure has become the mainstream E2E ASR framework [4].

*Chengfei Li is the corresponding author.

Due to the sequence-to-sequence form of E2E ASR, acoustic features are usually mapped directly onto characters without intermediate phoneme representations. However, this mapping may have some bias. For example, among all Chinese characters, a part derives from pictographs, and a part is ideographic in origin, including compound ideographs, but the vast majority originated as phono-semantic compounds [5]. This means that many Chinese characters are not directly related to acoustic features. With the frames' conditional independence assumption of CTC, in practical applications, the prediction of CTC often gains other characters with the same pronunciation as the target.

E2E ASR based on auxiliary modeling of phonemes or syllables has raised the interest of some researchers. R. Sanabria et al. [6] used a hierarchical multi-task learning method for hybrid modeling of phonemes and characters, and K. Krishna et al. [7] further studied the impact of resources, number of layers on hierarchical multi-task learning based on phoneme and character modeling. H. Futami et al. [8] modeled phonemes and characters, then used a phone-conditioned masked language model (PC-MLM) to correct characters with low confidence in the predicted sequence. X. Wan et al. [9] and Y. Yang et al. [10] only used syllables as modeling units, respectively established the mapping from acoustic features to syllables and from syllables to characters, and then cascades the two as the acoustic model. J. Yuan et al. [11] studied the improvement of pinyin with tones and pinyin without tones on Mandarin ASR and achieved high syllable accuracy using wav2vec 2.0 [12]. The result shows that pinyin with tones is better for Mandarin ASR.

Aiming at the problems existing in character-based Mandarin ASR, this paper uses characters as the main modeling unit, pinyin with tones as an auxiliary syllable modeling unit. The contributions of this paper are summarized as follows:

- This paper proposes an acoustic model for simultaneously modeling syllables and characters with a special transformer decoder that uses syllables to predict characters in order to explicitly construct the relationship between syllables and characters.
- This paper proposes a rescoring method using a hybrid attention-rescoring of characters and syllables. Compared with the current best attention-rescoring method using characters, the introduction of syllable information helps to improve the accuracy of the inference process.

II. Related Work

A. CTC-based ASR

CTC assumes conditional independence between different frames and tokens [2]. Given the acoustic features $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_t, \ldots, \boldsymbol{x}_T)$ of a speech, and the corresponding label $\boldsymbol{Y} = (y_1, \ldots, y_i, \ldots, y_L)$, the number of time steps T and the sequence length L are usually different. In ASR, T is always larger than L.

The main idea of CTC is that the posterior probability of **Y** given **X** can be directly computed by multiplying the probabilities for each frame with each other. Due to the silent segment in the speech, and to facilitate the calculation of the loss function, a special label $< blank >$ is added to the dictionary, and $< blank >$ can be predicted as the output of the model.

Let $\boldsymbol{H} = \{h_1, \ldots, h_l, \ldots, h_{T'}\}$ be the output of the linear layer after encoder, to map **H** to a shorter sequence **Y**, $< blank >$ tokens in H are removed and adjacent repeated tokens are merged, which is defined as the mapping rule α. The loss function of CTC is defined as the equation 1:

$$\begin{aligned} \mathcal{L}_{CTC} &= -\log P(Y \mid X) = -\log \sum_{H \in \alpha^{-1}(Y)} P(H \mid X) \\ &= -\log \sum_{H \in \alpha^{-1}(Y)} \prod_{t=1}^{T'} P\left(h_t \mid X\right) \end{aligned} \tag{1}$$

Where α^{-1} is the inverse of the mapping rule α, representing the set of **H** of length T' that satisfy the mapping rule α.

B. Joint CTC-Attention based ASR

In recent years, transformer has been the most famous and widely used model among the attention-based ASR models[13], [14]. Subsequently, many excellent acoustic models have been proposed, such as Conformer [15], Efficient Conformer [16], Squeezeformer [17], but the whole follows the transformer's encoder-decoder architecture.

In the training process of joint CTC-Attention model, the CTC loss and Attention loss are combined in equation 2.

$$\mathcal{L}_{\text{combined}}(\mathbf{X}, \mathbf{Y}) = \lambda \mathcal{L}_{\text{CTC}}(\mathbf{X}, \mathbf{Y}) + (1-\lambda)\mathcal{L}_{\text{Attention}}(\mathbf{X}, \mathbf{Y}) \tag{2}$$

Where λ is a hyperparameter that balances the importance of CTC and Attention loss.

In the inference process, since both CTC and Attention decoder have the ability to map the encoder output to character sequences, many decoding methods have emerged [18], [19]. The current mainstream non-autoregressive methods are greedy search, prefix beam search and attention-rescoring. The first two only use the CTC decoder, while attention-rescoring combines the CTC and attention decoder so that gets better performance obtained among non-autoregressive methods.

The attention-rescoring method is a two-stage approach. The first stage obtains a set of complete hypotheses with CTC scores, then passes these hypotheses through the attention decoder to get the attention scores. The second stage rescores the complete hypotheses using the CTC and attention scores. Let $\hat{\Omega}$ be a set of hypotheses of **X** by CTC prefix beam search, and $y \in \hat{\Omega}$, the rescoring pass obtains the final result according to equation 3,

$$\text{Prediction} = \arg\max_{y \in \hat{\Omega}} \left\{ \lambda \alpha_{\text{ctc}}(y, X) + (1-\lambda)\alpha_{\text{att}}(y, X) \right\}, \tag{3}$$

where

$$\begin{cases} \alpha_{\text{ctc}}(y, X) = \log p_{\text{ctc}}(y \mid X) \\ \alpha_{\text{att}}(y, X) = \log p_{\text{att}}(y \mid X) \end{cases} \tag{4}$$

The inference speed of attention-rescoring is faster than the autoregressive method due to the non-autoregressive nature, while it has better performance than other non-autoregressive methods.

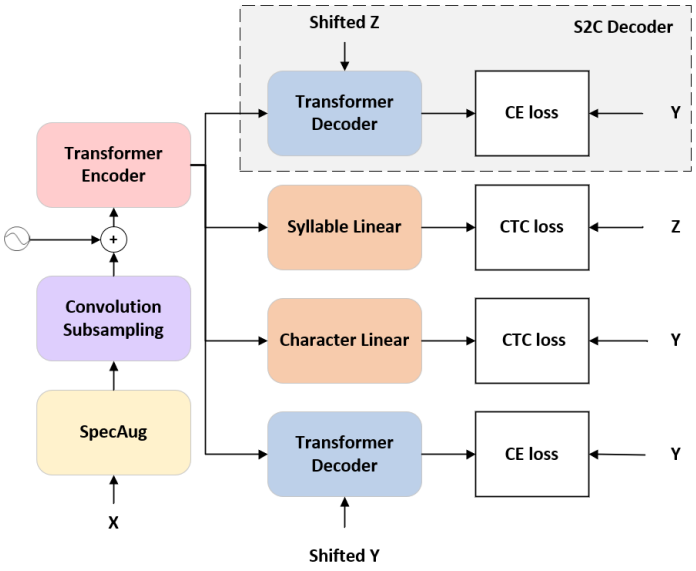

Fig. 1. Model architecture. X. Y and Z represent acoustic features, character sequences, and syllable sequences, respectively. In particular, the transformer decoder that inputs the shifted Z and outputs the probability of Y is called Syllable-to-Character (s2c) Decoder.

III. Proposed Method

In this section, two proposed methods based on syllables and characters will be introduced. One is an acoustic model with multi-task form loss functions that takes character accuracy as the main optimization goal. The other is an inference method that uses syllable information to improve character recognition performance.

A. Acoustic Model

Conventionally, the modeling units of the Hidden Markov Model (HMM) based ASR system are usually pronunciation representations. Common pronunciation representations include phonemes, initial and final consonants of syllables, syllables, etc. Introducing syllable modeling units into existing E2E acoustic models to compensate for the pronunciation information of characters is regarded as a central issue. Figure 1 shows the structure of the acoustic model.

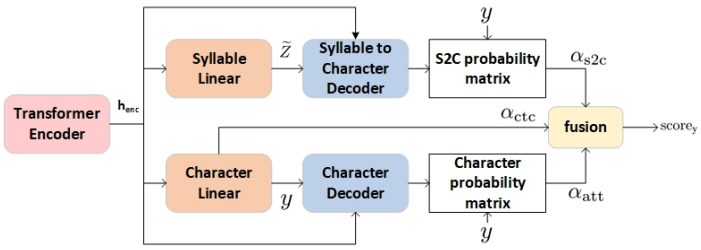

Fig. 2. The pipeline of the inference process. $\widetilde{Z}$ is obtained through greedy search, and $\hat{\Omega}$ is obtained through prefix beam search, while $y \in \hat{\Omega}$ is one of the hypotheses.

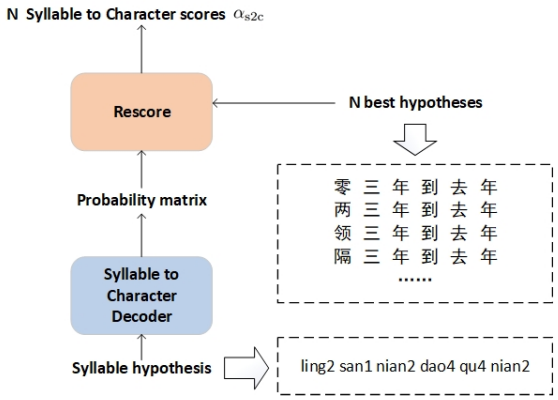

Fig. 3. The pipeline of the syllable auxiliary attention rescoring. The best syllable sequence is obtained by greedy search, and the N best character sequences are obtained by prefix beam search. The rescore process is to calculate the negative logarithm of the probability of the current character hypotheses in the probability matrix as α_{s2c}.

A hybrid modeling method of syllables and characters is adopted. For each training sample, in addition to the paired acoustic features $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_t, \ldots, \boldsymbol{x}_T)$ and character sequence $\boldsymbol{Y} = (y_1, \ldots, y_i, \ldots, y_L)$, the syllable sequence $\boldsymbol{Z} = \{z_1, \ldots, z_i, \ldots, z_L\}$ is obtained corresponding to $\mathbf{Y}$. In Chinese, $\mathbf{Y}$ and $\mathbf{Z}$ have the same length L.

After the acoustic feature is fed into the encoder and obtains h_{enc}, the character CTC decoder maps h_{enc} to $\hat{Y}_{ctc}$, then calculates the CTC loss L_{char}^{ctc} with ground truth $\mathbf{Y}$. The character transformer decoder obtains $\hat{Y}_{att}$ by inputting shifted $\mathbf{Y}$, then calculates the cross entropy (CE) loss L_{char}^{att} with ground truth $\mathbf{Y}$. The part of the model mentioned above is the same as the current transformer-based acoustic model.

The success of unsupervised pre-training models such as wav2vec 2.0 [12], HuBERT [20], and WavLM [21] use self-supervised learning to learn speech representations, and have achieved performance close to supervised learning, which proves that pronunciation features are easy to distinguish and learn. S. Zhang et al. [22] used hybrid character and syllable modeling in the Listen, Attend and Spell (LAS) [13] to reduce substitution errors, especially those caused by homophones in Mandarin. Inspired by their work, we aim at the auxiliary modeling of syllables, adding a parallel syllable CTC decoder on the decoder side, which maps h_{enc} to syllable sequences $\hat{Z}_{ctc}$ and calculates L_{syl}^{ctc} with ground truth $\mathbf{Z}$. The above three decoders have a parallel structure. The design of multi-task loss functions enables each decoder to optimize its parameters, and jointly optimize the parameters of the encoder so that the encoder can learn representations that are applicable to both characters and syllables. Since syllables and characters have an explicit correspondence and the above decoders only establish the mapping from the acoustic features to the characters/syllables, we propose a syllable-to-character (s2c) decoder to further strengthen the mapping between syllables and characters. The process of syllables to characters is shown in equation 5, 6, 7.

$$\mathrm{h_{dec}} = \mathrm{Transformer}\left(\mathrm{h_{enc}}, \mathrm{Embedding}(\widetilde{\mathrm{Z}})\right) \tag{5}$$

$$\mathrm{Prob_{char}} = \mathrm{Softmax}\left(\mathrm{Linear}\left(\mathrm{h_{dec}}\right)\right) \tag{6}$$

$$\mathcal{L}_{s2c}^{att} = -\log P_{\mathrm{att}}\left(\mathrm{Y} \mid \mathrm{Prob_{char}}\right) \tag{7}$$

In the above equations, $\widetilde{Z}$ is obtained by shifting $\mathbf{Z}$ and adding an attention mask. Linear layer projects the feature dimension of $\mathrm{h_{dec}}$ to the dictionary size of character. Finally calculate the CE loss L_{s2c}^{att} of the probability matrix $\mathrm{Prob_{char}}$ and ground truth $\mathbf{Y}$.

The total loss function of the model can be described as equation 8, and each sub-loss function corresponds to a decoder.

$$\mathcal{L}_{\mathrm{combined}} = \lambda_1 \mathcal{L}_{char}^{ctc} + \lambda_2 \mathcal{L}_{char}^{att} + \lambda_3 \mathcal{L}_{syl}^{ctc} + \lambda_4 \mathcal{L}_{s2c}^{att} \tag{8}$$

Compared to conventional character-based methods, the additional $\mathcal{L}_{syl}^{ctc}$ and $\mathcal{L}_{s2c}^{att}$ are used for syllable modeling.

B. Syllable Auxiliary attention-rescoring

As is described in equation 3 and 4, conventional character-based attention-rescoring method uses the fusion of CTC score α_{ctc} and attention score α_{att} to rescore N hypotheses $y \in \hat{\Omega}_N$ from prefix beam search. CTC prefix beam search to get N hypotheses $\hat{\Omega}_N$ of $\mathbf{X}$, where N denotes the beam width. Then the attention decoder calculates the probability of $\hat{Y}_i \in \hat{\Omega}_N$ to get the attention score α_{att}, and weights with the CTC score α_{ctc} to regain the score of each hypothesis, and the hypothesis with the highest score is the prediction.

Since syllables only contain phonetic information, unlike the situation where multiple characters may correspond to the same pronunciation, a syllable can only correspond to one pronunciation and there is no syllable with the same pronunciation. In this paper, it can be seen from the experimental results in [11] that the mapping of acoustic features to syllables is simpler and easier to learn than characters, which means that on the same experimental configuration and dataset, syllables have a high probability of achieving higher accuracy than characters.

We assume that the prediction $\widetilde{Z}$ obtained from the syllable CTC decoder using greedy search is close enough to ground truth, the shifted $\widetilde{Z}$ is used as the input of the s2c decoder to get the score α_{s2c} of y, then combine it with the CTC score α_{ctc} and the score α_{att} of character attention above as the final

score of y. Figure 2 depicts this process. The final prediction is obtained by equation 9.

$$\text{Prediction} = \arg\max_{\bar{Y}_i \in \hat{\Omega}} \{\lambda_1 \alpha_{\text{ctc}} + \lambda_2 \alpha_{\text{att}} + \lambda_3 \alpha_{\text{s2c}}\} \quad (9)$$

where

$$\begin{cases} \alpha_{\text{ctc}}(y, X) = \log p_{\text{ctc}}(y \mid X) \\ \alpha_{\text{att}}(y, X) = \log p_{\text{att}}(y \mid X) \\ \alpha_{\text{s2c}}(y, X) = \log p_{\text{s2c}}(y \mid X, \widetilde{Z}) \end{cases} \quad (10)$$

For all $y \in \hat{\Omega}$, the $\widetilde{Z}$ of the s2c decoder input is the same, and α_{s2c} represents the possibility of character $\bar{Y}_i$ mapping to $\widetilde{Z}$.

In the real-world inference process, there are usually insertion and deletion errors, which means that the inferred result and the ground truth may have different lengths. We consider that insertion and deletion errors account for a very small fraction of substitution errors. In the process of syllable auxiliary rescoring, among the N best hypotheses of characters, the hypotheses whose length is different from the syllable hypothesis are discarded. The following experiments also proved that this selection is effective and does not increase the number of insertion and deletion errors.

IV. Experiments

A. Dataset

In this paper, we evaluate the proposed syllable auxiliary modeling method on the Aishell-1 [23], a commonly used dataset for evaluating Mandarin ASR. The Aishell-1 dataset contains recordings and corresponding character transcriptions. The syllable of the corresponding character is obtained through the open-source toolkit pypinyin[1]. Pypinyin has two forms when converting characters into syllables, one is pinyin with tones, and the other is pinyin without tones. Fig 4 shows a sample from the dataset. It has been proved in [11] that although the use of pinyin without tones can achieve higher accuracy of syllables, the improvement of the accuracy of characters is not as good as that of pinyin with tones. Therefore pinyin with tones is used as the modeling unit of syllables. Since multiple characters can correspond to the same syllable called homophones, the character dictionary consists of 4233 tokens and the syllable dictionary consists of 1183 tokens, including $< blank >$ and $< sos/eos >$ tokens.

B. Experimental Setup

In all experiments, the acoustic feature is 80-dimensional log Mel-filterbank (FBank) with window size of 25ms and window shift of 10ms. For data augmentation, 0.9, 1, 1.1 times speed perturbation and SpecAugment [24] are applied to the input. The acoustic model consists of a transformer encoder with L = 12, H = 512, A = 8, two parallel transformer decoders with each L = 6, H = 512, A = 8, and two parallel CTC linear layers, where L, H and A denotes the number of layers, hidden units, and attention heads respectively. Adam optimizer is used with Noam learning rate scheduling of learning rate at 0.002, warmup steps at 25, 000, gradient clipping at 5, and gradient accumulation at 1 [14]. During training, by experience, we set $\lambda_1 = 0.21, \lambda_2 = 0.4, \lambda_3 = 0.09, \lambda_4 = 0.3$ in equation 8. During inferring, we set $\lambda_1 = 1, \lambda_2 = 1, \lambda_3 = 0.5$ in equation 9. When using prefix beam search, the beam width is set to 10.

Pinyin without tones: zai chang da liang nian de shi jian li
Pinyin with tones   : zai4 chang2 da2 liang3 nian2 de5 shi2 jian1 li3
```

Fig. 4. The character and syllable sequence of a sample in Aishell-1. Compared with pinyin without tones, the last number of pinyin with tones expresses tone information, and no number indicates a special soft tone.

V. Results and Analysis

A. Main Results

Table I shows the comparison of the proposed method with other approaches based on syllable and character modeling. All the methods only used the data of Aishell-1, without introducing external data. Different approaches are compared in terms of modeling units and Character Error Rate (CER). The character-only approach is to directly use an E2E method to establish the mapping of acoustic features to character sequences. A syllable-only approach is roughly a two-stage form. First, the syllable sequences are obtained through the acoustic features, and then the internal or external language model is used to map the syllable sequences to the character sequences. The approach of hybrid character and syllable modeling obtains the mapping of acoustic features to characters and syllables respectively, and then uses rescoring or error correction methods to obtain better character sequences through syllable sequences.

TABLE I
CER of different methods on Aishell-1 test set

Methods	Modeling units	CER (%)
Transformer [25]	Character	5.3
RNN-T [9]	Character	6.1
Syllable-level Transformer [10]	Syllable	5.2
Cascade RNN-T [9]	Character + Syllable	5.7
Decoupling Pinyin-T [11]	Syllable	7.1
Decoupling Pinyin+T [11]	Syllable	5.3
Proposed method	Character + Syllable	**4.8**

As can be seen from Table I, the proposed method achieves a competitive CER of 4.8%. Our model structure is similar to [25] and [10] which forms a transformer encoder-decoder architecture, but achieves better results. We consider that mapping from acoustic features to both character sequences and syllable sequences is important. Only mapping to character sequences will lose pronunciation information. Since the transformer encoder has the ability to capture contextual information, the character CTC decoder can use this information to better predict, and only mapping to syllables will lose the contextual information of the characters.

B. Syllable Accuracy

Table II shows the syllable error rate (SER) of part of the methods that counted the SER of syllables in Table I.

TABLE II
SER OF DIFFERENT METHODS ON AISHELL-1 TEST SET

Methods	SER (%)
Syllable-level Transformer [10]	3.2
Decoupling Pinyin-T [11]	2.7
Decoupling Pinyin+T [11]	3.6
Proposed method	3.0

In Table II, only Decoupling Pinyin-T [11] uses pinyin without tones, and pinyin with tones is used in all other methods. Among the results for pinyin with tones, the SER of our proposed method is the lowest. In the process of multi-task learning, although the CTC decoder of the syllable has only a weight of 0.09, it can still achieve a high accuracy rate. Besides, it can be seen that compared with the modeling method using only syllables, the modeling of hybrid characters and syllables can improve the accuracy of both syllables and characters. This is due to the fact that the modes of multi-task learning of syllables and characters are mutually reinforcing. Moreover, it can also be seen that the accuracy of syllables is significantly higher than characters, which means that the inference process of using syllables to assist characters' recognition is reasonable.

C. Analysis of Character Error Rate

Table III shows the error type of Transformer [25] with attention-rescoring and our proposed method with syllable auxiliary attention-rescoring.

From Table III it can be seen that in Mandarin speech recognition, substitution error is the main error type. The proposed auxiliary syllable modeling method significantly reduces the substitution error. We consider that by introducing the modeling of syllables, a more accurate mapping relationship between Chinese characters and acoustic features is established while preserving the semantic information of Chinese characters.

Discording the character hypotheses whose lengths are different from the syllable hypothesis in the rescoring process does not increase the number of insertion and deletion errors, which confirms our previous assumption. Compared to characters, syllables also have fewer insertion and deletion errors, and it is feasible to align the length of character hypotheses with the length of the syllable hypothesis.

TABLE III
ERROR OF DIFFERENT METHODS ON AISHELL-1 TEST SET

Methods	Transformer	Proposed method	Relative drop (%)
Insert	106	101	4.7
Delete	139	128	7.9
Substitute	5260	4804	8.7
total	5505	5033	8.6

D. Ablation Study

Ablation studies are conducted to demonstrate the effectiveness of each proposed method as shown in Table IV. The acoustic model shown in Figure 1 and the rescoring method shown in Figure 2 are used as benchmarks (A1). Auxiliary rescoring for syllables is first removed, and only character rescoring is used for inference (A2). No rescoring method is then used, only CTC greedy search for character is used during inference (A3). Then the inference method is not changed, and the s2c decoder is removed. (A4). Compared with the conventional transformer-based acoustic model for character modeling [14], the model only has an extra syllable CTC decoder. Finally, the syllable CTC decoder is removed, and the model is exactly the same as the implementation in [25]. From the results, it can be seen that introducing hybrid modeling of syllables and characters gains a relative drop of 6.9% from 5.8% to 5.4% in CER even without introducing complex inference methods. After adding s2c decoder and using syllable auxiliary rescoring, compared with the CTC greedy search and attention-rescoring in [25], CER obtioned by proposed method is relatively dropped by 17.2%/9.4%.

TABLE IV
ABLATION STUDY OF ALL COMPONENTS PROPOSED

ID	model	CER (%)
(A1)	Proposed method	4.8
(A2)	-Syllable rescoring	4.9
(A3)	-Character rescoring	5.3
(A4)	-s2c decoder	5.4
(A5)	-Syllable modeling	5.8

VI. CONCLUSIONS

In this paper, we propose a novel hybrid syllable and character modeling approach to better model the mapping of acoustic features to characters. The paradigm of multi-task learning is applied to our model. In particular, we propose a transformer-based decoder from syllables to characters. On this basis, we propose a method of syllable auxiliary rescoring. By introducing these methods, our method outperforms other methods based on syllable modeling on the test set of Aishell-1. We will explore pronunciation representations suitable for other languages in our future work.

***Abstract*—Automatic pronunciation assessment is an important part of computer-aided pronunciation training. Due to the scarcity of non-native pronunciation assessment datasets and the fact that traditional speech assessment usually uses Goodness of Pronunciation(GOP) features, this may not provide enough information for word or sentence-level assessment. This paper aims to improve the performance of automatic pronunciation assessment from two aspects. First, to alleviate the problem of insufficient training data for pronunciation assessment, we use the weakly supervised learning model Whisper to build a pronunciation assessment model. With the Whisper encoder, Pearson correlation coefficient(PCC) performance is significantly improved compared to traditional acoustic features. Second, we propose a multi-adapters method that uses a multi-task loss to fine-tune the adapter while simultaneously learning phone, word, and sentence assessment tasks to boost sentence-level assessment task performance. In addition, through the experimental comparison of different scale models in the Whisper, the experimental results on the open-source dataset speechocean762 show that our proposed method achieves the best results in the medium.en model.**

Index Terms: pronunciation assessment, weakly supervised learning, Whisper, multi-adapters

I. Introduction

Automatic pronunciation assessment technology is a very important technology for computer-aided pronunciation training systems (CAPT). Compared with traditional manual assessment technology, automatic pronunciation assessment technology can not only provide accurate, timely, and comprehensive pronunciation feedback and pronunciation scores to second language learners but also has more objectivity[1]. However, it is a low-resource task due to the scarcity of high-quality pronunciation assessment datasets annotated by experts. Therefore, the improvement of model performance requires full use of data and effective modeling.

Traditional automatic pronunciation assessment technology usually uses Goodness of Pronunciation(GOP) to measure the pronunciation quality of non-native speakers[2], [3]. Specifically, it is pointed out in [4] that the log-posterior probability score has the highest correlation with human expert assessment scores. Subsequently, a posterior probabilistic variant, also known as GOP, is proposed for phone-level pronunciation quality scoring [5]. Several recent studies are based on deep neural network pronunciation assessment methods[6], [7]. A novel GOPT model that can assess different aspects of different pronunciation granularities at the same time was proposed[8]. In subsequent studies, a multi-view, multi-granularity, and multi-aspect(3M) pronunciation assessment model was proposed[9]. Furthermore, considering phones, words, and sentences contain grammatical structures, a Hierarchical Pronunciation Assessment with Multi-aspect Attention(HiPAMA) model is proposed[10]. The accuracy of pronunciation quality assessment for second language learners depends partly on manually designed features.

Since end-to-end (E2E) pronunciation assessment or mispronunciation detection models can avoid the mismatch problem between feature extraction and modeling in traditional methods, E2E models have become an important research direction in the field of automatic pronunciation assessment[11]–[14]. In [15], scoring spontaneous speech in a second language is achieved by combining temporally aggregated features with time-series features. In [16], it is proposed to use acoustic cues and vocabulary for encoding to score spontaneous spoken speech. In [17], a Siamese network is proposed to extract phone instance-level distance metric features to score the proficiency of non-native speakers' spontaneous speech. However, these methods still may require the design of more advanced features by knowledgeable people in the professional field. More importantly, it will be limited by data scarcity.

In this paper, we try to improve the performance of pronunciation assessment models from two perspectives. First, we experimented with using a Whisper encoder as the backbone of the pronunciation assessment model and explored the impact of using a single adapter on different sizes of Whisper models on pronunciation assessment performance. Then, inspired by the recent weakly supervised learning method Whisper's use of multi-task fine-tuning to achieve SOTA performance in speech recognition[18], we use this technique to improve pronunciation assessment performance. According to the alignment information, the multi-adapters are used to fine-tune the representations of different pronunciation granularities obtained by different layers of the Whisper encoder. Experimental results show that the performance of multi-adapters fine-tuning for multi-tasking is better.

In general, the main contributions of this paper include the following aspects: 1) To the best of our knowledge, we are the first to employ a weakly supervised pre-trained Whisper model on the pronunciation assessment task and demonstrate its effectiveness by fine-tuning only a single adapter. 2) In

Code at https://github.com/LijingDK/pronunciation-accessment-whisper

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

order to make use of multi-aspect information, we propose to use different aspects of adapters in different layers, and use multi-task loss to fine-tune multi-adapters, and the performance has been further improved.

II. RELATED WORKS

A. Whisper for WSL Representation

Weakly supervised learning methods in Whisper have been widely used in multilingual and multitask speech recognition and translation. It is worth noting that its performance in these domains has reached the same level as humans. However, current pre-trained models based on weak supervision mainly focus on ASR performance improvement[19]. Pronunciation assessment as a downstream task has not received enough attention. Therefore, in this study, we use Whisper to generate weakly supervised learning representations for our pronunciation assessment model. Unlike the Wav2vec 2.0 self-supervised pre-training learning model [20], Whisper uses 680k hours of weakly supervised data for training, and uses the encoder and decoder of the Transformer[21] architecture as the backbone.

B. Adapter for Fine-tuning

Pre-trained models usually contain a large number of parameters and require a lot of computing resources, making the optimization of the model more difficult. To solve this problem, research in recent years has paid more attention to how to introduce a small number of task-specific parameter-sharing techniques to improve the efficiency of pre-trained models. Adapter[22] is a novel fine-tuning method, which is usually injected between pre-trained network layers, and then fine-tuned on the adaptive corpus to adapt to specific tasks. Crucially, the Adapter can effectively reduce the parameter amount and size of the model, making the model have stronger generalization ability.

III. PROPOSED METHOD

Since Whisper is a weakly supervised model for multi-language and multi-task training, the multi-task pronunciation assessment task mode needs to be fine-tuned on the basis of Whisper. Our proposed model architecture is shown in Figure 1(c).

A. Single-Adapter

Adapter fine-tuning has been widely used in various tasks, but it is better at fine-tuning in the pre-training field. In addition, a lightweight Adapter fine-tuning method can achieve the same function as the full fine-tuning[23]. The mechanism of adapters is defined as:

$$F_A(Z) = f_{\theta^S}(f_{\theta^U}(\sigma(f_{\theta^D}(Z))) + Z) \tag{1}$$

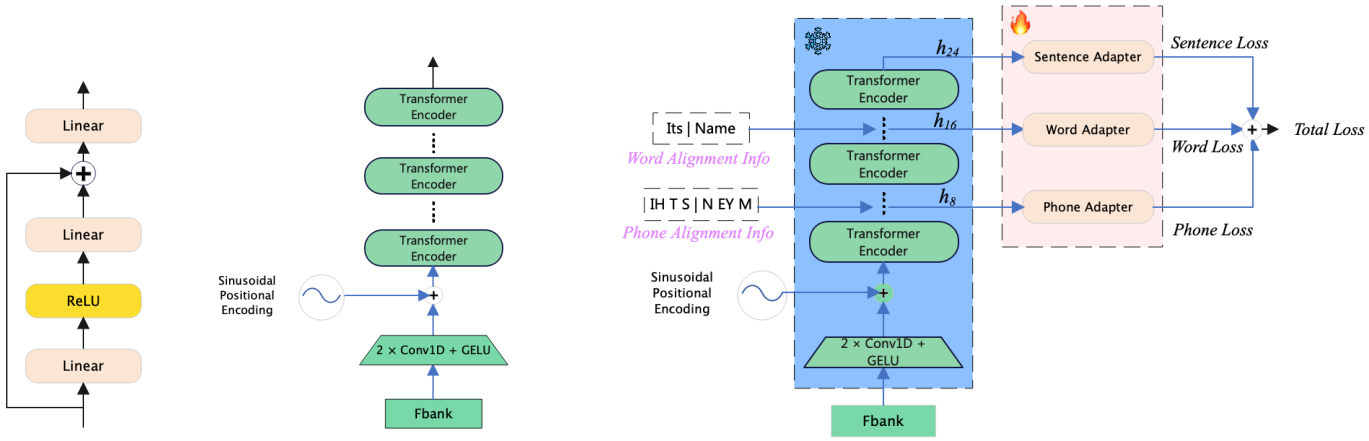
where Z is the input of the adapter, $\sigma(\cdot)$ is an activation function, and the three linear layers $f_{\theta^D}, f_{\theta^U}, f_{\theta^S}$ represent downsampling, upsampling ,and scoring respectively.

Specifically, given a speech signal, we define $X = (x_t \in \mathbb{R}^d \mid t = 1, ..., T)$ as the input fbank features. We use the Whisper encoder architecture as the backbone model, denoted F_w^h, which maps fbank features to the speech representation Z^h. Here, h represents the number of layers of the Whisper encoder. We add a sentence adapter on top of the Whisper encoder, and during the entire training period, freeze the Whisper encoder and only fine-tune the sentence adapter. The whole procedure is as follows:

$$\begin{aligned} Z^h &= F_w^h(X) \\ \bar{Z} &= AvgPool(Z^h) \\ Score_{sent} &= F_A^{sent}(\bar{Z}) \end{aligned} \tag{2}$$

$$Loss_{sent} = \sum_{i=1}^{n}(Label_{sent}^i - Score_{sent}^i)^2 \tag{3}$$

where Z^h is the output of the top layer of the Whisper encoder, and $\bar{Z}$ is the mean vector after the global average pooling. n is the total number of samples.



B. Multi-Adapters

Although weakly supervised learning can learn rich speech representations, how to apply general speech representations to downstream pronunciation assessment tasks is still a challenging problem. In the previous work, the research found that the phone information is encoded in the shallow layer of the pre-training model, and the content related information is encoded in the top layer[24], [25]. Inspired by this, we use the Whisper backbone to explore a multi-adapters architecture that is effective for pronunciation assessment tasks, as shown in the right architecture of Figure 1(c).

In the process of model training, the training samples of the pronunciation assessment data set are limited and the scoring tasks of phones, words and sentences are extremely related. As previous studies have shown, simultaneous training and sharing of network parameters across tasks can improve performance. Therefore, we take sentence assessment as the main task, phone and word assessment as auxiliary tasks, and then use multi-task learning (MTL) to combine the three. Specifically, the phone adapter, word adapter, and sentence adapter are respectively injected into the 8th, 16th, and 24th layers of the Whisper encoder. We use the kaldi based acoustic model[1] to obtain alignment information, and according to the alignment information, perform average pooling on the weakly supervised pre-training representations of the corresponding frames of each phone to obtain the acoustic representation of the phone, then input to the phone adapter to get the phone score. The entire process can be interpreted with the following expressions:

$$\begin{aligned} Z_t^8 &= F_w^8(X) \\ \bar{Z}_{phone_i} &= \frac{1}{m}\sum_{t=1}^{m} Z_{t \in phone_i}^8 \\ Score_{phone_i} &= F_A^{phone}(\bar{Z}_{phone_i}) \end{aligned} \tag{4}$$

[1]https://kaldi-asr.org/models/m13

(a) Adapter (b) Whisper encoder (c) Multi-Adapters

Fig. 1: Pronunciation assessment architecture based on multi-adapters Whisper model. Snowflakes represent frozen parameters, and flames represent trainable.

where m refers to the number of corresponding frames belonging to the same phone, which is obtained from the alignment information.

In the same way, the acoustic representation for a word is obtained by averaging the phone representations in the word. The typical part of the process is as follows:

$$\begin{aligned} Z_t^{16} &= F_w^{16}(X) \\ \bar{Z}_{word_i} &= \frac{1}{n}\sum_{t=1}^{n} Z_{t\in word_i}^{16} \\ Score_{word_i} &= F_A^{word}(\bar{Z}_{word_i}) \end{aligned} \tag{5}$$

where n refers to the corresponding phone belonging to the same word, which is obtained according to the alignment information and the pronunciation dictionary.

Finally, we fine-tune the network based on the MTL architecture, the loss is defined as shown in Eq. 6.

$$L_{total} = \alpha L_{phone} + \beta L_{word} + \gamma L_{sent} \tag{6}$$

where L_{phone}, L_{word} and L_{sent} are defined as Mean squared error (MSE) losses for phones, words, and sentences, respectively. α, β, and γ is a weight parameters to balance the loss between phone, word, and sentence scores.

IV. Experiments

A. Data Description

In this paper, we conduct experimental research on the speechocean762[2] dataset[26], an open-source pronunciation assessment corpus and also known as a benchmark for pronunciation assessment tasks. The dataset was scored by five experts on the phone with 0-2 points, and the pronunciation quality of words and sentences was scored from 0-10 points. In order to achieve the same scoring interval as the phone score, we scaled the word and sentence level scores to the 0-2 interval. Although the score range is narrowed, it does not affect the calculation of subsequent PCC values. The Train and Test sets are subject to the official release numbers, each containing 2,500 sentence pronunciations.

TABLE I: Architecture details of the Whisper model family.

Model	Layers	Width	Heads	Parameters
base.en	6	512	8	74M
small.en	12	768	12	244M
medium.en	24	1024	16	769M
large-v2	32	1280	20	1550M

B. Experiment Setup

All experiments in this paper are only trained on 2080TiGPU with 16GB of memory, batch size=20, epoch=25, learning rate=1e-5, $\alpha = \beta = \gamma$=1, because the labels in speechocean762 tend to have high scores, we use PCC to evaluate the model and expert scoring consistency.

C. Backbone Architecture

We use the ESPnet speech toolkit[27] to build a pronunciation assessment model based on the Whisper encoder. The input part of the model consists of two CNNs and an activation function GELU, where the stride of the second CNN is 2, and the 80-dimensional Fbank feature becomes 1024 dimensions after passing through the second CNN layer, and the number of frames will become the original half, the frame corresponding to each phone is halved. Then add the input module and the sinusoidal position code input to the transformer encoder module. Figure 1(b) shows the Whisper encoder architecture, Table I shows the architecture of the Whisper model family details.

D. Adapter Fine-tuning Architecture

For the fine-tuning stage of the pronunciation assessment model, the internal structure of the three Adapters used in the experiment is consistent. Each Adapter module consists of four parts, including three linear layers, an activation layer (ReLU), and a residual connection, as shown in Figure 1(a).

[2]https://www.openslr.org/101/

V. RESULTS

First, we show the performance comparison results using a single-adapter under different scale models of Whisper. Then, on this basis, the best scale model is selected and compared with different baselines. Finally, training with multiple losses further demonstrates the effectiveness of our proposed multi-adapters fine-tuning method.

From Table II we can find that larger scale models can achieve more significant results compared to using small scale models. However, large-v2 is 0.006 lower than the medium.en model. We guess that this may be because large-v2 is a multilingual training model and may not be good at fine-tuning pure English corpora. In the following experiments, we use the medium.en model to conduct multi-adapters experiments and conduct a comparative study with the baseline.

TABLE II: The PCC results for Whisper at different scales using a single sentence adapter

Model	Size	PCC
Whisper	base.en	0.66
	small.en	0.68
	medium.en	0.717
	large-v2	0.711

We used five baselines to compare with our proposed method. The two methods using GOP features as input are based on GOP[5] and GOPT model[8], one uses deep features as input[7], the other two baselines are a zero-short pronunciation assessment method proposed using the self-supervised learning(SSL) pre-training model[28] and an E2E multi-encoder method[11]. The experimental results are shown in Table III, we can observe that compared with the state-of-the-art GOPT baseline, the performance of single-adapter is about 0.023 lower than that of GOPT, but much higher than the value of about 0.077 of the most basic GOP method. Moreover, in the pre-training domain, it is about 0.117 higher than the latest benchmark model zero-shot. It is worth noting that the weakly supervised learning method achieves more significant performance improvements compared to the SSL method.

To further verify the performance of multi-adapters, we compared this method with the single-adapter and the baselines. It can be seen that multi-task training method is better than the result of single-task training, and the performance is significantly improved by the value of 0.003. This also demonstrates the effectiveness of our proposed method.

VI. DISCUSSION

Although our proposed weakly supervised pronunciation assessment method does not outperform the GOPT baseline, there may be several reasons for this result. First, the hyperparameters in our model may not have been chosen well, and a more complete hyperparameter search algorithm may need to be designed. Secondly, we did not use GOP features, were limited to unilateral research at the sentence level, and did not study the assessment of pronunciation quality at multiple granularities from multiple aspects like the GOPT method, which may have led to the low performance of our model, in future work, we will try to combine GOP features and weakly supervised pre-training representations to explore multi-aspected pronunciation assessment studies of phones, words, and sentences. Despite the limitations of the above factors, our proposed method still makes a certain contribution to the field. We use Whisper to learn a more general feature representation, which reduces the tendency of the model to overfit and helps the model to quickly adapt to various speech pronunciation assessment tasks. Moreover, the weakly supervised representation we use can capture not only phone information but also semantic information, so speech with high articulation quality can still achieve high scores even without artificially designing higher-level features.

TABLE III: Comparison of our method with different baselines on PCC.

Model	**PCC**
Regression based	
GoP[5]	0.64
DeepFeature[7]	0.72
GOPT[8]	0.74
End2End based	
Zero-shot[28]	0.60
Multi-encoder[11]	0.70
Proposed Methods	
Only Utterance Adapter	0.717
Phone + Word + Utterance Adapter	0.72

VII. CONCLUSIONS

In this paper, we use weakly supervised learning representations extracted from Whisper and fine-tune a single adapter to address the data insufficiency problem in the pronunciation assessment task. The use of the weakly supervised method achieves more significant performance improvements compared to E2E baselines, demonstrating the efficacy and importance of the weakly supervised method in pronunciation assessment tasks, and worthy of further research. In addition, we propose different aspects of using adapters at different layers of the Whisper encoder considering the correlation between different pronunciation granularities. We use multi-task loss to fine-tune the adapters, and the performance is further improved significantly. Experiments demonstrate the effectiveness of our proposed method on an open-source speech assessment dataset.

***Abstract*—The estimation of direction of arrival (DoA) for coherent sound sources, such as direct sound and early reflections in a room environment, is crucial. However, most traditional algorithms, like the multiple signal classification (MUSIC) algorithm, require observed signals to be non-coherent and can only be applied to narrowband signals. To tackle this issue, this paper introduces a neural network (NN)-based broadband MUSIC algorithm. By substituting the covariance matrix in the MUSIC algorithm with a pseudo-covariance matrix estimated through the network, this method can overcome the limitation of locating coherent broadband sources. Simulation results have shown that this proposed approach can accurately estimate the DoAs of direct sound and first-order reflections in both noisy and reverberant environments.**

I. Introduction

In a room sound field, the speech signals captured by a microphone array typically consist of direct sound, early reflections, and reverberation. For many tasks, such as in speech enhancement [1], immersive audio, and augmented reality (AR) [2], obtaining the DoA information for direct sound and early reflections is essential. However, accurately estimating the DoAs of direct sound and early reflections poses a challenge for traditional algorithms since they are coherent signals.

Traditional DoA estimation algorithms such as MUSIC and minimum variance distortionless response (MVDR) are unable to estimate the DoAs of coherent sound sources because of the rank-deficient covariance matrix [3],[4]. To address this limitation, additional processing is often required, such as spatial smoothing using the MUSIC algorithm. Spatial smoothing involves dividing the original array into multiple subarrays and reconstructing the received data covariance matrix using the covariance of the subarray matrices. This process partially restores the rank of the covariance matrix, thereby reducing coherence [5],[6]. However, this method has some drawbacks, including compromised accuracy and a limited ability to resolve coherent signals.

With the advancements in deep learning, numerous NN-based DoA estimation techniques have emerged for various scenarios and tasks. These methods often employ popular network architectures, including multi-layer perceptron (MLP) [7],[8],[9], convolutional neural network (CNN) [10],[11],[12], and convolutional recurrent neural network (CRNN) [13],[14]. However, these algorithms suffer from two key limitations. Firstly, due to the black-box nature of deep neural networks, the models lack interpretability, making it difficult to understand how the model works. Secondly, these algorithms heavily rely on large amounts of training data, which can be challenging and time-consuming to acquire.

As a solution to the limitations of NN-based DoA estimation methods, a recent trend has been to combine NNs with traditional algorithms. In these approaches, the NN replaces certain steps of the traditional algorithm. For instance, [15] proposed a method that uses the spatial pseudo-spectrum generated by the MUSIC algorithm as input to a CNN. The CNN directly outputs the posterior probability of the DoA. Similarly, [16] introduced a hybrid method that combines the traditional MUSIC algorithm with an NN-based algorithm to handle the processing of broadband coherent signals. This approach employs the coherent signal subspace method (CSSM) [17] and replaces the steps of computing the observed signal covariance matrix with a recurrent neural network (RNN). Nonetheless, accurately estimating the DoAs of coherent broadband sound sources remains an unresolved challenge.

Motivated by the successful combination of traditional algorithms and deep learning, this study aims to address the challenge of accurately estimating the DoAs of broadband coherent signals. Specifically, we focus on the direct sound and early reflections of speech signals in a reverberant room as typical examples of broadband coherent sound sources. Our proposed approach builds upon the framework of the broadband MUSIC algorithm using the independent subspace spatial matching (ISSM) technique [18],[19]. To achieve this, we first perform a short-time Fourier transform (STFT) on the observation signal. Next, we utilize the frequency bins of the STFT as input to the NN. The designed NN learns the pseudo-covariance matrix of both direct and reflected sources for all frequency bins, which can to some extent overcome the rank deficiency problem inherent in the original covariance matrix. By applying the ISSM-based MUSIC algorithm, we compute the MUSIC spatial spectrum for each frequency point and average them to obtain a final MUSIC spatial pseudo-spectrum. The peak of the final MUSIC spatial pseudo-spectrum corresponds to the estimated DoA. This enables us to estimate the DoAs of the direct sound and first-order reflections accurately. Compared to traditional algorithms, our proposed method demonstrates superior performance in precisely estimating the DoAs of direct sound and first-order reflections in a room sound field.

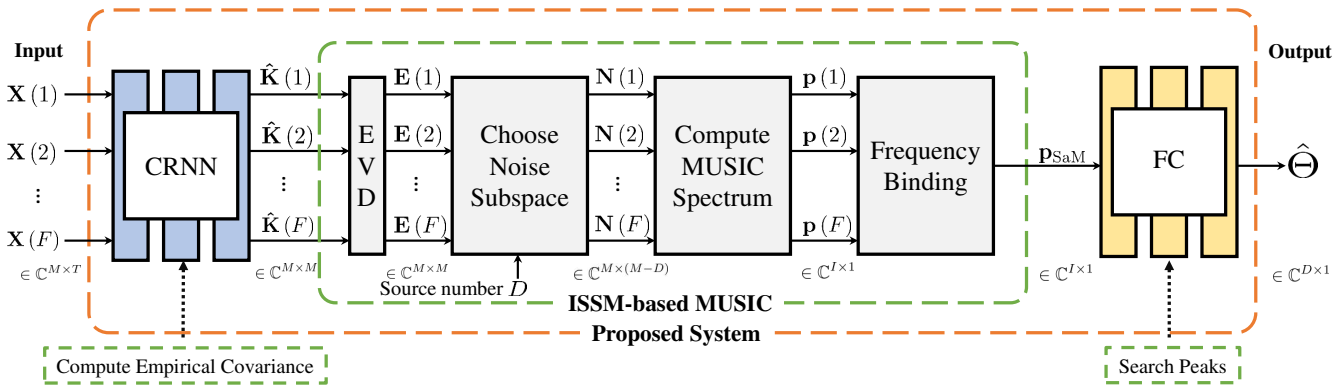

Fig. 1. Block diagram of the proposed NN-based DoA estimation algorithm, where the block in green dashed line displays the basic steps of the ISSM-based MUSIC algorithm, the block in orange dashed line displays the basic steps of the proposed approach, and the black dashed line indicates that these two steps are replaced by NNs.

The rest of the paper is structured as follows. Section II presents the signal model, along with an analysis of the challenges and underlying causes associated with the traditional MUSIC algorithm. Section III describes the overall framework and details of the proposed algorithm. Section IV validates the performance of the proposed algorithm through simulation experiments. Section V provides a discussion and summary of the entire paper.

II. Signal Model and Problem Formulation

Consider the scenario where there are D broadband signals captured by a microphone array with $M(M > D)$ elements, the observed signal of the mth sensor for $m = 1, 2, \ldots, M$ can be presented in the time-frequency (TF) domain through STFT transformation as

$$X_m(t,f) = \sum_{d=1}^{D} e^{-j2\pi f \tau_{md}} S_d(t,f) + V_m(t,f), \tag{1}$$

where $t = 1, 2, \ldots, T$ and $f = 1, 2, \ldots, F$ are the indexes of the time frames and frequency bins, respectively, T is the number of time frames and F is the number of frequency bins. S_d denotes the dth signal source, where d ranges from 1 to D, and D is the number of sources. The term $e^{-j2\pi f \tau_{md}}$ is the phase delay of the dth source at the mth array element relative to the reference element. This phase delay is used to construct the steering vectors, which describe the spatial characteristics of the array. V_m is the additive noise.

Equation (1) can be written in matrix form as

$$\mathbf{x}(t,f) = \mathbf{A}(f,\mathbf{\Theta})\mathbf{s}(t,f) + \mathbf{v}(t,f), \tag{2}$$

with

$$\mathbf{x}(t,f) = [X_1(t,f)\ X_2(t,f)\ \cdots\ X_M(t,f)]^T, \tag{3}$$

$$\mathbf{s}(t,f) = [S_1(t,f)\ S_2(t,f)\ \cdots\ S_D(t,f)]^T, \tag{4}$$

$$\mathbf{v}(t,f) = [V_1(t,f)\ V_2(t,f)\ \cdots\ V_M(t,f)]^T, \tag{5}$$

where $\mathbf{\Theta} = [\Theta_1\ \Theta_2\ \cdots\ \Theta_D]^T$ contains all DoA of D source signals, $\Theta_d = [\theta_d, \phi_d]$ contains the azimuth angle θ_d and the elevation angle ϕ_d of the dth signal. $\mathbf{A}(f,\mathbf{\Theta}) = [\mathbf{a}(\Theta_1)\ \mathbf{a}(\Theta_2)\cdots\ \mathbf{a}(\Theta_D)] \in \mathbb{C}^{M\times D}$, where $\mathbf{a}(\Theta_d) \in \mathbb{C}^{M\times 1}$ is the steering vectors of the dth signal, that is $[\mathbf{a}(\Theta_d)]_m = e^{-j2\pi f \tau_{md}}$. $\mathbf{x}(t,f) \in \mathbb{C}^{M\times 1}$, $\mathbf{s}(t,f) \in \mathbb{C}^{D\times 1}$, and $\mathbf{v}(t,f) \in \mathbb{C}^{M\times 1}$ are the signal vectors of the observed signal, source signal, and additive noise signal in the STFT domain, respectively.

The MUSIC algorithm is based on matrix eigenspace decomposition that relies on an accurate mathematical description of non-coherent narrowband sources. As the following processing is implemented for each frequency, the notation f is omitted for notional simplicity, so (2) becomes

$$\mathbf{x}(t) = \mathbf{A}(\mathbf{\Theta})\mathbf{s}(t) + \mathbf{v}(t). \tag{6}$$

The covariance matrix of $\mathbf{x}(t)$ can be calculated using $\mathbf{R}_x = \mathbb{E}\left[\mathbf{x}(t)\mathbf{x}^H(t)\right] \in \mathbb{C}^{M\times M}$. Here, $\mathbb{E}[\cdot]$ denotes the expectation operation using an empirical estimate $\hat{\mathbf{R}}_{\mathbf{x}} = \sum_{t=1}^{T} \mathbf{x}(t)\mathbf{x}^H(t)/T$, where T is the total number of samples. The symbol $(\cdot)^H$ represents the Hermitian transpose. We can obtain the eigenvectors and eigenvalues of $\mathbf{R}_x$ by performing the eigenvalue decomposition (EVD). The eigenvectors corresponding to the $M - D$ smallest eigenvalues form the noise subspace $\mathbf{N} \in \mathbb{C}^{M\times(M-D)}$. Then, the spatial spectrum of the MUSIC algorithm can be obtained as

$$\mathbf{p}_{\text{MUSIC}}(\mathbf{\Phi}) = \frac{1}{\mathbf{a}^H(\mathbf{\Phi})\mathbf{N}\mathbf{N}^H\mathbf{a}(\mathbf{\Phi})}, \tag{7}$$

where $\mathbf{a}(\mathbf{\Phi})$ is the steering vector for all possible looking directions $\mathbf{\Phi} = [\Phi_1\ \Phi_2\ \cdots\ \Phi_I]^T$ in space. The values corresponding to the peaks in the MUSIC spatial spectrum $\mathbf{p}_{\text{MUSIC}}(\mathbf{\Phi}) \in \mathbb{C}^{I\times 1}$ can be used to estimate DoAs of the sources.

Taking the microphone array receiving two incident signals $\mathbf{s}(t) = [S_1(t)\ S_2(t)]^T$ as an example, the covariance matrix can be obtained as

$$\begin{aligned}\mathbf{R}_x =& \mathbb{E}\left[\mathbf{x}(t)\mathbf{x}^H(t)\right] \\ =& \mathbf{A}(\mathbf{\Theta})\mathbf{R}_s\mathbf{A}^H(\mathbf{\Theta}) + \mathbb{E}\left[\mathbf{v}(t)\mathbf{v}^H(t)\right],\end{aligned} \tag{8}$$

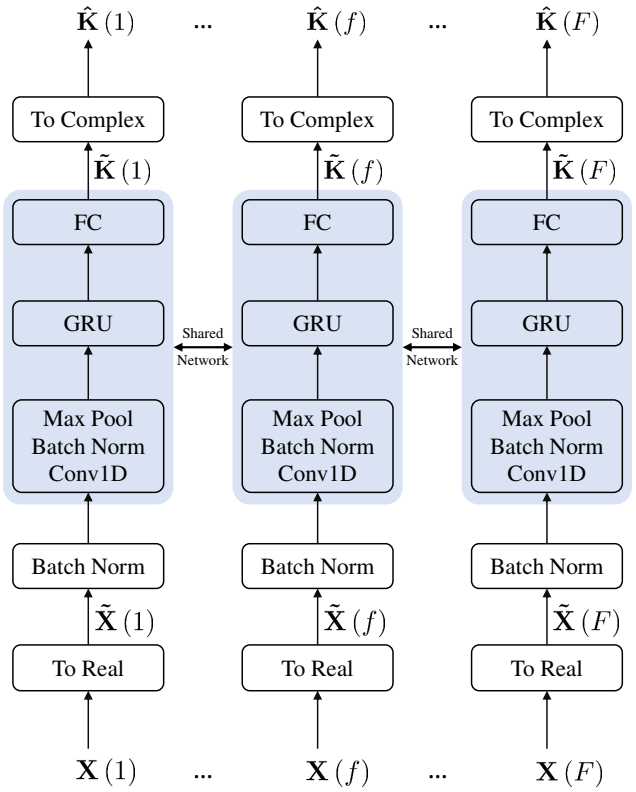

Fig. 2. Architecture of CRNN to obtain all pseudo-covariance matrix $\hat{\mathbf{K}} = \left[\hat{\mathbf{K}}(1)\ \hat{\mathbf{K}}(2)\ \cdots\ \hat{\mathbf{K}}(F)\right]$ corresponding to different frequency bins.

and the covariance matrix of the incoming signal is given by

$$\begin{aligned}\mathbf{R}_s =& \mathbb{E}\begin{bmatrix} S_1(t)S_1^H(t) & S_1(t)S_2^H(t) \\ S_2(t)S_1^H(t) & S_2(t)S_2^H(t) \end{bmatrix} \\ =& \begin{bmatrix} \sigma_1^2 & \rho_{12}\sigma_1\sigma_2 \\ \rho_{12}^H\sigma_1\sigma_2 & \sigma_2^2 \end{bmatrix},\end{aligned} \tag{9}$$

where σ_1^2 and σ_2^2 are the auto-correlation results of signals $S_1(t)$ and $S_2(t)$, respectively. When the two signals are coherent, meaning that they have a high degree of correlation with each other, $\rho_{12} = 1$, and $\mathbf{R}_s$ becomes rank deficiency. This leads to a situation where the eigen decomposition of $\mathbf{R}_s$ cannot accurately estimate the DoAs of coherent signals.

III. Proposed Approach

A. Architecture

To tackle the challenge of estimating the DoAs of broadband signals using the narrowband MUSIC algorithm, the ISSM-based deep MUSIC algorithm is proposed. As illustrated in Fig. 1, the proposed method is based on applying the narrowband MUSIC algorithm to each frequency bin to calculate the corresponding MUSIC spatial spectrum [18],[19]. Additionally, the spectra of all frequency bins are summed and averaged according to the equation

$$\mathbf{p}_{\text{MUSIC-ISSM}}(\mathbf{\Phi}) = \frac{1}{F}\sum_{f=1}^{F}\mathbf{p}_{\text{MUSIC}}(f, \mathbf{\Phi}), \tag{10}$$

where $\mathbf{p}_{\text{MUSIC}}(f, \mathbf{\Phi}) \in \mathbb{C}^{I\times 1}$ is the MUSIC spatial spectrum of the fth frequency bin, and F is the total number of frequency bins. The peaks of $\mathbf{p}_{\text{MUSIC-ISSM}}(\mathbf{\Phi})$ correspond to the estimated DoAs of the sources.

In Section II, it was highlighted that the limitation of the narrowband MUSIC algorithm in estimating the DoAs of coherent signals is attributed to the rank deficiency of the covariance matrix. This deficiency causes the energy of the incoming signal to disperse into the noise subspace, making it challenging to accurately compute the DoA. As a solution, this study proposes the use of a NN to replace the covariance matrix computation step.

The proposed algorithm's overall framework flow is illustrated in Fig. 1. It starts with the microphone array receiving broadband speech signals, which are then transformed into $\mathbf{X} \in \mathbb{C}^{M\times T\times F}$ using STFT. Each frequency bin $\mathbf{X}(f) \in \mathbb{C}^{M\times T}$ is then input into a CRNN composed of a convolutional module, gated recurrent unit (GRU), and uses a fully connected (FC) layer to perform linear transformation to obtain all pseudo-covariance matrix $\hat{\mathbf{K}} = \left[\hat{\mathbf{K}}(1)\ \hat{\mathbf{K}}(2)\ \cdots\ \hat{\mathbf{K}}(F)\right]$ corresponding to different frequency bins, where $\hat{\mathbf{K}}(f) \in \mathbb{C}^{M\times M}$. This network produces the pseudo-covariance matrix $\hat{\mathbf{K}}$ that replaces the conventional $\hat{\mathbf{R}}_{\mathbf{x}}$. Notably, the NN processes each frequency bin independently. Fig. 2 provides specific details of this NN architecture. It should be noted that before feeding into the NN, the real and imaginary parts of $\mathbf{X}(f)$ need to be concatenated to obtain the real-valued $\tilde{\mathbf{X}}(f) \in \mathbb{R}^{2M\times T}$. The NN outputs $\tilde{\mathbf{K}}(f) \in \mathbb{R}^{2M\times M}$, which should then be split into real and imaginary parts to obtain $\hat{\mathbf{K}}(f) \in \mathbb{C}^{M\times M}$.

Subsequently, the MUSIC spatial spectrum is computed for each frequency bin, resulting in $\mathbf{p}_{\text{all}} = [\mathbf{p}(1)\ \mathbf{p}(2)\ \cdots\ \mathbf{p}(F)] \in \mathbb{C}^{I\times F}$. These responses are then averaged using (10) to obtain $\mathbf{p}_{\text{SaM}} \in \mathbb{C}^{I\times 1}$. Because the gradient propagation of the NN affects the conventional search-peaks operation, it cannot be used to extract the estimated DoA values. To address this, FC layers are employed as a replacement, enabling the estimation of $\hat{\mathbf{\Theta}}$ for the direct sound and first-order reflection. Consequently, the entire DoA estimation algorithm is treated as a supervised regression task.

B. Training Loss

To address the issue of permutation inconsistency between the estimated and ground truth DoA orders, an improved Root Mean Square Period Error (RMSPE) based on permutation invariant training (PIT) [16] is integrated into the proposed system. This metric is defined as follows

$$\text{RMSPE}(\mathbf{\Theta}, \hat{\mathbf{\Theta}}) = \min\left(\frac{1}{d}\left\|\text{G}(\mathbf{\Theta}, \hat{\mathbf{\Theta}})\right\|^2\right)^{\frac{1}{2}}, \tag{11}$$

$$\text{G}(\mathbf{\Theta}, \hat{\mathbf{\Theta}}) = \min\left[|\mathbf{\Theta} - \text{P}(\hat{\mathbf{\Theta}})|, 2\pi - |\mathbf{\Theta} - \text{P}(\hat{\mathbf{\Theta}})|\right], \tag{12}$$

where $\mathbf{\Theta} = [\Theta_1\ \Theta_2\ \cdots\ \Theta_D]$ and $\hat{\mathbf{\Theta}} = [\hat{\Theta}_1\ \hat{\Theta}_2\ \cdots\ \hat{\Theta}_D]$ are the true and estimated DoAs of all D sources, respectively, and $\text{P}(\cdot)$ computes all possible permutations of the DoAs.

IV. EXPERIMENTS AND ANALYSES

A. Experimental Setup

To simulate the 2D room sound field, we generate the reverberated signals by convolving the audio signals with the room impulse responses (RIRs). We generate the RIRs using the *pyroomacoustics* library [20]. The speech signals used in the simulation are obtained from the TIMIT dataset [21]. We consider different reflection orders to achieve a more realistic representation of the sound field within the room.

The dataset we use is specifically designed to cover various room characteristics such as size, wall sound absorption coefficients, microphone position, and sound source position. To obtain all angles in a 2D room, a uniform circular array (UCA) with $M = 9$ and a radius $R = 0.05$m is used. The specific parameter settings can be found in Table I. To ensure diversity in our data, each speech sample in the TIMIT database is convolved with different RIR parameters. We generate RIR signals with random room sizes ranging from $4-7$m in width and $3-5$m in height. The absorption coefficients for each wall are also randomly set between $0.2-0.8$. Furthermore, the source position of each direct sound signal and the receiving position of the microphone array are randomly placed within the room, ensuring a separation of at least 1m for far-field signals.

For model training, validation, and testing, we obtain true DoA values using the image source method [22]. This method provides the DoA for both the direct sound and the first-order reflection for each sample in the dataset.

To evaluate the robustness of the model, we train and test it under various reflection orders and noise conditions. Specifically, we consider reflection orders of $1, 2, 5, 10$, and 20, representing different levels of sound reflections in the room. We also vary the signal-to-noise ratio (SNR) during training and testing. The SNR values we use are infinity, 30 dB, 20 dB, and 10 dB, which cover a range of noise levels from clean signals to increasingly noisy conditions.

To ensure a fair evaluation, we divide the generated dataset into training and testing sets based on the TIMIT dataset. One-tenth of the training set is further set aside as a validation set for monitoring the model's performance during training. The final dataset consists of 3696 samples in the training set, 924 samples in the validation set, and 1680 samples in the testing set. This division allows us to adequately train and evaluate the model's performance across different reflection orders and noise conditions.

During the training process, the training set is first transformed using the STFT before being passed through the model. We train the model for a total of 50 epochs using the *Adam* optimizer [23]. To optimize the learning process, we set an initial learning rate of 10^{-3}. This learning rate is adjusted throughout training based on the validation set's error rate. The learning rate decreases gradually, ensuring that the model converges effectively. We set a minimum learning rate of 10^{-4} to prevent the learning rate from decreasing too much.

For more detailed information on the model's parameters, please refer to Table I where all the parameter settings are listed. These settings ensure the model is trained effectively and allow for meaningful comparisons across different reflection orders and noise conditions.

To establish a comparison baseline for broadband coherent signal localization, we utilize the traditional ISSM-based MUSIC method. Since there is currently no existing baseline method specifically designed for this task, the ISSM-based MUSIC method serves as a suitable alternative.

To evaluate the performance of our proposed model, we use the RMSPE metric, as defined in equation (11). RMSPE provides a comprehensive measure of the model's accuracy in localizing broadband coherent signals. By comparing the RMSPE scores of our model with those of the ISSM-based MUSIC method, we can assess the effectiveness of our proposed approach.

B. Results and Discussion

During the testing of the traditional ISSM-based MUSIC algorithm, it is observed that not all samples are able to obtain the direct sound and first-order reflections in a 2D room, i.e., at least five peaks, resulting in the estimation of fewer than five $\hat{\theta}$ values. As a consequence, the RMSPE metric cannot be calculated for these un-detected samples. In order to ensure consistency in the test samples used by both methods, the entire test set is divided into two parts based on whether the traditional ISSM-based MUSIC algorithm can obtain five peaks (resulting in five estimated $\hat{\theta}$ values).

For the traditional ISSM-based MUSIC algorithm, we only calculate RMSPE on the samples where five peaks can be obtained. All tests are carried out under varying reflector orders and SNRs. In Fig. 3 and Table II, the abbreviation "Proposed" represents the Proposed-NN-MUSIC algorithm, while "ISSM-based" represents the traditional ISSM-based MUSIC algorithm.

Fig. 3 displays the RMSPE of both methods on the test samples where the ISSM-based MUSIC algorithm can extract five estimated DoAs. Table II provides the results for the situation where the ISSM-based MUSIC algorithm fails to obtain five estimated DoAs (referred to as "Undetected test samples") while the Proposed-NN-MUSIC algorithm still works effectively. The results as shown in Fig. 3 and Table II demonstrate that the Proposed-NN-MUSIC algorithm achieves significantly smaller RMSPE errors compared to the conventional ISSM-based MUSIC algorithm. This indicates that the proposed system effectively overcomes the limitations of the traditional method, successfully estimating all target DoA values in certain cases. Consequently, the Proposed-NN-MUSIC algorithm enhances the overall robustness and accuracy of the DoA estimation algorithm.

Furthermore, Fig. 3 clearly illustrates that the Proposed-NN-MUSIC algorithm consistently outperforms the ISSM-based MUSIC algorithm across all scenarios. As the SNR increases, the RMSPE tends to decrease and reach a stable level. Particularly under high SNR conditions, the RMSPE remains consistently low and exhibits minimal variation with respect to the reflector order, mostly below 0.2 rad. However, it is worth noting that under low SNR conditions, the RMSPE increases significantly, reaching up to 0.5 rad even when the reflector order is 1.

To gain a deeper understanding of the estimation by the two algorithms, Table III presents the true values, estimated values, and RMSPE for a set of direct sound DoA and its four first-order reflections for both algorithms. It is evident that the traditional ISSM-based MUSIC algorithm can accurately estimate three or four angles, but there is typically one angle with a large deviation or is unattainable, resulting in a high overall RMSPE for the algorithm. On the other hand, although the Proposed-NN-MUSIC algorithm may have slightly lower accuracy in estimating the DoA of the direct sound or one of its reflections in comparison to the traditional ISSM-based MUSIC algorithm, it avoids significant biases in estimating all angles. As a result, the Proposed-NN-MUSIC algorithm achieves a noteworthy reduction in its overall performance.

V. CONCLUSIONS

In this paper, we proposed a system for accurately estimating the DoA of coherent broadband sound sources in a room environment. Our system expands upon the traditional ISSM-based MUSIC algorithm by incorporating a neural network

that is specifically designed to learn the pseudo-covariance matrix for each coherent source. This novel design allows our Proposed-NN-MUSIC algorithm to overcome the limitations of the traditional ISSM-based MUSIC algorithm in accurately estimating the DoA of coherent broadband sound sources. By utilizing the neural network to process multiple frequency bins simultaneously, our algorithm achieves improved accuracy and can handle a wider range of sound sources. We validate the effectiveness of our Proposed-NN-MUSIC algorithm through experiments using speech signals as coherent broadband sound sources in various room environments. These experiments demonstrate that our algorithm achieves higher accuracy in DoA estimation compared to the traditional algorithm.

***Abstract*—Multimodal emotion recognition plays a pivotal role in the advancement of natural human-computer interaction systems. Recent studies have attempted to apply multi-task learning to emotion recognition. However, the multi-task shared feature extractor of traditional methods needs to integrate the feature representations of different tasks, which may lead to the feature extractor failing to focus on the learning of emotion representations. To address this problem, we propose a hybrid multi-task learning framework for end-to-end multimodal emotion recognition, in which the primary task is emotion classification, and the auxiliary tasks are emotion regression and gender classification. This framework consists of two networks specialized in gender and emotion recognition, where the latter transfers knowledge from the former through our proposed Deep Aggregation LSTM (DA-LSTM). The DA-LSTM could more precisely capture emotional information in discourse by aggregating emotion and gender feature extractors. Experimental results on a commonly used dataset IEMOCAP demonstrate the effectiveness of our proposed method.**

I. Introduction

Emotion recognition plays a pivotal role in the advancement of natural human-computer interaction systems, which could automatically detect emotions by analyzing information from multiple modalities such as speech, text, and facial expressions. Emotion recognition has diverse applications across various domains, including the prevention of traffic accidents by detecting driver fatigue and emotional distress [1], as well as aiding physicians in the diagnosis of mental health conditions such as depression and anxiety during psychological evaluations [2]. In human-computer interaction systems, speech and text are the most convenient and straightforward media for expressing emotions. Therefore, we focus on speech and text-based multimodal emotion recognition (MER) in this paper.

Traditional MER methods [3]–[5] commonly employ acoustic features such as MFCC and spectrograms, as well as word embeddings generated using pre-trained language models like Glove and ALBERT. Recent researches [6]–[8] have shown that extracting high-level features directly from raw utterances using pre-trained self-supervised models, particularly WavLM [9] and BERT [10], yields superior results compared to traditional MER approaches. Additionally, incorporating multi-head attention mechanisms to capture complementary information between modalities has also been shown to achieve remarkable performance in recent studies [11]–[13].

Furthermore, several studies have explored the incorporation of multi-task learning techniques to enhance emotion recognition performance. For instance, Mukherjee et al. [14] adopted a joint training approach to simultaneously perform emotion classification and emotion regression, to detect emotions expressed in tweets. Similarly, Li et al. [15] incorporated gender classification as an auxiliary task and shared the feature extractors with the emotion classification task, thereby facilitating the learning of emotion representations that capture gender-related characteristics. Despite the impressive achievements of these approaches, they suffer from a limitation. The multi-task shared feature extractor in traditional methods needs to balance and integrate the feature representations of different tasks, potentially resulting in the feature extractor neglecting the focused learning of emotion representation.

In this paper, we propose a hybrid multi-task learning framework for end-to-end multimodal emotion recognition, in which the primary task is emotion classification, and auxiliary tasks are emotion regression and gender classification. Considering that both emotion regression and emotion classification focus on emotional information, while gender classification focuses more on gender-related cues, we design the framework as a combination of two networks specialized in gender and emotion recognition, respectively. The first network is composed of a gender feature extractor and a gender classifier. The second network is composed of an emotion feature extractor, two cross-modal fusion modules, an emotion classifier, and three emotion regression modules that share representations with the emotion classifier. In addition, a Deep Aggregation LSTM (DA-LSTM) is designed to enable the emotion feature extractor to focus on the learning of emotion representation while transferring knowledge from the gender feature extractor.

We can summarize the main contributions of this paper as: 1) We propose a hybrid multi-task learning framework for end-to-end multimodal emotion recognition, which could comprehensively capture and analyze emotional information

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

in multimodal data; 2) We propose an LSTM-based module, referred to as Deep Aggregation LSTM (DA-LSTM), which enables the integration of both emotion and gender feature extractors for conditioning emotion recognition on gender; 3) Experimental results on the dataset IEMOCAP [16] demonstrate the effectiveness of our proposed method.

II. Method

In this section, we address the proposed hybrid multi-task learning framework, with emotion classification as the primary task while emotion regression and gender classification as auxiliary tasks. The proposed framework consists of feature extractors, cross-modal fusion modules, and output modules. These modules are introduced in order. After that, two different multi-task learning strategies with these modules are introduced, including our proposed hybrid multi-task learning and traditional multi-task learning.

A. Feature Extractors

In this subsection, we provide a detailed description of the gender feature extractor and the emotion feature extractor. Both extractors comprise a speech feature encoder and a text feature encoder, each serving a specific purpose in capturing gender-related and emotional cues, respectively.

1) Gender Feature Extractor: As shown in Fig. 1, the speech encoder consists of a pre-trained WavLM-base-plus model, two LSTM layers, and one LayerNorm layer. WavLM-base-plus is a variant of WavLM, which consists of a CNN encoder and 24 Transformer encoders. WavLM-base-plus takes the raw speech signal and outputs a frame-level embedding in the shape of N $\times$ 768 after a nonlinear transformation, where N and 768 denote the number of frames and the representation of one frame, respectively. Then, two LSTM layers with 256 cells process these embedding features to obtain high-level speech feature representations of shape N $\times$ 256. Finally, layer normalization is applied to these representations to obtain a more stable distribution. The text encoder consists of a pre-trained BERT model, two LSTM layers, and one LayerNorm layer. Sentences are segmented into words, mapped into word IDs based on the BERT lexicon, and fed into the pre-trained BERT model to obtain M $\times$ 768 word-level embeddings, with M and 768 denoting the number of words and word representations, respectively. Finally, these word-level embeddings are processed into high-level text feature representations of shape M $\times$ 256 using LSTM and LayerNorm with the same structure as the speech encoder.

2) Emotion Feature Extractor with DA-LSTM: As illustrated in Fig. 2, the emotion feature extractor is structurally identical to the gender feature extractor except that the LSTM is replaced by the DA-LSTM, which could transfer knowledge from the gender feature extractor to the emotion feature extractor. Thus, our proposed DA-LSTM is described in detail below.

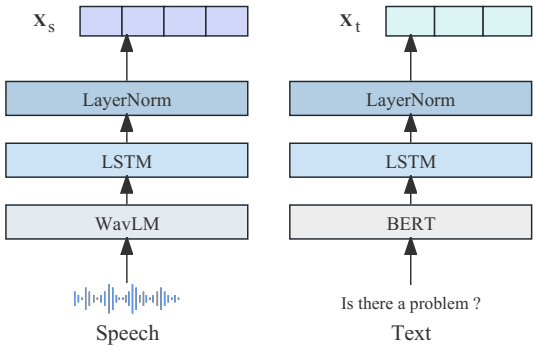

Fig. 1. A speech feature encoder and a text feature encoder.

After the k-1_{th} epoch of training, the parameters of two feature extractors with the same shape are obtained as follows:

$$\mathcal{P}^{em,k-1} = \{W_x^{em,k-1}, W_h^{em,k-1}, b^{em,k-1}\} \quad (1)$$

$$\mathcal{P}^{ge,k-1} = \{W_x^{ge,k-1}, W_h^{ge,k-1}, b^{ge,k-1}\} \quad (2)$$

where $\mathcal{P}^{em,k-1}$ comes from the emotion feature extractor, which extracts emotional information from utterances, and $\mathcal{P}^{ge,k-1}$ comes from the gender feature extractor, which extracts gender-related information from utterances. It is imaginable that $\mathcal{P}^{ge,k-1}$ could complement $\mathcal{P}^{em,k-1}$. Thus, it is valuable to aggregate them as the emotion feature extractor in the k_{th} epoch.

In this work, we propose a Deep Aggregation LSTM (DA-LSTM) as shown in Fig. 2. After the training of the k-1_{th} epoch, the $\mathcal{P}^{em,k-1}$ and $\mathcal{P}^{ge,k-1}$ are aggregated as follows:

$$W_x^{em,k} = \alpha * W_x^{em,k-1} + (1-\alpha) * W_x^{ge,k-1} \quad (3)$$

$$W_h^{em,k} = \alpha * W_h^{em,k-1} + (1-\alpha) * W_h^{ge,k-1} \quad (4)$$

$$b^{em,k} = \alpha * b^{em,k-1} + (1-\alpha) * b^{ge,k-1} \quad (5)$$

where $W_{(\cdot)}^{em,k-1}$ and $b^{em,k-1}$ are parameters in DA-LSTM of emotion feature extractor after the training of the k-1_{th} epoch, $W_{(\cdot)}^{ge,k-1}$ and $b^{ge,k-1}$ are parameters in LSTM of gender feature extractor after the training of the k-1_{th} epoch, α is the weight of the emotion classification task, and $W_{(\cdot)}^{em,k}$ and $b^{em,k}$ are set as the initial parameters of DA-LSTM in the k_{th} epoch.

B. Cross-Modal Fusion Modules

Since the high-level feature representations (HFR) of speech and text are in different dimensional spaces, we compress and map the HFRs of different modalities into the same shape before modal fusion to further extract emotional information and reduce the number of parameters. Taking speech modality as an example, the HFR with shape N $\times$ 256 is downscaled and input to a fully connected layer for compression, and then upscaled and fed to a LayerNorm layer to obtain the aligned HFR with shape D $\times$ 32. A similar process is applied for the HFR of text to obtain the aligned HFR with shape D $\times$ 32, and D is the minimum of M and N.

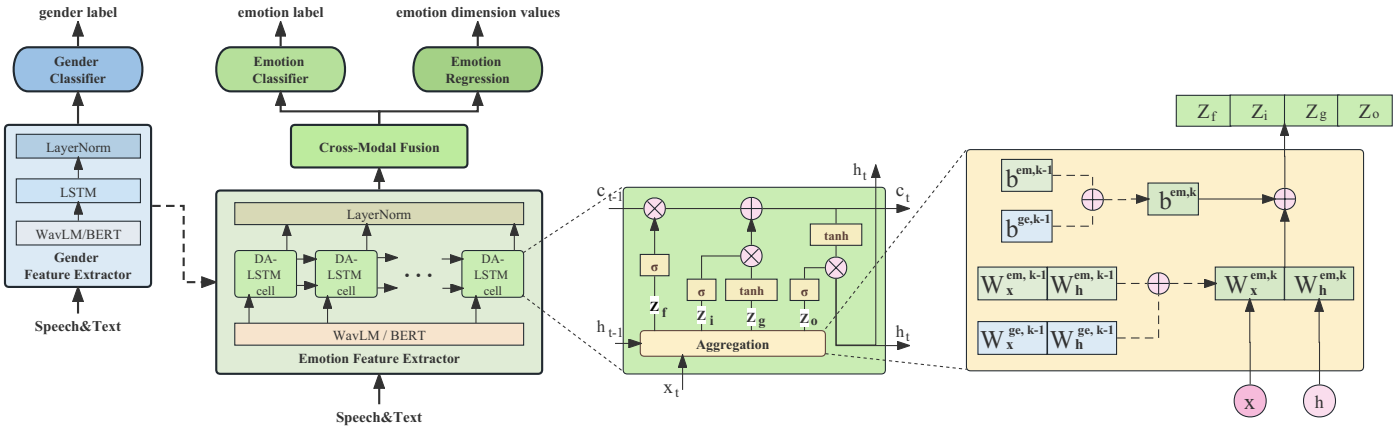

Fig. 2. Our proposed hybrid multi-task learning framework with Deep Aggregation LSTM (DA-LSTM) for end-to-end multimodal emotion recognition.

After aligning the HFRs of the two modalities, multi-head attention is employed to capture the interaction information between different modalities, allowing parallel processing of different attention heads to accelerate the inference process. Given a source sequence $X_s \in \mathbb{R}^{D\times 32}$ and a target sequence $X_t \in \mathbb{R}^{D\times 32}$, these sequences are employed with linear transformation and performed with attention h times to obtain h heads, and these heads are concatenated and employed with linear transformation. The process by which the source sequence X_s obtains complementary information from the target sequence X_t is denoted as Cross-Modal Multi-Head Attention $CM\text{-}MHA_{s\to t}$:

$$head_i = Attention(X_s W_i^Q, X_t W_i^K, X_t W_i^V) \quad (6)$$

$$CM\text{-}MHA_{s\to t} = Concat(head_1, ..., head_h)W^O \quad (7)$$

where W_i^Q, W_i^K, W_i^V and W^O are learnt parameters. Based on the $CM\text{-}MHA_{s\to t}$, the cross-modal representations of speech and text are obtained by treating the aligned HFRs of speech and text as source sequences respectively.

C. Output Modules

In this work, we employ five output modules, including an emotion classifier, three emotion regression modules (Valance, Activation, Dominance), and a gender classifier, all of which consist of a fully connected layer, a ReLU activation function, a dropout layer, and an output layer. In unimodal systems, the five output modules use only unimodal HFR as input. In multimodal systems, the emotion classifier and the emotion regression modules predict four emotion labels and three sentiment-dimensional values using a joint emotion representation that combines unimodal HFRs and cross-modal representations, respectively, and the gender classifier predicts two gender labels with a joint gender representation that combines HFRs of speech and text.

D. Multi-Task Learning Strategies

To demonstrate the difference between our proposed hybrid multi-task learning and traditional multi-task learning, these two strategies are described in detail in this subsection. Both of them consider three tasks, with emotion classification as the primary task while emotion regression and gender classification as auxiliary tasks. Let $\mathcal{L}_{ec}$ and $\mathcal{L}_{ge}$ denote the cross entropy losses of emotion and gender classification respectively, $\mathcal{L}_{er}$ the sum loss of emotion regression, $loss_{val}$, $loss_{act}$, $loss_{dom}$ the MSE losses of the valance, activation, dominance dimensional value prediction tasks respectively, and β the weight of the emotion regression task. The detailed description of the computation functions for these two strategies is as follows:

1) Hybrid Multi-Task Learning: As illustrated in Fig. 2, on the one hand, the knowledge of gender classification is transferred to emotion classification through our proposed DA-LSTM, thus improving the discrimination of the same emotion on different genders. On the other hand, since the goal of both emotion regression and emotion classification is to learn discriminative emotion representations, they can naturally share the emotion feature extractor and cross-modal fusion modules. The entire emotion recognition model is optimized by the following loss function $\mathcal{L}$:

$$\mathcal{L}_{er} = loss_{val} + loss_{act} + loss_{dom} \quad (8)$$

$$\mathcal{L} = \mathcal{L}_{ec} + \beta * \mathcal{L}_{er} \quad (9)$$

2) Traditional Multi-Task Learning: The output modules of all auxiliary tasks share the emotion feature extractor and cross-modal fusion modules with the emotion classifier. The entire model is optimized by the following function $\mathcal{L}$:

$$\mathcal{L}_{er} = loss_{val} + loss_{act} + loss_{dom} \quad (10)$$

$$\mathcal{L} = \alpha * (\mathcal{L}_{ec} + \beta * \mathcal{L}_{er}) + (1-\alpha) * \mathcal{L}_{ge} \quad (11)$$

where α is the weight of the weighted combination of emotion classification and emotion regression.

III. Experiment

A. Emotion Dataset

To evaluate the performance of our proposed method, we conducted experiments on the Interactive Emotion Dyadic Motion Capture (IEMOCAP) dataset, which is a public English

emotion corpus recorded by the University of Southern California. The IEMOCAP dataset contains 12 hours of audio-visual data with corresponding transcripts. The audio-visual data is guided by 10 professional actors in a dialogue scene with script and improvisation, and divided into five sessions. Each session contains some conversation between a female actor and a male actor. These conversations are artificially split into sentence-level utterances. Each utterance is marked by at least three markers for discrete emotion labels (neutral, happy, sad, angry, excited, etc.) and three dimension values (Valance, Activation, Dominance). To stay consistent with the prior studies [17]–[19], we select 5531 utterances with four emotions: neutral, happy (the emotion 'excited' is merged into 'happy'), sad, and angry. And five-fold cross-validation with a leave-one-session-out (LOSO) strategy is conducted for classification evaluation.

B. Experimental Setup

In this experiment, the maximum length of the speech utterance was adjusted to 3 seconds by truncating and zeroing. The same operation was used to set the maximum length of the text utterance to 40 tokens. The optimizer AdamW with a learning rate of $1e^{-5}$ and a weight decay of $1e^{-3}$ is employed to optimize the model. The rate of dropout is set to 0.5. Moreover, in order to obtain the best performance, the coefficients of multi-task learning α and β are set to 0.7 and 0.3 respectively.

IV. Results and Discussion

In this section, we evaluate the performance of the proposed method by weighted accuracy (WA) and unweighted accuracy (UA), which are commonly employed in the evaluation of emotion classification models. The weighted accuracy is the overall classification accuracy, and the unweighted accuracy is the average recall over the emotion categories. TABLE I shows the performance comparison of multi-task learning methods for unimodal and multimodal emotion recognition systems, and all results are averaged over five-fold cross-validation on the IEMOCAP dataset. TABLE I is composed of three parts: speech emotion recognition systems (Sys. 1-4), text emotion recognition systems (Sys. 5-8), and multimodal emotion recognition systems (Sys. 9-12). Each part incorporates four different multi-task learning strategies. The first strategy (Sys. 1,5,9) involves solely the primary task without any auxiliary tasks. The second strategy (Sys. 2,6,10) includes emotion regression as the only auxiliary task. The third strategy (Sys. 3,7,11) employs traditional multi-task learning. Lastly, the fourth strategy (Sys. 4,8,12) adopts our proposed hybrid multi-task learning. The performance comparisons of systems in TABLE I with different modalities or multi-task learning strategies are as follows:

A. Comparison of Different Modal Systems

The audio modal systems (Sys. 1-4) demonstrated a lower performance than text modal systems (Sys. 5-8), which may be attributed to the fact that audio utterances are more individual in terms of emotional expression than text utterances. The multimodal systems (Sys. 9-12) achieve at least 7.01% and 6.97% improvement in WA and UA respectively compared to the unimodal systems (Sys. 1-8), which shows that multimodal systems perform better than unimodal systems. These results are consistent with many previous studies [24]–[26].

TABLE I
PERFORMANCE COMPARISON OF MULTI-TASK LEARNING METHODS FOR UNIMODAL AND MULTIMODAL EMOTION RECOGNITION SYSTEMS. "A" AND "T" REFER TO AUDIO AND TEXT MODALITIES RESPECTIVELY. EC, ER, AND GC DENOTE EMOTION CLASSIFICATION, EMOTION REGRESSION, AND GENDER CLASSIFICATION. THE SUPERSCRIPT * INDICATES THAT DA-LSTM IS ADOPTED FOR THIS TASK.

Sys.	Modal	Task	WA(%)	UA(%)
1	A	EC	68.32	68.17
2	A	EC + ER	66.57	67.55

12	A&T	EC + ER + GC*	**77.34**	**77.91**

TABLE II
PERFORMANCE COMPARISON BETWEEN OUR METHOD AND LATEST METHODS ON IEMOCAP. THE SYMBOL '-' INDICATES THAT THE VALUE IS NOT MENTIONED IN THE REFERENCE. BOLD INDICATES THE BEST PERFORMANCE.

Method	WA(%)	UA(%)
Zhang et al. [20]	56.87	59.47
Deschamps et al. [21]	62.00	63.00
Li et al. [22]	63.40	-
Ours (audio only)	68.72	69.21
Liu et al. [5]	72.39	70.08
Chen et al. [6]	74.30	75.30
Lin et al. [23]	76.40	76.90
Wang et al. [4]	76.80	77.10
Ours (audio&text)	**77.34**	**77.91**

B. Comparison of Different Multi-Task Learning Strategies

As shown in TABLE I, using more auxiliary tasks can usually increase the accuracy of emotion classification (except Sys. 2,7), which demonstrates that multi-task learning helps to more comprehensively parse the emotions contained in the discourse and that traditional multi-task learning could occasionally experience negative migration issues. Significantly, systems with hybrid multi-task learning (Sys. 4,8,12) achieved superior results in all modalities compared to those with traditional multi-task learning (Sys. 3,7,11). This shows that DA-LSTM can more effectively learn gender-specific emotional representation thus accurately identifying emotions. Finally, the multimodal system with hybrid multi-task learning achieves the best performance.

TABLE II shows the performance comparison between our proposed method and the latest methods, where the upper part

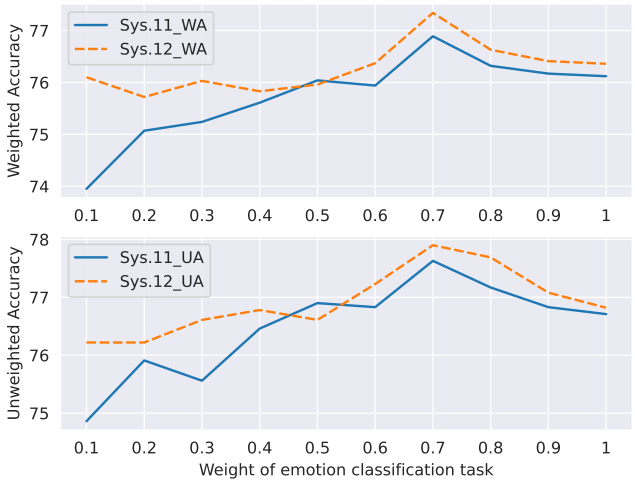

Fig. 3. Performance comparison between hybrid multi-task learning (the orange dotted line) and traditional multi-task learning (the blue line) with different weights of the emotion classification task.

uses only audio modality and the lower part uses multimodal data as input. As shown in the results, our hybrid multi-task learning model achieves improved performance compared to the recent studies employing either multi-task [20]–[23] or single-task [4]–[6] approaches. We incorporated multiple auxiliary tasks based on similar architecture as in [6] and achieved gains of 3.04% and 2.61% in WA and UA, respectively.

In addition, to comprehensively compare the performance of hybrid multi-task learning and traditional multi-task learning, we adjust the value of α based on the multimodal systems Sys. 11 and Sys. 12 in TABLE I. Fig. 3 shows the performance of Sys. 11 and Sys. 12 with different values of α which is the weight of emotion classification. As shown in Fig. 3, the performance of Sys. 11 and Sys. 12 under different weights of the primary task has roughly the same trend, with the latter having a flatter trend, which indicates that DA-LSTM can effectively mitigate the negative migration problem. Second, Sys. 12 shows better performance than Sys. 11 in most settings, and when both systems reach the best performance, Sys. 12 achieves 0.45% and 0.28% improvement in WA and UA, respectively, which demonstrates that DA-LSTM can improve the emotion recognition accuracy more effectively than sharing the feature extractors within traditional multi-task learning.

V. Conclusion

In this paper, we propose a hybrid multi-task learning framework for end-to-end multimodal emotion recognition, where the primary task is emotion classification and the auxiliary tasks are emotion regression and gender classification. In addition, we design a Deep Aggregation LSTM (DA-LSTM) to transfer knowledge from gender classification to the primary task. The experimental results show that: 1) hybrid multi-task learning performs better than traditional multi-task learning. 2) DA-LSTM can effectively transfer knowledge from the gender feature extractor to the emotion feature extractor.

***Abstract*—Podcasts are a relatively new media type, consisting of spoken documents or conversations with a wide range of topics, genres, and styles. It is of utmost importance to understand what makes a podcast more popular than others or which tags help to characterize a podcast. Here, we provide a comprehensive analysis of widely used traditional features from two modalities, i.e., audio and text. We explore multiple feature combinations considering podcast popularity prediction and multi-label tag assignment as proxy downstream tasks. Our analysis is focused on examining prevalent hypotheses and identifying new perspectives about the podcast content.**

I. Introduction

Podcasts have emerged as an exciting medium for entertainment, advertisement, news, and information dissemination. According to Nielsen [1], the total number of podcast titles is reaching 2 million with a steady increase in listeners across all demographics. With a significant increase in the listener base and podcast content, several open problems in handling and accessing this information have emerged. Jones et al.[2] highlight some of the unique challenges and future directions in the domain of podcast information access. They point out that the existing technologies addressing tasks such as *Search*, *Recommendation*, *Summarization*, and *User experience* are inadequate to handle the multi-genre, multi-style, and multi-format composition of podcasts. As this opens up an exciting landscape for future research, we believe that a comprehensive feature analysis of podcasts can serve as an important groundwork in tackling some of these problems.

Podcasts represent inherently heterogeneous data consisting of music and speech in different spoken and written styles and formats. With this work[1], we investigate the efficacy of individual traditional features and their combinations in understanding *what* the podcast contains and *how* the podcast is delivered. Traditionally various downstream applications use Textual and audio features such as tags, sentiment, emotions, Mel-frequency Cepstrum Coefficients (MFCC), and the multiband modulation features. We formulate an application-oriented framework to evaluate and understand the interplay among these features. We consider two separate applications, i.e., *Podcast Popularity Prediction*, and *Podcast Tag Assignment*. To summarize, we evaluate various hand-crafted audio and textual features described in Section III. In Section IV, we curate and enhance the dataset introduced in [3]. Experiments and in-depth analysis are detailed in Sections V and VI respectively. Our contribution in this work is a detailed feature analysis on the two aforementioned downstream tasks along with key insights focused on podcast data. We pose a baseline for the podcast tag assignment task. We also share the enhanced dataset[2] to facilitate future research in the podcast domain.

II. Related Work

Clifton et al. [4] introduced a large-scale *Spotify* podcast dataset (≈1,00,000 podcasts & ≈60,000 hours of speech) for search and summarization. Recent work in [5] further enriches this dataset with precomputed audio features based on voice and MFCCs. They demonstrate the effectiveness of these features in podcast segment categorization based on delivery. We use a similar feature set and even capture the speech modulation variation to understand podcast data but on a different dataset. In our study, we enhance the data compiled by Yang et al.[3]. They introduce an Adversarial Learning-based Podcast Representation (ALPR) that captures non-textual aspects of podcasts. They evaluate these representations in the context of podcast popularity prediction. On the same dataset, Joshi et al. [6] consider DistilBERT based embeddings with triplet loss and report state-of-the-art results for podcast popularity prediction. Due to the unavailability of the source code and unclear experimental setup, direct comparison with their score is not appropriate. Alternatively, we seek to understand the interplay between various hand-crafted features from podcast audio and its transcript.

Recently, Reddy et al. in [7] investigated the correlation between various syntax level linguistic features and podcast engagement. In contrast, we use content-specific textual features in our study. The efficacy of hand-crafted audio and textual features remains relatively unexplored in the podcast domain. Inspired by these works, we seek to understand

[1]Neil Shah, Vivek Srivastava, and Mohit Bhardwaj contributed equally in implementation, experimentation, and writing the manuscript. Satej Kadlay and Dharmeshkumar Agrawal worked on dataset collection and feature extraction. Savita Bhat and Niranjan Pedanekar contributed to the formulation and manuscript writing.

how data from different modalities perform (separately or combined) in the context of podcast data.

III. Features

A podcast is essentially an audio experience with focused textual content. Accordingly, we consider both audio and text modalities in this study. Next, we present a brief overview of hand-crafted features and their characteristics in the context of a podcast.

A. Audio Features

We consider audio features that are appropriate to represent *how* a podcast is delivered. To that extent, we use short-time modulation features derived through multi-band filtering and energy operators and the other traditional speech processing features such as MFCC, voice features, and emotions to extract salient properties.

Modulation Features: The presence of amplitude and frequency modulations in speech formats improves the performance in voice activity detection, audio event detection, and audio summarization tasks [8], [9]. To extract these representations, we rely on the multiband filtering method proposed in [8] that tracks a filter that records Maximum average Teager Energy (MTE) and also computes their corresponding values of Mean Instantaneous Amplitude (MIA) and Mean Instantaneous Frequency (MIF). In this work, we extract 1198-dimensional modulation features using 40 Gabor filters, resample the podcast at $16kHz$, and use a window size and a window shift of $25ms$ and $10ms$, respectively.

MFCC: MFCC is based on the human auditory system [10]. It employs a non-linear scale to correlate with the human perception of the spectral contents of a sound. We consider 39-dimensional delta and double-delta MFCC representation using the similar parameters adopted for extracting modulation features.

Voice Features: It is possible to capture the speaker characteristics, their speaking style, and approximately identify the listener's interest towards a section of an audio [11]. We use PRAAT to extract 15-dimensional voice features on the entire podcast data [12]. The voice features include $F0$-median, $F0$-mean, $F0$-standard deviation, $F0$-minimum, $F0$-maximum, number of pulses, number of periods, their mean and standard deviation, number of unvoiced frames, number and degree of voice breaks, mean autocorrelation, mean noise-to-harmonic (NHR) and mean harmonic-to-noise (HNR) ratio.

Affective Audio Features: The emotional state in audio is one of the most important paralinguistic messages captured during human interactions. We use a Wav2Vec2 fine-tuned model on the IEMOCAP database to extract 4-dimensional audio emotions features (*neutral*, *happy*, *sad*, and *angry*) of an entire podcast [13], [14].

B. Textual Features

According to Nielsen[1], podcast engagement has steadily seen growth in the number of listeners owing to quality content. As an exercise to understand the characteristics of such content, we evaluate various textual features. We consider a set of textual features that can help understand *what* a podcast talks about.

Tags: It is observed that every podcast is assigned a set of tags representing its categorization such as *Arts*, *Society & Culture*, *Sports*, *Business*, etc. This assignment is user-defined and captures the scope of the podcast. We use an average 100-dimensional Glove embedding vector representing the assigned set of tags to the podcast.

Topics: Even though a set of tags can describe a podcast, topics give a detailed list of concepts covered in a podcast. We use the unsupervised topic detection algorithm Top2Vec [15] to generate a list of topics for a given podcast. We represent the topic words using an average 100-dimensional Glove embedding vector for a given podcast.

Affective Textual Features: Emotions play an important role in human cognition, including perception, attention, learning, and reasoning [16]. Affective content is more engaging to users than neutral content [17]. Accordingly, we consider two perspectives of affective features given below. leftmargin=*

1) **Sentiment**: Sentiment of a podcast refers to the inclination of the podcast content towards positive or negative polarity. We use the NLTK sentiment analyzer to create a 3-dimensional sentiment representation vector for each podcast with scores corresponding to *negative*, *neutral*, and *positive* sentiment that sum up to 1.
2) **Text Emotions**: We consider six basic human emotions, i.e., *happy*, *sad*, *anger*, *fear*, *surprise*, and *disgust*, assigned to sentences in podcast transcripts. We use a zero-shot sentence classification setup with task-aware sentence representations [18] to predict the emotion and the corresponding confidence for each sentence. We combine confidence score of the emotion detection model and sentence count for an emotion to calculate a posterior probability of each emotion. This results in a 6-dimensional emotion vector representing a given podcast.

Named Entities: Named entities like *person*, *organization*, *location*, and *others* can play a significant role in attracting audience attention. From the podcast title, we predict named entities and the corresponding confidence score using the TARS [18] zero-shot sentence classification setup. To obtain a four-dimensional named entities representation for a podcast, we use the similar formulation used in the text emotion feature representation.

Document Embeddings: Pre-trained language models are often used to extract contextual representations. Considering the longer length of podcast transcripts, we use Longformer embeddings (LF Embeddings) [19] to extract podcast content representations.

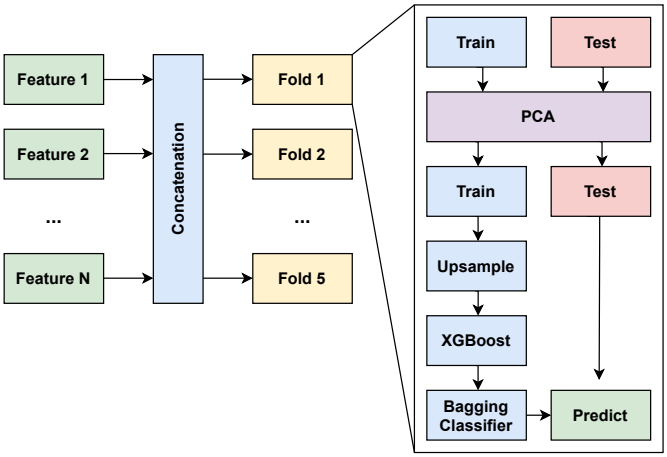

Fig. 1. Proposed architecture for podcast popularity prediction. For every fold, the classification setup involves PCA, upsampling, XGBoost, and a bagging classifier.

IV. Dataset

For the task of popularity prediction, Yang et al.[3] introduced a dataset of $6,511$ English language podcasts - 837 popular, and 5674 unpopular. For a podcast, we scrape its audio file and tags using the RSS feed of the podcast. It is possible to assign one or more tags to a podcast from 105 fine-grained tags. However, to increase the reach of a podcast, some creators label their podcast into multiple categories that don't especially fit their content [20]. To reduce noise in the tag set, we merge these 105 fine-grained tags into 19 coarse-grained tags as described by Apple podcasts[3], which results in a cleaner data with only 0.2% of the podcasts having three or more tags as opposed to 46.18% earlier. Since the transcripts had no punctuation, we punctuate the transcripts using a bidirectional RNN and attention-based punctuation restoration technique [21]. Further, we extract the audio and text features mentioned in Section III. Finally, we end up with a dataset of 3306 podcasts (444 popular, and 2862 unpopular) as either some audio links were broken or information was missing.

V. Experimental Setup

The podcast data is multimodal and heterogeneous, motivating us to experiment with combinations of diverse feature sets for both the downstream tasks. We conduct our experiments using a 20 core CPU with $64GB$ RAM.

A. Podcast Popularity Prediction

In this task, we seek to investigate the factors influencing the popularity of a podcast using a fine-tuned XGBoost and bagging classifier-based architecture. We perform the grid search on hyperparameter space to find the best parameter combination[4]. Fig. 1 shows our binary podcast popularity classification model. We use upsampling with SMOTE[22] and bagging to address the data imbalance. We report the experimental results using the macro-F1 score.

(−) Voice	0.791
(−) Topics	0.798
(−) MTE	0.801
(−) MIA	0.801
(−) Sentiment	0.801
(−) MFCC	0.801
(−) Audio Emotions	0.802
(−) NER	0.802
(−) Tags	0.809
(−) Text Emotions	0.812

B. Podcast Tag Assignment

In the novel multi-label podcast tag assignment task, we seek to automatically assign appropriate coarse-grained tags to a podcast. We consider a unified two-layer perceptron network with dropout after the first layer[5]. We use binary cross-entropy loss function with *class_weights* to handle dataset imbalance. We calculate *class_weights* for each tag l as N/N_l, where N is the total number of podcasts in the training dataset, and N_l denotes the numbers of podcasts with tag l. Since the dataset is highly imbalanced, we use the weighted-F1 score (w-F1) as the primary evaluation metric. Similar to [23], we also evaluate the features on tag recall (TR) and unique tags learned (TL) over weighted-F1 scores.

VI. Results and Analysis

In this section, we report our results and analysis on the performance of features in different modalities for the two aforementioned downstream tasks.

A. Podcast Popularity Prediction

In Table I, we present the ablation study of text, audio, and multimodal features for popularity prediction. Using the textual modality, the tags and affective features (text emotions and sentiment) are the most significant in predicting the podcast popularity since their exclusion results in a drop of

[5]*no. of epochs* = 75, *learning rate* = 0.0001, *batch size* = 4, *optimizer* = Adam, *dropout=0.3*

TABLE II
ABLATION ANALYSIS FOR MULTI-LABEL TAG ASSIGNMENT TASK.

Feature(s)	w-F1	TR	TL
All Text	44.02	78.22	19
(−) Topics	35.31	76.34	19
(−) LF Embeddings	41.89	71.85	19
(−) Named Entities	43.37	79.44	19
(−) Sentiment	43.42	77.07	19
(−) Text Emotions	43.83	79.34	19
All Audio	18.79	80.40	18
(−) Voice	16.26	57.89	14
(−) MIA	17.55	51.20	15
(−) MTE	17.87	40.78	15
(−) Audio Emotions	18.68	71.84	15
(−) MFCC	19.30	63.84	17
(−) MIF	22.54	70.39	17
All Text + Audio	18.62	69.36	17
(−) LF Embeddings	17.57	70.23	16
(−) Voice	17.71	63.86	15
(−) MTE	17.90	53.89	15
(−) Audio Emotions	17.91	54.09	12
(−) Topics	18.36	71.92	16
(−) Sentiment	18.49	52.59	15
(−) Named Entities	18.60	59.59	17
(−) MIA	18.63	58.46	15
(−) Text Emotions	18.98	65.40	17
(−) MFCC	19.26	55.45	15
(−) MIF	31.14	55.47	16

8.25%, 1.46%, and 1.10% in the macro-f1 score, respectively. However, the topics and named entities negatively contribute to the popularity prediction results. The MIF and voice features contribute the most in popularity prediction amongst all audio features as with their exclusion, we report a drop of 24.81% and 2.24% in the macro-f1 score. Additionally, we observe that the features such as MFCC, MTE, MIA, and audio emotions do not show significant performance improvement in audio and multimodal experiments.

Since the combinations of all audio and text representations report the highest macro-F1 score of 0.807, we further experiment with different combinations of these features to identify the best performing multimodal feature combination. The top multimodal feature combination with the highest macro-F1 score is 0.820 for (modulation + voice + tags). Experiments with only textual dataset in [6] report the best performing system with a 0.820 macro-F1 score. In contrast, we use a much smaller dataset of 3306 podcasts compared to 6511 podcasts in [6] and report similar results for the best performing system. The multiband modulation features with their ability to model dynamic aspects of audio are the most significant ones in capturing the intricacies of a podcast for this task [8].

B. Podcast Tag Assignment

In Table II, we present our ablation study for multi-label tag assignment for text, audio, and multimodal frameworks. Topics emerge as the most prominent feature as their exclusion results in a 19.78% drop in the weighted-F1 score. The audio features as standalone representations do not perform well in tag assignment tasks. Even with all the audio features, the model fails to learn all the tags and perform relatively poor when compared with the text modality. Voice features dominate the audio modality as with their exclusion, the model fails to learn five tags altogether while also producing a significant drop of 13.46% and 27.99% in the weighted-F1 score and tag recall, respectively.

The model also does not benefit from multimodal setup. Similar to the audio modality, the MFCC, and MIF features fail to capture the tags appropriately. We note an increase of 67.23% in the weighted-F1 score with the removal of MIF features. In a multimodal framework, LF embeddings perform the best, followed by audio emotions, voice features, and sentiments.

C. Key Insights

In addition to the above findings, we report insights that help in understanding *whats* and *hows* of the podcast. We select all available 444 popular podcasts and select an equal subset of the unpopular podcast in 6-folds.

Young and energetic voice contribute to the podcast's popularity The mean pitch values in voice features are consistently higher in the popular podcast, as is high MIA values. The lower *p-values* in the statistically significant *t-test* metric of 0.003 and 0.014 for mean pitch and MIA between popular and unpopular distributions indicates that on average, a more young and energetic voice contributes to the podcast's popularity [24].

Speakers in popular podcasts tend to speak relatively fast The higher pulses and periods in data indicates that on average popular podcast tends to have high periodic speech variations and high speech rate, as also reported in [7]. We report the *p-value* of 0.042 for periodicity in the *t-test* metric between the popular and unpopular distributions.

Emotions from audio and text modalities capture different aspects of a podcast We observe a non-trivial dissimilarity between emotion identified using audio signal and textual content. The audio emotion features associate the music category with the most share for '*sad*' emotion as compared to other categories. Whereas text emotions portray a low share for '*sad*' emotion and instead associate music category having maximum share for '*happy*' emotion. Since audio and text capture different aspects of the content, both modalities are equally important to understand the podcast content better.

Podcasts categories tend to have preference for speaker's gender Though the voice features help us to extract the speaker's gender information, we rely on the pre-trained model [25] to gather the gender-specific segments. The gender share for every podcast varies depending on the podcast category. It is interesting to note that podcasts under '*Kids & Family*' category have significant '*Female*' voice (56%) whereas '*Sports*', '*Technology*', and '*News*' categories are dominated by speakers tagged as '*Male*' (82%, 79% & 77% respectively).

At times speaker's gender influences podcast popularity We investigate the distribution of speakers' gender among popular and unpopular podcasts. We observe that unpopular podcasts under categories such as '*Kids & Family*' have a high percentage of '*Male*' voice share (72%). However, popular podcasts under the same category have a high '*Female*' voice share (65%). On the other hand, unpopular podcasts within the '*Sports*' category have a high percentage of '*Female*' voice share (48%) as compared to the '*Male*' voice share (42%). Popular podcasts in '*Sports*' have 82% '*Male*' voice share as compared to 8% '*Female*' voice share. Even though we observe a slight association between gender and popularity across certain categories, its causality should be validated. We need to exercise caution in generalizing these associations because of uncertainty in underlying models used for identifying voice information and the lack of enough data.

Popular podcasts contain more musical content We use the pre-trained model [25] to extract music segments for every podcast. Popular podcasts have 64.81% more musical content than unpopular podcasts. Also, we observe that popular podcasts under the '*Music*' category on average have 46.05% of musical content as compared to 3.17% in unpopular podcasts.

Topics effectively captures *what* is covered in a podcast Topics provide a detailed list of concepts covered within the podcast. It is essential to understand *what* the podcast is about, which also helps to assign relevant tags. We observe that podcasts under the '*Technology*' category are associated with topics like apps, software, iPhone, and similarly, podcasts under the '*Leisure*' category are associated with topics like games, racing, and cards.

VII. Conclusion

Podcasts are spoken documents ranging across several genres, topics, and styles. With the rapid growth in popularity and global reach, there is a definite need to explore and investigate this new engagement medium and relevant research landscape. In this work, we use the podcast audio and its transcript to characterize the podcast data. We observe that the hand-crafted features capturing distinct qualities like speaker's style, emotion, and subject content coverage (i.e., voice, emotions, sentiment, and topics) are significant irrespective of the downstream task. Even though we report various insights relevant to podcast popularity, tag assignment, and content features, care must be taken while using and generalizing these results. We believe this analysis can benefit several other downstream tasks such as podcast summarization, retrieval, and recommendation.

***Abstract* — In the field of computer vision (CV), convolutional neural networks (CNN) have demonstrated superior capability in feature extraction. However, the translation during the process of capturing finger vein images can potentially degrade the accuracy rate of the model, making it challenging to apply CNN to real-time and high accuracy finger vein recognition. Additionally, while CNN offers high accuracy, they also require a high number of parameters. Previous studies also confirmed the absence of shift-invariant features in CNN. In the light of these issues, this research proposes a lightweight attention convolution neural network (LACNN) for applications in finger vein recognition. The model incorporates diverse branch block (DBB), adaptive polyphase sampling (APS), and coordinate attention mechanism (CAM). To evaluate the performance of the model under finger vein recognition, the finger-vein by university sains malaysia (FV-USM) public database is employed for analysis and comparison with recent research methods. According to the result, the new model achieves an accuracy recognition rate of 99.82% with a parameter count of only 1.23 million. Thus, the LACNN presented in this study surpasses the other recent finger vein recognition methods.**

I. INTRODUCTION

With rapid development of information technology, the significance of personal data has grown increasingly prominent. Utilizing biometric recognition, which includes the identification of individuals based on distinctive physiological or behavioral characteristics, has captured the attention of the public. Hsia *et al.* [1] identified the four fundamental characteristics of biometric recognition: *1)* Universality: the presence of biological characteristics that are possessed by every individual, such as fingerprints, iris patterns, and finger veins; *2)* Distinctiveness: the uniqueness of these biological features among different individuals. Even in the case of identical twins, their biometric characteristics are distinct and can be utilized for identity recognition; *3)* Permanence: an individual's biometric traits should remain constant and stable over time, without significant changes; *4)* Collectability: the feasibility of conveniently and rapidly measuring biometric features using sensors. Chen *et al.* [2-3] further categorized the acquisition regions of biometric traits into two types: *1)* external biological characteristics, including features such as fingerprints, iris patterns, and facial characteristics; and *2)* internal biological characteristics, such as finger veins and palm veins. However, the accuracy of external biological characteristics is more susceptible to environmental factors, leading to a decrease in accuracy compared to internal biological characteristics. Finger veins, on the other hand, represent a more stable internal biological characteristic. Therefore, veins are more suitable for applications related to identity recognition.

In recent years, Liu *et al.* [4] proposed a novel CNN architecture for finger vein recognition. However, the complexity of this model results in a parameter count of over 5 million, which may pose limitations when deploying the model in practical settings due to hardware constraints. Chai *et al.* [5] utilized convolution layers and global average pooling (GAP) to avoid an increase caused by fully connected layers. However, significantly increasing the channel dimension of the model can lead to an increase in the number of parameters, making the model less amenable to lightweight implementation. Chai *et al.* [6] uses continuous convolutional layers and ACE to improve model generalization. However, this model did not address the translation issue of finger vein features, potentially resulting in inconsistent recognition due to variations in user operations.

The objective of this study is to address the issue of excessive parameter count in deep learning networks applied to finger vein recognition, while simultaneously improving the model's ability to handle translation variations in finger vein features. To achieve this, we propose an lightweight attention convolution neural network (LACNN) structure and evaluate its performance using the finger-vein by university sains malaysia (FV-USM) database. Experimental results demonstrate that our proposed approach successfully reduces the model's parameter count while maintaining high accuracy in recognition results.

II. METHODOLOGY

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

In this study, we propose a finger vein recognition system based on the LACNN model, which can be divided into training and testing stages, as illustrated in Fig. 1. During the training stage, the back propagation network (BPN) is employed to iteratively optimize the model's weight parameters. In the testing stage, the optimized lightweight model is used for finger vein recognition. The model takes an input image and predicts the identity based on the vein patterns. When the model's output probability is above 50%, the image is classified as the predicted identity. Otherwise, it is considered a prediction error.

A. Model Compression

The classical CNN structure often exhibits high accuracy in many recognitions but comes with a large number of parameters, making them less suitable for practical deployment. Structural re-parameterization is a method that uses functions to transform the parameters of a complex model structure into those of a simplified model structure. This training strategy allows the model to utilize abundant computational resources during the training stage for optimization. A series of transformation functions is applied to convert the complex model structure into an equivalent simplified model structure for inference. Ding *et al.* [7] proposed the diverse branch block for structural re-parameterization. By extracting feature maps of different scales using branches of complexities, the module enriches the model's diversity in the feature space. Therefore, we use DBB modules to replace all convolutional layers in the model structure for training. After completing the training, we will use the original model structure for inference.

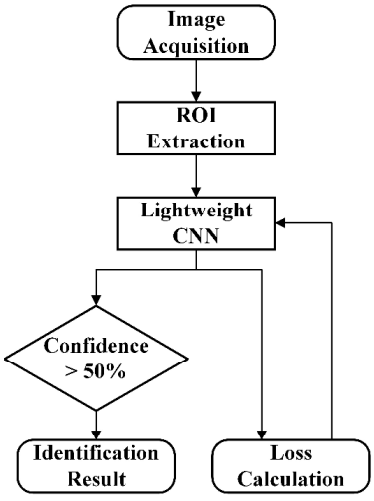

Figure 1. Flowchart of the proposed finger vein recognition

B. Attention Mechanism

To further enhance the ability of the model to extract effective features in finger vein recognition tasks, the proposed lightweight model structure incorporates the use of an attention mechanism. Hou *et al.* [8] introduced a novel attention mechanism named the coordinate attention mechanism (CAM). CAM compresses the spatial information of the input feature map using two separate average pooling layers in different directions. The resulting one-dimensional features from the two directions are then concatenated and fed into a convolutional layer to encode the channel-wise representation of the feature map. By using the same convolution weights for the two directions, the information between the vectors can be shared. It helps the model improve its ability to recognize vein features. In this study, we will use the CAM attention mechanism to enable the model to extract more discriminative features for recognition and enhance the accuracy of identity recognition for different individuals.

C. Shift-Invariant Features

CNN is generally believed to be able to extract features that are invariant to translation. However, recent studies have found that making subtle changes to the input image can greatly affect the output of the model. In the task of finger vein recognition, the captured images may undergo translation due to user manipulation. Therefore, image translation becomes one of the factors that have to be considered when designing finger vein recognition model structure. Chaman *et al.* [9] proposed adaptive polyphase sampling (APS) to address the issue of inconsistency features in neural network structures. When down sampling the input feature map, APS generates four potential candidate sampling results, which are referred to as polyphase components. At this point, we can compute the L_p normalization for each candidate sampling result and choose the one with the highest computed value as the optimal sampling result. In this study, we will use APS sampling to replace the original pooling layers, allowing the model to maintain consistency in the extracted features and achieve stable recognition results in finger vein recognition.

D. Margin-based Loss Functions

In recent years, various forms of margin-based Softmax loss function have been proposed with the aim of minimizing intra-class variations and maximizing inter-class differences to enhance the accuracy of model recognition. Deng *et al.* [10] applied L_2 normalization to the deep feature x and the weights W_{y_i} of the last fully connected layer in the model. However, normalizing both the deep feature and the weights with L_2 normalization can sometimes lead to less distinct feature differences in the model's output. Therefore, we employ elastic penalty margin loss (EPML) function [11] for finger vein recognition, in which the margin penalty is determined by

random values obtained from a Gaussian distribution. This approach provides the model with greater flexibility and a more adaptable space for learning class separability.

E. Proposed Lightweight Model Structure

Given the need to reduce model parameters and maintain high accuracy in finger vein recognition tasks, this study proposes an LACNN structure for one-to-many identity recognition. To address the challenges of gradient degradation caused by increasing model depth and decreasing gradient correlation between neurons, we propose an improved DBB residual module based on the ResNet residual module. Residual modules are effective in solving the problem of gradient vanishing. The DBB residual module consists of a DBB module, APS sampling, and CAM attention mechanism. The DBB module replaces all convolutional layers in the original residual module to increase the model's complexity and enhance the diversity of feature extraction. During the inference phase, the module's parameters are transformed using a function that maintains the optimal parameters while achieving lightweight representation. The CAM attention mechanism identifies important features in the input feature map to enhance the model's sensitivity to critical features, thereby improving overall accuracy. APS sampling effectively addresses the translation effects in the input feature images caused by user operations and improves the consistency of the model's feature extraction across different translations.

The LACNN structure, constructed using the proposed DBB residual module (DBB ResBlock), is shown in Fig. 2. The model structure is divided into two main parts: Input flow, and Output flow and described in the following:

1) Input flow

First, to meet the computational limitations of the model structure and avoid distortion caused by changes in image scale, we employ padding to expand the vein image to a square shape. Then, the image is resized to a side length of 112 before being inputted into the model for feature extraction. After using the DBB module to extract features, the ReLU activation function is applied to filter the features and enable the model to express nonlinear characteristics. Finally, the CAM attention mechanism and APS sampling are applied consecutively to focus on important feature regions in the feature maps and reduce their size. This reduction in feature map size helps reduce the computational load in subsequent stages of the model.

2) Output flow

In the final stage, we first utilize global average pooling to compress the spatial information of the feature maps, avoiding direct computations with fully connected layers to reduce computational complexity. Simultaneously, we obtain a feature vector of length 256, which is then input into fully connected layers to obtain two types of feature results: normalized features obtained by applying normalization to the weights and input features, and identification results without normalization. In particular, the normalized features are used to calculate the loss value in the EPML, which is utilized for model weight updates to optimize the model. On the other hand, the identification results can be directly used to examine the predicted identity class by the model and perform subsequent metric computations. It is worth noting that in the output flow, we place the Dropout layer before the output layer to improve generalization ability, thereby further enhancing recognition accuracy of the model.

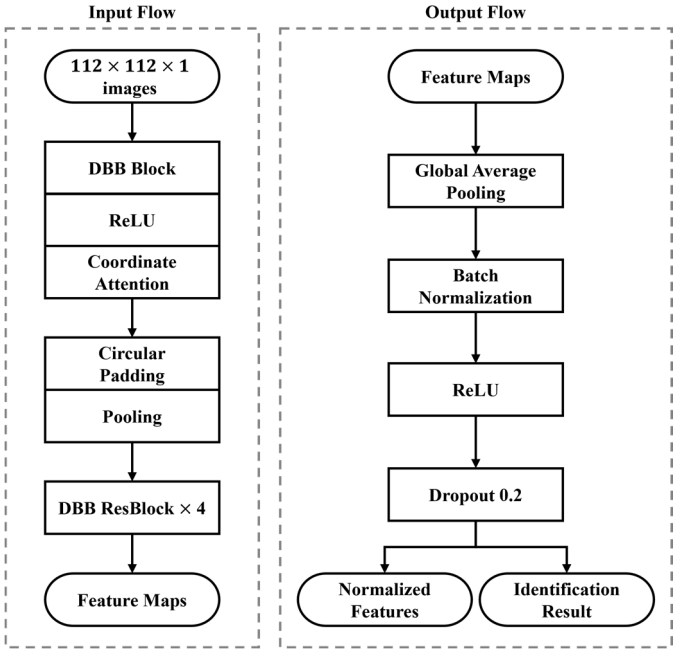

Figure 2. Proposed LACNN structure

III. EXPERIMENTS

A. Database

This study utilized the FV-USM public database [12] for implementing deep learning. The database contains 5,904 infrared finger vein images with a resolution of 640x480, collected from 123 subjects, resulting in a total of 492 classes in the database.

B. Experimental Environment and Model Parameter Setting

In this study, we utilized a custom designed LACNN structure for finger vein recognition. For model training, we employed the EPML and used the AdamW optimizer. In terms of hyperparameter settings, the image size was set to 112, the batch size was set to 32, the number of epochs was set to 500,

and the initial learning rate was set to 2e-4. In this study, we implemented all training processes using the Pytorch DL framework on Intel® Core TM i7-8700 CPU and Nvidia GTX 1060 GPU.

C. Experiment Results

We evaluated the overall performance of the proposed structure using the FV-SUM database. The evaluation metric used was the correct identification rate (CIR), which measures the security of the model. Based on the same database, we compared the performance with other lightweight research methods in terms of CIR and model parameters, as shown in Table 1. It can be observed that our proposed model structure achieves the best result in terms of CIR while having the lowest number of model parameters. Compared to the previous model with the minimum number of parameters, our model structure reduces the parameter count by approximately 53%. This reduction makes our method less contained by hardware limitations and easily applicable to handheld platforms or embedded systems.

Table 1. CIR and number of parameters of each method.

Methods	CIR (%)	Parameters (M)
Liu *et al.* (2021) [4]	98.58	5.85
Semi-PFVN (2022) [5]	94.67	3.35
LightFVN + ACE (2022) [6]	96.17	2.65
LFVRN_CE + ACE [13]	99.09	4.93
Ke *et al.* (2023) [14]	99.80	75.00
LACNN (2023)	**99.82**	**1.23**

IV. Conclusion

Finger vein recognition technology has undergone continuous development and has been proven to be an effective and reliable biometric identification method. Yet for high security applications requiring one-to-many identification, there are still many challenges that need to be addressed. In this study, we propose a novel finger vein recognition technique that enhances the model's diversity in feature learning by increasing the complexity of the model structure during the training stage. The proposed technique also enables the model to capture globally important features and exhibit robustness against translation, thus addressing the issue of feature instability in extraction. Experimental results demonstrate the proposed model achieves a high recognition rate of 99.82%. Furthermore, the performance of the proposed model surpasses that of the latest research methods.

***Abstract*—Accurate estimation of the sound field around a rigid sphere necessitates adequate sampling on the sphere, which may not always be possible. To overcome this challenge, this paper proposes a method for sound field estimation based on a physics-informed neural network. This approach integrates physical knowledge into the architecture and training process of the network. In contrast to other learning-based methods, the proposed method incorporates additional constraints derived from the Helmholtz equation and the zero radial velocity condition on the rigid sphere. Consequently, it can generate physically feasible estimations without requiring a large dataset. In contrast to the spherical harmonic-based method, the proposed approach has better fitting abilities and circumvents the ill condition caused by truncation. Simulation results demonstrate the effectiveness of the proposed method in achieving accurate sound field estimations from limited measurements, outperforming the spherical harmonic method and plane-wave decomposition method. Our code is available at github.com/xingyuaudio/pinn_estimation.**

I. Introduction

Sound field analysis is a key topic of research with a wide range of applications, including spatial audio processing [1], [2], augmented reality/virtual reality [3], and active noise control [4], [5]. To determine the distribution of acoustic pressure in a region, researchers often use microphone arrays. However, microphone arrays cause reflections and scattering, which potentially impacts the accuracy of the sound field estimation. Therefore, understanding the scattering field is essential to ensure the accuracy of the sound field estimation.

Rigid spherical microphone arrays are extensively employed in sound field analysis due to their theoretically derived scattering fields, enabling the estimation of sound fields in three-dimensional space surrounding the array [6]–[8]. Conventional methods, such as the spherical harmonic (SH) method [9], represent the sound field by a set of orthonormal modes. However, these methods have inherent limitations in practical applications. For instance, the limited number of microphones leads to a discrete representation through integration, resulting in truncation errors [10]. Plane-wave decomposition method assumes that the sound field only consists of plane waves [11]. It neglects the spatial variation within each wavefront, which may not fully capture the intricacies of the scattering fields.

Learning-based methods have been employed in scattering problems, and have demonstrated effectiveness in fitting nonlinear mappings [12], [13]. Among these methods, Convolutional Neural Networks (CNNs) have gained popularity due to their ability to promote parameter sharing and reduce the number of trainable parameters [14]. However, in the context of sound field estimation, convolutional and max-pooling layers introduce pixel spaces that can lead to discontinuities in sound pressure continuity. This discontinuity potentially undermines the physical interpretation of the data [15]–[17]. Additionally, the heavy reliance on training data often necessitates a large simulated dataset.

Recently, researchers introduced Physics-Informed Neural Networks (PINNs) as a method to incorporate physical knowledge into the network architecture and training [17]–[24]. This integration allows PINNs to achieve physically feasible estimations and require less training data. Fully connected Neural Networks (FNNs) are commonly employed as part of PINN due to their ability to approximate any continuous function, as guaranteed by the Universal Approximation Theorem [25].

In this paper, we propose a method for sound field estimation around a rigid sphere using PINNs. We employ a small FNN network structure and incorporate two constraints: the Helmholtz equation and the fact that sound pressure cannot generate radial motion at the sphere boundary. We use the FNN to model the mapping between Euclidean space positions and sound pressure and use these constraints as a loss function to train the network. Notably, our method relies solely on measured data from microphones, eliminating the need for setting up a grid and using simulated datasets. Simulation results demonstrate the effectiveness of our method, outperforming the spherical harmonic method and the plane-wave decomposition method.

II. problem formulation

We introduce two coordinate systems, as shown in Fig. 1, where $\boldsymbol{x} = (x, y, z)$ and $\boldsymbol{r} = (r, \theta, \phi)$ represent Cartesian and spherical coordinates, respectively. Our study focuses on a sound field $\mathcal{V} \subset \mathbb{R}^3$, which includes a rigid sphere located at the origin O with a radius of a. We aim to estimate the sound field $P(\boldsymbol{r}, \omega)$ at position $\boldsymbol{r}$ and angular frequency ω around the sphere $r \geq a$, by using measurements from Q microphones mounted on the rigid sphere.

For a homogeneous sound field (absence of sound sources) around a rigid sphere, theoretical solutions for the sound field have been established [6]. The spherical harmonic (SH) method decomposes $P(\boldsymbol{r}, \omega)$ into a series of orthonormal

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

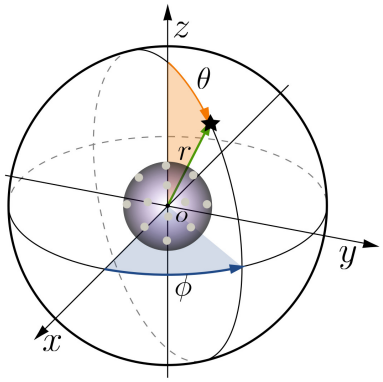

Fig. 1: System setup: A rigid sphere with microphones showing Cartesian and spherical coordinates. • represent the microphones, and ⋆ represents a reference point.

modes [6]

$$P(\boldsymbol{r},\omega)=\sum_{n=0}^{\infty}G_n(r,a,\omega)\sum_{m=-n}^{n}\mathcal{P}_n^m(a,\omega)Y_n^m(\theta,\phi), \quad (1)$$

where $G_n(r,a,\omega)$ is the radial propagator, $\mathcal{P}_n^m(a,\omega)$ are the spherical harmonic coefficients, and $Y_n^m(\theta,\phi)$ is the spherical harmonic of order n and degree m. $\mathcal{P}_n^m(a,\omega)$ are obtained by integrating $P(\mathbf{a},\omega)$ over the surface of the sphere

$$\mathcal{P}_n^m(a,\omega)=\iint P(\mathbf{a},\omega)Y_n^m(\theta,\phi)^*d\Omega, \quad (2)$$

where $\mathbf{a}=(a,\theta,\phi)$, $\Omega=(\theta,\phi)$, and $\iint(\cdot)d\Omega\equiv\int_0^{2\pi}\int_0^{\pi}(\cdot)\sin\theta d\theta d\phi$. $G_n(r,a,\omega)$ must satisfy the boundary condition on the rigid sphere, leading to

$$G_n(r,a,\omega)=j_n(\frac{\omega r}{c})-\frac{j_n'\left(\frac{\omega a}{c}\right)}{h_n^{(2)'}\left(\frac{\omega a}{c}\right)}h_n^{(2)}(\frac{\omega r}{c}), \quad (3)$$

where $j_n(\cdot)$ and $h_n^{(2)}(\cdot)$ are the spherical Bessel function of the first kind and the spherical Hankel function of the second kind, respectively, and $j_n'(\cdot)$ and $h_n^{(2)'}(\cdot)$ are corresponding derivatives [8], c is the speed of sound.

There are three issues with the implementation of the theoretical method. First, the infinite series in (1) needs to be truncated at limited order N [10]. Second, the pressure on the sphere is sampled at a limited (Q) number of positions. Hence, the integral in (2) needs to be discretely approximated. Third, in the low-frequency region where the distance r increases ($r>a$), the propagators $G_n(r,a,\omega)$ approximately follow a power law of the form $\frac{n+1}{2n+1}\left(\frac{r}{a}\right)^n$. These increasing values have significant implications as they indicate an ill-posed problem [8]. Consequently, small variations in $\mathcal{P}_n^m(a,\omega)$ resulting from truncation errors or noise will be magnified through the propagator.

To overcome these challenges and obtain more accurate estimations, we propose a neural network approach integrated with physics laws. This method aims to establish a regression relationship between coordinates and sound pressure while satisfying the governing Helmholtz equation and the boundary condition.

III. PINN METHOD

In this section, we present the PINN method, which consists of three steps: (1) constructing an FNN using microphone positions and measured sound pressure as training pairs, (2) incorporating physical knowledge as a constraint in the network, and (3) adjusting the weight of the loss function to facilitate convergence. The workflow of the PINN method is presented in Fig. 2.

FNN is a composition of multiple layers, and the nodes between adjacent layers are fully connected. A single layer of the network is denoted as

$$F(\boldsymbol{x})=\sigma\left(\boldsymbol{x}^{\intercal}\mathbf{w}+b\right), \quad (4)$$

where $\boldsymbol{x}\in\mathbb{R}^3$ is the inputs, which in this case are the Cartesian positions in the sound field $\mathcal{V}$, $\mathbf{w}$ represents the weights, b is the bias, and σ is the activation function. The FNN is a composition of multiple layers

$$\Phi(\boldsymbol{x},\omega;\psi)=\left(F_n\circ\ldots\circ F_2\circ F_1\right)(\boldsymbol{x}), \quad (5)$$

where ψ represents the set of all trainable parameters $\mathbf{w}$ and b. Hereafter, ω is omitted in $\Phi(\boldsymbol{x};\psi)$ when representing acoustic quantities for notional simplicity. ψ is learned by minimizing the mean squared error (MSE) loss $\mathcal{L}_{\text{data}}$ with respect to the training data

$$\psi^*=\arg\min_{\psi}\mathcal{L}_{\text{data}}(\boldsymbol{x};\psi), \quad (6)$$

where $\mathcal{L}_{\text{data}}$ is defined as

$$\mathcal{L}_{\text{data}}(\boldsymbol{x}_i;\psi)=\frac{1}{Q}\sum_{i=1}^{Q}\left(P(\boldsymbol{x}_i,\omega)-\Phi\left(\boldsymbol{x}_i;\psi\right)\right)^2. \quad (7)$$

It fits the regression relationship between the spatial coordinates of the microphones $\boldsymbol{x}$ and the corresponding sound pressure values $P(\boldsymbol{x},\omega)$. The network results $\Phi(\boldsymbol{x};\psi)$ represent the estimated sound pressure $\hat{P}(\boldsymbol{x},\omega)$.

The aforementioned approach represents a purely data-driven method. It needs a large dataset, which is not always possible. We incorporate domain knowledge to reduce the data requirements and generate physically meaningful estimations.

For sound field estimation around a rigid sphere, we can leverage two domain knowledge to improve the estimation accuracy. Firstly, sound fields are governed by the Helmholtz equation

$$\left(\triangle+(\frac{c}{\omega})^2\right)P(\boldsymbol{r},\omega)=0, \quad (8)$$

where $\triangle=\partial^2/\partial x^2+\partial^2/\partial y^2+\partial^2/\partial z^2$ denotes the Laplace operator. Therefore, we require the PINN estimation to satisfy (8), i.e.,

$$\left(\triangle+(\frac{c}{\omega})^2\right)\Phi(\boldsymbol{x};\psi)=0. \quad (9)$$

Secondly, radial velocity is zero on the rigid sphere:

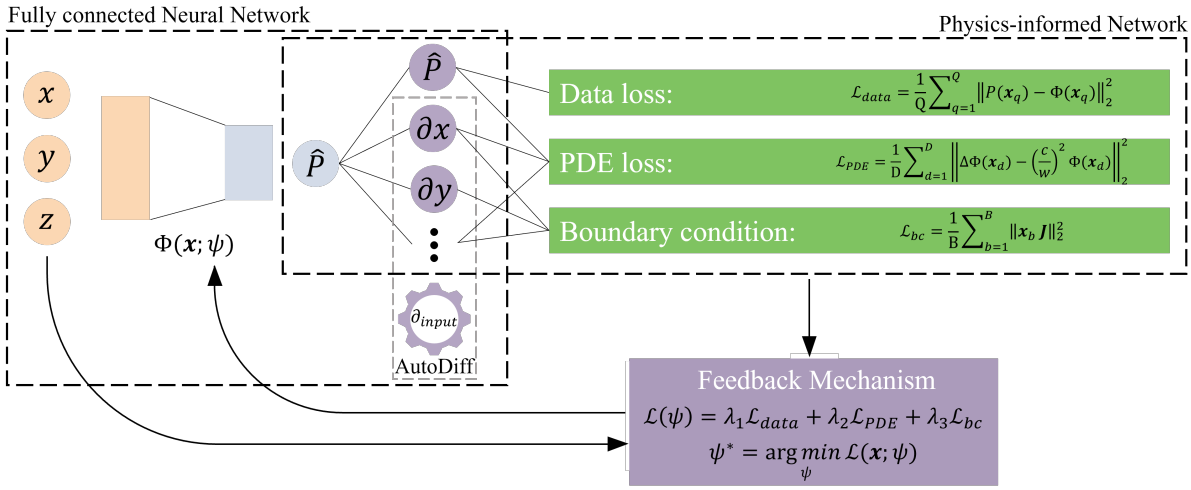

Fig. 2: The workflow includes three components: an FNN for mapping inputs to outputs with trainable parameters ψ, a Physics-Informed Network that incorporates governing Helmholtz equations and boundary conditions, and a feedback mechanism to minimize the loss function and update ψ.

$$\left.\frac{\partial P(\boldsymbol{r},\omega)}{\partial r}\right|_{r=a} = 0. \tag{10}$$

It represents the derivative of the sound pressure with respect to the radius of the sphere and can be written in terms of derivatives with respect to the Cartesian coordinates as

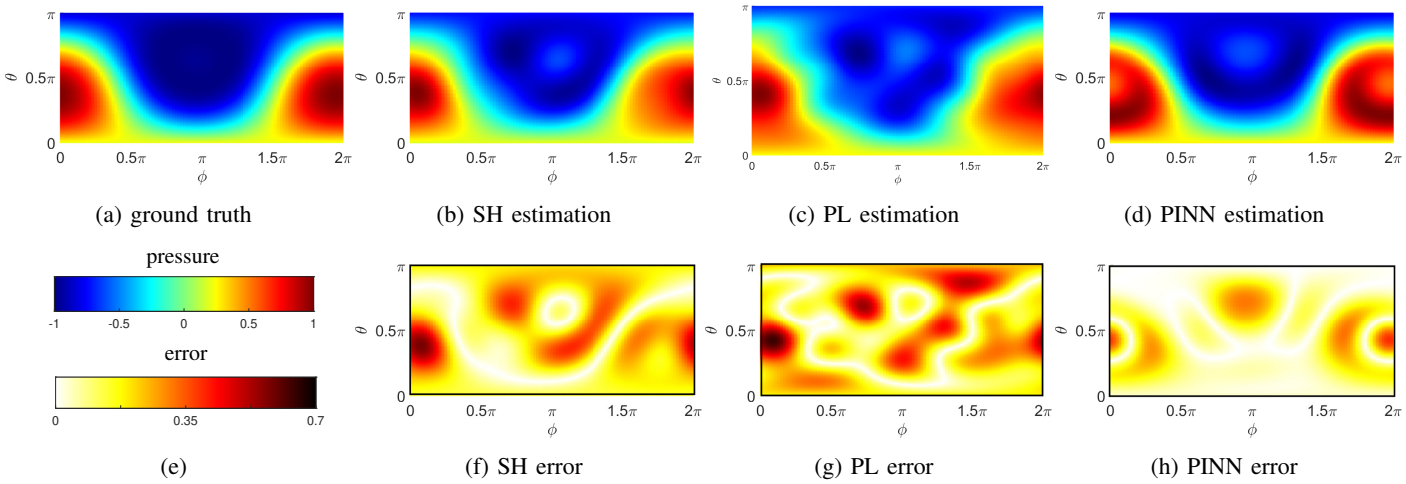
$$\frac{\partial P(\mathbf{r},\omega)}{\partial r} = \frac{\partial P(\mathbf{r},\omega)}{\partial x}\frac{\partial x}{\partial r} + \frac{\partial P(\mathbf{r},\omega)}{\partial y}\frac{\partial y}{\partial r} + \frac{\partial P(\mathbf{r},\omega)}{\partial z}\frac{\partial z}{\partial r}. \tag{11}$$

Conduct the substitutions $\frac{\partial x}{\partial r} = \frac{x}{r}$, $\frac{\partial y}{\partial r} = \frac{y}{r}$, $\frac{\partial z}{\partial r} = \frac{z}{r}$, (10) can be expressed in a matrix form

$$\left.\frac{\partial P(\boldsymbol{r},\omega)}{\partial r}\right|_{r=a} = \begin{bmatrix} x & y & z \end{bmatrix} \begin{bmatrix} \frac{\partial P(\mathbf{r},\omega)}{\partial x} \\ \frac{\partial P(\mathbf{r},\omega)}{\partial y} \\ \frac{\partial P(\mathbf{r},\omega)}{\partial z} \end{bmatrix} = 0. \tag{12}$$

We denote $\boldsymbol{x_b}$ as a point on the rigid sphere with radius a and $\begin{bmatrix} \frac{\Phi(\boldsymbol{x};\psi)}{\partial x} & \frac{\Phi(\boldsymbol{x};\psi)}{\partial y} & \frac{\Phi(\boldsymbol{x};\psi)}{\partial z} \end{bmatrix}^{\mathsf{T}}$ as $\boldsymbol{J}$. Therefore, we require the PINN estimation to satisfy (12), i.e.,

$$\boldsymbol{x_b J} = 0. \tag{13}$$



At present, we have constructed an FNN and acquired physical knowledge, which allows us to develop a PINN. Leveraging automatic differentiation within the neural network, we can efficiently compute the first-order and second-order derivatives of $\Phi(\boldsymbol{x};\psi)$ as required in (9) and (13). These derivatives are essential for updating the network parameters ψ using gradient descent.

We formulate the loss function to include three terms, each contributing to the overall training process

$$\begin{aligned} \mathcal{L}(\psi) = \lambda_1 \underbrace{\frac{1}{Q}\sum_{q=1}^{Q} \|P(\boldsymbol{x}_q) - \Phi(\boldsymbol{x}_q;\psi)\|_2^2}_{\mathcal{L}_{\text{data}}} \\ + \lambda_2 \underbrace{\frac{1}{D}\sum_{d=1}^{D} \left\|\triangle\Phi(\boldsymbol{x}_d;\psi) + (\frac{c}{\omega})^2\Phi(\boldsymbol{x}_d;\psi)\right\|_2^2}_{\mathcal{L}_{\text{PDE}}} \\ + \lambda_3 \underbrace{\frac{1}{B}\sum_{b=1}^{B} \|\boldsymbol{x}_b\boldsymbol{J}\|_2^2}_{\mathcal{L}_{\text{bc}}}, \end{aligned} \tag{14}$$

where $\|\cdot\|_2$ is the 2-norm, $\mathcal{L}_{\text{data}}$ represents the discrepancy between the PINN estimations $\Phi(\boldsymbol{x})$ and the actual measurements $P(\boldsymbol{x}_q)$ obtained from microphones. $\mathcal{L}_{\text{PDE}}$ ensures that the Helmholtz equation is satisfied for the positions $\boldsymbol{x}_d$ within the domain $\mathcal{V}$, and $\mathcal{L}_{\text{bc}}$ imposes the boundary condition of zero radial velocity on the rigid sphere. D are positions surrounding the sphere, and B are positions on the rigid sphere. To control the relative importance of these terms and ensure similar influences on the training process, we introduce weight factors λ_1, λ_2, and λ_3.

The weights in the loss function significantly influence the convergence and accuracy of the PINN. By balancing loss weights, a compromise can be achieved between accurately fitting the microphone measurements and adhering to the physical constraints. Since all three losses aim to approach zero, direct normalization is not feasible. $\mathcal{L}_{\text{data}}$ is influenced by data noise. To address the issue, we balance $\mathcal{L}_{\text{PDE}}$ and $\mathcal{L}_{\text{bc}}$ to the same order of magnitude during the initial stages of training. Specifically, We set λ_1 to 1, λ_2 to $(\frac{c}{\omega})^2$, and λ_3 to r.

IV. SIMULATION

We conduct simulations in a 3D free field to evaluate the proposed method regarding the sound field estimation surrounding a rigid sphere and compare the performance of three methods: the spherical harmonic method (SH) [9], the plane wave decomposition method (PL) [26], and the proposed method (PINN).

We uniformly mount 32 omnidirectional microphones on a rigid sphere with a radius of $a = 0.042$ m as shown in Fig. 1. We simulate the transfer functions between the sound source and the microphones on the rigid sphere according to [27]. Specifically, we place two point sources at coordinates $(2.5, 0.8, 0.0)$ m and $(-2.0, -0.6, 1.2)$ m, both with an amplitude of 1. The speed of sound is set to $c = 343$ m/s. In order to account for realistic conditions, we add white Gaussian noise to the observation signals, resulting in a signal-to-noise ratio (SNR) of 30 dB. The pressure values are then normalized within the range of $[-1, 1]$.

For the PINN method, we construct a 3-layer FNN with 4 nodes with the hyperbolic tangent (tanh) activation function. To train the PINN, we employ the Adam optimizer [28] with a learning rate of 10^{-5} for a total of 10,000 epochs. We set $\mathcal{L}_{\text{data}}$ based on the 32 microphone measurements, $\mathcal{L}_{\text{PDE}}$ based on 1000 randomly distributed points surrounding the sphere, and $\mathcal{L}_{\text{bc}}$ based on 500 uniformly distributed sampling points on the rigid sphere. As we train the network in Cartesian coordinates, we calculate the spherical coordinates $\boldsymbol{r}$ and then convert them to Cartesian coordinates $\boldsymbol{x}$.

In Fig. 4, we illustrate the training process. It demonstrates the simultaneous and nearly synchronized reduction of the training error $\mathcal{L}_{\text{PDE}}$ and $\mathcal{L}_{\text{bc}}$ in the initial stages of training for the first 2000 epochs. Subsequently, a gradual decline in $\mathcal{L}_{\text{data}}$ is observed. This observation suggests that the weight configurations of $\lambda_1 = 1$, $\lambda_2 = (\frac{c}{\omega})^2$, and $\lambda_3 = r$ achieve a good balance.

We define the pressure error between the true and estimated

sound fields as

$$\text{error} := \|P(\boldsymbol{x}_g, \omega) - \hat{P}(\boldsymbol{x}_g, \omega)\|, \tag{15}$$

where $P(\boldsymbol{x}_g, \omega)$ and $\hat{P}(\boldsymbol{x}_g, \omega)$ represent the true and estimated pressures, respectively.

Fig. 3 presents the ground truth, estimated sound pressure using these three methods, and error at a frequency of 1000 Hz and a radius of 0.072 m. It is observed that the SH method exhibits higher errors around $\theta = 0.5\pi$, the PL method performs the worst among the three due to its assumption of far-field conditions, which ignore the scattering information. the PINN method achieves the best results overall, although it still experiences relatively higher errors at $\theta = 0.5\pi$.

To evaluate the overall performance, we defined the normalized mean squared error (NMSE) as

$$\text{NMSE} := 10\log_{10} \frac{\sum_{g=1}^{10000} \|P(\boldsymbol{x}_g, \omega) - \hat{P}(\boldsymbol{x}_g, \omega)\|_2^2}{\sum_{g=1}^{10000} \|P(\boldsymbol{x}_g, \omega)\|_2^2}, \tag{16}$$

The estimation was performed at 10,000 evaluation positions uniformly sampled within a sphere with a specific radius and frequency.

Fig. 5 illustrates the relationship between the radius r of the estimation sphere and the NMSE at a frequency of 1000 Hz. When $r = a$, which corresponds to estimating the sound pressure on the rigid sphere, all three methods yield comparable results. However, as the radius increases, both the SH method and PL method show a significant surge in error. In contrast, the PINN method exhibits a more gradual increase in error as the radius increases. It has a lower NMSE of $7 - 10$ dB for $r > 0.05$ m than SH and PL methods. This indicates that the PINN method performs better compared to the conventional methods.

V. Conclusion

In this study, we propose a PINN method to estimate the sound field around a rigid sphere based on the measurement of a small number of microphones mounted on the rigid sphere. Our method employs an FNN to model the mapping between space positions and sound pressure. We incorporate the Helmholtz equation and the fact that sound pressure cannot generate radial motion at the sphere boundary as part of the loss function. This integration of physical knowledge into the network architecture and training process enhances the accuracy of estimation. A major advantage of our approach is that it relies solely on measured data, eliminating the need for grid setup and simulated datasets. Simulation results demonstrate that our method outperforms the spherical harmonic method and the plane-wave decomposition method.

It is hard to derive theoretical solutions for the scattering sound of complex geometries, but PINN can use physical and geometric constraints to fit the sound pressure distribution. It allows our method to potentially estimate the sound field of arbitrary geometry.

***Abstract*—This paper deals with the problem of multichannel noise reduction and a controlled Wiener filter is developed in the frequency domain by minimizing the subband mean-squared error between the clean speech of interest and its estimate subject to a constraint on the residual noise level. Using the Lagrange multiplier, we then transform the constrained minimization problem into one of quadratic eigenvalue problem. Different forms of the controlled Wiener filter are then derived. Depending on how the quadratic eigenvalues are used, these filters can control the amount of noise reduction as well as the compromise between the amount of noise reduction and the level of speech distortion. Simulation results justify the properties of the controlled Wiener filter.**

I. Introduction

Noise reduction is the process of recovering a clean speech signal of interest from microphone observations corrupted by additive noise [2]–[10]. Depending on the number of microphones, those methods can be divided into two classes, i.e., single-channel [11], [12], [13], [14], [15], [16] and multichannel methods [18], [19], [20].

Typical multichannel noise reduction approaches include the optimal filtering [18], [19], [20], the subspace based methods [21], [22], the statistical approach [23], [24], and the data driven based machine learning approaches [25], [26]. Optimal filtering based algorithm is one of the most straightforward ways to achieve noise reduction. Representative algorithms include the classical Wiener filter, maximum SNR filter, minimum variance distortionless response (MVDR) filter, linearly constrained minimum variance (LCMV) filter, etc, which are designed based on different criteria [17]. The classical Wiener filter is derived by minimizing the MSE between the desired clean speech and its estimate. Though widely used, the Wiener filter lacks flexibility to control the amount of noise reduction and speech distortion. One way to deal with the flexibility issue is by using the so-called tradeoff Wiener filter filter, which controls the compromise between noise reduction and speech distortion by a tunable parameter. The tunable parameter can be either set in a heuristic manner [17], or converted into a masking threshold, which can then be determined by the psychoacoustically motivated algorithm [27] or other methods as in [28].

In this paper, we present a controlled Wiener filter in the frequency domain. This controlled Wiener filter is developed by minimizing the subband MSE between the desired clean speech and its estimate subject to a constraint on the level of the residual noise. Using the Lagrange multiplier, we then transform the constrained minimization problem into one of quadratic eigenvalue problem. The controlled Wiener filters are then derived. The experiment results justify the flexibility of the deduced filters.

II. Signal Model, Problem Formulation, and Performance Measures

We consider a microphone array consisting of M microphones. In a general way, the received signals at the frequency index f are expressed as [1], [2]

$$\begin{aligned} Y_m(f) &= G_m(f)S(f) + V_m(f) \\ &= X_m(f) + V_m(f),\ m = 1, 2, \ldots, M, \end{aligned} \tag{1}$$

where $Y_m(f)$ is the mth microphone signal, $S(f)$ is the unknown speech source, $G_m(f)$ is the acoustic channel transfer function from the position of $S(f)$ to the mth microphone, $X_m(f) = G_m(f)S(f)$ is the convolved speech signal, and $V_m(f)$ is the additive noise. All signals are considered to be zero mean. It is assumed that $X_i(f)$ and $V_j(f)$ are incoherent, i.e., $E[X_i(f)V_j^*(f)] = 0,\ \forall i, j = 1, 2, \ldots, M$, where $E[\cdot]$ denotes mathematical expectation and the superscript * is the complex-conjugate operator. By definition, the terms $X_m(f),\ m = 1, 2, \ldots, M$ are coherent while the terms $V_m(f),\ m = 1, 2, \ldots, M$ are either partially coherent or incoherent. Without loss of generality, let us choose Microphone 1 as the reference. Then, the objective of multichannel noise reduction in the frequency domain is to estimate the desired signal, $X_1(f)$, from the M observations $Y_m(f),\ m = 1, 2, \ldots, M$, in the best way we can.

In a vector form, (1) is expressed as

$$\begin{aligned} \mathbf{y}(f) &= [Y_1(f)\ Y_2(f)\ \cdots\ Y_M(f)]^T \\ &= \mathbf{x}(f) + \mathbf{v}(f), \end{aligned} \tag{2}$$

where the superscript ^{T} is the transpose operator, and $\mathbf{x}(f)$ and $\mathbf{v}(f)$ are defined similarly to $\mathbf{y}(f)$. It follows immediately that the covariance matrix of $\mathbf{y}(f)$ is

$$\mathbf{\Phi}_{\mathbf{y}}(f) = E\left[\mathbf{y}(f)\mathbf{y}^H(f)\right] = \mathbf{\Phi}_{\mathbf{x}}(f) + \mathbf{\Phi}_{\mathbf{v}}(f), \tag{3}$$

where the superscript ^{H} is the conjugate-transpose operator, and $\mathbf{\Phi}_{\mathbf{x}}(f)$ and $\mathbf{\Phi}_{\mathbf{v}}(f)$ are the covariance matrices of $\mathbf{x}(f)$ and $\mathbf{v}(f)$, respectively.

In the frequency domain, multichannel noise reduction is generally performed by applying a complex-valued filter, $\mathbf{h}(f)$

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

of length M, to the observation signal vector, $\mathbf{y}(f)$, i.e.,

$$Z(f) = \mathbf{h}^H(f)\mathbf{y}(f) = X_{\rm fd}(f) + V_{\rm rn}(f), \tag{4}$$

where the filter output, $Z(f)$, is the estimate of $X_1(f)$, $X_{\rm fd}(f) = \mathbf{h}^H(f)\mathbf{x}(f)$ is the filtered desired signal, and $V_{\rm rn}(f) = \mathbf{h}^H(f)\mathbf{v}(f)$ is the residual noise. The objective of multichannel noise reduction is then to find an optimal filter, $\mathbf{h}(f)$, in such a way that $Z(f)$ is as close as possible to the desired signal, $X_1(f)$. According to (4), the variance of $Z(f)$ is written as

$$\phi_Z(f) = \mathbf{h}^H(f)\mathbf{\Phi}_{\mathbf{y}}(f)\mathbf{h}(f) = \phi_{X_{\rm fd}}(f) + \phi_{V_{\rm rn}}(f), \tag{5}$$

where $\phi_{X_{\rm fd}}(f) = \mathbf{h}^H(f)\mathbf{\Phi}_{\mathbf{x}}(f)\mathbf{h}(f)$ and $\phi_{V_{\rm rn}}(f) = \mathbf{h}^H(f)\mathbf{\Phi}_{\mathbf{v}}(f)\mathbf{h}(f)$ are the variances of $X_{\rm fd}$ and $V_{\rm rn}$ respectively.

Given the signal model in (1), the input signal-to-noise ratio (SNR) is defined as

$$\text{iSNR}(f) = \frac{\phi_{X_1}(f)}{\phi_{V_1}(f)}, \tag{6}$$

where $\phi_{X_1}(f)$ and $\phi_{V_1}(f)$ are the variances of $X_1(f)$ and $V_1(f)$, respectively. Now, with the signal model in (1) and the multichannel noise reduction model in (4), we can define the following narrowband performance measures [2]:

- the noise reduction factor:

$$\xi_{\rm n}\left[\mathbf{h}(f)\right] = \frac{\phi_{V_1}(f)}{\phi_{V_{\rm rn}}(f)}, \tag{7}$$

- the speech reduction factor:

$$\xi_{\rm s}\left[\mathbf{h}(f)\right] = \frac{\phi_{X_1}(f)}{\phi_{X_{\rm fd}}(f)}, \tag{8}$$

- the output SNR:

$$\text{oSNR}\left[\mathbf{h}(f)\right] = \frac{\phi_{X_{\rm fd}}(f)}{\phi_{V_{\rm rn}}(f)}, \tag{9}$$

- and the speech distortion index:

$$\upsilon_{\rm sd}\left[\mathbf{h}(f)\right] = \frac{E\left\{\left|X_1(f) - X_{\rm fd}(f)\right|^2\right\}}{\phi_{X_1}(f)}. \tag{10}$$

It can be verified that

$$\frac{\text{oSNR}\left[\mathbf{h}(f)\right]}{\text{iSNR}(f)} = \frac{\xi_{\rm n}\left[\mathbf{h}(f)\right]}{\xi_{\rm s}\left[\mathbf{h}(f)\right]}. \tag{11}$$

III. Multichannel Wiener Filter

We define the error signal between the estimated and the desired signals at frequency f as

$$\begin{aligned}\mathcal{E}(f) &= Z(f) - X_1(f)\\ &= \mathbf{h}^H(f)\mathbf{y}(f) - X_1(f).\end{aligned} \tag{12}$$

The (narrowband) mean-squared error (MSE) criterion is then

$$\begin{aligned}J\left[\mathbf{h}(f)\right] &= E\left[\left|\mathcal{E}(f)\right|^2\right]\\ &= \phi_{X_1}(f) + \mathbf{h}^H(f)\mathbf{\Phi}_{\mathbf{y}}(f)\mathbf{h}(f) - \mathbf{h}^H(f)\boldsymbol{\phi}_{\mathbf{x}}(f)\\ &\quad - \boldsymbol{\phi}_{\mathbf{x}}^H(f)\mathbf{h}(f),\end{aligned} \tag{13}$$

where $\boldsymbol{\phi}_{\mathbf{x}}(f) = \mathbf{\Phi}_{\mathbf{x}}(f)\mathbf{i}$, with $\mathbf{i}$ being the first column of the $M \times M$ identity matrix, $\mathbf{I}_M$.

The minimization of $J\left[\mathbf{h}(f)\right]$ leads to the well-known multichannel Wiener filter:

$$\begin{aligned}\mathbf{h}_{\rm W}(f) &= \mathbf{\Phi}_{\mathbf{y}}^{-1}(f)\boldsymbol{\phi}_{\mathbf{x}}(f)\\ &= \mathbf{\Phi}_{\mathbf{y}}^{-1}(f)\mathbf{\Phi}_{\mathbf{x}}(f)\mathbf{i}\\ &= \left[\mathbf{I}_M - \mathbf{\Phi}_{\mathbf{y}}^{-1}(f)\mathbf{\Phi}_{\mathbf{v}}(f)\right]\mathbf{i}.\end{aligned} \tag{14}$$

It can be shown that [2], [16]

$$\text{oSNR}\left[\mathbf{h}_{\rm W}(f)\right] \geq \text{iSNR}(f) \tag{15}$$

and

$$\xi_{\rm n}\left[\mathbf{h}_{\rm W}(f)\right] \geq 1. \tag{16}$$

So, noise reduction is possible with the Wiener filter. However, there is no way to control the amount of noise reduction (or, equivalently, the amount of speech distortion).

IV. Controlled Multichannel Wiener Filter

In this section, we drop the dependence on f for the sake of readability. Let us assume that we want to find a filter, $\mathbf{h}$, whose noise reduction factor is equal to $\xi_0 > 1$, i.e., $\xi_{\rm n}(\mathbf{h}) = \xi_0$, and, at the same time, minimizes the MSE. The controlled Wiener filter is obtained from the criterion:

$$\min_{\mathbf{h}} J\left(\mathbf{h}\right) \quad \text{subject to} \quad \mathbf{h}^H\mathbf{\Phi}_{\mathbf{v}}\mathbf{h} = \xi_0^{-1}\phi_{V_1}. \tag{17}$$

From the above criterion, we can write the Lagrange function:

$$\begin{aligned}\mathcal{L}\left(\mathbf{h},\lambda\right) =& \phi_{X_1} + \mathbf{h}^H\mathbf{\Phi}_{\mathbf{y}}\mathbf{h} - \mathbf{h}^H\boldsymbol{\phi}_{\mathbf{x}} - \boldsymbol{\phi}_{\mathbf{x}}^H\mathbf{h}\\ &- \lambda\left(\mathbf{h}^H\mathbf{\Phi}_{\mathbf{v}}\mathbf{h} - \xi_0^{-1}\phi_{V_1}\right),\end{aligned} \tag{18}$$

where λ is the Lagrange multiplier. Differentiating $\mathcal{L}\left(\mathbf{h},\lambda\right)$ with respect to $\mathbf{h}$ and λ yields the following equations:

$$\mathbf{\Phi}_{\mathbf{y}}\mathbf{h} - \lambda\mathbf{\Phi}_{\mathbf{v}}\mathbf{h} = \boldsymbol{\phi}_{\mathbf{x}}, \tag{19}$$

$$\mathbf{h}^H\mathbf{\Phi}_{\mathbf{v}}\mathbf{h} = \xi_0^{-1}\phi_{V_1}. \tag{20}$$

It can be shown [3], [4] that the smallest solution λ of the two previous equations is needed to solve (17).

Assume that λ is not an eigenvalue of $\mathbf{\Phi}_{\mathbf{v}}^{-1}\mathbf{\Phi}_{\mathbf{y}}$, so that the matrix $\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}$ is invertible, and let

$$\begin{aligned}\overline{\mathbf{h}} &= \left(\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}\right)^{-1}\mathbf{\Phi}_{\mathbf{v}}\left(\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}\right)^{-1}\boldsymbol{\phi}_{\mathbf{x}}\\ &= \left(\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}\right)^{-1}\mathbf{\Phi}_{\mathbf{v}}\mathbf{h}.\end{aligned} \tag{21}$$

We can rewrite (19) and (20) in terms of $\overline{\mathbf{h}}$:

$$\left(\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}\right)\mathbf{\Phi}_{\mathbf{v}}^{-1}\left(\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}\right)\overline{\mathbf{h}} = \boldsymbol{\phi}_{\mathbf{x}}, \tag{22}$$

$$\begin{aligned}\overline{\mathbf{h}}^H\left(\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}\right)\mathbf{\Phi}_{\mathbf{v}}^{-1}\left(\mathbf{\Phi}_{\mathbf{y}} - \lambda\mathbf{\Phi}_{\mathbf{v}}\right)\overline{\mathbf{h}} &= \xi_0^{-1}\phi_{V_1}\\ &= \overline{\mathbf{h}}^H\boldsymbol{\phi}_{\mathbf{x}}.\end{aligned} \tag{23}$$

From (23), we can check that

$$\frac{\boldsymbol{\phi}_{\mathbf{x}}^H\overline{\mathbf{h}}}{\xi_0^{-1}\phi_{V_1}} = 1. \tag{24}$$

Developing (22) and exploiting the previous result, we get

$$\begin{aligned}\left(\mathbf{\Phi}_{\mathbf{y}}\mathbf{\Phi}_{\mathbf{v}}^{-1}\mathbf{\Phi}_{\mathbf{y}} - 2\lambda\mathbf{\Phi}_{\mathbf{y}} + \lambda^2\mathbf{\Phi}_{\mathbf{v}}\right)\overline{\mathbf{h}} &= \boldsymbol{\phi}_{\mathbf{x}}\\ &= \frac{\boldsymbol{\phi}_{\mathbf{x}}\boldsymbol{\phi}_{\mathbf{x}}^H}{\xi_0^{-1}\phi_{V_1}}\overline{\mathbf{h}}.\end{aligned} \tag{25}$$

As a consequence, (25) can be rewritten as

$$\left[\lambda^2\mathbf{\Phi_v} - 2\lambda\mathbf{\Phi_y} + \left(\mathbf{\Phi_y}\mathbf{\Phi_v}^{-1}\mathbf{\Phi_y} - \frac{\boldsymbol{\phi}_\mathbf{x}\boldsymbol{\phi}_\mathbf{x}^H}{\xi_0^{-1}\phi_{V_1}}\right)\right]\overline{\mathbf{h}} = \mathbf{0} \quad (26)$$

or, in a more standard form:

$$\left(\lambda^2\mathbf{A}_2 + \lambda\mathbf{A}_1 + \mathbf{A}_0\right)\overline{\mathbf{h}} = \mathbf{Q}(\lambda)\overline{\mathbf{h}} = \mathbf{0}, \quad (27)$$

where

$$\mathbf{A}_2 = \mathbf{\Phi_v},$$
$$\mathbf{A}_1 = -2\mathbf{\Phi_y},$$
$$\mathbf{A}_0 = \mathbf{\Phi_y}\mathbf{\Phi_v}^{-1}\mathbf{\Phi_y} - \frac{\boldsymbol{\phi}_\mathbf{x}\boldsymbol{\phi}_\mathbf{x}^H}{\xi_0^{-1}\phi_{V_1}},$$

and $\mathbf{Q}(\lambda)$ is called the λ-matrix, which is an $M \times M$ matrix polynomial of degree 2. In (27), we recognize the quadratic eigenvalue problem (QEP) [5], where $\overline{\mathbf{h}}$ is the right eigenvector corresponding to the eigenvalue λ. Therefore, the solution of (17) is $\mathbf{h} = \left(\mathbf{\Phi_y} - \lambda\mathbf{\Phi_v}\right)^{-1}\boldsymbol{\phi}_\mathbf{x}$, where λ is the smallest eigenvalue of (27). Depending on the value of λ, we have the following cases for $\mathbf{h}$:

- $\lambda = 0$ gives the classical Wiener filter,
- $\lambda = 1$ leads to $\mathbf{h} = \mathbf{i}$, an all-pass filter which achieves no noise reduction and adds no speech distortion as well,
- $\lambda < 0$ gives more noise reduction at an expense of more speech distortion than the classical Wiener filter,
- $0 < \lambda < 1$ gives less noise reduction and less speech distortion than the classical Wiener filter, and
- $\lambda > 1$ gives less noise reduction and more speech distortion, which is the worst case.

The QEP is a generalization of the standard eigenvalue problem (SEP), $\mathbf{Au} = \lambda\mathbf{u}$, and the generalized eigenvalue problem (GEP), $\mathbf{Au} = \lambda\mathbf{Bu}$. With a λ-matrix of size $M \times M$, the QEP has $2M$ eigenvalues (finite or infinite) with up to $2M$ right and $2M$ left eigenvectors, and if there are more than M eigenvectors they are not, of course, linearly independent [5]. In our context, since $\mathbf{A}_2 = \mathbf{\Phi_v}$ is nonsingular, the QEP has $2M$ finite eigenvalues. Since $\mathbf{A}_0, \mathbf{A}_1$, and $\mathbf{A}_2$ are Hermitian, the eigenvalues are real or come in pairs (λ, λ^*) [5].

One important aspect of the QEP is the linearization process, which is not unique. We say that a $2M \times 2M$ matrix $\mathbf{A} - \lambda\mathbf{B}$ is a linearization of the $M \times M$ λ-matrix $\mathbf{Q}(\lambda)$ if the eigenvalues of these matrices coincide. Thanks to this process, we can solve the QEP with the GEP. One possibility is to take

$$\mathbf{A} = \begin{bmatrix} \mathbf{0} & \mathbf{A}_0 \\ \mathbf{A}_0 & \mathbf{A}_1 \end{bmatrix}, \quad (28)$$

$$\mathbf{B} = \begin{bmatrix} \mathbf{A}_0 & \mathbf{0} \\ \mathbf{0} & -\mathbf{A}_2 \end{bmatrix}. \quad (29)$$

It can be verified that if $\mathbf{t}$ is an eigenvector of $\mathbf{Q}(\lambda)$ then

$$\mathbf{u} = \begin{bmatrix} \mathbf{t} \\ \lambda\mathbf{t} \end{bmatrix} \quad (30)$$

is an eigenvector of $\mathbf{A} - \lambda\mathbf{B}$. This process corresponds to the symmetric linearization since both $\mathbf{A}$ and $\mathbf{B}$ are Hermitian. The accuracy of this approach will depend on the conditioning of $\mathbf{A}_0$ and $\mathbf{A}_2$. Another possibility is to take

$$\mathbf{A} = \begin{bmatrix} \mathbf{0} & -\mathbf{I}_M \\ \mathbf{A}_0 & \mathbf{A}_1 \end{bmatrix}, \quad (31)$$

$$\mathbf{B} = \begin{bmatrix} -\mathbf{I}_M & \mathbf{0} \\ \mathbf{0} & -\mathbf{A}_2 \end{bmatrix}. \quad (32)$$

This linearization is not symmetric. Different linearizations may give different results, so it is important to choose the right one.

Let us order the eigenvalues of $\mathbf{Q}(\lambda)$:

$$\Re(\lambda_1) \leq \Re(\lambda_2) \leq \cdots \leq \Re(\lambda_{2M}), \quad (33)$$

where $\Re(\cdot)$ is the real part of a complex number. Then, the controlled multichannel Wiener filter that will give exactly a noise reduction factor equal to ξ_0 is

$$\mathbf{h}_{\mathrm{CW}} = \left[\mathbf{\Phi_y} - \Re(\lambda_1)\mathbf{\Phi_v}\right]^{-1}\boldsymbol{\phi}_\mathbf{x}. \quad (34)$$

Now, if we consider the eigenvalues with the P smallest real parts, we can get another version of the controlled Wiener filter:

$$\mathbf{h}_{\mathrm{CW},P} = \left(\mathbf{\Phi_y} - \overline{\lambda}_P\mathbf{\Phi_v}\right)^{-1}\boldsymbol{\phi}_\mathbf{x}, \quad (35)$$

where

$$\overline{\lambda}_P = \frac{1}{P}\sum_{p=1}^{P}\Re(\lambda_p). \quad (36)$$

In general, $\xi_{\mathrm{n}}\left(\mathbf{h}_{\mathrm{CW},P}\right) \neq \xi_0$, but $\mathbf{h}_{\mathrm{CW},P}$ may lead to less speech distortion than $\mathbf{h}_{\mathrm{CW}}$ in practice.

An alternative approach is to use the distortion-based MSE criterion instead, which is given by

$$J_{\mathrm{d}}\left(\mathbf{h}\right) = E\left(\left|\mathbf{h}^H\mathbf{x} - X_1\right|^2\right). \quad (37)$$

The controlled Wiener filter is derived from the criterion:

$$\min_{\mathbf{h}} J_{\mathrm{d}}\left(\mathbf{h}\right) \quad \text{subject to} \quad \mathbf{h}^H\mathbf{\Phi_v}\mathbf{h} = \xi_0^{-1}\phi_{V_1}. \quad (38)$$

Following the same steps as above, the obtained QEP is

$$\left[\lambda^2\mathbf{\Phi_v} - 2\lambda\mathbf{\Phi_x} + \left(\mathbf{\Phi_x}\mathbf{\Phi_v}^{-1}\mathbf{\Phi_x} - \frac{\boldsymbol{\phi}_\mathbf{x}\boldsymbol{\phi}_\mathbf{x}^H}{\xi_0^{-1}\phi_{V_1}}\right)\right]\overline{\mathbf{h}} = \mathbf{0}. \quad (39)$$

Now, the solution of (38) is $\mathbf{h} = \left(\mathbf{\Phi_x} - \lambda\mathbf{\Phi_v}\right)^{-1}\boldsymbol{\phi}_\mathbf{x}$, where λ is the smallest eigenvalue of (39).

V. Simulations

In this section, we study the performance of the developed controlled multichannel Wiener filter through simulations. We consider a reverberant enclosure of size 3 m × 3 m × 4 m [the coordinates are denoted as (x, y, z)], where a uniform linear array with 8 microphones is located along the x axis with an interelement spacing of 0.02 m, i.e., the position of sensors are (x, 2.5 m, 1.0 m) with $x = 1.64 : -0.02 : 1.50$. A source (the target) is located at (2.5 m, 1.0 m, 2.5 m), and an interference source is located at (1.0 m, 2.5 m, 0.5 m). The impulse responses from the source signal to the microphones (as well as that from the interference to the microphones) are generated with the image model method [6] with all the wall reflection coefficients being 0.6 (the corresponding reverberation time

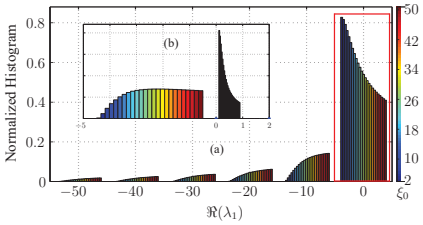

Fig. 1. The normalized histogram of $\Re(\lambda_1)$ as a function of ξ_0, where $\xi_0 = 2:2:50$: (a) the rough one and (b) details of the red box.

T_{60} is 140 ms approximately). The target source signal consists of 20 sentences extracted from the TIMIT database [7], with 10 from a male speaker and the other 10 from a female speaker. The interference is a babble noise taken from the NoiseX92 database [8]. Furthermore, a computer generated multichannel Gaussian noise is added with a specified interference-to-noise ratio (INR). The overall noise at the mth microphone is in the form of $V_m(f) = I_m(f) + \beta W_m(f)$, where $I_m(f)$ is the interference, $W_m(f)$ is the Gaussian white noise and β is a constant controlling INR. In this work, the value of β is adjusted so that the INR is 5 dB. Thus, the noise at different sensors are partially coherent. Then, $V_m(f)$ is properly scaled and added to the clean speech signal at an iSNR of 10 dB. To implement the algorithm, we choose a frame size of 32 ms with 75% overlap and a Kaiser window is used for data framing. The correlation matrix of $\mathbf{y}(f)$ and $\mathbf{v}(f)$ are computed recursively, i.e.,

$$\mathbf{\Phi}_{\mathbf{y}}(f,k) = \alpha_{\mathbf{y}}\mathbf{\Phi}_{\mathbf{y}}(f,k-1) + (1-\alpha_{\mathbf{y}})\mathbf{y}(f,k)\mathbf{y}^H(f,k), \tag{40}$$

$$\mathbf{\Phi}_{\mathbf{v}}(f,k) = \alpha_{\mathbf{v}}\mathbf{\Phi}_{\mathbf{v}}(f,k-1) + (1-\alpha_{\mathbf{v}})\mathbf{v}(f,k)\mathbf{v}^H(f,k), \tag{41}$$

where k is the frame index, and $\alpha_{\mathbf{y}}$ and $\alpha_{\mathbf{v}}$ are the forgetting factors, which are both set to 0.95 in this work.

As seen in (34) and (35), the values of $\Re(\lambda_1)$ and $\overline{\lambda}_P$ play an important role on the performances of the filters $\mathbf{h}_{\mathrm{CW}}$ and $\mathbf{h}_{\mathrm{CW},P}$. So, let us first examine the values of $\Re(\lambda_1)$ as a function of ξ_0. We set $\xi_0 = 2:2:50$. Figure 1 plots the histogram of $\Re(\lambda_1)$ and Fig. 1(b) is a zoomed part with $\Re(\lambda_1) \in [-5, 2]$. As discussed in Section IV, the controlled multichannel Wiener filter, $\mathbf{h}_{\mathrm{CW}}$, degenerates to the classical Wiener filter if $\Re(\lambda_1) = 0$ while it degenerates to an all-pass filter if $\Re(\lambda_1) = 0$. One can see from Fig. 1 that more than 80% values of $\Re(\lambda_1)$ lie in the range of $[0, 1]$ when $\xi_0 = 2$. However, as the value of ξ_0 increases, $\Re(\lambda_1)$ decreases towards negative values. This indicates that with ξ_0 increasing, $\mathbf{h}_{\mathrm{CW}}$ could achieve more noise reduction; but of course at the expense of more speech distortion as compared to the classical Wiener filter. Moreover, one can infer that as the value of P increases, the value of $\overline{\lambda}_P$ increases, in which case $\mathbf{h}_{\mathrm{CW},P}$ would achieve less noise reduction with less speech distortion as compared to $\mathbf{h}_{\mathrm{CW}}$.

Now, in the second simulation, we evaluate the performance of different noise reduction filters as a function of ξ_0. Again, we set $\xi_0 = 2:2:50$. Three performance measures are used: the output SNR, the speech distortion index, and the perceptual evaluation of speech quality (PESQ) score, which are defined, respectively in (9), (10), and [9]. Figure 2 plots the results

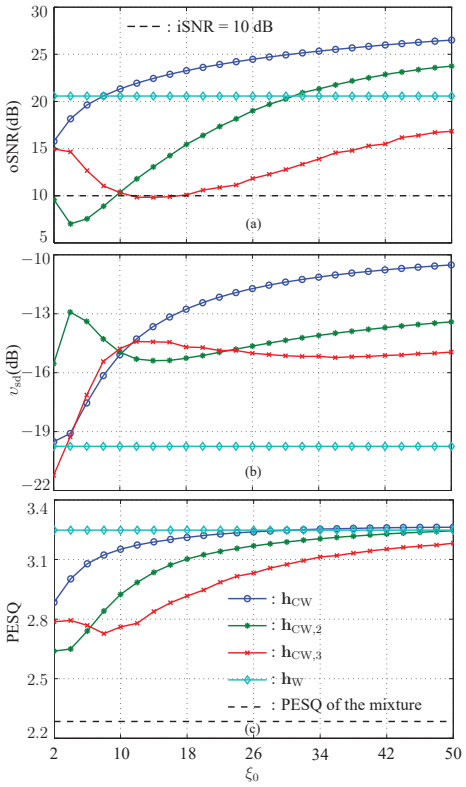

Fig. 2. Performance of $\mathbf{h}_{\mathrm{CW}}$, $\mathbf{h}_{\mathrm{CW},2}$, $\mathbf{h}_{\mathrm{CW},3}$, and the classical Wiener filter, $\mathbf{h}_{\mathrm{W}}$, as a function of the noise reduction factor, ξ_0. The input SNR is 10 dB and the PESQ score of the noisy signal is 2.28.

of the controlled Wiener filter, i.e., $\mathbf{h}_{\mathrm{CW}}$ in (34), $\mathbf{h}_{\mathrm{CW},P}$ in (35) with $P = 2$ and $P = 3$, as well as the classical Wiener filter in (14). The input SNR is 10 dB and the PESQ score of the noisy signal is 2.28. One can see from Fig. 2 that the oSNR, v_{sd}, and PESQ of the controlled Wiener filter, $\mathbf{h}_{\mathrm{CW}}$, $\mathbf{h}_{\mathrm{CW},2}$, and $\mathbf{h}_{\mathrm{CW},3}$, all increase with the increasing of ξ_0. The reason for this is that the value of $\overline{\lambda}_P$ decreases as the value of ξ_0 increases (as seen in Fig. 1), which leads to more noise reduction and more speech distortion. So, unlike the classical Wiener filter, the controlled noise reduction Wiener filter can make a compromise between the amount of noise reduction and the level of speech distortion by adjusting the value of ξ_0. Generally, as the value of P increases, the amount of speech distortion with $\mathbf{h}_{\mathrm{CW},P}$ decreases, but at the cost of less noise reduction as compared to the classical Wiener filter.

VI. Conclusions

In this paper, we proposed a controlled Wiener filter for multichannel noise reduction in the frequency domain. The filter is derived by minimizing the MSE criterion with a constraint on the amount of noise reduction. Using the Lagrange multiplier, we then transformed the constrained minimization problem into one of quadratic eigenvalue problem. The optimal and sub-optimal controlled Wiener filters were subsequently derived. Simulation results show that the proposed filters are able to control the amount of noise reduction as well as the tradeoff between noise reduction and speech distortion by adjusting a parameter that is equal to the average of the eigenvalues with smallest real parts.

***Abstract*—The objective of a target speaker extraction system is to extract the speech of the target speaker from a mixture of multiple speakers and noises using a certain amount of additional information of the target speaker. In this paper, we investigate the improvements of the baseline system by incorporating the light-weight CBAM module in the target extractor, and the gated fusion module (GFM) in the fusion layer. The CBAM introduces attention enhancement to baseline model with no significant increase in the number of parameters and complexity, and the previous concatenation-based fusion method used for speaker embedding and input mixture (or intermediate output) is replaced by GFM, enabling the model to better leverage the supplementary information provided by speaker embedding. Experimental results on datasets built from WSJ0-2mix and WHAM! demonstrate that both the CBAM module and the light-weight GFM module individually improve the model performance, and the GFM module shows better improvement on WHAM!. However, the combination of these two modules only exhibits mutually beneficial effects on the clean dataset WSJ0-2mix, while the performance of the combined module on the noisy dataset WHAM! is inferior to that of using the GFM module alone.**

***Index Terms*—target speaker extraction, attention, gated fusion, multi-task learning.**

I. Introduction

Target speaker extraction is a necessary and vital front-end task that has significant practical implications for voice related tasks, such as speech understanding and speaker verification [1]. It addresses challenging scenarios, including the cocktail party problem [2] and typical indoor environments with multiple speakers and non-speech noise interferences, such as electrical appliances and object collisions. Humans (animals alike) possess certain attentive biological mechanism which can employ selective attention to focus on specific audio sources. This filtering ability can be simulated with source separation techniques. However, the blind source separation (BSS) task and its specific applications like target speaker extraction (TSE) are difficult challenge for machines.

There are two approaches to addressing the target speaker extraction problem. The first approach involves utilizing speech separation (SS) techniques to separate the speech signals of all speakers and subsequently identifying the speech corresponding to the target speaker [3], [4]. The second approach, proposed by subsequent researchers, is the target speaker extraction (TSE) method which is developed based on speech separation. The research on target speaker extraction can be categorized into two stages. The first stage involves traditional signal processing methods, primarily employing microphone arrays, sound source localization, and other techniques to achieve the objective of target speaker extraction, these methods often require multiple microphones or prior knowledge of the source positions, and their separation performance may not be satisfactory when dealing with complex mixed speech signals. In the second stage, deep learning-based methods come into play, these methods primarily employ neural networks, speaker embedding features, attention mechanisms, and other techniques. Unlike the previous stage, these methods typically operate with a single channel and do not rely on prior knowledge of the source positions, achieving significant improvements in separation performance, especially when confronted with complex mixed speech signals.

Earlier methods for speaker extraction mainly focused on frequency domain, examples include SpeakerBeam [5]–[7] and Voice-Filter [8], etc. Similar to speech separation techniques, these frequency domain approaches suffer from the issue of inaccurate phase estimation during time domain signal reconstruction. To overcome this limitation, Luo et al. introduced Conv-TasNet [9], a method for speaker separation in the time domain, and some researchers use this architecture to serve for back-end tasks [3]. Building upon this idea, Spex [10] applied Conv-TasNet to speaker extraction, leading to significant improvements compared to the optimal baseline. Additionally, Spex+ [11] introduced twin speech encoders, where the same encoder is used to simultaneously encode the mixture and reference audio, this innovative approach further enhances the performance of speaker extraction.

In recent studies focusing on target speaker extraction, the typical module consists of two main components: embedding extractor and speech extractor. The embedding extractor is responsible for deriving an embedding that captures the characteristics of the target speaker from a pre-registered reference audio. This module can be trained independently or jointly with the speech extraction module, ensuring that resulting embedding is optimized for the extraction task. The speech extractor module comprises four key components: speech encoder, fusion layer, target extractor, and speech decoder. Speech encoder transforms the audio signal from the time domain into a latent space representation, fusion layer aims to integrate the speaker embedding with the mixture representation, target extractor serves as a masking network to obtain

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

the latent space representation of the target speech, lastly, speech decoder reconstructs the representation back into the time domain.

Regarding the key module of the target extractor mentioned above, its core components have been evolving, primarily benefiting from continuous improvements and refinements in models related to the blind source separation (BSS) problem. The Spex series models utilize the TCN block from Conv-TasNet [10], [11] and propose the use of DPRNN as the core of the masking net, which has shown promising results. Additionally, transformer and conformer models have been applied to target speaker extraction tasks [12]. Attention mechanisms have been widely explored in related studies on target speaker extraction with two main aspects being investigated. The first aspect focuses on the use of attention mechanisms when combining embeddings with the mixture, for instance, there is a study introduces a dynamic attention mechanism that adjusts the embedding for each frame based on the acoustic similarity between the anchor speech and the mixture, leading to favorable results [13], [14]. Furthermore, multimodal research incorporates attention mechanisms to combine features from different modalities [15]. The second aspect concentrates on the use of attention mechanisms in the target extractor module. The ExARN model combines self-attention and recurrent neural networks (RNNs) to learn speaker embeddings [16], Av-Sepformer introduces Sepformer into the multimodal domain [17]. Exformer employs a separator network based on transformer encoder blocks, achieving superior speaker extraction performance compared to other time-domain models [18].

It is evident that relevant clues about the target speaker are crucial for selecting the target speech from a mixture. Commonly utilized clues include audio clues, visual clues, and spatial clues. In this paper, our focus is specifically on audio clues, and extensive research has been conducted on extracting target speakers based on audio clues. Typical audio clue embedding types include I-vectors [19], x-vectors [20], d-vectors [21] or even jointly-learned embedding [5], [10].

Various methods have been explored to fuse embeddings and speech encoder outputs. These methods include concatenation [22], [23], addition, multiplication [5], as well as more complex approaches such as combining addition and multiplication, and utilizing factorized layers which involve combining different mixture embedding weighted by a clue factor. Furthermore, some studies have investigated fusion styles based on gating mechanisms [24] or attention mechanisms. Another possibility is to use multiple clues and perform embedding fusion at different positions within the model.

This paper builds upon the widely recognized Spex+ model in the field of target speaker extraction. Specifically, we enhance the target extractor module by introducing a lightweight CBAM module after each TCN stack, thereby improving the representation of TCN output with no significant increase in the number of parameters and complexity. To fuse the embedding and encoded mixture (or intermediate result), we adopt a fusion mechanism based on gate units. The proposed improvement methods is evaluated on speaker extraction datasets constructed from WSJ0-2mix and WHAM!. Experimental results demonstrate a significant enhancement compared to the baseline TCN-based model.

II. Proposed Method

In this section, we introduce the overall framework of the target speaker extraction model adopted in this paper and propose improvement methods for the target extractor and embedding fusion layer. To address the issue that the target extractor relys solely on TCN blocks, we enhance the output of individual TCN stacks by incorporating the channel block attention mechanism (CBAM) with channel attention and spatial attention. For the fusion of speaker embedding and encoded mixture, we employ a gating mechanism, which allows the network to selectively utilize the auxiliary information in the speaker embedding. This enhances the focus on important information, improves the expressiveness and generalization capacity of the entire target speaker extraction model.

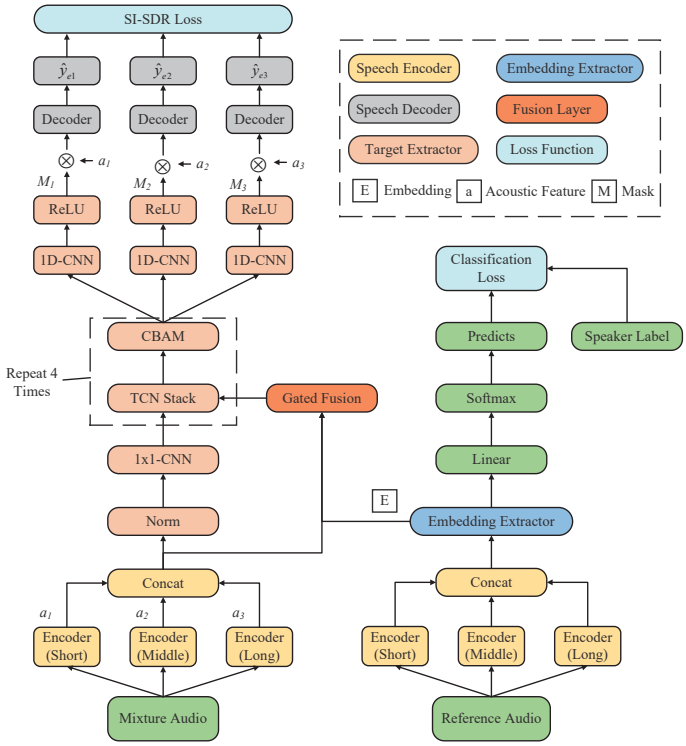

Fig. 1: The overall architecture of the proposed TSE system

A. The Overall Framework of the Proposed TSE Module

The overall framework used in this study, as shown in Fig. 1, is similar to the typical representative Spex+ model which consists of an embedding extractor and a speech extractor. After extracting the embedding, a speaker classification task is performed to enhance the discriminative features of the extracted embedding for different speakers. The speech extractor can be further divided into speech encoder, fusion layer, target

extractor, and speech decoder. In this study, we investigate the impact of attention and gated fusion mechanisms on model performance by incorporating CBAM and GFM in the target extractor and fusion layer, respectively.

First, we utilize the embedding extractor module to obtain an embedding vector $e \in \mathcal{R}^{N_e}$ that corresponds to the target speaker based on the reference audio $x_r \in \mathcal{R}^{N_r}$, this process can be represented by Equation (1):

$$e = f_{emb}\left(x_r; \theta_{emb}\right) \tag{1}$$

The speech encoder encodes the input mixture $x_m \in \mathcal{R}^{N_m}$ to obtain acoustic features a:

$$a = f_{enc}\left(x_m; \theta_{enc}\right) \tag{2}$$

The latent representation of the estimated target sound $\hat{y}_e$ can be derived based on the obtained embedding e and acoustic features a mentioned above:

$$\hat{y}_e = f_{tar}\left(a, e; \theta_{tar}\right) \tag{3}$$

The obtained results from the previous step can be passed through the speech decoder to obtain the final multi-scale time-domain representation of the target speech $\hat{y}_{el}$:

$$\hat{y}_{el} = f_{dec}\left(\hat{y}_e; \theta_{dec}\right)\left(l = 1, 2, 3\right) \tag{4}$$

where N_r, N_m and N_e are the dimensions of the reference audio, the mixture audio, and the embedding vector respectively. The f and θ refer to corresponding components and parameters.

B. Target Extractor with CBAM Attention Enhancement

Fig. 1 also illustrates the architecture of the target extractor incorporating the CBAM module for target speaker extraction. The fundamental concept behind this module is to employ the CBAM module to process the intermediate output of the TCN block. The Convolutional Block Attention Module (CBAM) is an light-weight attention mechanism that combines spatial and channel attention. As depicted in Fig. 2, the CBAM module sequentially generates attention feature maps in both channel and spatial dimensions. These two types of feature maps are then multiplied with the original input feature map for adaptive feature refinement, resulting in the final feature map.

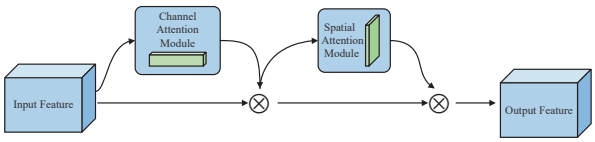

Fig. 2: Typical architecture of the CBAM module

In this study, we propose integrating the CBAM module after each TCN stack. This decision is motivated by the fact that the TCN module itself utilizes causal convolutions, dilated convolutions, and residual connections to extract features at different levels and expand the receptive field with attention mechanism absent. To address this limitation, we leverage the CBAM module's channel attention block to process the intermediate feature maps generated by the TCN stack. By calculating attention weights for each channel in a sequential manner, we can adaptively refine the feature representation by multiplying the weights with the input feature map. Furthermore, the CBAM module incorporates a spatial attention mechanism that operates on the intermediate feature maps. This mechanism computes attention weights for each spatial position, effectively emphasizing the importance of different positions and enhancing the expressiveness and discriminability of the features. It is important to note that in the context of the TCN stack output, the spatial attention mechanism is specifically applied to temporal chunks. This consideration is necessary due to the arbitrary length of time series compared to two-dimensional images. Therefore, our CBAM module operates solely along the chunk size dimension. In summary, the channel attention mechanism of CBAM allows for adjusting the importance of individual channels, while the spatial attention mechanism adjusts the importance of spatial positions. This combined attention mechanism facilitates adaptive feature optimization and improves the overall performance of the model with no significant increase in the number of parameters and complexity.

C. Gated Fusion Layer

The gated mechanism is a widely used technique in deep learning that selectively transmits or blocks information based on the relationship between input and output. It draws inspiration from the gate control theory of pain, which suggests that non-nociceptive inputs can close the "gate" for nociceptive inputs, thereby preventing pain signals from reaching the central nervous system. This technique has been extensively applied in recurrent neural networks such as LSTM and GRU. In addition, gated fusion layers are employed to selectively merge features from different modalities or sources by assigning appropriate weights to different features. This enables the transmission of more important features to deeper layers of the network.

As mentioned earlier, the gated unit was initially employed in network architectures such as LSTM and GRU [25], [26]. In 2017, Dauphin et al. introduced the Gated Linear Unit (GLU), a feedforward neural network that calculates the element-wise product of two linear projections, with one of the projections being processed by a sigmoid function. GLU has been widely adopted in natural language processing architectures, including the gated CNN [27]. The specific formula for GLU can be described as follows:

$$\text{SiGLU}\left(x, W, V, b, c\right) = \text{Sigmoid}\left(xW + b\right) \otimes \left(xV + c\right) \tag{5}$$

Later some researchers introduced several variations of GLU, including ReGLU, SwiGLU, and GEGLU, which employ different nonlinear (or even linear) functions instead of the sigmoid function. Through their experiments, they demonstrated that these GLU variants can significantly enhance

the performance of transformer models across various natural language understanding tasks [28]. Here are a few examples of the expressions utilized:

$$\begin{aligned} \text{ReGLU} &= \max(0, xW + b) \otimes (xV + c) \\ \text{GEGLU} &= \text{GELU}(xW + b) \otimes (xV + c) \\ \text{SwiGLU} &= \text{Swish}(xW + b) \otimes (xV + c) \end{aligned} \tag{6}$$

In this study, we utilize the idea of GEGLU for merging speaker embedding with the input mixture (or intermediate output). Our goal is to extract the target speech from the input mixture by considering it as the primary source while leveraging the auxiliary information provided by the target speaker embedding. To achieve this, we incorporate the input mixture (or intermediate output) as the "x" term and include a linear transformation of the speaker embedding as part of the bias term. The speaker embedding term remains fixed and non-trainable, to enhance the adaptability of the bias term to different target speakers, we choose to preserve the bias term of the convolutional operation itself. Additionally, we introduce a global layer normalization (GLN) module before the GELU activation function, this step aims to improve the data distribution, enhance the network's representation and learning capabilities, so as to enhance the overall generalization capacity and noise robustness of the model. The inclusion of the GLN layer also ensures consistency between the model's training and testing phases. Fig. 3 depicts a specific diagram illustrating these concepts, and the corresponding mathematical expressions are provided below:

$$\begin{aligned} \hat{a} = \widetilde{a} &+ (\widetilde{a} * W + b_1) \\ &\otimes \text{GELU}(\text{GLN}(\widetilde{a} * V + (b_2 + Ge))) \end{aligned} \tag{7}$$

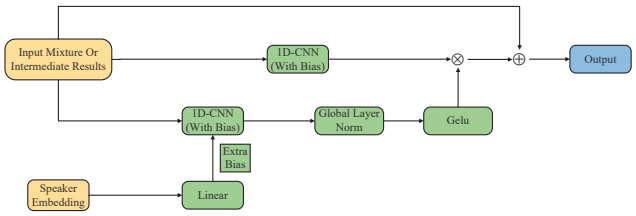

Fig. 3: Proposed gated fusion method

where $\widetilde{a}$ represents the encoded mixture (or intermediate output) of the model, W and V correspond to convolutional operations, the bias terms (b_1 and b_2) of the two convolutional operations are both retained, e represents the embedding vector extracted from the reference audio by the embedding extractor, G denotes the linear transformation applied to the embedding, GLN represents global layer normalization, GELU represents the non-linear activation function, the symbol $*$ represents the convolutional operation, and the symbol $\otimes$ denotes the Hadamard product.

The specific process of their combination is as follows: firstly, the encoded mixture $\widetilde{a}$ undergoes the first convolutional operation with a bias term of b_1, and the resulting output is denoted as c_1. Subsequently, $\widetilde{a}$ is processed by the second convolutional operation with a bias term of $b_2 + Ge$, the output of the second convolutional operation is sequentially passed through the global layer normalization and GELU layers, resulting in c_2. The Hadamard product is then computed between c_1 and c_2, and the resulting output is added to $\widetilde{a}$ using residual addition, this combined result is then passed as input to the subsequent layer of the network.

III. Experiments and Results

In this section, we focus on the experimental details, including the datasets used for training, validation, and testing. We also discuss the relevant hyperparameters of the model and explain the training process of the proposed target speech extraction system.

A. Dataset

We obtain our datasets from the widely used WSJ0-2mix dataset designed for speech separation task, as well as its noise-corrupted counterpart, the WHAM! dataset. To adapt these datasets for target speaker extraction, we perform additional preprocessing. Specifically, we assign the first speaker as the target speaker and the second speaker as the interference speaker. Moreover, we randomly select a distinct speech segment, which is different from the corresponding component in the mixture, as the reference audio for the target speaker. The training set consists of 20,000 samples, while the validation and testing sets comprise 5,000 and 3,000 samples, respectively.

B. Experimental setup

For all models, the training is conducted on 2-second segments for a total of 100 epochs. The initial learning rate is set to 1e-3, if the validation performance don't improve for two consecutive epochs, the learning rate is reduced by a factor of 0.5, in case of no improvement in the validation set for six consecutive epochs, early stopping is employed, and the Adam optimizer is utilized for optimization. The sampling rate for both mixtures and reference audio is set to 8kHz. The convolutional layers in the multi-scale speech encoder and decoder have filter lengths of L1=2.5ms, L2=10ms, and L3=20ms. The target extractor consists of 4 TCN stacks, in the benchmark model Spex+, each TCN stack has 8 TCN layers, for models that use lightweight attention module, each TCN stack is transformed into 7 TCN layers + 1 light-weight attention module. A gated fusion layer is introduced in the first layer of each TCN stack to integrate the speaker embedding with the input mixture (or intermediate output). The auxiliary embedding extractor network has the same structure as the Spex+ model, featuring three ResNet blocks and a speaker embedding dimension of 256. For multi-task training, the parameters of the encoders for reference audio and mixture are shared, with the scaling factors of SI-SDR loss and cross-entropy loss ratio set to 1, 10, respectively, the actual loss function is defined as follows:

$$L_{\text{total}} = L_{\text{SI - SDR}} + 10L_{\text{CE}} \tag{8}$$

where L_{total} represents the overall loss, $L_{\text{SI-SDR}}$ denotes the reconstruction loss for the target speaker's speech, and L_{CE} represents the speaker classification loss. The remaining hyperparameters involved in the loss function align with those of the Spex+ model.

C. Evaluation and results

TABLE I: Comparison of the number of parameters for each model

Model No.	Number of Parameters(Million)
1	11.41
2	10.1
3	12.45
4	11.42

TABLE II: Experimental results of various models on WSJ0-2mix dataset

Model No.	Methods	SI-SDR(dB)	PESQ
1	(Spex+)(Baseline)	15.39	3.16
2	(Spex+) + CBAM	15.77	3.23
3	(Spex+) + Gated Fusion	16.43	3.30
4	(Spex+) + CBAM + Gated Fusion	16.95	3.42

TABLE III: Experimental results of various models on WHAM! dataset

Model No.	Methods	SI-SDR(dB)	PESQ
1	(Spex+)(Baseline)	8.34	2.07
2	(Spex+) + CBAM	8.74	2.14
3	(Spex+) + Gated Fusion	9.75	2.26
4	(Spex+) + CBAM + Gated Fusion	9.36	2.20

We compared the baseline model with improved models using two evaluation metrics, SI-SDR and PESQ, Table I compares the number of parameters for each model, note that in the benchmark model Spex+, each TCN stack has 8 TCN layers, for models that use lightweight attention module CBAM, each TCN stack is transformed into 7 TCN layers + 1 light-weight attention module.

Table II presents the results of each model on the WSJ0-2mix test set, the histogram version is on the left side of Fig. 4 and Fig. 5. Model 1, Model 2, Model 3, and Model 4 represent Spex+ (baseline), the improved model incorporating the CBAM module, the improved model incorporating the GFM, and the improved model combining both modules, respectively. It can be observed that the number of parameters and complexity of the improved models don't significantly increase, and in

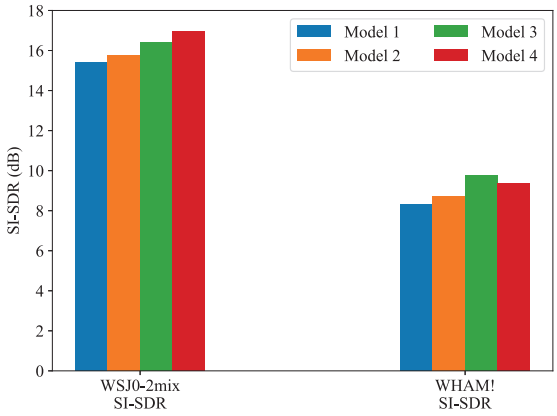

Fig. 4: Comparison of experiment results for SI-SDR

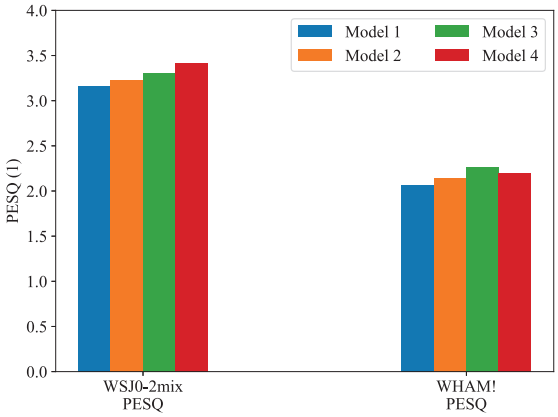

Fig. 5: Comparison of experiment results for PESQ

terms of SI-SDR, the addition of the CBAM module in the target extractor provides a gain of 0.38 dB compared to the baseline Spex+, this improvement is mainly attributed to the channel attention and spatial attention mechanisms introduced by the CBAM module, which are not present in the original model. Regarding the fusion of speaker embedding and input mixture (or intermediate result), the proposed GEGLU-based method brings a significant gain of 1.04 dB. During the training process, the performance gap between the validation and test sets of Model 3 is notably reduced compared to Model 1 and Model 2. This indicates that the gated fusion method used for speaker embedding and input mixture (or intermediate result) effectively selects more generalizable and important features from the embedding for fusion, resulting in improved generalization performance of the TSE model. Furthermore, Model 3 relative to Model 1 and Model 4 relative to Model 2 consistently demonstrate gains of 1.04 dB and 1.18 dB, respectively. This suggests the potential of applying the gated fusion method to different TSE models. Additionally, the combination of CBAM and GFM exhibits a synergistic effect, surpassing the individual contributions of each module, this indicates that advanced attention mechanisms can better utilize the more generalizable intermediate features obtained from

gated fusion, highlighting the amplifying effect of attention mechanisms in the TSE process. Moreover, the evaluation metric PESQ shows a similar trend to SI-SDR, specifically, the CBAM module or GFM module both lead to noticeable improvements in the quality of the extracted speech, and the combination of the two modules further enhances PESQ, exceeding the sum of the individual modules, which suggests that the CBAM and GFM mutually reinforce each other and jointly improve PESQ on the WSJ0-2mix dataset.

Table III presents the test results of various models on the WHAM! dataset, the histogram version is on the right side of Fig. 4 and Fig.5, and it is evident that the performance of all models in extracting target speech from noisy mixtures is significantly reduced. The improvement of Model 2 over Model 1 is 0.40 dB, while the improvement of Model 3 over Model 1 is 1.41 dB, which is higher than the improvement caused by GFM on the clean dataset WSJ0-2mix (1.04dB), this may be attributed to the following reasons: firstly, gated fusion can provide a richer representation of speech features by fusing outputs from different modules, in clean datasets, the target speech is usually clearer and easier to extract, and the model may already capture the features of the target speech effectively, however, in noisy datasets, the interference of noise reduces the effectiveness of the model in extracting the target speech, therefore the enhancement effect of gated fusion may be more pronounced on noisy datasets. Secondly, gated fusion introduces more parameters and complexity, which can provide more flexibility and expressive power to adapt to different speech scenarios and noise environments, this increased complexity may play a larger role on noisy datasets, helping the model better handle the competition between noise and target speech. In addition, the improvement generated by GFM (Model 3) is superior to the improvement generated by the combined module (Model 4) (1.41 dB vs. 1.02 dB, respectively). The possible reason for this is that noisy datasets typically contain various complex noise types and intensities, which can interfere with the extraction of the target speech, and a single module may have better performance in noise suppression, while the combination of CBAM and GFM may not effectively handle the complexity and interference of noise, thus affecting performance on noisy datasets. Also, combining CBAM and GFM increases the complexity and number of parameters in the model, while this can provide stronger feature representation and fusion capability, it may also lead to a decrease in the model's generalization ability on noisy datasets, the combined model may be more prone to fitting clean speech data and may not effectively adapt to the characteristics of noisy datasets. While PESQ exhibits a similar trend to SI-SDR, with improvements observed in Model 2 and Model 3 relative to Model 1, but the improvement of the combined module (Model 4) is inferior to that of the individual GFM module (Model 3).

IV. Conclusion

In this study, we focus on enhancing the key components of TSE model, particularly the target extractor and fusion layer. Specifically, we investigate the impact of integrating CBAM and GFM into the baseline model. CBAM adds a lightweight attention block after each TCN stack, introducing channel and spatial attention. The fusion layer replaces conventional concatenation with GFM, which better leverages embeddings, conveying crucial data to deeper layers. Experiments on WSJ0-2mix dataset exhibit noteworthy improvements in extraction performance, measured by SI-SDR and PESQ, without significant increase in the number of parameters and model complexity. GFM consistently enhances performance in various models, with combined attention and gated fusion yielding synergistic effects. Experiments on the WHAM! dataset show that the improved models incorporating CBAM module or GFM module achieve improvements in terms of both SI-SDR and PESQ on the test set. However, the combined module exhibit inferior performance than that of individual GFM, and the GFM module demonstrates better improvement on noisy dataset than that of clean dataset WSJ0-2mix. Future work entails refining models for superior performance on noisy datasets.

***Abstract*—Despite recent strides made in Speech Separation, most models are trained on datasets with neutral emotions. Emotional speech has been known to degrade performance of models in a variety of speech tasks, which reduces the effectiveness of these models when deployed in real-world scenarios. In this paper we perform analysis to differentiate the performance degradation arising from the emotions in speech from the impact of out-of-domain inference. This is measured using a carefully designed test dataset, Emo2Mix, consisting of balanced data across all emotional combinations. We show that even models with strong out-of-domain performance such as Sepformer can still suffer significant degradation of up to 5.1 dB SI-SDRi on mixtures with strong emotions. This demonstrates the importance of accounting for emotions in real-world speech separation applications.**

***Index Terms*—speech separation, transformer, deep learning, emotional speech, emotion classification**

I. Introduction

Speech Separation is the task of obtaining single speaker speech from a mixture of speakers, also known as the cocktail party problem [1]. It has been the focus of much recent research, as many downstream speech models for tasks such as Automatic Speech Recognition (ASR) [2] are trained on single talker speech. For deployment, mixed speech received from the wild should ideally be separated before performing ASR.

The effect of a speaker's emotions on their speech [3] and speaker emotion recognition [4] are well studied research areas. The emotions of a speaker or the intention of a speaker to convey emotion can result in differences in speech. While some of the differences are semantic [5], there are clear differences also manifest in the prosody [6] and articulation [7] of words. Thus, emotional differences in speech can show up at the frame level, where speech separation models operate.

The difference in sound between neutral or read speech and emotional speech has been shown to lead to performance degradation on a number of speech tasks such as speaker verification [8] and ASR [9]. Conversely, a mixture of speakers with different emotions also results in a degradation of emotion recognition performance [10].

The separation of emotional speech is important because overlapping speech often occurs when speakers are at heightened emotional states, such as in a heated argument or excited conversation, where the typical decorum of turn taking is breached[11]. Speech Separation models are often trained on datasets built from neutral speech. The most common datasets used for speech separation are LibriMix[12] created from the LibriSpeech[13] corpus and WSJ0Mix[14] created from the WSJ0[15] corpus. Both datasets consist of read speech recorded under controlled conditions and neither are explicitly emotional datasets. This results in a potential mismatch between speech separation models trained primarily on neutral speech and the real-world emotional speech mixtures.

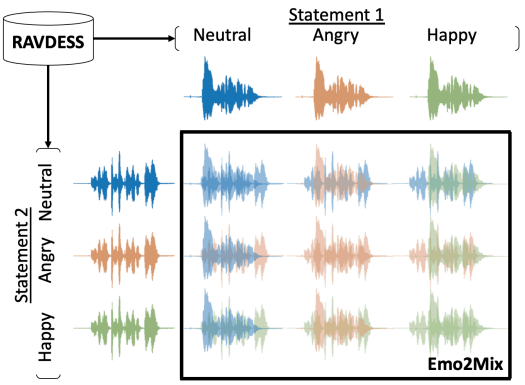

Fig. 1. Illustration of the mixing strategy. Only three emotions are shown here for brevity but the full set of available emotions are used in the dataset (8 at normal intensity and 7 at strong intensity). Each mixture consist of different speakers each vocalizing different statements. The same two statements are shared across emotions and speakers to control for semantic differences.

A. Our Approach

In this paper analyses the performance degradation of speech separation models using a custom speech separation test dataset, Emo2Mix, built based utterances from the Ryerson Audio-Visual Database of Emotional Speech and Song (RAVDESS) [16]. To the authors' knowledge this is the first study to properly investigate the impact of emotions on speech separation with a test dataset that is balanced across multiple emotions at two different emotional intensities.

Using this dataset, we conduct a detailed analysis of the impact of emotional speech on state-of-the-art speech separation models that were trained on neutral speech. To control for the out-of-domain issue due to the unseen speakers in the Emo2Mix test dataset, we make use of the neural emotion utterances present within the RAVDESS dataset as a baseline for an out-of-domain speaker with an "in-domain" emotion.

We show that Emo2Mix presents a significant challenge to speech separation models trained on neutral speech with a

979-8-3503-0067-3/23/$31.00 ©2023 IEEE

recent state-of-the-art Sepformer model [17][18] experiencing a performance degradation of 7.0dB compared to its Libri2Mix baseline. Of this, a performance difference of 1.9dB can be attributed to emotions alone, when comparing against the in-domain neutral emotion baseline.

B. Related Work

Recently, [19] also proposed an emotional mixture test dataset based on the RAVDESS [16] dataset, RAVDESS2Mix. The dataset consists of mixtures from the RAVDESS dataset and LibriSpeech [13] dataset, as well as enrollment speech from the RAVDESS dataset for the target speaker extraction task.

Compared to RAVDESS2Mix [19], our proposed Emo2Mix dataset does not consist of any utterances from the LibriSpeech corpus. This is for two reasons. Firstly, the LibriSpeech corpus consists exclusively of neutral speech, which limits the number of emotion combinations possible for the dataset. Secondly, many speech separation models are trained on the Libri2Mix dataset, which uses utterances from the LibriSpeech corpus. This makes the RAVDESS2Mix test dataset biased, as models pretrained on Libri2Mix will have and advantage over models pretrained on other datasets such as the commonly used WSJ02Mix dataset, which creates utterances from the WSJ0 corpus. Based on the RAVDESS2Mix [19] proposed that target speaker extraction is negatively impacted by emotional speech while blind source separation was not as significantly impacted. However, using Emo2Mix, we can show that the same performance degradation is observed once the in-domain advantage of Librispeech models are removed.

II. Methodology

A. Evaluation

The performance of the models are measured using Scale-invariant signal-to-distortion ratio improvement (SI-SDRi) which is measured by comparing the output waveforms of the models with the ground-truth waveforms. Since there are multiple outputs, the final performance is calculated using the permutation invariant approach.

B. The RAVDESS dataset

The RAVDESS dataset[16] is an emotional dataset consisting of 7356 recordings by 24 actors, gender balanced with 12 male and 12 female. The actors vocalize two lexically-matched statements in a neutral North American accent at two emotional intensities, normal and strong. At the normal emotional intensity, 8 emotions are expressed (neutral, calm, happy, sad, angry, fearful, disgust, surprised) while the strong intensity share the same emotions except for neutral.

RAVDESS has a number of advantages over other emotional speech databases because of its inclusion of two neutral emotions, "neutral" and "calm" and two emotional intensities "normal" and "strong". These features are useful for comparison with existing corpora like LibriMix and WSJ0Mix which also call in this emotional category. These baselines can help differentiate between the performance impact of out-of-domain inference from the unseen speakers and the actual performance impact of the emotional speech.

C. Emo2Mix

The Emo2Mix dataset draws from the RAVDESS dataset to produce two-speaker mixtures of emotional speech. The subset of RAVDESS selected for Emo2Mix excludes singing speech. It also excludes the audiovisual data. A breakdown of the features in the chosen subset of the RAVDESS dataset is shown in Table I.

TABLE I: Breakdown of the features of the selected subset of the RAVDESS dataset used to create Emo2Mix

Feature	**Normal**	**Strong**
Number of Speakers	24	24
Number of Emotions	8	7
Number of Statements	2	2
Number of Repetitions	2	2
Total Recordings	768	672

The mixtures are created with an even distribution across 64 combinations of 8 emotions at a normal emotional intensity and 49 combinations of 7 emotions at a strong emotion intensity. Each statement in the mixture is different, so the mixtures are produced as permutations and not combinations of emotions. While each actor will vocalize the same statement at the same emotion twice, to reduce superfluous mixtures we simply randomly select one of the two repetitions.

For each of the 113 emotion-intensity combinations, each actor vocalizes 2 different statements, from which we can create $N \times (N-1)$ combinations can be obtained, since we cannot mix a actor with themselves. For the full dataset, $N = 24$, which results in 552 mixtures per emotion-intensity permutation which would result in $552 \times 113 = 62,376$ mixtures overall. To reduce the number of testing mixtures, we reduce the number of speakers in the test set by setting $N = 8$, which results in 56 mixtures per emotion-intensity permutation. This gives $56 \times 64 = 3,584$ mixtures for the normal intensity test set, and $56 \times 49 = 2,744$ mixtures for the strong intensity test set. This is done by selecting only every third speaker (1,4,7,10,13,17,21,24) from the dataset. This approach, as opposed to randomly selecting 8 out of 24 of the speakers, is chosen so as to enable the possibility of future work on fine-tuning-models on the other 16 held-out speakers.

The utterances selected from the RAVDESS dataset are dynamically mixed [20] so that the mixture test set does not have to be separately stored. During mixing, a number of pre-processing steps are performed in line with the parameters used for dynamic mixing [20] implemented on the Speechbrain [21] framework. Two audio segments are first cropped to the length of the minimum of the two, then downsampled to 8kHz and normalized. These processed segments are then combined at equal weights if no clipping is observed, or reweighted if

TABLE II: Overall results across different datasets, with aggregated results reported for the emotional datasets. The performance degradation due to only emotional mixtures is calculated by (4)-(6) which is the difference in performance between the Strong emotion and the Neutral emotion baseline. Out-of-domain performance degradation, independent of emotions can be measured by the difference between the original baseline and the Emo2Mix (Neutral) mixtures, calculated by (1)-(4).

clipping is present. To ensure the reputability of the results we used fixed random seeds for all dataset generation and provide a standard script for generation which we release on GitHub[1].

D. Training Datasets

In this work we focus on models that have been trained on the Libri2Mix [12] and WSJ0-2Mix [14] datasets. The Libri2Mix training set consists of 50,800 mixtures while WSJ0-2Mix training set consists of 20,000 mixtures. Both have test sets of 3,000 mixtures. We note that 3,000 mixtures are comparable to the 3,584 and 2,744 mixtures in the Emo2Mix test set.

E. Baseline Models

We make use to two baseline models, Sepformer which adopts a dual-path speech separation architecture with transformer blocks, and ConvTasNet [22] which utilizes temporal convolution blocks. Both models are seminal in the field of speech separation, with Sepformer [17] [18] being the more recent state-of-the art model. We implement the two models on the Speechbrain framework as per their respective papers. For Sepformer we make use of pre-trained checkpoints available from the speechbrain huggingface[2]. Two versions of the model are available, one trained on Libri2Mix (Sepfromer-L2M) and one trained on WSJ0-2Mix (Sepformer-WJ2). For ConvTasNet we train the model from scratch and validate the model replicating the Libri2Mix-Test baseline. To align with the models available on hugging face, we also train the model on both the Libri2Mix (ConvTasNet-L2M) and WSJ0-2Mix (ConvTasNet-WJ2) datasets. Although newer models surpassing Sepformer have recently been released [23][24], Sepformer and ConvTasNet are currently still more widely used and replicated and thus serve as better baselines.

III. Results

In Table II we compare the overall separation performance of the baseline models against three different datasets, the original Libri2Mix Test dataset, RAVDESS2Mix and Emo2Mix. For each of the baseline models, we report the results based on pre-training on two different sets of training data, Libri2Mix and WSJ02Mix. The results on the RAVDESS2Mix dataset are provided as a point of comparison between related emotional speech separation test sets.

A. Performance degradation due to emotional speech

The results presented in Table II for Emo2Mix-Normal and Emo2Mix-Strong are aggregated across all emotional combinations through simple averaging, since all emotional combinations are equally weighted. The Emo2Mix (Neutral) test is a subset of the Emo2Mix-Normal test data and consists of 56 mixtures of different speakers where both speakers are portraying neutral emotions. The purpose of Emo2Mix (Neutral) is to serve as a baseline where the speaker is out-of-domain, but has a neutral emotion matching the emotions in the training data. This allows us to measure the out-of-domain performance degradation, as per (7) in Table II, independent of the impact of emotions.

Any further performance degradation beyond the Emo2Mix (Neutral) baseline, i.e. (8) in Table II, is unlikely to be due to the out-of-domain inference. If emotions do not impact speech separation performance, we should see the values in row (8) approach zero. However, the results of our experiments in Table II show that this is not the case, as the values for (8) range between 1.6dB and 4.0dB. Thus, based on the comparisons of the out-of-domain and emotional degredation in (7) and (8) of Table II, we can conclude that emotions do result in performance degradation in speech separation models. However, the performance impact of performing inference on an unseen speaker is greater than the performance impact from the within-speaker variance resulting from emotions.

TABLE III: Performance of Sepformer-L2M on the Emo2Mix-Normal dataset broken down by emotion combination reported using SI-SDRi.

	RD2M	calm	happy	sad	angry	fearful	disgust	surprised	neutral
calm	**20.6**	16.0	15.6	16.0	**17.1**	15.0	14.9	14.6	15.9

surprised	19.7	14.4	12.7	**15.3**	15.2	14.5	13.8	12.5	14.5
neutral	19.9	15.8	15.8	16.3	16.2	**16.8**	15.9	14.8	15.5

TABLE IV: Performance of Sepformer-L2M on the Emo2Mix-Strong dataset broken down by emotion combination reported using SI-SDRi.

	RD2M	calm	happy	sad	angry	fearful	disgust	surprised
calm	20.4	15.9	17.1	15.8	**18.6**	17.7	16.9	15.9
happy	**20.6**	**17.2**	12.4	13.8	10.9	11.2	14.8	12.2
sad	20.1	15.7	13.6	14.7	**15.8**	12.5	13.1	13.0
angry	20.4	**17.6**	11.6	15.9	9.3	10.6	15.7	13.6
fearful	20.3	**18.4**	11.9	14.1	11.6	9.7	14.9	11.7
disgust	19.8	**17.4**	11.7	14.4	13.9	11.8	13.4	10.7
surprised	19.7	**16.7**	12.4	14.3	13.0	11.9	12.4	10.4

Taking (8) divided by (7), we see across multiple models that strong emotions can cause an additional 35-55% performance drop on top of the out-of-domain performance drop (7) when compared to the in-domain baseline (1). This shows that although the performance degradation due to emotions (8) is less than that from out-of-domain inference (7), the impact is still significant.

We can further support the above conclusion using at the internal consistency in the results of the Emo2Mix test datasets at different emotional intensities. From the results of (4), (5) and (6) in Table II we see a significant performance gap between Emo2Mix-Normal and Emo2Mix-Strong, while the gap between Emo2Mix (Neutral) and Emo2Mix-Normal is much smaller. This suggests that emotional speech causes a deterioration in speech separation performance. If emotions do not impact speech separation performance, we should see that Emo2Mix-Normal and Emo2Mix-Strong have the similar performance. Since this is also a within-dataset comparison, the performance difference is not due to differences in speakers, since the speakers in both Emo2Mix-Normal and Emo2Mix-Strong are identical.

B. Comparison with RAVDESS2Mix

The RAVDESS2Mix dataset consists of mixtures of 2 speakers where one speaker is drawn from the RAVDESS dataset while the other speaker is drawn from the Libri2Mix-Test dataset. This means that for a model trained on the Libri2Mix dataset, one of the speakers would be in-domain while the other is out-of-domain. In a 2-speaker separation problem, knowing the mask for one speaker could allow a model to infer the mask for the other speaker. This gives a model trained on the Libri2Mix dataset a big advantage. This is observed across all models, where we see little to no performance degradation for Sepformer-L2M and ConvTasNet-L2M but a significant performance drop for Sepformer-WJ2 and ConvTasNet-WJ2.

Furthermore, when comparing the performance of RAVDESS2Mix-Normal and RAVDESS2Mix-Strong, the latter test set results in a lower performance for models trained on the WSJ0-2Mix dataset but this is not observed for the models trained on the Libri2Mix dataset. This lack of internal consistency across models trained on different training datasets, points to the fact that the use of the Libri2Mix-Test set in the RAVDESS2Mix mixtures allow for the model to bypass having to recognise emotional speech by inferring from the neutral speech from the in-domain Libri2Mix-Test utterance.

In comparison to RAVDESS2Mix, Emo2Mix does not suffer from such an issue and is able to accurately benchmark the impact to performance caused by emotional speech. Across all the models tested, for both Libri2Mix and WSJ0-2Mix trained versions, there is a significant performance difference. This shows that the test dataset we have developed for our analysis, Emo2Mix, is a better benchmark for emotional speech separation than the previously reported RAVDESS2Mix.

C. The benefits of a larger training dataset

It is common to find in various speech domains such as ASR [2] and Keyword spotting [25] [26], that a larger training dataset results in better performance. Since the Libri2Mix training dataset is significantly larger than WSJ0-2Mix we would expect to see a similar trend. Furthermore, Libri2Mix consists of LibriSpeech utterances which come from audio-

books which may be closer in domain to the RAVDESS datset. That said, the larger size of the Libri2Mix dataset likely improves the performance of the model on Emo2Mix. Looking only at the Sepformer experiments, we see that on Emo2Mix-Neutral the Sepformer-WJ2 model has a lower SDRi of 12.0 dB compared to 15.5 dB for Sepformer-L2M. The difference in SDRi performance for Emo2Mix-Strong is 1.9 dB on Sepformer-L2M compared to 2.6 dB for Sepformer-WJ2. A similar trend can be found for the ConvTasNet model, with the SDRi dropping to barely above noise at 0.9 dB on Emo2Mix strong. This mirrors the finding of [27] where emotional recognition performance benefited from non-emotional large scale pretraining.

D. Performance Comparisons by emotions

To streamline the performance comparison, we only report here the SI-SDRi metric of the best performing model, Sepformer-L2M. Table III shows the results of the model tested on the Emo2Mix-Normal dataset, while Table IV shows the results of the model tested on the Emo2Mix-Strong dataset. In each of the tables, the highest value in each row is listed in bold and while lowest value is underlined.

In the first column of each table, we also report the comparison with the RAVDESS2Mix dataset (RD2M) to which consists only of a combination of 1 emotional utterance from the RAVDESS dataset and 1 neutral utterance from the Libri2Mix Test dataset. In this comparison we also see that there is a minimal variation in the RD2M dataset across the various emotions of 0.9dB for both the Strong and Normal emotional intensities. Meanwhile the average difference between the min and max emotions across combinations is 2.5dB for the normal intensity and 6.1dB for the strong intensity, with the lowest being 1.5dB for the "sad" emotion row in the normal dataset. Across all combinations in the entire dataset, the difference between the min and max for Emo2Mix-normal is 4.7dB and for Emo2Mix-strong is 9.3dB.

Considering the results on the Emo2Mix-Normal dataset in Table III we see a trend that having an utterance with the surprise emotion consistently results in the worst performance compared to the other emotions, with the worst results arising from a combination of two surprise utterances. One possible explanation is that the actors in the dataset simply found it difficult to express surprise at a low emotional intensity and exhibited the most intense emotions in their surprised utterances compared to the other emotions expressed at normal intensity. Meanwhile sad and angry are emotions expressed at normal intensity could simply be close to neutral, resulting in better SI-SDRi results compared to the other emotions.

Finally, considering the results on the Emo2Mix-Strong dataset in Table IV we see a slightly different dynamic. The Calm utterances consistently have the best results in the Strong dataset compared to the Normal dataset. This could be that Calm utterances are closer to neutral at Strong emotional intensity and thus their contrast with the other strong emotions results makes it easier for the model to differentiate the speakers.

IV. Conclusion

In this work we have shown that, contrary to previous work [19], emotions play an important role in the speech separation performance. Our results show that models trained on neutral speech will suffer a performance degradation when the mixture contains strong emotional expressions at inference time. Thus, this work makes the case for the need of including emotional speech into speech separation training datasets.

Geometrically Constrained Blind Moving Source Extraction based on Constant Separation Vector and Auxiliary Function Technique

Ruifeng Zhang, Tetsuya Ueda and Shoji Makino
Waseda University
2-7 Hibikino, Wakamatsu-ku, Kitakyushu, Fukuoka 808-0135, Japan

***Abstract*—This paper focuses on the permutation problem in Blind Source Extraction (BSE) by employing beamforming-based Geometrical Constraints (GC). Specifically, we focus on the recently proposed auxiliary function-based Independent Vector Extraction (Aux-IVE) with Constant Separation Vector (CSV) mixing model. Building upon this mixing model, we provide the source signals' spatial information, utilizing GC based on beamforming. We facilitate the extraction of moving target source and improve the extraction performance. Furthermore, we discuss the effect of the number of constraints on the extraction performance. Experimental results confirmed that our proposed method, GC-CSV-Aux-IVE, exhibits superior extraction performance and achieves nearly 100% accuracy in extracting the moving target source.**

I. Introduction

Recently, the applications of Blind Source Separation (BSS) [1]–[3] span across a wide range of fields, contributing to advancements in speech recognition, audio processing, and speech enhancement. BSS algorithms can separate individual speech signals in scenarios where multiple speeches overlap, improving speech recognition accuracy and estimating the speaker's location.

In the field of BSS, Independent Component Analysis (ICA) [4], [5] and Independent Vector Analysis (IVA) [6], [7] have emerged as prominent techniques for separating mixed signals into their constituent sources. Auxiliary function-based Independent Vector Analysis (Aux-IVA) [8], [9] is an extension of IVA that incorporates auxiliary functions to improve the separation performance.

Moreover, in environments with noisy or degraded speech, Blind Source Extraction (BSE) methods [10]–[12] offer the capability to enhance the target speech by extracting it from the mixture, leading to improved speech intelligibility and quality. BSE techniques have emerged as effective methods for extracting specific source signals from mixtures. By utilizing various algorithms and signal processing methods [13], BSE focuses on extracting the Source of Interest (SOI) while suppressing or removing interference from other sources in the mixture.

In recent years, the Constant Separating Vector (CSV) model [14], [15] proposed in the BSE domain has demonstrated significant advancements in the moving source extraction. Based on the CSV model, [16] proposed CSV-Aux-IVE, which estimates a time-varying mixing vector and a time-invariant filter and utilizes an auxiliary function technique to enhance the extraction performance and the convergence speed of Independent Vector Extraction (IVE).

However, since the permutation problem exists, it is often difficult to determine which source will be extracted in the field of BSE. An important consideration is ensuring that the extracted signal corresponds to SOI. In [14], they addressed this problem by employing the pilot signal which is a signal that is mutually dependent with the corresponding source signal. This method uses prior information about the sound source to resolve the permutation ambiguity.

On the other hand, we propose to solve this ambiguity using Geometric Constraints (GC) [17]. Moreover, we aim to give several constraints for the moving speaker. By employing GC method [18]–[21], we can enhance the accuracy of signal extraction by only requiring approximate location information of the target signal and sensors positions. Consequently, it can be widely applied in scenarios where the signal's moving range is known, such as conferences and speech monitoring. GC method is based on beamforming, which utilizes spatial information and sensor positions to optimize BSS problems. It exploits spatial information to guide the separation matrix to obtain the signal in the desired direction. This method optimizes the constraint weights to ensure that extracted source signal keeps unit energy. Therefore, it is our objective to address the permutation problem and improve the performance of moving target source extraction by applying the GC method.

II. Problem Formulation

A. Blind Source Extraction

Considering the situation in BSE, we assume there are M microphones in the room. After the Short Time Fourier Transform (STFT), we obtain microphone signals $\boldsymbol{x}_{f,l}$ and source signals $\boldsymbol{s}_{f,l}$, where f and l represent the frequency bin and time frame index. Our main task is to extract SOI $s_{f,l}$ from M microphones, and $\boldsymbol{z}_{f,l}$ represent the remaining background signals. Generally, we can assume that $s_{f,l}$ corresponds to the

first source of $\boldsymbol{s}_{f,l}$ without loss of generality. So the relationship of microphone signals $\boldsymbol{x}_{f,l} = [x_{f,l,1}, \ldots, x_{f,l,M}]^{\mathsf{T}} \in \mathbb{C}^M$ and source signals $\boldsymbol{s}_{f,l} = [s_{f,l}, \boldsymbol{z}_{f,l}^{\mathsf{T}}]^{\mathsf{T}} \in \mathbb{C}^N$ where $\boldsymbol{z}_{f,l} = [z_{f,l,1}, \ldots, z_{f,l,N-1}]$ can be written as

$$\boldsymbol{x}_{f,l} = \boldsymbol{A}_{f,l}\boldsymbol{s}_{f,l} = \boldsymbol{A}_{f,l}\begin{bmatrix} s_{f,l} \\ \boldsymbol{z}_{f,l} \end{bmatrix}, \tag{1}$$

where $\boldsymbol{A}_{f,l}$ stands for $M \times N$ mixing matrix and $(\cdot)^{\mathsf{T}}$ denotes the transpose. If M is equal to N, the inverse matrix of $\boldsymbol{A}_{f,l}$ exists and is called separation matrix $\boldsymbol{W}_{f,l} \in \mathbb{C}^{M\times M}$, so (1) can be written as:

$$\boldsymbol{s}_{f,l} = \boldsymbol{W}_{f,l}\boldsymbol{x}_{f,l} = \begin{bmatrix} \boldsymbol{w}_f^{\mathsf{H}} \\ \boldsymbol{B}_{f,l} \end{bmatrix}\boldsymbol{x}_{f,l}. \tag{2}$$

Here $(\cdot)^{\mathsf{H}}$ denotes Hermit transpose. Then we divide mixing matrix as $\boldsymbol{A}_{f,l} = [\boldsymbol{a}_{f,l}\ \boldsymbol{D}_{f,l}]$ which implies that $\boldsymbol{a}_{f,l}$ is the first column of $\boldsymbol{A}_{f,l}$ while $\boldsymbol{D}_{f,l}$ is the remaining part. Similarly, $\boldsymbol{w}_f^{\mathsf{H}}$ refers to the first row of the matrix, and $\boldsymbol{B}_{f,l}$ refers to the rest. Then the mixing and separation model (1) and (2) can be written as:

$$\boldsymbol{x}_{f,l} = \boldsymbol{a}_{f,l}s_{f,l} + \boldsymbol{D}_{f,l}\boldsymbol{z}_{f,l}, \tag{3}$$
